Turska's formula is a well-used old-time naturopathic treatment for decreasing aberrant cancer cell growth. A tincture of this formula is useful in endometriosis owing to the similarities in cell growth found in the pelvis. This formula contains *Aconite napellus* (monkshood), *Gelsemium sempervirens* (yellow jasmine), *Bryonia alba* (bryony), and *Phytolacca americana* (poke root). Monkshood and yellow jasmine contain various alkaloids that have been known to disrupt the assembly of microtubules, which eventually aid in the formation of undifferentiated mesenchymal cells. Quite possibly, these herbal alkaloids interfere with the induction of abnormal ectopic lesions within the pelvis (consistent with the theory of cells left behind in embryonic development). Bryonia is also known to provide antitumor effects. Poke root contains glycoproteins, which are known to stimulate lymphocyte transformation for immune enhancement. In addition, poke root also has anti-inflammatory properties. Owing to its toxic properties, however, this tincture can be provided only by a licensed health professional.

Bioidentical Progesterone

Progesterone has the beneficial effect of downregulating estrogen receptors, thereby decreasing estrogen effects in the normal breast and endometrium. Progesterone, however, is difficult to measure in blood or urine because of its many pathways of use, metabolism, and excretion. Additionally, many, if not most, articles on progesterone are actually written about man-made progestins, which have a very different biological profile. Progesterone induces a secretory endometrium, preparing it for normal menstruation (or pregnancy). Progesterone in the form of artificial progestins has long been used to control the overgrowth of eutopic endometrium when administering estrogens, so it is not surprising that progestins have been proposed as a treatment for endometriosis. The use of bioidentical progesterone in the treatment of endometriosis is not well accepted because endometriosis appears to be progesterone resistant. In eutopic endometrium, however, progesterone may produce benefits for women with endometriosis. In the perimenopausal period, when estrogens are high and progesterone from the corpus luteum is low or absent, endometriosis is often seen to flourish. Balancing estrogen and progesterone would be expected to have the benefits of (1) lowering estrogen effect and decreasing menstrual flow ergo retrograde menstruation; (2) decreasing uterine cramping and pain ergo retrograde flow; and (3) improving psychological distress and lowering catecholamines, thereby reducing pain. Bioidentical progesterone is usually not used alone as a treatment for endometriosis but as part of a comprehensive natural treatment plan. Bioidentical progesterone creams can be applied in various regimens. In women attempting pregnancy, application should begin *after* ovulation to avoid inhibiting ovulation or interfering with the establishment of the corpus luteum. Administration can be transdermal (15–30 mg/day in divided doses), preferably on nonfatty areas of the skin, such as the forearm, to avoid deposition in fat. Micronized progesterone in cream or oil can be used vaginally. An oral micronized progesterone approved by the U.S. Food and Drug Administration (FDA) is available if sedating effects are desired. (Note: It is delivered in peanut oil, so allergic patients will have to get an alternative from a formulating pharmacy.) An FDA-approved vaginal preparation is also available and recommended in luteal-phase defects in women attempting pregnancy. If a luteal-phase deficiency is suspected, progesterone application should continue until the placental production of progesterone is well established (around 12 weeks) and then weaned slowly to prevent a sudden change in progesterone level, which could lead to uterine irritability. For the treatment of nonpregnant patients, antispasmodic, anticramping effectiveness may require higher doses, and the application may need to be extended into the menstrual phase of the cycle. Bioidentical progesterone is usually not used alone as a treatment for endometriosis but as part of a comprehensive natural treatment plan.

A COMPREHENSIVE APPROACH TO THE PATIENT WITH ENDOMETRIOSIS

Because very young women can have symptoms that cannot be differentiated from early endometriosis, such as heavy periods and cramping, addressing these symptoms early may prevent or delay the onset and severity of disease as well as preserve fertility.

Assessment of gastrointestinal function, the microbiome, and the diet is a critical first step that will have far-reaching effects outside of endometriosis. These are areas young women do not often wish to address, but heavy, painful periods may provide an impetus for early correction and the establishment of good habits, which can have long-lasting effects. Simplifying the recommendations may be helpful. The primary dietary recommendation is to increase the consumption of high-fiber vegetables, especially crucifers, *Allium family,* beta-carotene, and fruits high in antioxidants. Decrease sources of saturated and trans fats, and increase the consumption of foods rich in omega-3 fatty acids, especially fatty fish (salmon, herring, sardines, mackerel). Sources of sugar, caffeine, and alcohol should be limited.

Pharmaceutical approaches with oral contraceptives and NSAIDs and progestin-eluting intrauterine devices (IUDs), GNRH agonists, and aromatase inhibitors have been the mainstay of conventional treatment. However, all are fraught with side effects. Oral contraceptives would be the best approach if pregnancy prevention is desired because they have the overall effect of lowering estrogen levels and decreasing menstrual flow with the most acceptable side-effect profile.

Supplements

- An antioxidant combination containing vitamin C 500 mg, beta-carotene, vitamin E (as d-mixed tocopherols) 200 IU, and selenium 100 to 200 mcg. Adding these together improves the body's ability to detoxify and remove free radicals while keeping the doses relatively low.
- N-acetylcysteine 800 to 1000 mg/day
- Pycnogenol: 60 to 150 mg a day and/or resveratrol
- Fish oil: 1000 mg EPA + docosahexaenoic acid (DHA) a day for inflammation and to improve bowel function and the health of gut flora
- B complex: containing folate as 5-methyl folate, B6 as P5P, cobalamin as methyl or hydroxocobalamin, thiamine, choline or betaine, and methionine, to improve the epigenetic health and estrogen metabolism. Dosing will be patient specific.

Botanical Medicines

- Chaste tree, dandelion root, prickly ash, and motherwort tincture (equal parts): 1½ tsp to 1 tsp three times a day
- Turska's formula (*Aconite* 1½ drams, *Bryonia* 1½ drams, *Gelsemium* 1½ drams, Phytolacca 3 drams, and ½ dram water): five drops four times a day

Topical

- Progesterone cream (Table 166.1; Option 1 should only be used in anovulatory women not attempting pregnancy)
- Castor oil packs to the abdomen

Stress Reduction

- Stress reduction to relieve pain and lower cortisol steal. Many options are available: yoga, meditation, HeartMath, transcutaneous electrical nerve stimulation (TENS), progressive relaxation.

TABLE 166.1 Progesterone Cream Schedule

Option 1	Days 1–7	No cream
	Days 8–28	¼ to ½ tsp twice a day
Option 2	Days 1–14	No cream
	Days 15–28	¼ to ½ tsp twice a day
Option 3	Days 1–21	No cream
	Days 22–28	¼ to ½ tsp twice a day

Surgery

Surgical treatment of endometriosis is both the first and last line of treatment in conventional medical practice. Laparoscopic surgery has advanced dramatically in the past 40 years. Endometriosis surgery, however, can be quite difficult because of adhesions and distortion of the anatomy. The surgical approach usually includes confirmation of the presumed diagnosis with biopsy, identification of the extent and location of disease, debulking disease and lysing adhesions, removal of endometriomas, ablation of the uterosacral nerves by electrocautery, laser or endocoagulation, and presacral neurectomy or hysterectomy with bilateral salpingo-oophorectomy as a last resort. Damage to the bowel, bladder, ureters, and blood vessels is not unusual and is commonly related to the depth of disease and the experience of the operator. The management of ovarian disease at surgery varies; some surgeons prefer to keep as much ovarian tissue as possible, and some will sacrifice severely damaged adnexa to allow for regular ovulation each month on the remaining, less damaged side. Surgery has been shown to increase pregnancy rates in the immediate postoperative period.[113]

Epilepsy

Gaetano Morello, ND

OUTLINE

DIAGNOSTIC SUMMARY

- Recurrent seizures
- Characteristic electroencephalographic changes accompanying seizures
- Mental status abnormalities or focal neurological symptoms potentially persisting for hours postictally

GENERAL CONSIDERATIONS

The word *epilepsy* derives from the Greek word *epilepsia,* which means "to take hold of" or "to seize." Epilepsy is not a disease in itself but rather a symptom of disease. The epilepsies are a group of disorders characterized by sudden, recurrent, episodic changes in neurological function caused by abnormalities in the electrical activity of the brain.[1–4] Each episode of neurological dysfunction is called a seizure. Seizures are termed *convulsive* when accompanied by motor manifestations or *nonconvulsive* when accompanied by sensory, cognitive, or emotional events. Epilepsy can occur because of a number of abnormalities, such as neurological injuries, structural brain lesions, or some systemic diseases. Epilepsy is termed *idiopathic* when there is neither a history of neurological insult nor other apparent neurological dysfunction.[3] Whatever the etiology, the common denominator in all these conditions is the epileptic attack or seizure.

Epidemiology

The reported incidence and prevalence rates of epilepsy have varied widely because of uncontrolled methodological factors.[5] According to the best available data, the prevalence of chronic recurrent epilepsy is about 10 per 1000, and it has been estimated that 10% of the population will have one or more seizures at some point in life. The cumulative lifetime incidence of epilepsy is approximately 3%.[6] An additional 2% to 5% of children experience febrile convulsions during the first several years of life. About 10% of these children, especially those in whom the febrile seizure is prolonged, develop epilepsy later in life.[1] Prospective studies show that more than 60% of newly diagnosed patients enter remission with conventional treatment.[7]

Etiology

Epilepsy may be idiopathic, cryptogenic, or symptomatic.[8] Idiopathic epilepsies are generally genetic in origin and account for 70% to 80% of all cases of epilepsy. The role of genetic factors in the pathogenesis is complex because of diverse conditions leading to the common symptom of seizures. In general, the prevalence of seizures in close relatives is three times that of the overall population.[1] William Lennox meticulously studied the relationship of epilepsy to genetics from 1934 through 1958, using twin studies. He concluded that epilepsy was a condition in which genetic and exogenous factors interact in all patients, with variable weighting in each particular case.[9]

This understanding sparked the concept that many factors play a role in the epileptic condition. Cryptogenic epilepsies are those in which an underlying cause is suspected but the etiology remains undetected. Finally, epilepsies for which there is an underlying structural cause or major metabolic derangement are considered symptomatic, for a probable cause has been identified.[4] As shown in Table 167.1, probable causes can be determined by age at onset of seizures. Box 167.1 lists the most common etiological factors.

Classification

The current classification of epileptic seizures is based on clinical and electroencephalographic criteria proposed by the International League Against Epilepsy. Box 167.2 lists the clinical features.

TABLE 167.1 Presumptive Causes of Epilepsy According to Age at Onset of First Seizure

Age at Onset	Presumptive Causes
Birth to 2 years	Birth injury, degenerative brain disease
2–19 years	Congenital birth injury, febrile thrombosis, head trauma, infection (meningitis or encephalitis)
20–34 years	Head trauma, brain neoplasm
35–54 years	Brain neoplasm, head trauma, stroke
55 years and older	Stroke, brain neoplasm

Data from Hauser WA, Hesdorfer DC. *Epilepsy: Frequency, Causes, and Consequences*. New York: Demos; 1990; Freeman JM, Vining EPG, Pillas DJ. *Seizures and Epilepsy in Childhood: A Guide for Parents*. Baltimore: Johns Hopkins University Press; 1990.

BOX 167.1 The Most Common Etiological Factors in Epilepsy

- Brain damage before or at birth (congenital malformations, anemia, fetal infection)
- Head trauma significant enough to injure the brain and cause gliosis
- Central nervous system infections such as meningitis, encephalitis, brain abscess, neurosyphilis, rabies, tetanus, falciparum malaria, toxoplasmosis, and cysticercosis of the brain
- Metabolic disorders: hypocalcemia, hypoglycemia, hypoparathyroidism, phenylketonuria, and withdrawal from alcohol and drugs
- Brain tumors and other space-occupying lesions
- Stroke and other vascular disorders
- Degenerative brain disease
- Genetic disease
- Toxic conditions
- Idiopathic causes

BOX 167.2 Classification of Epileptic Seizures in Adults

Partial (Focal, Local) Seizures

- Simple partial seizures (consciousness not impaired)
- Motor signs
- Somatosensory or special sensory symptoms
- Autonomic symptoms or signs
- Psychic symptoms
- Complex partial (consciousness impaired)
- Simple partial onset followed by impaired consciousness
- Consciousness impaired at onset
- Partial seizures evolving to generalized seizures (tonic, clonic, or tonic-clonic)
- Simple partial seizures evolving to generalized seizures
- Complex partial seizures evolving to generalized seizures
- Simple partial seizures evolving to partial seizures evolving to generalized seizures

Generalized Seizures (Convulsive or Nonconvulsive)

- Absence seizures
- Typical (brief stare, eye flickering, no emotion)
- Atypical (associated with movement)
- Myoclonic seizures
- Clonic seizures
- Tonic seizures
- Tonic-clonic seizures
- Atonic seizures
- Unclassified seizures

Modified from Willmore LJ, Ferrendelli JA. Epilepsy. In Dale DC, Federman DD, eds. *Scientific American Medicine*. New York: Scientific American; 1997: 11, XII-1-14.

DIAGNOSIS

Differentiating between partial or focal seizures and generalized seizures is of great clinical significance. Partial seizures begin focally with a specific sensory, motor, or psychic aberration that reflects the affected part of the cerebral hemisphere.[5] These types of seizures may remain localized, whereas generalized seizures appear to spread from their onset and usually affect both consciousness and motor function.[2–5] Differentiation is important because partial seizures are usually indicative of focal brain disorders such as tumors or gliosis, whereas generalized seizures rarely have a definable etiology (although some studies now implicate metabolic disorders).

An eyewitness account of a typical attack can be of great value in classifying the seizure. Past trauma, infections, and the use of drugs and alcohol should be fully explored, as should the family history. A complete neurological examination should be performed as a preliminary screen for neoplasms. Laboratory work should include the following[4]:

- Serum glucose and calcium
- Complete blood cell count
- Liver and kidney function tests
- Serological test for syphilis
- Skull radiographs
- An electroencephalogram (EEG)
- A computed tomography (CT) scan
- Magnetic resonance imaging (MRI)

Examination of the cerebrospinal fluid is indicated if infection or meningeal neoplasm is suspected.[1] MRI is considered the gold standard in evaluating epilepsy because the resolution is superior to that of the CT scan.[6] Newer studies also employ EEG recording during functional MRI scanning to map normal and pathological brain function.[10] Epilepsy should not be diagnosed on the basis of a solitary seizure. The recurrence rate after a single seizure is approximately 27% over 3 years.[11]

PATHOPHYSIOLOGY

The hallmark of the altered physiological state of epilepsy is a rhythmic, repetitive, synchronous discharge of many neurons in a localized area of the brain.[3] This discharge pattern is easily recorded on the EEG during an attack. However, the cause of the abnormal discharges is still not known. Research shows that the synchronous depolarization of masses of neurons is the result of a combination of increased excitatory mechanisms and decreased inhibitory mechanisms.[12]

Seizures can be induced in experimental models by blocking inhibitory mechanisms. For example, agents that block the action of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) are potent convulsants in humans. Conversely, the antiepileptic drugs phenobarbital and benzodiazepines enhance GABA, thus supporting the inhibitory mechanism. In some forms of chronic focal epilepsy, inhibitory terminals on neurons in areas around cortical gliotic lesions are in fact diminished.

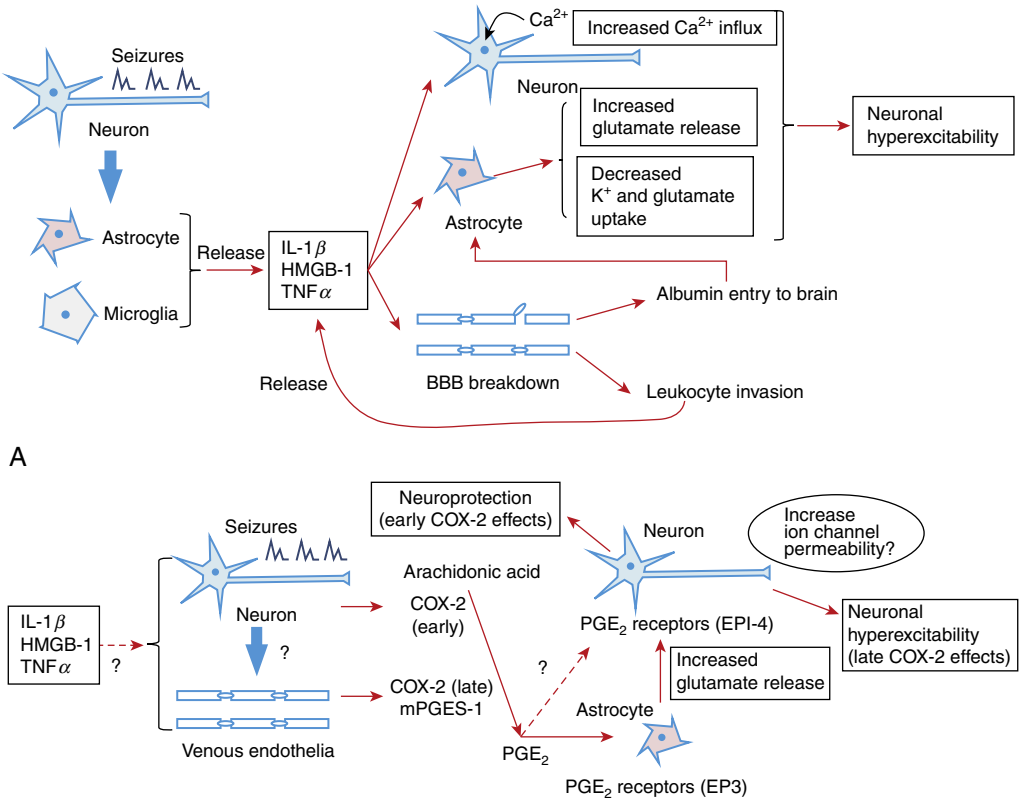

Fig. 167.1 Proposed inflammatory mechanisms in epileptogenesis. (a) Epileptic seizures induce the release of cytokines from glial cells, thereby (1) increasing the influx of neuronal calcium, (2) enhancing extraneuronal glutamate concentration, (3) decreasing K^+ and glutamate uptake by glia, and (4) impairing the blood–brain barrier (BBB). BBB breakdown leads to albumin entry and leukocyte invasion into the brain, resulting in a further release of inflammatory cytokines. Such inflammatory responses cause an induction of neuronal hyperexcitability, reoccurrence of seizures, and finally, the development of refractory epilepsy. (b) Seizures induce cyclooxygenase-2 (COX-2) in neurons (early phase) and vascular endothelial cells (late phase) and mPGES-1 in endothelial cells. These inducible prostaglandin (PG) synthases cooperate to produce PGE2, most likely in endothelial cells. Endothelial PGE2 might cause neuronal hyperexcitability by enhancing glutamate release from astrocytes via the glial EP3 receptor, whereas neuronal PGs may protect neurons against seizures. (From Shimada T, Takemiya T, Sugiura H, Yamagata K. Role of inflammatory mediators in the pathogenesis of epilepsy. *Med Inflamm.* 2014;901–902. PubMed PMID: 25197169.)

Other research demonstrates the instability of the nerve cell membranes in patients with epilepsy. During seizure activity, intracellular Ca^{2+} stored in the cell organelles is released and moves toward the inner cell membranes, where it binds to specific Ca^{2+}-receptive proteins, causing conformational changes in the protein's structure. These changes cause the transmembranal Ca^{2+}, K^+, and Na^+ channels to pathologically remain open, potentiating the excitatory state and hence the convulsive activity.[1,2]

Accumulating preclinical and clinical evidence suggests that there is a positive feedback cycle between epileptogenesis and brain inflammation. Epileptic seizures increase key inflammatory mediators, which in turn cause secondary damage to the brain and increase the likelihood of recurrent seizures (Fig. 167.1).

The earliest symptomatology, or aura, that is generated by a focal discharge provides the best clue to the localization and occasionally to the characterization of the responsible lesion. For example, a generalized seizure after an aura of a peculiar abdominal sensation or ill-defined odor indicates a lesion in the temporal lobe. A Jacksonian seizure beginning in the fingers and spreading up the arm before becoming generalized and producing a coma indicates a focal lesion in the convexity of the opposite motor cortex.[1]

THERAPEUTIC CONSIDERATIONS

Environmental Toxins

Metals

Metals such as lead, mercury, cadmium, and aluminum can induce seizures by disrupting neural function.[13] Metal toxicity should be ruled out as a possible cause in all seizures. A hair mineral analysis provides the most cost-effective screening method for the detection of heavy metals. Urine testing may be beneficial in examining the long-term, low-dose, chronic exposure to toxic compounds and qualitatively reflect excretion of an unknown fraction of the total body pools of assimilated metals. Metal mobilization testing using a chelating agent such as calcium disodium ethylenediaminetetraacetic acid or dimercaptosuccinic acid provides the best estimation of body burden for mercury and lead (see Chapter 35).

Neurotoxic Chemicals

A great number of commonly present environmental toxicants adversely affect the central and peripheral nervous systems, especially

in the fetus and children. These adverse effects are a result of both direct and indirect action and result in cognitive, mood, and movement disorders and have been linked to the major chronic neurological diseases. Chlorinated pesticides, for example, impair the sodium channels in the neurons, preventing proper transmission of the nerve impulse. Solvents are fat soluble and therefore readily cross the blood–brain barrier. Once in the brain, they diminish the axonal transmission of electrical impulses along the neurons. Minimizing exposure and improving the body's ability to eliminate neurotoxic agents become important aspects of the therapeutic approach. Chapter 35 discuss the effect of these neurotoxins.

Dietary Considerations

Hypoglycemia

Focal neurological deficits associated with hypoglycemia have been well described in adults with diabetes,[14] and some researchers believe that hypoglycemia is the most important metabolic cause of seizures.[13] Researchers have found the following[13,15–18]:

- Serum glucose levels are unusually low before a seizure.
- Of patients with epilepsy, 50% to 90% have constant or periodic low blood sugar.
- Of patients with epilepsy, 70% or more have abnormal glucose tolerance tests.

Although the correlation of blood sugar abnormalities and epilepsy seems well documented, the mechanism of action is unknown. It has been suggested that low blood sugar could impair adenosine triphosphate (ATP) production in nerve cells, reducing the efficacy of the sodium ATPase pump. A defective sodium pump allows for increased intracellular sodium concentrations, which depolarize the cell membrane and thus lowers the firing threshold.

Observational studies have pointed to leptin as a factor that may help in regulating the occurrence of seizures. Animal studies have confirmed that injecting leptin reduces the occurrence and severity of seizures. It is well established that low blood sugar results in low circulating leptins levels, suggesting another possible mechanism of action.[19]

Single measurements of serum glucose levels are inadequate to determine glycemic status; only an extended glucose tolerance test will give a complete picture.

Ketogenic Diet

Originally introduced by Wilder in 1921,[20] the ketogenic diet (KD) has a long history of use for the reduction of seizure activity.[21–23]

The diet is composed of more than 90% fat by weight; low in carbohydrates; and adequate in proteins, vitamins, and minerals. The low carbohydrate intake inhibits fat metabolism, resulting in the production of excessive levels of ketone bodies (acetone, acetoacetic acid, and beta-hydroxybutyric acid), the intermediary oxidation products. Presumably, the beneficial effects of such a diet are due to its induction of metabolic acidosis, which corrects an underlying tendency of patients with epilepsy toward the spontaneous development of alkalosis.[20–22] This acidification is thought to normalize nerve conductivity, irritability, and membrane permeability.

Another possible benefit of the KD may be in augmenting ATP production by utilizing ketone bodies in place of glucose. It has been documented that many patients with epilepsy are hypoglycemic, thus compromising mitochondrial ATP production. The KD may provide an alternative route for balancing this deficit.[24]

The two main types of KDs are (1) the classic diet and (2) the medium-chain triglyceride diet. The classic KD produces ketosis by limiting the intake of carbohydrates and protein to less than 10% of energy combined. The medium-chain triglyceride ketogenic diet uses medium-chain triglyceride fat to produce ketosis. This allows for a larger intake of carbohydrates and protein.[20]

Research continues to document the efficacy of these types of dietary therapy. For example, one study of 27 children from 1 to 16 years of age using the classic diet found that 40% experienced a reduction of seizures of more than 50%, with 25% becoming seizure-free.[25] However, 35% discontinued the diet owing to difficulty in following the rigorous guidelines. A review from 1996 concluded that the KD had efficacy in one third to one half of childhood epilepsy cases and was partially effective in another one third of cases.[26] A review article from 1997 states that the success rate of the KD "greatly exceeds that of the medications" and that its side effects are fewer and the therapy cheaper.[27]

One prospective nonrandomized study measured the nutrient intakes, growth, and biochemical indexes of 30 children from 1 to 16 years of age who had intractable epilepsy before and after a 4-month protocol using a KD. Fourteen children on the classic diet and 11 on the medium-chain triglyceride diet completed the study. The results indicated that linear growth was maintained in patients from baseline to 4 months on both therapies. However, body weight decreased for children on both diets, which could be a result of inadequate energy intake. Protein intake met recommendations for both diets. In the medium-chain triglyceride group, there was a 0.7 decrease in the ratio of total cholesterol to high-density lipoprotein ratios at 4 months. All biochemical indices, including albumin levels, remained within normal limits.[20] Longer-term evaluations may show eventual unwanted changes in these parameters. The authors concluded that the medium-chain triglyceride diet may be more nutritionally adequate and thus confer an advantage over the classic KD.

The long-term risks of a high-fat diet are well known, and a KD may prove unhealthy for a growing child. One retrospective investigation found that the linear growth of some children might be slowed.[28] When treating children on a KD, clinicians should recommend adequate intake of energy and protein, a higher proportion of unsaturated to saturated dietary fats, and also consider vitamin and mineral supplements.[20] Small, frequent meals may be appropriate and may decrease hypoglycemic episodes.

In a study appearing in *Seizure,* researchers evaluated the long-term efficacy and tolerability of the KD in pediatric patients with drug-resistant epilepsy. The results pointed to good long-term effects of the KD on seizure frequency, EEG readings, and neurological development.[29]

The Atkins diet, which gained great popularity in past years as a weight-loss tool, theoretically may be useful to treat epilepsy.[30] Like the KD, it, too, produces a ketotic state, but it creates this effect with less restriction on protein intake. In one pilot study, 6 patients ranging from 7 to 52 years of age were prescribed the Atkins diet for intractable focal and multifocal epilepsy. Five of the patients maintained moderate to large ketosis for periods of 6 weeks to 24 months, and 3 experienced seizure reduction. As a result, they were able to reduce their antiepileptic medications.[31] Larger trials are necessary to explore whether the Atkins diet may be useful to treat patients with epilepsy.

Leptin

Leptin is a protein hormone that plays a key role in regulating appetite and metabolism. Acting on the receptors of the hypothalamus, it inhibits hunger by counteracting the effects of neuropeptide Y and anandamide, two powerful feeding stimulants. Research demonstrates the ability of leptins to act on receptors that activate signaling proteins, which, in turn, trigger changes that reduce brain excitability and thus seizures frequency and intensity.[19,32]

The anticonvulsant action of leptin was tested in animal seizure models by either injecting leptin directly into the cortex or

administering it intranasally. Focal seizures in these animals were induced by neocortical injections of 4-aminopyridine, an inhibitor of voltage-gated K^+ channels. Results showed that seizures were briefer and less frequent upon coinjection of 4-aminopyridine and leptin. In mice, intranasal administration of leptin produced elevated brain and serum leptin levels and delayed the onset of chemical convulsant pentylenetetrazole-induced generalized convulsive seizures.[33]

The theorized mechanism of action may involve leptin's effect in activating two signaling proteins known as JAK2 (Janus kinase) and PI3K (phosphatidylinositol 3-kinase). These proteins blocked nerve impulses triggered by the neurotransmitter glutamate, thus reducing the severity and frequency of seizures. PI3K is also involved in regulating GLUT4, a cytoplasmic protein essential for sugar regulation. This may be another important mechanism of action of elevated leptins.[33,34]

Although these preliminary studies show that leptin can reduce seizures in acute settings, leptin's usefulness in chronic cases is yet to be determined. One challenge would be the fact that leptin has a relatively short half-life (15–30 minutes), leading to dosing problems. However, creating a physiological environment that improves blood leptin levels through dietary and supplemental intervention could prove therapeutic.

There appears to be a link to the KD because this diet increases the amount of circulating leptins, perhaps another plausible mechanism of action of KD. Future research may involve testing foods that have a propensity to increase circulating leptins and examining their effect on seizure frequency and intensity.[34]

Another link to the anticonvulsant action of leptin is hypoglycemia. It has been established that low blood sugar is associated with an increase in seizure formation, and hypoglycemic individuals also have low leptin levels. This may explain in part why hypoglycemia is associated with the occurrence of seizures.

Although the use of leptin as an anticonvulsant is in its early stages of research, the strategy of increasing blood levels of leptin to reduce seizure formation warrants consideration.

Food Allergy

There has been little research into the correlation between food allergy and epilepsy, with only anecdotal case histories[35,36]; single-case, double-blind, placebo-controlled studies[37,38]; and uncontrolled studies being reported. It is postulated that patients with epilepsy may have allergic reactions in the brain that are similar to the swelling, anoxia, and inflammatory chemical reactions seen at other sites of local allergic reactions.[35]

One uncontrolled study evaluated oligoantigenic diets in 63 children with epilepsy. Of 45 children with recurrent headaches, hyperkinetic behavior, or abdominal symptoms, 25 ceased to have seizures during diet therapy, and 11 had fewer seizures. Headaches, abdominal pain, and hyperkinetic behavior resolved in all patients whose seizures ceased and in some of those whose seizures did not cease. Reintroduction of foods reproduced symptoms. Of 24 children with generalized epilepsy, 18 recovered or improved, as did 18 of 21 children with partial epilepsy. In double-blind provocation, 15 of 16 children experienced recurrence of symptoms, including seizures in 8, whereas none improved in the placebo group. Another group of 18 children who had epilepsy alone had no improvement with dietary change.[39] This study suggests that food allergy should be suspected in patients with epilepsy who suffer from multiple other symptoms of food allergy (see Chapter 15).

Another study evaluated two females, 5 and 23 years of age, who had focal occipital epilepsy with cerebral calcifications and were not responding well to antiepileptic therapy. Both had celiac disease as well as documented folic acid deficiency (a common side effect of most antiepileptic drugs). A gluten-free diet combined with supplementation with folic acid (dosage not reported) led to complete normalization of the EEG in the 5-year-old and cessation of seizures. The 23-year-old experienced significant improvement in her EEG and enhanced seizure control. Folic acid returned to the normal range within several months.[40]

A larger study looked more closely at the association between celiac disease and epilepsy. A total of 43 patients (15 male) between 4 and 31 years of age were evaluated for the association between celiac disease, epilepsy, and cerebral calcifications. Intestinal biopsy on the 31 patients with cerebral calcifications of unexplained origin and epilepsy found a flat intestinal mucosa in 24, suggesting celiac disease. CT scans showed cerebral calcifications in 5 of the 12 patients with celiac disease and epilepsy. Antibodies to gluten and folic acid serum concentrations were measured, and histocompatibility leukocyte antigen typing was done in most patients. Only two patients with cerebral calcifications and epilepsy had gastrointestinal symptoms at the time of biopsy. A gluten-free diet in epilepsy was found to be inversely related to the duration of epilepsy before the diet and to the patient's age at the beginning of the diet.

Celiac disease should be considered in all cases of epilepsy and cerebral calcifications of unexplained origin, especially when the epilepsy is characterized by occipital seizures and the calcification is located bilaterally in the posterior regions.[41] One work involving 72 children with epilepsy and 202 controls revealed significantly higher rates of eczema in the mothers and rhinitis in the siblings of the patients with epilepsy, as well as a generally higher incidence of allergic pathologies in both of these groups compared with the controls. Additionally, a significantly higher incidence of allergy to cow's milk as well as asthma was documented in the children with epilepsy with respect to the control group. Prick tests gave a significantly higher rate of positive results for cow's milk proteins in the patients with epilepsy versus controls.[42]

Mitochondrial ATP

Direct research into the possible benefits, with regard to seizure formation, of optimizing mitochondrial ATP production is minimal. However, there is peripheral evidence supporting this idea. For example, it is well accepted that individuals with mitochondrial diseases compromising ATP production have an increase in seizure frequency. This may be related to ATP production and the importance of this respiratory chain substrate in controlling the stability of cell membranes.[43]

In one observational study, 37 family members with a genetic mitochondrial disease (a mild defect in the NADH-ubiquinone oxidoreductase step) showed a significant increase in seizures (22% of the group developed epilepsy).[44]

Studies of subjects with mitochondrial encephalopathies have consistently shown epileptic seizures as a main recognized symptom. Partial seizures, chiefly with elementary motor symptoms, and focal or multifocal EEG epileptiform activity characterized the epileptic presentation in 71% of these patients.[45]

These results support the possibility that compromised ATP production may be playing a role in provoking seizures.

Supplementation with ubiquinone has shown positive effects in improving symptomatology produced by mitochondrial encephalopathies. A study of patients with mitochondrial encephalopathies (which can lead to seizures) showed a significant improvement in fatigability and muscle endurance after the administration of supplemental ubiquinone. Ubiquinone has been shown to have significant benefits in several neurological disorders (e.g., Parkinson's disease, Huntington's chorea). Thus using this agent as part of the anticonvulsant protocol may have some merit.[46–48]

Even the positive effects of the KD may have some relationship to mitochondrial functionality. One study showed that animals placed on a KD had a 46% increase in the density of mitochondria in neuronal tissues. KD has been hypothesized to work on several levels, and it is plausible that increasing mitochondrial density, and thus ATP production, could be one possible mechanism.[49,50]

Microbiome

The gut–brain axis is a two-way communication system between the central nervous system (CNS) and the gastrointestinal (GI) tract. It is becoming increasingly recognized that the presence of a healthy and diverse gut microbiome is important to cognitive and emotional well-being. Recent research is showing that a relationship may exist between GI disorders, particularly those with an immunological pathogenesis, and neurological diseases, pointing to a probable new pathogenic pathway involving the microbiome and the gut–brain axis.[51,52]

Some hypotheses propose blood–brain barrier (BBB) disruption leading to inflammation through autoimmune mechanisms. This may involve etiologies from food allergens and bacteria disrupting the "gut barrier" and imparting systemic consequences through the translocation of pathogen-associated molecular patterns (PAMPs) and other molecular entities.

Interestingly, in a recent publication in the *Journal of Pediatric Neurosciences,* the authors review the case of a 10-month-old infant admitted for drug-resistant epilepsy associated with GI discomfort, secondary to a milk allergy. They noted seizure frequency up 15 to 20 episodes daily with no effective anticonvulsant drug therapy. The only effective intervention turned out to be a diet free of cow's milk, initiated due to gastroenteritis and surprisingly stopping the seizures. This case demonstrated the exposure of the BBB to neurological episodes related to systemic inflammation, again highlighting the gut–brain axis.[53]

The human intestinal microbiome consists of trillions of bacteria affecting human health on various levels and, interestingly, having numerous dynamic interactions with our immune systems. It has been well established that gut microbes control pathogenic microbial growth, assist in digestive function, and support the functionality of the important intestinal epithelium (gut–blood barrier). The relationship is definitely cooperative and one that has far-reaching effects.[54,55]

Evidence continues to mount supporting the premise that the gut microbiome and immune system are closely connected and can influence each other. An important observation is that immune modulation by the microbiome is not exclusive to the GI environment but, rather, affects other systems in a variety of ways.[56,57]

Therefore it is not surprising that gut-residing bacteria are involved in the pathogenicity of autoimmune disorders. For example, patients with Crohn's disease or ulcerative colitis presented abnormal intestinal microbiome, characterized by depletion of two bacterial genera—the phyla *Firmicutes* and the *Bacteroidetes*.[58] In other words, the alteration of the microbiome may turn out to be an important treatment consideration for Crohn's.

This research has led scientists to continue evaluating the relationships between the gut microbiome and epileptic seizures. In that vein, a recent study looked at the relationship between the microbiome and patients with drug-resistant epilepsy. The question was whether or not an altered microbiome (dysbiosis) was involved in the mechanism of drug-resistant epilepsy. Patients were grouped into drug-resistant (n = 42) and drug-sensitive (n = 49) groups, and another 65 were used as healthy controls. Fecal samples were collected from all the study participants, and the microbiome composition was analyzed.

The researchers found that the gut microbiome of the drug-resistant epilepsy group was significantly altered, with an abnormal increased level of rare bacteria. Conversely, the gut microbiome makeup of the drug-sensitive epilepsy group was similar to that of the healthy controls. Also, patients with four seizures per year or fewer showed an increase in *Bifidobacteria* and *Lactobacillus* compared with those with more than four seizures per year.[59] The researchers concluded that dysbiosis or an altered gut microbiome may be involved in the mechanism of drug-resistant epilepsy, and thus restoring the gut microbiome may be a novel therapeutic approach for drug-resistant epilepsy.

In another study appearing in *Beneficial Microbes,* researchers examined the effectiveness of probiotics for controlling seizures in 45 patients with drug-resistant epilepsy. The study patients were given a probiotic mixture for 4 months. Assessment of the participants was carried out before and after the administration of probiotics; including number of seizures; patient's quality of life; and levels of CD-14, interleukin 6, and γ-aminobutyric acid. Of the patients, 28.9% showed a reduction of greater than 50% in the number of epileptic seizures and a significant improvement in quality of life. The researchers concluded that probiotics may contribute to improving seizure control and quality of life in patients with drug-resistant epilepsy.[60]

An area that is gaining significant recognition in the treatment of the challenging *Clostridium difficille* infections of the GI tract is fecal microbiome transplantation (FMT). FMT is another exciting and promising field in gut microbiome research that involves the reconstruction of the gut microbial environment by the transplantation of healthy bacteria from a human donor.

In a recently published report, FMT cured epilepsy in the case of a patient with Crohn's disease. This was the first case to not only achieve remission of Crohn's disease but also resolve neurological symptoms in a girl with a 17-year history of epilepsy. More impressive was the fact that after a 20-month follow-up, FMT therapy had proven its efficacy in preventing relapse of seizures, even after withdrawing the antiepileptic drugs. This again highlights the role of the microbiome–gut–brain axis and hints at a potential new treatment for epilepsy through reconstruction of the gut microbiome.

Nutritional Considerations

Pyridoxine

Two types of vitamin B_6–related seizures are known in newborns and infants younger than 18 months of age: vitamin B_6-deficient and vitamin B_6-dependent. They cause similar neurologic symptoms and EEG abnormalities; if not treated, they carry a prognosis of significant developmental disabilities.[62]

Pyridoxine-dependent seizure is an autosomal, recessively inherited inborn error of metabolism. In affected patients, long-lasting seizures usually begin in infancy, but they may also appear up to 3 years of age and recur. They are resistant to conventional anticonvulsants. The condition ends fatally if diagnosis and administration of pyridoxine in pharmacological doses are delayed too long.[63] The diagnosis of pyridoxine dependency should be suspected in every infant with convulsions in the first 18 months of life. Certain clinical features may be especially suggestive, including the following:

- Seizures of unknown origin in a previously normal infant without an abnormal gestational or perinatal history
- A history of severe convulsive disorders
- The occurrence of long-lasting focal or unilateral seizures, often with partial preservation of consciousness
- Irritability, restlessness, crying, and vomiting preceding the actual seizure

MRI with spectroscopy may be a useful tool in the neuroimaging evaluation of parenchymal changes, despite a normal-appearing brain MRI in patients with pyridoxine-dependent seizures.[64] Because atypical presentations of pyridoxine-responsive seizures have been

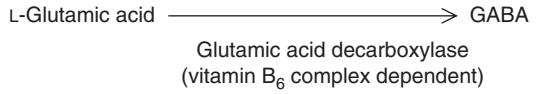

Fig. 167.2 The conversion of glutamic acid to gamma-aminobutyric acid.

reported, it has been recommended that an empiric trial of parenteral pyridoxine be tried in any neonate or infant with long-lasting convulsions, especially when no clear-cut etiology is present.[62,65] A 100- to 200-mg intravenous dose or 20-mg dose every 5 minutes to a total of 200 mg is recommended. If the seizures stop, it is likely that the child has pyridoxine-responsive seizures.[62,65] The chance to identify a pyridoxine-responsive seizure is lost if pyridoxine is given together with or after most anticonvulsant drugs.[65]

Although vitamin B_6-deficient seizures are promptly corrected by the administration of dietary amounts of pyridoxine, vitamin B_6-dependent seizures require continuous high-dose supplementation in the range of 25 to 50 mg/day.[62,65-67]

Although the mechanism by which pyridoxine decreases seizure activity is not fully understood, it is undoubtedly related to its role as a necessary cofactor in the metabolism of various neurotransmitters, the production of which depends on amino acid decarboxylation. Once absorbed, pyridoxine is phosphorylated to pyridoxal-5-phosphate, a coenzyme in the reaction converting glutamic acid to GABA (Fig. 167.2). GABA, as mentioned earlier, is an important inhibitory neurotransmitter.

One proposed mechanism for pyridoxine dependency is that pyridoxal phosphate does not bind with its usual affinity to glutamic acid decarboxylase, resulting in reduced GABA production. In these patients, higher-than-normal levels of pyridoxine are required to allow for the activity of this enzyme.[62,65-67]

One study of infants and children with uncontrollable infantile spasms or their sequelae found improvement in 2 to 14 days using oral pyridoxine phosphate (20–50 mg/kg). Of the 17 total subjects, 3 had complete relief, 6 showed transient relief, and 8 showed a marked reduction in seizures and improvement in their EEGs.[67] Some adverse reactions were seen, including elevated transaminases, nausea, and vomiting.

Administration of vitamin B_6 to patients with epilepsy must be strictly monitored. Although some improvements have been noted, daily doses in the range of 80 to 400 mg have been shown to interfere with commonly used anticonvulsants.[68]

Folic Acid

Serum and red blood cell folate levels are reduced in up to 90% of patients receiving phenytoin, carbamazepine, or barbiturates. These drugs interfere with the intestinal uptake of folic acid at the mucosal level. Lamotrigine and zonisamide appear to not be associated with low levels of folic acid. Most reports state that valproate does not reduce folate levels, although some of the literature is inconsistent. A convincing argument now suggests that routine folic acid supplementation is important for adults receiving antiepileptic medication.[69]

The U.S. Food and Drug Administration (FDA) has directed that oral tablets of folic acid not exceed 1 mg because of concerns brought forward more than 30 years ago that larger amounts might counteract the antiseizure effects of antiepileptic drugs and increase the frequency of seizures in some children.[70] Although that concern is no longer considered valid by epilepsy specialists, the dose restriction has not been lifted. Supplementation with folic acid appears safe even up to doses as high as 15 mg/day[69] and can protect both against birth defects for women of childbearing potential and also lower homocysteine levels, a risk factor for cardiac disease for adults using antiepileptic medications.

Thiamine

In an interesting study, 16 of 50 consecutive neurological patients with a diagnosis of thiamine deficiency showed epileptic manifestations. It is possible that thiamine deficiency may promote epileptic episodes in those who have a subclinical predisposition to seizures. For example, the stimulation of nerve fibers in vitro causes them to lose significant amounts of thiamine pyrophosphate in the surrounding fluid, suggesting a significant role for thiamine in nerve-to-nerve conduction. In addition, thiamine deficiency may be accompanied by low concentrations of GABA, which, as noted earlier, is significant in seizure disorders. The authors suggested that, in patients with late-onset epilepsy, thiamine deficiency may be considered one of the possible causes.[71]

Taurine

Taurine is one of the most abundant amino acids in the mammalian brain.[72,73] It is involved in hyperpolarizing neurons by changing ion permeability and may mimic the effects of GABA and glycine.

Since the early 1970s, considerable clinical and experimental evidence has accumulated supporting the anticonvulsive activity of taurine.[72-85] The primary mode of action responsible for taurine's activity in epilepsy is its membrane-stabilizing effects (i.e., it seems to normalize the flow of Na^+, K^+, and Ca^{2+} into and out of the cell).[72-74]

In addition to acting as a GABA-like neurotransmitter,[72-75] taurine may also help decrease seizure activity by increasing GABA levels through the enhancement of glutamic acid decarboxylase.

Patients with epilepsy have been shown to have significantly lower levels of taurine in platelets than control patients.[76] Although several studies have shown lower taurine levels in the plasma, serum, and urine of patients with epilepsy, other research has yielded disparate results.[77-80] The cellular concentration of taurine as determined by platelet level is thought to be of much greater significance.

The first clinical trials of taurine were undertaken by Barbeau and Donaldson[81] in 1973 and Bergamini and colleagues[82] in 1974. The results were encouraging, and several additional reports have confirmed taurine's anticonvulsant effects.[72,74,81-87] However, the rate of effectiveness of taurine is far below the level where it could be recommended as a standard treatment for epilepsy. At this time, there is no consensus on the seizure types for which taurine is most suitable, nor is there agreement on an appropriate dose. Even more, it is questionable whether taurine may even have the ability to effectively traverse the blood–brain barrier to gain an effect.[88]

At a daily oral dose of 0.05 to 0.3 g/kg in one study and 750 mg in another, taurine has demonstrated efficacy in some cases of intractable epilepsy, decreasing seizures by more than 30% in 11 of 34 subjects.[86,87] This is highly significant because these patients were unresponsive to any other anticonvulsants. Patients with partial epilepsy demonstrated the best results, with those achieving the highest taurine concentrations showing the best response.

The positive clinical response of some patients with epilepsy to supplemental taurine and the apparent cellular deficiency of taurine suggest that taurine supplementation be tried in most patients. Therapeutic monitoring of platelet or plasma taurine levels may prove useful.

Magnesium

Patients with epilepsy have been shown to have significantly lower serum magnesium levels, with seizure severity correlating with the level of hypomagnesemia.[89-92] Although the mechanism of action is not fully understood, in uncontrolled trials, magnesium has been shown to be of benefit in the control of seizures.[89,93] It has also been postulated that like those of folic acid, magnesium levels may be lowered by antiepileptic medications.[92]

Pfeiffer[93] found that a magnesium deficiency induces muscle tremors and convulsive seizures and reported success in controlling the seizure activity of 30 patients with epilepsy with 450 mg/day of magnesium.

Manganese

The link between epilepsy and manganese was first suggested in 1963, when Hurley and associates[94] observed that manganese-deficient rats were more susceptible to seizures than manganese-replete animals and that manganese-deficient animals exhibit an epileptic-like EEG. This prompted researchers to measure manganese concentrations in patients with epilepsy. Low manganese levels in whole blood and hair have been found in patients with epilepsy, and those with the lowest levels typically have the highest seizure activity.[95-99]

Manganese plays a significant role in cerebral function, as it is a critical cofactor for glucose utilization within the neuron, adenylate cyclase activity, and neurotransmitter control. Optimal central nervous system function requires proper manganese levels. Manganese supplementation may be helpful in controlling seizure activity in some patients.[100]

Zinc

Children with epilepsy have been found to have significantly lower levels of serum zinc, especially those with West's or Lennox syndrome.[91,101] More importantly, it appears that patients with epilepsy may have an elevated copper:zinc ratio.[101] Seizures may be triggered when zinc levels fall, as in the absence of adequate taurine. Although the exact role of zinc or the copper:zinc ratio is not clearly understood, it appears to involve either the storage or binding of GABA.[101]

Zinc supplementation appears to be warranted, especially in light of the observation that anticonvulsants may cause zinc deficiency.[102]

Choline, Betaine, Dimethylglycine, and Sarcosine

Choline, betaine (N,N,N,-trimethylglycine), dimethylglycine (DMG), and sarcosine have exhibited some anticonvulsant activity in human and animal studies. Choline is converted to betaine when it acts as a methyl donor, whereas betaine is converted to DMG when it donates a methyl group. This is most evident in the transformation of homocysteine to methionine. Supplemental betaine has also been shown to be effective in preventing various induced seizures in rats and in alleviating seizures in humans with homocystinuria.[103-107]

DMG has also been shown to block induced seizures in rats and mice.[105,106] Roach and Carlin[108] reported a striking decrease in seizure frequency in a patient with long-standing mental retardation when 90 mg of DMG was administered twice daily. Despite treatment with phenobarbital and carbamazepine, the patient had an average of 16 to 18 generalized seizures each week. Within 1 week of starting DMG, seizure frequency dropped to three per week. Two attempts to withdraw the DMG caused dramatic increases in seizure frequency.

It has been suggested that glycine and betaine may act indirectly on glycine metabolism and glycine-mediated neuronal inhibition, enhance GABA activity, or may have a nonspecific effect on biological membranes.

Vitamin D

The association of anticonvulsant drugs with disorders of mineral metabolism—including hypocalcemia, rickets, and osteomalacia—is well documented.[109] Conflicting results have been published concerning the serum levels of vitamin D in patients with epilepsy. Studies have reported increased,[110] normal,[111] and decreased levels.[112]

Supplemental vitamin D intake is recommended when climatic conditions or the patient's lifestyle do not allow adequate exposure to sunlight.[113] Supplementing the diets of 23 patients with epilepsy with 4000 to 16,000 IUs of vitamin D resulted in a significant decrease in the number of seizures, indicating a possible therapeutic effect.[114] Doses of this magnitude can, however, be toxic, requiring careful monitoring.

Vitamin E, Selenium, and Antioxidants

Vitamin E and selenium function synergistically in many physiological functions. Vitamin E deficiency is known to produce seizures,[115] and antiepileptic drugs have been shown to decrease the levels of vitamin E[116,117] as well as those of other antioxidants, like beta-carotene. Studies have shown both vitamin E and selenium to be low in patients with epilepsy.[115,118] Phosphate diesters of vitamins E and C have been shown to prevent the formation of epileptogenic foci and to attenuate seizure activity in animal models of epilepsy.[119] Supplementation with vitamin E and selenium may result in improved control of seizures.[115]

A double-blind placebo-controlled study of 24 children with epilepsy unresponsive to antiepileptic drugs found that supplementation with 400 IU/day of vitamin E provided a significant reduction in the number of seizures in 10 of 12 children. The 2 unresponsive children were noncompliant. All the children continued their normal doses of antiepileptic drugs. No benefit was seen in the 12 placebo children, and, as expected, no negative side effects resulted from the vitamin E therapy.[120]

One report described four children with reduced glutathione peroxidase activity, intractable seizures, multiple infections, and resistance to anticonvulsant treatment. All had seizures within the first 6 months of life. There was no evidence of known inborn errors of metabolism; however, all four patients had low intracellular levels of glutathione peroxidase. Two had normal whole-blood selenium levels, whereas the other two had low levels. Once anticonvulsant therapy was stopped and selenium administered, all four patients experienced clinical improvement.[121]

For epileptic discharges induced in animal models, other antioxidants, such as alpha-lipoic acid and those found in green tea, have been shown to scavenge radical oxygen species and may be prophylactic.[119,122]

Essential Fatty Acids

Animal studies have demonstrated that long-chain polyunsaturated fatty acids may alleviate or prevent cerebrovascular pathophysiology and can improve the competence of the blood–brain barrier.[123] One human 5-patient study using 5 g/day of a 65% omega-3 fatty acid spread demonstrated a marked reduction in both the frequency and strength of epileptic seizures.[124] However, three hospitalized patients with schizophrenia treated with gamma-linolenic acid and linoleic acid in the form of evening primrose oil developed temporal lobe epilepsy following ingestion of the oil. This epilepsy ceased once carbamazepine treatment was initiated.[125] It may be important to monitor the use of oils and fatty acids in closely treating epilepsy; also, more research is needed to determine which agents are most beneficial. At this point, omega-3 fatty acids seem to be the best choice, and evening primrose oil should be used with caution.

Melatonin

It is well documented that melatonin (*N*-acetyl-5-methoxytryptamine) is a powerful antioxidant. Melatonin is often used to treat abnormalities in sleep–wake cycles, jet lag, cancer, and Parkinson's disease. Children with epilepsy have a higher incidence of sleep problems, and epilepsy is exacerbated by sleep deprivation.[126] Animal studies have demonstrated melatonin to have antiepileptic activity. Although not entirely clear, it is possible that melatonin exerts an antiexcitotoxic neuroprotective effect by lowering lipid peroxidation and raising coenzyme Q_{10} levels within the central nervous system.[127]

One randomized, double-blind, placebo-controlled trial included 31 children 3 to 12 years of age who had been taking sodium valproate (10 mg/kg per day) for 6 months and were seizure-free. Of these children, 16 received a fast-release 3-mg melatonin tablet and 15 received a placebo, all 1 hour before bedtime. Using standard Quality of Life in Childhood Epilepsy scales, it was revealed that attention, memory, language, anxiety, behavior, and other cognitive processes all improved in the group receiving melatonin. The general health score also improved marginally. Although not objectively assessed, perceptible increases in appetite and the quality of sleep were reported by most in the melatonin group.[128] Given that high doses have been well tolerated in adults (up to 300 mg/day),[129] it may be possible to slowly increase the 3-mg dose of melatonin for even better results.

Botanical Medicines

Chinese Herbal Medicines

Botanical medicines have played a significant role in the treatment of epilepsy in both the Eastern and Western healing arts. Western scientific methodologies have been used to evaluate the efficacy of the Chinese herbal medicine combination known as saiko-keishi-to (SK).[130] SK demonstrated dramatic therapeutic effects on some difficult cases of epilepsy that had long been unsuccessfully treated with standard allopathic anticonvulsive drugs. SK is a combination of nine botanical drugs:

- *Bupleuri radix* (5 g)
- *Scutellaria radix* (3 g)
- *Pinelliae tuber* (5 g)
- *Paeoniae radix* (6 g)
- *Cinnamon cortex* (2 g)
- *Zizyphi fructus* (4 g)
- *Ginseng radix* (30 g)
- *Glycyrrhizae radix* (1.5 g)
- *Zingiber rhizoma* (2 g)

In one experiment, seizure-like activity was induced in snail neurons by the drug pentylenetetrazol.[131,132] SK was found to do the following:

- Inhibit the intracellular shift of Ca^{2+} toward the cell membrane
- Inhibit the binding of Ca^{2+} to Ca^{2+}-receptive membrane proteins and the Ca^{2+}-calmodulin complex
- Inhibit the conformational changes of the Ca^{2+}-receptive membrane proteins
- Inhibit the pathological transmembrane current of Na^+, K^+, and Ca^{2+}

The researchers presumed that SK's experimental effects were similar to its mode of action in humans. When an attempt was made to isolate purified chemicals from the component herbs, the crude drug's efficacy was lost. This suggests a synergistic effect between the component botanical agents.

Clinical research has shown some benefit in patients with epilepsy. One study reported that 8 of 28 patients with epilepsy experienced a 25% decrease in the number of seizures after 8 weeks of treatment.[132]

More recent research has shown that SK also has a protective effect on neuron damage produced by various factors, including stress. This may point to possible antioxidant-specific compounds within the formula, affecting the central nervous system. Supporting this hypothesis is the fact that the same researchers found SK to have preventive effects on abnormal expression of one of the seizure-related genes.[133] Research showing that the cyclic nucleotides involved in the pathophysiology of seizures has elucidated a possible mechanism for the action of several botanical medicines used in the treatment of seizure activity.[134] Cyclic adenosine monophosphate (cAMP) has been demonstrated to depress electrical activity in cat hippocampal slices, whereas cyclic guanosine monophosphate can produce seizure-like discharge in the same tissues.[135] In addition, cAMP inhibits Ca^{2+} from binding to intracellular proteins like calmodulin, resulting in a decrease in the extrusion of neurotransmitters into the synapse.

Coleus forskolii. The botanical *Coleus forskolii,* an important plant medicine in the Ayurvedic treatment of epilepsy, activates adenylate cyclase, thus increasing the levels of cAMP.[136,137] This action is thought to be due to forskolin, a diterpene, which has been found to increase adenylate cyclase activity by 530%.[137] This is the greatest activity found in 100 plants studied for the ability to increase cAMP. The same study found that seven of the nine botanicals in SK—*B. radix, C. cortex, G. radix, P. radix, G. radix, S. radix,* and *Z. rhizoma*—were found to display significant cAMP enhancement, either by enhancing adenylate cyclase or inhibiting cAMP phosphodiesterase.[137] *B. radix,* a key component of the SK formula, was found to increase cAMP by 170%.

Ginkgo biloba. *Ginkgo biloba* is well known for its usefulness as a memory aid, for cerebral insufficiency, and for its powerful antioxidant properties. However, some of the literature has cited the possibility that it may be responsible for precipitating seizures in two individuals with prior well-controlled seizures. In both patients (78 and 84 years of age), seizures commenced after taking gingko, and they were both seizure-free after the ginkgo was discontinued. The flavonoid components in gingko have been shown to exert GABAergic activity as partial agonists at benzodiazepine receptor sites, and this activity could play a role.[138] As a prudent measure, patients with a seizure history should probably stay away from this botanical until more research has been conducted.

Cannabinoids

There has been interest in the use of cannabis for the treatment of epileptic seizures for hundreds of years. In fact, the first studies on the medical use of cannabis actually date back thousands of years; Sumerian and Akkadian records indicate the use of a medicinal plant (probably cannabis) for nocturnal convulsions.[139-141] Records in the Arabic and Islamic literature also identify cannabis as a treatment for seizures and epilepsy.[142]

The first detailed descriptions of the efficacy of cannabis as an antiseizure medication were reported by W.B. O'Shaughnessy, a physician at the Medical College of Calcutta. Dr. O'Shaughnessy tested the behavioral effects of various preparations of cannabis on healthy animals and military assistants. It was during this period that he reported the impressive antiseizure effect on an infant girl with recurrent convulsive seizures.[143]

During the 20th century, the interest in the use of cannabis declined because of the illegality of the plant and thus the inability to carry out proper clinical trials. However, in recent years, interest in cannabis-based products has shifted dramatically, and we are now beginning to see the evidence beyond just anecdotal reports.

With more than 100 different cannabinoids and numerous terpenes, the plant has a plethora of active components adding to its vast therapeutic potential and complexity. It has been established that the cannabinoids interact with numerous cellular pathways implicated in a range of diseases. In a nutshell, cannabinoids act as ligands, modulating numerous receptors and, consequently, their downstream biological pathways. Interestingly, although cannabinoids may have similar structures, their actions vary significantly.

In general, research surrounding epileptic seizures has focused on nonpsychotropic cannabinoids; these are cannabinoid extracts void of tetrahydrocannabinol (THC) because this psychotropic cannabinoid is not suitable for seizure treatment. Instead, researchers have focused on cannabidiol (CBD), a nonpsychotropic cannabinoid with an impressive anticonvulsant profile and devoid of adverse psychoactive effects.

This accumulation of safety data has spawned an increasing use of CBD extracts for seizure disorders, specifically in children.

Endocannabinoid System

To better understand cannabinoids and their effect on human physiology, it is important to have an overview of the endocannabinoid system (ECS). The ECS has been extensively studied in regards to its biochemistry and physiology. It is a complex system made up of receptors, ligands, and enzymes, with far-reaching effects. Regarded as one of the largest receptor systems in the human body, the ECS is able to send and deliver important information to numerous cell types and impart important downstream physiological actions.

Research over the years has revealed that modulating the activity of the ECS through cannabinoids plant compounds found in cannabis, like CBD, holds therapeutic promise for a number conditions, ranging from anxiety disorders to Parkinson's, Huntington's disease, multiple sclerosis, neuropathic pain, atherosclerosis, myocardial infarction, stroke, hypertension, glaucoma, metabolic syndrome, osteoporosis, and probably one of the most exciting and best-studied areas, epileptic seizures.[144,145]

Endocannabinoid Receptors, Ligands, and Enzymes

The ECS includes a group of endogenous cannabinoid receptors, ligands, and enzymes that are found in both the CNS and the peripheral nervous system (PNS) and throughout most organ systems in the body.

Cannabis contains compounds similar to these ligands known as cannabinoids, with an affiliation not only with these receptors but also affecting G-protein–coupled receptor 55 (GPR55), adenosine receptor, tumor necrosis factor-alpha (TNF-α), transient receptor potential of vanilloid type 1 (TRPV1), and others. Some of the cannabinoids found in cannabis are well known, whereas others are just starting to gain attention. Tetrahydrocannabinol (THC), cannabidiol (CBD), cannabinol (CBN), cannabigerol (CBG), cannabidivarin (CBDV), and cannabichromene (CBC) are just some of the interesting active components. New research is giving us valuable information about the possibilities of these cannabinoids being used as medicines.

The two main endocannabinoid receptors are cannabinoid receptor type 1 (CB1) receptors, found in the CNS as well as peripheral organs and tissues, and cannabinoid receptor type 2 (CB2) receptors, predominantly present in the immune system and associated structures. Both of these receptors are the main molecular targets of the endocannabinoid ligands, anandamide and 2-arachidonoglycerol (2-AG).

Although endocannabinoid receptors and ligands are often what we associate with the ECS, there is actually more. Enzymes also play an important role in the process. For example, the enzyme fatty acid amide hydrolase (FAAH) breaks down anandamide, pulling it out of circulation. Anandamide is an important endocannabinoid that helps reduce the feelings of anxiety and stress. Elevated levels of FAAH will reduce the levels of anandamide, leading to amplified feelings of anxiety. Interestingly, it may be a deficiency in endocannabinoid activity that is a contributing factor in seizure disorders and other conditions like multiple sclerosis, chronic fatigue, fibromyalgia, migraines, irritable bowel syndrome (IBS), and others.[146] This deficiency could be due to lifestyle, drug abuse, genetic predisposition, poor diet, omega-3 imbalance, and possible environmental toxins. In 2003 Ethan Russo, MD, coined the term *clinical endocannabinoid deficiency syndrome* (CEDS), reflecting the observations seen in clinical research.[147]

There are numerous chronic conditions where symptomatic success has been difficult to achieve and often involves using a plethora of prescription medications. The concept of toning the ECS opens up a whole new arena of treatment possibilities involving not only seizure disorders but other conditions as well.

CBD for Seizures

For centuries, there have been numerous cases treated with cannabis for epileptic seizures. Unfortunately, the lack of properly controlled clinical trials has clouded the outcomes and understanding of mechanisms of action. However, recent research has given rise to high-quality placebo-controlled trials of purified CBD extracts showing significantly better outcomes than placebo in treating specific types of seizure disorders. For example, in a large, prospective, single-center, open-label study recently published in *Epilepsy Behavior,* 72 children and 60 adults with treatment-resistant epilepsy (TRE) were given CBD at 5 mg/kg/day and titrated up to a maximum dosage of 50 mg/kg/day (most patients landed at treatment dosages between 20 and 30 mg/kg/day) The objective of this study was to characterize the changes in adverse events, seizure severity, and frequency in response to a pharmaceutical formulation of highly purified cannabidiol (CBD).

Data evaluation of the pediatric and adult subgroups revealed similar outcomes. Both groups showed significant improvements in both seizure frequency and severity by week 12 that sustained over the 48-week treatment period.[148]

What can be called a breakthrough study in CBD use for seizures was published in the *New England Journal of Medicine* in May 2017. This was the first randomized, placebo-controlled, double-blind trial of CBD in Dravet syndrome (a rare genetic epileptic encephalopathy). One hundred and twenty patients with Dravet syndrome participated in the study that involved 23 centers in the USA and Europe. These patients varied in ages from 2.3 to 18.4 years (mean age 9.8 years) and were randomized to receive either 20 mg/kg/day of CBD in two divided doses or placebo.

The baseline was set to include patients who had at least four convulsive seizures during a preceding 4-week period. Duration of treatment was 14 weeks, including a 2-week titration phase. Compared with the start of the treatment, the median monthly frequency of convulsive seizures (defined as the sum of tonic-clonic, tonic, clonic, and atonic seizures) decreased from 12.4 to 5.9 in the CBD group and from 14.9 to 14.1 in the placebo group.[149]

This trial was considered a "game-changer" because, for the first time, we had robust evidence that CBD added on to preexisting antiepileptic drug treatment reduced the frequency of convulsive seizures in children and young adults with Dravet syndrome.

Another study appearing in the *Lancet*—titled "Cannabidiol in Patients with Seizures Associated with Lennox-Gastaut Syndrome [LGS; LGS is characterized by two or more types of seizures, mental retardation, and a particular EEG pattern with a slow spike-and-waves pattern], a Double-Blind, Placebo-Controlled Phase 3"—also showed positive outcomes. This study demonstrated that CBD, given as an adjunct treatment to patients with LGS taking anticonvulsant drugs, significantly decreased the frequency of monthly drop seizures compared with placebo.

The multicenter study enlisted 171 patients with LGS (mean age 15 years) whose seizures failed to respond to treatment with antiepileptic drugs. Patients were randomized to receive either 20 mg/kg of oral CBD (86 patients) or placebo (85 patients) for 14 weeks.

A key study objective was to measure the baseline change in the number of atonic, tonic, and tonic-clonic seizures (drop seizures) recorded during the treatment period in those randomized to receive CBD compared with those receiving placebo.

Before the treatment, patients had a baseline median frequency of 74 drop seizures per month. Compared with placebo-treated patients, those on CBD had a significantly higher median decrease in drop seizures—22% versus 44%, respectively. Importantly, improvements in drop seizure rates in patients on CBD were detected in the first month of treatment and maintained.

Additional (secondary) endpoints also supported CBD's efficacy: 44% of the patients had a 50% or higher reduction in drop seizures compared with 24% of placebo controls, and the total seizure frequency was significantly reduced in 41% of CBD-treated patients versus 14% in placebo. Also important to note is that CBD was generally well tolerated and safe.[150]

SUMMARY

After centuries of anecdotal reports, there is now conclusive evidence that cannabinoids have a place in treating seizure disorders. Double-blind, randomized clinical trials have shown CBD to be effective in treating two difficult epileptic disorders: Dravet and LGS. In fact, the FDA has approved CBD (Epidolex) oral solution for the treatment of these two epileptic disorders for patients 2 years of age and older. This is the first FDA-approved drug that contains a purified natural drug substance derived from cannabis.

These are very exciting times for cannabinoid research because this approval will open the doors to expand research into more epileptic seizure disorders. In many ways, we are just beginning to scratch the surface in uncovering the incredible treasure chest that lies within the family of cannabinoid molecules. The advantages of using CBD to treat certain forms of epileptic seizures are that they have fewer side effects than common antiepileptic drugs and are generally considered safe even at high doses. This has been proven by the clinical trials and supports the premise that many effective natural plant products have fewer side effects. It appears we have entered into a new era in seizure treatments where cannabinoids may become the treatment of choice.

Acupuncture

From work on animal models, it has been suggested that the mechanism of acupuncture in suppressing epileptic seizures involves the release of neurotransmitters such as endogenous opioid peptides, serotonin, and GABA.[151] Other studies have shown possible seizure inhibition through decreasing neuronal nitric oxide synthase transcription in the hippocampus.[152,153]

In humans, effective use of acupuncture, scalp needling, electroacupuncture, and embedding of acupuncture points to treat epilepsy and status epilepticus has been reported. However, one sham-controlled study of 34 patients found no benefit.[154] This research group reported similar results with a study of 29 patients. In a second study, many of the patients reported changes in their sense of well-being.[155] In both clinical trials, drug-resistant patients who had been considered intractable were given nearly identical treatments save one or two points, also without benefit. Given the individualized nature of traditional Chinese medicine, this may not be a reasonable representation of the acupuncture modality. Additionally, it may be possible that more benign cases of epilepsy may be more responsive, even if intractable cases are not.

Auricular, or ear, acupuncture was developed by Nogier, a French neurologist, in the 1950s. Unlike traditional Chinese acupuncture, which uses the meridian system, ear acupuncture uses points on the ear that represent different areas on the body, similar to the way reflexology works with points on the foot. In one study, epileptiform behaviors in rats were induced by intrahippocampal injection of penicillin. Radioimmunoassay techniques demonstrated that levels of somatostatin, aspartic acid, glutamine, and GABA were increased. One hour later, the lower-half auricular lobules of seizure rats, containing the ear-points Pizhixia and Shenmen, were electrically stimulated. After auricular treatment, the convulsion behaviors of the rats improved. Concomitantly, the content of the somatostatin, aspartic acid, and glutamine in the seizure rats' hippocampi was significantly decreased, whereas the content of glycine, taurine, and GABA had increased. These results suggest that ear-point electrical stimulation has antiepilepsy effects. Physiologically, given that amino acid concentrations may be involved in the pathogenesis of an epileptic seizure, auricular treatment might be involved in decreasing the content of the somatostatin, aspartic acid, and glutamine and increasing that of glycine, taurine, and GABA in the hippocampi of seizure rats.[156,157]

Ear acupuncture may then be more effective than traditional body acupuncture. More studies are necessary to determine the effectiveness of both auricular and body acupuncture in the treatment of epilepsy. The negative side effect profile of acupuncture is low, although one case report describes an episode of convulsive syncope, which occurred immediately after the insertion of acupuncture needles into the bilateral ST-36 acupuncture point.[158] Given the extraordinarily common use of these points and the extremely rare appearance of side effects due to acupuncture, this case report should be considered an anomaly.

Yoga and Meditation

Yoga teaches a variety of physical postures, breathing exercises, and meditation techniques with the goal of improving both physical and mental health. There are a number of types of yoga emphasizing harmony between the physical and energetic aspects of the body. It has been documented that yoga has a physiological effect that may offer benefit to the patient with epilepsy.[159]

Research has indicated that the meditative types of yoga (e.g., Sahajaea yoga) have the most benefits in reducing the intensity and occurrence of seizures. A Cochrane Review of yoga among patients with epilepsy showed significant improvement in one particular study involving 32 patients with epilepsy divided into an active group and two control groups. The results showed that the active group had a 50% reduction in the number of seizures at 1-year follow-up. Although these results are statistically significant, the authors concluded that further research with larger numbers was needed.[159-161]

Trigeminal Nerve Stimulation

Intractable epilepsy, which affects more than 1 million Americans and is often resistant to drug treatment, may be ameliorated by a procedure known as trigeminal nerve stimulation (TNS). The trigeminal nerve, which extends into the brain from the face and forehead, is known to play a role in the inhibition of seizures, and it has been shown that stimulating this nerve can reduce their occurrence.[162] TNS involves using a stimulator the size of a cell phone that fits into a pocket; its wires are connected to the forehead with adhesives. Electrical impulses are transmitted to the nerve, resulting in reduced seizure frequency.[162]

In a completed clinical trial, patients experienced significant reductions in seizure occurrence. The study demonstrated that those participating in the study experienced a 66% reduction of seizures in the first 3 months, a 56% reduction after 6 months, and a 59% reduction after 12 months, and one of the subjects experienced a nearly 90% reduction in seizures after 1 year. The therapy shows promise as an alternative mode of neurostimulation, especially because it is not invasive (compared with vagus nerve stimulation, which requires surgery).[163,164]

Exercise

There has been understandable caution in recommending exercise to patients with epilepsy, owing to fear of injury and the possibility of seizure induction. However, a review of the literature shows that there is no increase in the frequency of seizures with exercise. Some studies have shown that exercise reduces seizure frequency, specifically in patients with drug-resistant epilepsy. In one study, 15 women resistant to drug therapy engaged in 1-hour physical exercise sessions twice a week for 15 weeks. Seven patients had 27 seizures during the 30 exercise sessions; the self-reported seizure rate was significantly reduced

by the end of the 15-week period (2.9 seizures per week had dropped to 1.7 seizures per week). There were also other benefits to the exercise program, including reduced muscle spasms, improved sleep, and increased energy.[165]

In a review study, the authors discuss the positive effects of physical exercise programs in experimental models of epilepsy. Findings from animal studies show that exercise seems to modulate neuronal vulnerability to epileptic insults. The review also concludes that metabolic, electrophysiologic, and immunohistochemical evaluations have confirmed the positive influence of exercise on the patient with epilepsy.[166]

These findings seem to suggest that physical exercise should be considered and integrated into the therapeutic approach for reducing the intensity and frequency of seizures.

Patients with epilepsy should be advised to avoid situations that could provoke further seizures or could pose dangers in the event that a seizure should occur. Also, they should be made aware of state laws regarding epilepsy and driving. Patients with epilepsy should avoid known initiators of seizure activity (e.g., bright flashing lights, sudden loud sounds). Therapy should continue at full dose until the patient has been seizure-free for at least 2 years. Dosage reduction should then be gradual over a period of several months. Patients with epilepsy who are not controlled with natural therapies require drug therapy.

Patients should eliminate pyridoxine antagonists (isoniazid, cycloserine, hydralazine, dopamine, penicillamine), oral contraceptives, alcohol, and hydrazine dyes (Food, Drug, and Cosmetic Act yellow no. 5).

Note: Status epilepticus, a prolonged seizure lasting longer than 30 minutes that is not likely to stop spontaneously, is a medical emergency that inevitably results in serious neurological damage or death if untreated. Immediate hospitalization is required, preferably with ambulance or aid car transport, with the necessary equipment to maintain the patient's airway, assist in ventilation, and administer intravenous glucose and antiepileptic drugs.

Because endogenous depression is more prevalent in persons with epilepsy than in the general population,[167] monitoring for depressive illness is important in patients with epilepsy.

Diet

All sugar and other refined carbohydrates should be eliminated, and protein levels should be moderated. Food allergens should be identified and eliminated. Small frequent meals are best. If a ketotic effect is desired, all carbohydrates should be strictly limited and fat intake increased. Furthermore, adequate intake of energy and protein, plus a higher proportion of omega-3 unsaturated to saturated dietary fats, should be assured. Finally, vitamin and mineral supplements should be used with ketotic diets (ketotic diets should be used only under professional supervision).

Lifestyle

Regular sleep patterns should be encouraged, along with some form of physical exercise.

Nutritional Supplements

(The following are adult doses; reduce proportionately for children.)

- Vitamin B_6: 50 mg three times a day (if ineffective, try P5'P 5 mg three times a day)
- Folic acid: 0.4 to 4 mg/day (activated folates probably a better choice)
- Vitamin E: 400 IU/day (mixed tocopherols suggested)
- Taurine: 500 mg three times a day
- Magnesium: 300 mg three times a day
- Manganese: 10 mg three times a day
- Selenium: 100 mcg/day
- Zinc: 25 mg/day
- Ubiquinone: 100 mg/day
- Melatonin: 3 mg a day in children, increase up to 20 mg or more in adults

Botanical Medicines

- Saiko-keishi-to: 300 mL before bedtime
- *G. biloba*: contraindicated at this time
- CBD: 5 to 30 mg/Kg

Erythema Multiforme

Michael Traub, ND, DHANP, FABNO, John Nowicki, ND, and *Michael T. Murray, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Sudden onset of symmetrical erythematous, edematous, macular, papular, urticarial, bullous, or purpuric skin lesions
- Evolves into "target lesions" (lesions with clear centers and concentric erythematous rings)
- Characteristic first site: dorsum of the hand
- Characteristic distribution: extensor surfaces of extremities, with relative sparing of head and trunk
- Although rare, oral manifestations ranging from tender superficial erythematous and hyperkeratotic plaques to painful, deep, hemorrhagic bullae and erosions
- Tendency to recur in spring and fall

GENERAL CONSIDERATIONS

The term *erythema multiforme* (EM) includes a wide range of clinical expressions, from exclusive oral erosions (oral EM) to mucocutaneous lesions ranging from mild (EM minor) to severe involvement of multiple mucosal membranes (EM major, Stevens–Johnson syndrome [SJS]) or with involvement of a large area of the total body surface (toxic epidermal necrolysis [TEN]). EM, SJS, and TEN are all cutaneous hypersensitivity reactions to specific antigens. SJS and TEN were once classified as distinct entities but are now widely accepted as having similar etiopathogeneses, differing only in severity as measured by the percentage of body surface involvement. Identifying EM is critical because reexposure to the offending antigens is thought to allow for progression to more severe reactions, such as SJS and TEN.[1] Although significant differences exist among EM minor, EM major, SJS, and TEN regarding severity and clinical expression, all variants share two common features: typical or less typical cutaneous target lesions and satellite-cell or more widespread necrosis of the epithelium. Clinically, EM major is characterized by typical or raised atypical targets located on the extremities and/or face (Fig. 168.1). SJS is diagnosed when lesions are flat, atypical targets or purpuric maculae that are widespread or distributed on the trunk.[2]

Among the great number of suspected etiological factors, the differentiating feature between EM and SJS/TEN is that herpes simplex virus or mycoplasmal infections are involved in roughly 90% of cases of EM minor, whereas 80% of cases of SJS and TEN are caused by systemic drugs, mainly anticonvulsants, sulfonamides, nonsteroidal anti-inflammatory drugs, allopurinol, and antibiotics. It is possible that some cases of EM associated with a variety of respiratory, gastrointestinal, or urinary tract infections may represent a single specific delayed-sensitivity reaction to the bacterial endotoxin lipopolysaccharide.[3] Various vaccines (e.g., *Vaccinia;* tuberculosis; poliomyelitis; human papillomavirus; bacille Calmette-Guerin [BCG]; diphtheria, tetanus, and pertussis [DTaP]; measles, mumps, and rubella [MMR]; hepatitis B; meningococcal; pneumococcal; rabies), food additives (e.g., benzoates, nitrobenzene), food allergies, chemicals (e.g., perfume, terpenes), and other infectious organisms have all induced EM. Compounds such as formaldehyde, acrylonitrile, and chlorinated hydrocarbons have also been associated with case reports of either EM, SJS, or TEN.[4]

All variants of EM appear to have a common mechanism. Evidence points to a T-cell–mediated immune reaction to the precipitating agent, which leads to a cytotoxic immunological attack on keratinocytes that express nonself antigens. Subsequent subepithelial and intraepithelial vesiculation leads to widespread blistering and erosions.[5]

Human leukocyte antigen (HLA)-DQ3 correlates closely with recurrent EM and may be a marker to distinguish herpes-associated EM from other skin diseases.[6] Biopsy can help predict disease progression from EM lesions to SJS or TEN.[7]

EM typically occurs in young adults 20 to 40 years of age and is more common in women compared with men (1.5:1.0). The reported prevalence rate of EM is less than 1%, and prevalence rates of oral EM lesions vary from 35% to 65% among patients with cutaneous lesions.[8] The number of EM cases is increasing in cancer patients who have been prescribed immunotherapy or endocrine therapy drugs or are receiving radiotherapy.

THERAPEUTIC CONSIDERATIONS

Potassium Iodide

Potassium iodide has historically been used to treat various erythematous disorders, including the following:

- EM
- Erythema nodosum
- Nodular vasculitis
- Acute febrile neutrophilic dermatosis
- Subacute nodular migratory panniculitis

Fig. 168.1 Erythema multiforme.

Clinical studies have documented dramatic success with potassium iodide.[9–11] The mechanism is apparently related to the suppression of the generation of oxygen intermediates such as hydrogen peroxide and hydroxyl radicals by stimulated neutrophils.[12] Importantly, iodine therapy has occasionally been associated with various adverse skin reactions and gastrointestinal discomfort; it should never be used in pregnant women in the last trimester owing to its effect in suppressing the fetal thyroid.[13,14]

Zinc

Zinc sulfate (0.025%–0.05%) has been used locally at the site of herpetic infection and to prevent the relapse of postherpetic EM.[15]

Topical Vitamin A

Ocular involvement of EM can be treated with topical vitamin A ointment.[16]

THERAPEUTIC APPROACH

A careful search should be made to determine the initiating factor. Underlying infections should be treated, all unnecessary medications stopped, and an anti-inflammatory program initiated. In herpes-associated EM, antiviral treatment initiated after EM has erupted has shown no benefit. Symptomatic treatment—including local skin care, analgesics, and soothing mouthwashes—is important. Liquid antiseptics help prevent superinfection. In the severe form of EM, there may be extensive lesions and an inability to ingest foods. A liquid diet may be necessary. Intravenous fluid replacement with electrolytes and nutrients should be started as early as possible. The use of systemic corticosteroids is controversial, with some believing that it may increase the risk of complications.

Supplements

- Potassium iodide: 100 mg three times daily for 4 to 6 weeks, to be discontinued if there are adverse reactions
- Zinc sulfate: 0.025% to 0.05% solution applied locally to postherpetic lesions
- Topical vitamin A ointment for ocular lesions

Fibrocystic Breast Disease

Bethany Montgomery Hays, MD, and *Tori Hudson*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

Abnormalities of the breast, both benign and malignant, are increasing.[1] In one study, 16% of women who visited a doctor over a ten-year period had breast complaints. Only 4% of these women turned out to have breast cancer. Yet failure to diagnose breast cancer (often slow to develop and related to lifetime exposure to estrogen)[2] is the most common reason for a physician to be sued for malpractice.[3] Therefore attention to breast complaints and the relationship between benign and malignant lesions is paramount to women's health.

Characteristics of fibrocystic changes of the breast are as follows:

- They are common in reproductive-age women, usually worsening in the luteal phase and in perimenopause and improving after menopause, suggesting a relationship to elevated levels of estrogen (or estrogenic compounds) and/or imbalanced or decreased progesterone.
- They are sometimes asymptomatic or occurring throughout the month but often present as painful, lumpy breasts premenstrually and as part of the premenstrual syndrome (PMS)—also suggesting their relationship to elevated estrogen or estrogen unbalanced by progesterone.
- They are histologically characterized by fibrosis, ductal scarring, and cysts (of various sizes) which may be lined with epithelial cells, apocrine metaplasia, or unlined. The relationship of fibrocystic changes to breast cancer appears to depend on whether the remaining ductal and lobular tissue is found to be proliferative and whether there is atypia.[4]
- Paradoxically, as compared to women with breast cancer, they occur more frequently in women who have nursed multiple infants,[5] suggesting increased exposure to bacteria or antigenic substances in the milk.
- Mammographically, they are are dense, both increasing the risk of cancer[6] and making it difficult to see and diagnose embedded cancers.

*Previous edition contributor

GENERAL CONSIDERATIONS

Fibrocystic breasts or fibrocystic changes of the breast (no longer called "fibrocystic disease"[2,7]) is, in fact, a condition of clinical significance more than just annoyance. The condition is now referred to as fibrocystic changes (FCC), and its relationship to cancer risk has been debated in the past.[8] Currently, breast cancer risk is thought to be related to proliferation and atypia of the epithelial (ductal) component.[9] In fact, FCC may exist on a spectrum of changes that lead to breast cancer.[10] Perhaps the question should be: Do the same things that cause FCC over time cause breast cancer? And more importantly, can we use fibrocystic breast symptoms to begin treatments that will prevent later cancers? Studies of fibrocystic disease are surprisingly few since the 1980s. There is, however, a new understanding of fibrosis, its causes, and its relationship to breast cancer.[11] This new understanding points us to the extracellular matrix as well as the epithelial component of the breast and their response to the following:

1. Inflammation
2. Elevated estrogen/xenoestrogens
3. The breast microbiome

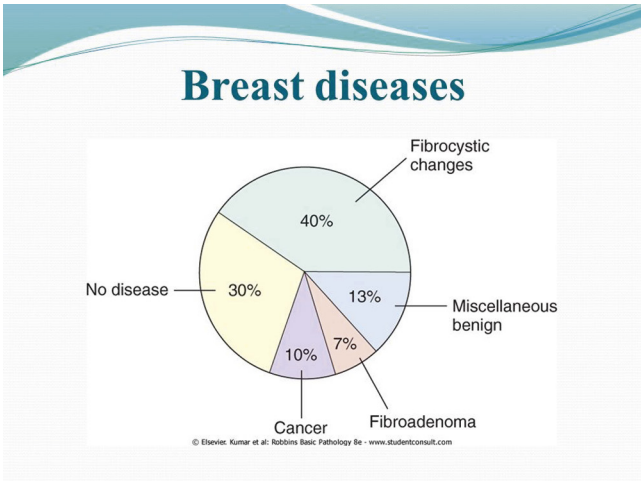
It is important to reconsider whether the condition of FCC, like many diseases, is another response of an organ or tissue to a hostile environment.

In this age of increasing rates of breast cancer, tender or lumpy breasts are among the most common reasons women consult their health practitioners for assessment and treatment. Many women

experience premenstrual discomfort and fullness of the breasts. When bilateral, cyclic, and repetitive and occurring in the luteal phase of the menstrual cycle, these symptoms are clearly hormonally related and suggest an effect of both estrogen *and* progesterone or, more specifically, the balance of the two. Symmetrical nodularity, particularly in the upper outer quadrant, is extremely common on physical examination. These areas may be so tender that palpation is difficult. An asymmetrical (unilateral) mass that can be clearly described (size, shape, distance from the nipple and quadrant of the breast) is a "dominant mass" and must be diagnosed or followed until a firm diagnosis is made by examination under a microscope, resolution (by either spontaneous resolution after one or more menstrual periods or by aspiration of a cyst without recurrence), or occasionally by a history of its presence without change for many years. It is the role of the practitioner to keep any dominant mass on his or her radar screen until convinced of its continuing benign nature. A fixed or changing mass or one accompanied by skin changes, tissue edema, or axillary nodes is clearly problematic and should be examined by mammography and diagnosed by biopsy.

Fibrocystic changes in the breast are so common (estimates vary, sometimes as high as 64%[12] in symptomatic women, although found in up to 54% of *asymptomatic* women in one autopsy study[13]) that they should not be labeled a "disease." Because these changes are frequent even in older women at a subclinical level, they should be considered a "functional change."[12]

It is likely that fibrocystic changes are a common response to the interactions of this unique organ with its environment.



Because many women have symptoms that wax and wane and resolve with strategies that lower estrogen or improve at menopause, and because there is a significant placebo effect in studies, FCC has not received much study or interest. But ask any woman about the discomfort of a mammogram or the annoyance of having to wear a "supportive" bra to bed or the recommendation that she consider psychotherapy, and she will tell you she would like answers and treatment.

ANATOMY AND PHYSIOLOGY OF THE BREAST

Breasts exist for two reasons: to feed babies and to feel good *to their owner* (releasing oxytocin) during sex. (The fact that they are extraordinarily interesting to the opposite sex should have a secondary place in how we care for them.) Both functions require a sensitive nipple, which will cause the release of oxytocin from the pituitary when stimulated.

The nipple has 8 to 10 lactiferous ducts connecting to lactiferous sinuses or ampullae underneath the pigmented areola. These dilated areas of the duct collect small amounts of milk to be expressed by the action of the nursing infant's tongue and jaws. The ducts are connected to 15 to 20 lobes composed of lobules of milk-producing alveoli or acini, with each lobe functioning semiautonomously to reproduce the amount of milk removed at each nursing before the next feeding. Additionally, the breast creates a formula ideal for the gestational age of the infant at birth and later to provide the nutritional needs for the growing infant.[14] (Contemplate how the same breast can completely feed a 2-lb premature newborn and a 1-year old toddler 10 times that size without appreciably changing the size or number of lobules.). The "growing edge" of the ductal system is the ducts within the lobule, which connect to the milk-producing acini (terminal duct lobular unit [TDLU]). These are the most cellularly active parts of the breast. It is in this location that cancers most often begin. The immature ductal system is stimulated to grow into lobules under the influence of increasing levels of estrogen and progesterone at menarche and to mature into milk-producing or mature lobules during pregnancy. Breast duct cells that have never undergone this maturation divide 20 times more often than cells that have acquired the mature phenotype.[15] Once the lobule has matured, it will remain relatively well differentiated under the influence of monthly progesterone until menopause when it regresses, leaving the more "at-risk" undifferentiated ductal system. The differentiated or mature lobule is less frequently the site of cancer, but when it occurs here, it can be more aggressive (lobular breast cancer).

The breast is also composed of connective tissue or stroma surrounding the acini (shown in the accompanying figure in light pink) and more dense stroma surrounding the lobules (shown in dark pink). This tissue is laid down by fibroblasts, which are sensitive to inflammation from various causes.

Each duct and its acinus are surrounded by myoepithelial cells that contract under the influence of oxytocin, pushing the milk to the lactiferous sinuses and allowing the infant to empty virtually the entire breast while suckling and compressing only the areola. The myoepithelial cells also rest upon a basement membrane around the ducts, which ductal cancers and lobular cancers must either break through or be allowed through, and are considered "natural tumor suppressors."[16]

Extracellular Matrix and Fibrosis

The TDLU is embedded in a myxomatous stroma containing fibroblasts, adipocytes, lymphocytes, macrophages, and plasma cells, as well as extracellular matrix (ECM) containing collagen; glycosaminoglycans, such as hyaluronic acid, chondroitin sulfate, dermatan sulfate, keratin sulfate, heparin sulfate, and other polar molecules[17]; and soluble factors (minerals, hormones, cytokines, growth factors and enzymes) at a specific pH and oxygen content. This partly liquid/partly solid matrix both supports the milk-producing lobules and ducts and allows them to expand and contract during milk production and storage. The development of the normal breast and the development of breast cancer depend on the "cross-talk" between these stromal and epithelial elements.[18] The stromal elements surround, nourish, and communicate with the ductal and milk-producing cells.[19] They are subject to epigenetic changes that have been shown to determine both the development of cancer and its ability to invade and metastasize.[20] Fibrocytes in the ECM respond to chronic inflammatory signals.[6] Fibrosis is defined by the overgrowth, hardening, and/or scarring of various tissues and is attributed to excess deposition of ECM components, including collagen.[21] In other words, fibrosis is a response of the ECM to chronic inflammation. "Fibrosis is the end result of chronic inflammatory reactions induced by a variety of stimuli including

persistent infections, autoimmune reactions, allergic responses, chemical insults, radiation, and tissue injury."[22]

This fibrous "scar" tissue, laid down in response to inflammatory signals, both compresses the ducts and obstructs them, producing cysts of various sizes, and through cross-talk and epigenetic changes, it produces alterations in the ductal and lobular epithelium. When these alterations are proliferative, the character of the cysts is different than when the epithelium is flattened, and the risk of breast cancer increases. (See later discussion of cysts.) Only fibrosis with involution of the lobules and nonproliferative changes in the epithelium qualifies as the type of fibrocystic change that does not increase the risk of breast cancer. It is likely that benign epithelium in a background of abnormal ECM, proliferative epithelium, and proliferative epithelium with atypia represents a continuum leading to cancer.

The stromal tissue, especially fibroblasts and immune cells, responds to the environment, which arrives via the blood supply and exits via the lymphatics. It also responds to the contents of the ductal lumen, consisting of the milk being produced, excreted immune cells, and the breast microbiome. The ductal cells also respond to both the ECM and the luminal environment, which, when hostile, can induce metaplastic changes (apocrine metaplasia[23–25]), hyperplasia, atypia, and ultimately, cancer. "Most chronic fibrotic disorders have in common a persistent irritant that sustains the production of growth factors, proteolytic enzymes, angiogenic factors, and fibrogenic cytokines, which stimulate the deposition of connective tissue elements that progressively remodel and destroy normal tissue architecture."[19] In fibrocystic breasts, these chronic irritant signals are likely arriving at the ECM via both the blood and the luminal contents.

Breast Cysts

The breast makes and reabsorbs small amounts of fluid in the ducts throughout life. If the duct is obstructed or scarred by infection or injury, or if fibrosis or fibrotic extracellular matrix is laid down, cysts can form behind the scarred or compressed portion of the duct.[26] Cysts can also form due to excessive secretions created by hyper-cellularity of the ducts and by poor drainage.[27] The former, called *type 2*[28] (compressed ducts), occurs in ~45% of cases and usually do not recur after needle aspiration. They have fluid that is a transudate of serum with a low K^+/Na^+ ratio. The latter, called type 1 (excessive secretions), occurs in ~55% of cases. They are more likely multiple, associated with apocrine metaplasia, often recur after aspiration, and have a high K^+/Na^+ ratio.[20,29,30] This is the classic picture of fibrocystic changes. Because both types of cysts can coexist in the same patient and one has an increased risk of breast cancer but the other does not, studies of fibrocystic breasts have shown conflicting results with regard to the risk of breast cancer. The current consensus is that breast cancer risk is related to the degree of cellular proliferation and atypia of the ductal cells.

Breast Microbiome

Breast tissue has its own microbiome.[31] Studies have recently been done looking at whether a bacterial population exists in the normal uninfected breast and whether that tissue microbiome changes or is different in women with infection or cancer.[30,32,33] Not surprisingly, both are true. Researchers found higher numbers of bacteria that are able to cause DNA damage and fewer *Lactobacillus* in the patients with breast cancer.[31] *Helicobacter pylori,* a known initiator of carcinogen production, has been found in the 4/66 breast milk samples.[34] There is evidence that some bacteria "prepare suitable microenvironments for tumor cell growth."[35]

The breast is one of the tissues "open" to the environment in the female (as are the nasopharynx, cervix/uterus, and bladder), so it should not be surprising to find bacteria and viruses (and occasionally parasites) in the ducts. Its microbiome, however, is different from the gut, mouth, or overlying skin. Mastitis is now thought to be due to dysbiosis or imbalance of the breast microbiome rather than the simple invasion of bacteria.[36] Acute mastitis is caused by pathological organisms (usually staph or strep). It occurs most often at the initiation of breastfeeding when previously unused ducts must dilate and acini and lobules must contract and clear the colostrum and milk being produced. (This early risk may be in part the reason that colostrum is composed primarily of immune cells *and* immunoglobulins.) Acute mastitis often goes untreated and clears spontaneously. When severe, it is usually treated with oral antibiotics. Recently, it has been shown that acute mastitis can be treated with an oral *pro*biotic containing *Lactobacillus salivarius* CECT 5713 or *Lactobacillus gasseri* CECT 5714. With no other treatment than continuing to nurse, the probiotic group had complete resolution by 14 days.[37] A second study compared the *Lactobacillus fermentum* CECT 5716 and *L. salivarius* CECT 5713 with antibiotics. The probiotic groups showed both significant lowering of pathogenic bacteria in the milk and better improvement in pain compared with antibiotics.[38] Another study prevented mastitis by pretreatment with *L. salivarius* in late pregnancy.[39] How do oral probiotics reach the breast? It may be the same way the breast microbiome is established: via immune cells from the gut that carry live bacteria through the bloodstream to the ECM and deliver them to the lumen of the acini and ducts.[35] Completing the loop of connection between the breast microbiome and fibrocystic changes, treatment of *H. pylori* in the gut has been found to be successful in the resolution of FCC symptoms in the breast.[32]

A much less common entity, "plasma cell mastitis"[40] is thought to be caused by chronic irritation of the ducts from secretory products that can produce an autoimmune reaction with infiltration of plasma cells.[41] Because it is most often seen in multiparous women, it may be an immune reaction to antigens seen in previous episodes of lactation. Free fatty acids are known to produce a marked inflammatory response in breast trauma, mimicking cancer as a hard, spiculated mass with microcalcifications on mammogram. Fat-laden macrophages differentiate its microscopical appearance from that of cancer (also thought to be an aberration of the healing process by some[42]).

These "open" channels to the outside world (oropharynx, cervix/uterus, rectum/anus, and bladder/prostate) are protected by locally increased lymphatics; by metaplasia of the interfacing epithelium; by iodine[43]; and in the breast, by lactoperoxidase, lysozyme, and a number of proteins secreted in the milk.[44] Dysbiosis of the breast, like that of the gut,[45] is a likely source of inflammatory signals[32] that can induce changes in the fibroblasts of the ECM,[18,46] causing both fibrocystic changes and potentially cancers. Because fibrosis (a tissue response to inflammation) is found almost universally in the breast (if autopsy studies are to be believed), it would appear that fibrocystic changes are a normal or at least common response to the degree of inflammation in the environment.

A number of additional protective mechanisms exist to prevent infection from the outside from entering the body via the ductal system. The ends of the ducts at the nipple are often sealed by desquamated epithelial cells producing a plug. When removed by the suckling infant or during sex, oral bacteria are more likely to enter, and the microbiome changes. Properties of the milk (lactoferrin, white blood cells [WBCs], various iodinated proteins, and immunoglobulins) act as antibacterial agents in the duct and in the milk being produced. If these fail, infection in the duct can produce oxidative stress, tissue damage, ductal scarring, and ultimately, cysts and fibrosis.

TABLE 169.1 Possible Causes of an Estrogen Effect

1. Overproduction of estrogen
2. Poor metabolism or excretion of estrogen
3. Exogenous estrogen or estrogen therapy
4. Xenoestrogens and metalloestrogens
5. Unbalanced estrogen and progesterone, with estrogen dominance or luteal-phase progesterone deficit
6. Pregnancy
7. Overabundance of estrogen receptors

Hormonal Milieu

The relationship of fibrocystic changes to cyclic mastalgia, increased lumpiness before menses, PMS, increased symptoms in perimenopause, and the resolution of most symptoms after menopause strongly suggest that fibrocystic changes are related to elevated estrogen and, in some cases, the decreased or unbalanced progesterone found at these times.[47,48] FCC has also been related to polycystic ovary syndrome (PCOS), a syndrome related to increased estrogen and insulin resistance.[49,50] The relationship between FCC and estrogen is so strong that many early studies implied that this hormone milieu was causative of FCC. It is more likely that it is important but ancillary. Both the immune system and the ductal system are under the influence of estrogen, progesterone, and estrogen and chemicals from the environment. Some of these environmental toxins are preferentially secreted in the milk.[51] Prolactin has been shown to be normal or mildly elevated in serum but also chronobiological (i.e., related to time of day, day of cycle, and also sleep related).[52] Differences in response to prolactin between normal patients and patients with FCC have been documented.[53] When breast symptoms are cyclic and present throughout the breast, more often than not, they are caused by or exacerbated by too much estrogen *effect.* Possible causes are listed in Table 169.1.

High levels of estrogen and progesterone in pregnancy or during the first few weeks of oral contraceptive use produce growth and differentiation of the milk-producing alveoli, which can also be uncomfortable for some women. These symptoms usually subside as the pregnancy progresses or the endogenous estrogen levels fall with oral contraceptive pill (OCP) suppression. Because hormones are closely linked to FCC and breast symptoms, they offer considerable opportunity for prevention and treatment. Although the traditional approach to hormonal treatment for FCC has been estrogen or prolactin-lowering drugs, which have substantial side effects, each of the noted causes of excess estrogen effect can be addressed with diet, supplements, and herbal therapies.

Environmental Toxins

A growing number of new-to-nature-chemicals in the environment that negatively affect humans are xenoestrogens. The breasts are particularly susceptible. Xenoestrogens can exert both genomic and nongenomic (cell-surface–receptor) effects.[54] Bisphenol A,[55] Glyphosate, plastics,[56] pesticides, (herbicides, insecticides, rodenticides),[57] chemicals used in hydraulic fracturing,[58] a panoply of chemicals in personal care products,[59] and more importantly, combinations of chemicals in doses considered unimportant when taken individually[60] are shown to create cellular changes in susceptible tissues such as the breast. These chemicals are now showing up in groundwater. We are all exposed.

In addition to man-made chemicals, environmental contamination with metalloestrogens, which are small ionic metals that activate the estrogen receptor (ER), are becoming a problem. Breast cysts can be induced by aluminum, a common component of underarm deodorant.[61] Aluminum can cause genomic instability and proliferation in breast epithelial cells. At lower levels, methyl mercury promotes the proliferation of breast cancer cells.[62] Other metalloestrogens, such as cadmium, are used in many everyday products, such as cosmetics, household items, and processed foods.[63] Prenatal exposure to arsenic has been shown to increase the number of mammosphere-forming cells and increase branching, epithelial cells, and density of the breast at puberty.[64,65]

Approaches that help a woman limit her exposure to chemicals in cosmetics, food additives, and household cleaning fluids, such as water filtration and the like, would be expected to have a positive effect if started early enough.

DIFFERENTIAL DIAGNOSIS

Benign breast lesions include benign neoplastic and nonneoplastic groups. The critical factor in the differential diagnosis is the identification of premalignant and malignant lesions.

Mass

The management of a breast mass is critical to the early and accurate diagnosis of benign versus malignant breast disease. Proper diagnosis and management of a breast mass should include the following:

1. A careful examination looking for dominant masses. Examination of a suspicious mass should preferably be done in the first week after a period when hormone levels are low.
2. A dominant mass is cancer until proven otherwise by its disappearance, its removal and microscopical diagnosis, by aspiration and resolution, or occasionally by long-term follow-up without change. The practitioner's job is not done until he or she is satisfied that there is no cancer. This does not mean every lump has to be surgically removed.
3. Breast symptoms while on hormone therapy of any sort should not be ignored. Practitioners commonly get the blame if there is a cancer or one develops.
4. Unilateral or asymmetrical masses or symptoms unrelated to menses require careful evaluation even though they are most often benign.
5. Never tell the patient "everything is fine" when she presents with a complaint even if you feel no mass. Tell her that you don't see anything to worry about, but if things change or she continues to have concern, she should be sure to return until you are both satisfied there is nothing to worry about. Encourage a return visit. Women know things about their bodies they can't always verbalize.

Lumps in the breast due to FCC are often difficult to describe because they meld with the dense areas of fibrosis. The fibrocystic breast is, by definition, lumpy. Because the fibrous component makes them tender and dense and the cystic component makes them lumpy, and these symptoms often get worse after ovulation, it is best to examine the breasts on day 4 to 9 of the menstrual cycle. If the examination is not reassuring and the examination is in the luteal phase, a return visit or an ultrasound is reasonable. Other benign masses include fibroadenoma; phyllodes tumor, which can be benign, borderline, or malignant; hamartoma; fibromatosis; and cysts of various sizes. Cysts that are proliferative have a 1.5 to 2.0 times higher risk of becoming cancers, and cysts with atypia have a relative risk of developing cancer as high as 3.9 to 13.[66]

Inflammation

As noted before, the breast ductal system is open to the outside world and is therefore a portal of entry for bacteria and viruses. An altered microbiome, cytokine signals (such as in patients with diabetes),

radiation, and trauma can all produce inflammation, which may incite fibroblast activity. Inflammation in the breast can present as pain, redness, or a mass, which should be addressed and treated.

Pain

Mastalgia refers to any breast pain severe enough to cause concern. Breast pain is categorized as cyclic (related to hormones) or noncyclic (related to drugs, pathology, or extramammary causes). Cyclic breast pain, because it is related to higher estrogen/progesterone effect, has been shown to be a risk factor for later breast cancer.[67] A careful history and physical can help rule out extramammary or nonhormonal causes of pain, such as costochondritis, cervical radiculopathy, myocardial ischemia, pneumonia, esophageal spasm, pleuritis, rib fracture, or shingles.[68]

HISTORY AND PHYSICAL EXAMINATION

Five major findings in benign breast disease that should be carefully evaluated are as follows:

1. Mass (size, shape, consistency, dominant, how long there, tenderness, history of trauma); cystic or solid
2. Pain (localized or general, constant or cyclic, drug or supplement related), which suggests inflammation
3. Discharge from nipple (spontaneous or expressed, history of breastfeeding, color, smell, volume)
4. Enlargement/swelling of the breast (related to menses, localized or unilateral, painful), suggesting tumor, edema, or lymphedema
5. Skin changes (dimpling, nipple retraction, peau d'orange, redness), suggesting underlying disease

These features should be carefully documented in the chart.

A common trap is the belief that the practitioner can differentiate benign from malignant disease on physical examination. Although the history and physical examination, mammogram, and ultrasound can increase or decrease the level of suspicion of malignancy, only histology on a specimen obtained by fine-needle biopsy, core biopsy, or open excision of suspicious lesions can determine whether a lesion is malignant, and even these methods are not perfect.[69]

Mammography is an appropriate way to obtain further information in women with a question of fibrocystic changes or a dominant mass. As stated before, dense fibrous areas make mammographic diagnosis difficult. In this situation, ultrasound of a mass can be helpful in differentiating a fibrocystic area from a cystic or solid lesion. Findings on routine mammogram, the risk of mammography, and whether and when to perform screening mammograms are important topics for discussion elsewhere.

Thermography can be useful in women with dense fibrocystic breasts. It is important to remember that increased temperature is a sign of inflammation and therefore an upstream indicator of potential risk. Thermograms have not been shown to be as accurate as mammography for identifying early cancers (which may be a benefit from the standpoint of overdiagnosis in the perimenopause) and therefore provide a different type of information (about inflammation) that may be helpful in decision making.

THERAPEUTIC CONSIDERATIONS

From the foregoing discussion, it should be clear that there are at least three areas that should be addressed in the treatment of fibrocystic symptoms: estrogen effect, inflammation, and the microbiome.

Because excessive estrogen or altered sensitivity to estrogen is the dominant theory of etiology,[70,71] interventions that modulate endogenous estrogens or limit exposure to exogenous estrogen or estrogen-like substances warrant consideration as potential treatments for symptomatic fibrocystic breast conditions and will be discussed first.

Premenstrual syndrome, which shares a common hormonal picture, is discussed elsewhere (see Chapter 212). In fact, breast pain is often a part of the PMS complex of symptoms. The factors discussed here are not covered in depth in Chapter 212 and are particularly relevant to fibrocystic breast disease.

Approaches that address excessive production or poor metabolism of estrogen include the following:

1. Inhibition of aromatase with diet and treatment of inflammation with curcumin, omega-3 fatty acids, and an anti-inflammatory diet (gluten-free and low in arachidonate)
2. Improved metabolism of estrogen by CYP-450 enzymes aimed at discouraging the 16OH and 4OH pathways, improving Phase II detoxification and preventing DNA adduct formation with adequate intracellular glutathione. Discouraging alcohol; preventing insulin resistance; addressing obesity; and encouraging crucifers, allium-containing vegetables, and B vitamins are all effective strategies.
3. Protection of glucuronidated estrogens from beta-glucuronidase in the gut (calcium-d-glucarate) preventing reabsorption of partially metabolized estrogens
4. Attention to regular excretion using fiber, especially freshly ground organic flax seed and omega-3 fatty acids, magnesium, and so forth
5. Blocking estrogen receptors with weaker estrogens, such as estriol[21] or phytoestrogens

Once elevated estrogens have been addressed, balancing estrogen with adequate progesterone can be helpful. Progesterone appears to improve iodine absorption,[42] in addition to its antiestrogen and pro-differentiation effects. Addition of progesterone before addressing estrogen, however, can put the breast in a pseudopregnancy or continuous luteal phase in which pain and cysts get worse.

Inflammation

Because the ECM responds to inflammatory signals from the bloodstream as well as from the bacteria that make up the breast microbiome, and because inflammation is known to increase estrogen production by increasing the activity of aromatase, a number of nutritional, supplemental, and herbal preparations would be expected to be useful in the treatment of FCC. Needless to say, the earlier they are instituted, the more likely they are to be successful; once significant fibrosis occurs, treatment is more difficult.

Treating the Breast Microbiome

Because the breast microbiome is a relatively new concept, therapies have not been established that might affect it. From the studies of treatment of mastitis with probiotics, however, it is apparent that oral probiotics have an effect on the breast microbiome and should be considered. Bacterial species that have been cultured from normal breasts may be beneficial and include *L. salivarius* CECT 5713, *L. gasseri* CECT 5714, *L. fermentum* CECT 5716, and possibly other friendly bacteria cultured from human milk.

Dietary Considerations

Although the literature is confusing with regard to whether dietary changes have a significant role in prevention and treatment,[22] this is likely due to the complexity of causes of FCC; the diversity of genetics involved in estrogen effect and inflammation in a given woman; and the likelihood that there is a long latent period between fibrosis, cyst formation, proliferative changes, and cancers.[72] There are, however, general principles in lowering the estrogen effect and reducing

inflammation that should be effective in most women (see previous suggestions). Additionally, the Mediterranean-type diet has been shown to positively affect the breast microbiome.[73]

Obesity[74] and type 2 diabetes are both associated with breast pathology and later breast cancer, so dietary changes in these patients should be included in therapy for FCC.

Methylxanthines

Epidemiologically,[21,75,76] experimentally,[77–80] and clinically,[81] there is strong evidence supporting an association between methylxanthine consumption and fibrocystic symptoms, although little research appears to have been done since 1996.[82] The methylxanthines—caffeine, theophylline, and theobromine—are all known to be competitive inhibitors of cyclic mononucleotide phosphodiesterase, which catalyzes the hydrolysis (removal) of cyclic adenosine monophosphate (cAMP), thereby elevating its level in breast tissue. In turn, increased levels of cAMP (a so-called second messenger) stimulate protein-kinase activities and causes the overproduction of epithelial elements and fibrous tissue.[21] Minton et al. found that levels of cAMP in fibrocystic breasts were higher than normal and even higher in women with breast cancer.[83]

In one study, limiting methylxanthines (coffee, tea, cola, chocolate, and caffeinated medications) in the diet resulted in improvement in 97.5% of the 45 women who completely abstained and in 75% of the 28 who limited their consumption. Those who continued with little change in their methylxanthine consumption showed little improvement.[84] According to this study, women may have varying thresholds of response to methylxanthines. Other studies have shown no association between methylxanthines and fibrocystic breast disease.[85–87] This disparity may have to do with the difference between causation, which is unlikely, and symptom exacerbation, which is likely, as well as genetic susceptibility in a given woman.

Fiber

Fiber is both anti-inflammatory by virtue of its support of a healthy gut microbiome and antiestrogen by virtue of its effect on estrogen excretion. A comparison between the diets of 354 women with "benign proliferative epithelial disorders of the breast" and those of 354 matched controls and 189 unmatched controls found an inverse association between dietary fiber and the risk of benign proliferative epithelial disorders of the breast.[88] An increased intake of dietary fiber may be associated with a reduced risk of both benign breast disease and breast cancer.[89]

Soy

It is likely that soy, when metabolized to equol, presents a weak estrogen to the receptor in high numbers, which displace the stronger estradiol and estrone, effectively decreasing the estrogen effect.[90]

An uncontrolled study of 64 premenopausal women with FCC who consumed soy protein for 1 year used breast-enhanced scintigraphy testing (BEST) to evaluate change in inflammation, using angiogenesis and mitochondrial activity, which vary with tissue metabolic activity. The women and their physicians reported subjective and objective reduction in both breast tenderness and FCC. Evaluation by BEST also showed that a nonstatistical reduction occurred in both the average and maximal breast tissue activity. There was a statistically significant reduction ($P < 0.01$) in the variability of tissue activity, however.[91] A study of the concentrations of the plasma isoflavones genistein and daidzein and the risk of benign breast disease in China showed an inverse relationship for both benign and malignant breast diseases.[92]

Fats and Essential Fatty Acids

Increased calories, fat intake, and saturated fat are associated with benign breast disease.[93,94] Because these are older studies, it is not known whether the increased risk is associated with fat intake per se or the intake of foods containing more xenoestrogens. Because of their anti-inflammatory properties as well as their effects on bowel regularity, omega-3 fatty acids in the diet and as supplements have been shown to be helpful in fibrocystic breasts.[95,96]

Nutritional Supplements

Evening Primrose Oil

Studies of evening primrose oil (EPO) are contradictory.[97] This may point to the difference between measuring essential fatty acids versus measuring ratios of fatty acids, as well as the function of the delta 5, 6, and 9 desaturases. Studies of the omega-3 fats appear consistent in showing a lower incidence of symptoms. The omega-6 fatty acids, such as EPO, may be confusing based upon whether they are converted to anti-inflammatory prostaglandins or converted to inflammatory arachidonate. Because EPA inhibits the pathway of arachidonate to prostaglandin E2 as a COX-2 inhibitor, it should always be given concurrently with EPO.

Several studies have examined EPO for both mastalgia and breast cysts. In general, these studies are old and included small numbers of subjects.[98–102] A more recent meta-analysis showed no difference between EPO-treated patients and controls.[103]

A single study done looking at breast cyst response to EPO was also disappointing. Two hundred women with breast cysts were randomly assigned either six capsules per day of EPO or placebo for 1 year. Although there were fewer cysts in the EPO group (92 vs. 113), this difference was not statistically significant.[104]

These studies demonstrate the importance of adequately powered studies using the correct essential fats at the correct dosage for a long enough time to accomplish change in both symptoms and disease. It is logical to assume that dietary fats and EPO would be more likely to prevent fibrosis and cyst formation when started at a young age and possibly to inhibit progression than to be effective in relieving symptoms or reversing well-established fibrosis and cyst formation.

Vitamin E

Studies of vitamin E were generally small and of poor quality due to the failure to differentiate between the available forms of tocopherols. The mode of action remains unclear but is likely related to the effect of tocopherols on the inflammatory effects of oxidative stress in the ECM or ductal system.[105]

A very small (23 patients) study of alpha-tocopherol in the 1980s was shown to relieve many PMS symptoms, particularly FCC.[106,107] The same authors demonstrated that vitamin E is clinically useful in relieving pain and tenderness, whether cyclic or noncyclic.[108] When larger numbers of women were studied by the same authors, vitamin E did not fare so well, showing no significant effects either subjectively or objectively.[109,110]

In 2004 Bespalov et al. studied the effects of supplementation with a combination of beta-carotene 5 mg/d, vitamin E (alpha-tocopherol 5 mg), vitamin C (30 mg), and garlic powder (150 mg) in 66 women. There was a reduction in the severity of mastalgia, PMS, infrequent menses, and menstrual cramping as well as a reduction in "palpable symptoms of fibromatosis" in 75% of the women compared with 45% of women on placebo.[111]

In 2009 another small double-blind, placebo-controlled trial of vitamin E supplementation (200 mg) in 150 women in Iran, chewable tablets containing either vitamin E (200 mg) or placebo were given twice daily for 4 months. The results at 2 months were dramatically

better for 70% of the group receiving vitamin E than for those on placebo, but there was no further improvement at 4 months.[112]

More recently (2015), a brief study (2 months) of 80 patients with cyclic mastalgia was done by Shobeiri et al. This study compared vitamin E and vitamin B_6. A trend toward improvement in symptoms was found in both groups.[113]

Although there is a suggestion that vitamin E is effective for the symptoms of fibrocystic breasts, much more work needs to be done to confirm this. It is unlikely this will happen. However, the safety profile of this treatment is excellent.

Vitamin A

A review in 2004 points out the difficulty in studying the relationship of vitamin intake, vitamin levels, levels in breast tissue, and outcome. Their review of the research is inconclusive with regard to vitamin A and breast cancer, let alone benign breast disease, which is often used as the "control."[114]

Vitamin A is involved in cellular proliferation and differentiation.[115] The carotenoids additionally have antioxidant properties.[116] Vitamin A has been only minimally studied for fibrocystic breasts. However, there are retinoid receptors in breast tissue, which can modulate breast changes, including their effect on iodine processing.[42] In a study of 12 women with fibrocystic breast disease, women were given 150,000 IU of vitamin A daily for 3 months (by current standards, a massive dose). Five of the nine patients who completed the study had full or partial remission of their fibrocystic breast disease. However, some patients developed mild side effects, leading 2 of the original 12 to withdraw because of headaches, and 1 patient required a reduction in dosage.[117] Beta-carotene would appear to be a safer approach (see Chapter 127). However, genetic inability to convert beta-carotene to retinol must be considered because a significant portion of the population has genomic variations that impair the conversion of beta-carotene to vitamin A (see Chapters 57 and 125).

Thyroid and Iodine

The breast is a site that concentrates iodine (a known antimicrobial) and contains both the NIS (sodium iodide symporter) and lactoperoxidase (oxidizing iodide to iodine). Both the milk produced and the tissue producing it show increased concentrations of iodine,[118] presumably to protect the nursing infant as well as the breast tissue itself from pathogenic bacteria and the ravages of inflammation.

Experimental iodine deficiency in rats resulted in a mammary dysplasia histologically similar to human FCC when either estrogen or testosterone was administered.[119] In animals treated with perchlorate to block the NIS, treatment with thyroxin did not improve the breast abnormalities, suggesting that the cause was iodine deficiency and not hypothyroidism.[120] In humans, benign breast disease, including cysts and fibrocystic changes, were associated with nodular thyroid disease and Hashimoto's thyroiditis in 54.9% and 47.4%, respectively, versus 29.2% in a control group[121] and has been shown to improve with thyroid treatment,[122] possibly due to the breast's ability to deiodinate T3 and T4 and use the iodine.[42] Thyroid hormone replacement therapy in women with mastodynia resulted in improvement based upon a thyroid-releasing hormone (TRH)–induced prolactin response.[123] More recent studies show that the antineoplastic effects of iodine require either elemental iodine (I^2) or a tissue that can both absorb iodide (NIS) and convert it to iodine via peroxidases such as lactoperoxidase.[124,125] These results suggest that subclinical hypothyroidism, iodine deficiency, or both may be etiological factors in both FCC and breast cancer.[126] Iodine absorption increases in pregnancy and lactation. This may explain the decrease in density of fibrocystic appearance after pregnancy and lactation.[127]

In studies in rats and humans, it was shown that there is a hierarchical response to the type of iodine compound used in correcting the abnormalities in mammary tissue due to iodine deprivation. Although iodide corrects the cystic spaces and partially corrects the ductal cell proliferation, it produces more side effects and more disruption of thyroid function. Iodine in its elemental form corrects the entire disease process, including the fibrosis. Additionally, iodide or iodine, excreted in the milk or into the ductal lumen, may change the microbiome of the milk. Both the beneficial effects on the microbiome and the direct effects on the ECM influence the cause of FCC.

Since 1975, four clinical trials of iodide or iodine have been performed in women with FCC[6]:

- An uncontrolled study with sodium iodide (Lugol's, which contains only ~5% iodine) and a protein-bound iodide (iodine caseinate or I-)
- A prospective controlled crossover study of patients failing iodide treatment who switched to molecular iodine (aqueous molecular iodine-I^2, 0.08 mg/kg)
- A prospective, controlled, double-blind study with molecular iodine (aqueous iodine-I^2, 0.07–0.09 mg/kg)
- A controlled study of IoGen (an iodide/iodate combination that produces approximately 50% iodine in the stomach)

The results from these studies indicate that although treatment with iodides was effective in about 70% of subjects, it was associated with a high rate of side effects (e.g., altered thyroid function in 4%, iodinism in 3%, and acne in 15%). Results with elemental iodine were equally if not more effective but were not associated with significant side effects. The most significant side effect with molecular iodine was a short-term increase in breast pain, which seemed to correspond to a softening of the breast and disappearance of fibrous tissue plaques on physical examination. The more recent study using IoGen (a mix of sodium iodide and sodium iodate that generates approximately 50% molecular iodine in the stomach resulted in 7 of 28 patients in the 3.0 mg group and 5 of 27 in the 6.0-mg group exhibiting a reduction in physician-assessed symptoms and findings compared with none of the 1.5-mg or placebo groups. Over 50% of the women on the drug reported a reduction in pain compared with only 8.3% of the placebo group.[128] The dose of molecular iodine was 0.07 to 0.09 mg/kg/d in the first three studies and a somewhat lower dose of 3 to 6 mg (1.5–3 mg of iodine) of IoGen in the fourth. These doses appear to be safe and effective in the treatment for FCC.

Although iodine (I^2) may be an effective treatment for FCC,[6,129] it has been shown that iodine stimulates the transcriptional activity of estrogen receptor alpha in breast cancer cells,[130] and because of the induction of lactoperoxidase or perhaps as an oxidant itself,[131] iodine may increase 4OH estrone production. Other researchers believe that lactoperoxidase is not present in cancer cells, and therefore the presence of higher amounts of iodide in tumors is unimportant.[42] More recent studies show that elemental iodine induces a caspase-independent and mitochondrial-mediated apoptosis pathway.[132] These conflicting studies make the use of iodine in the population most at risk (perimenopausal women) problematic.

The iodine supplements used in these studies are no longer clinically available in the United States. Although there appear to be some elemental iodine products on the market, none has been studied. If iodine is to be used clinically, care must be taken to select the correct form of iodine and not overdose with iodides, which affect the thyroid or induce iodism. Women at increased risk of breast cancer may not be candidates for iodine (I^2) therapy until further studies are available to identify who benefits and who does not. Increased iodine intake via seaweed uncontaminated by I^{131} should, however, be safe and is supported by both the lower risk of breast cancer both pre- and

postmenopause in Asian women consuming seaweed as a source of iodine[42] as well as animal studies adding seaweed to the diet without negative effect on the thyroid.[133–135]

Herbal Supplements

Vitex Agnus-Castus (Chasteberry)

Chaste tree berry has been a very important plant for the treatment of PMS, including breast complaints and premenstrual dysphoric disorder. The evidence for the use of chaste tree berry in the treatment of mastalgia has been reported in both randomized and nonrandomized studies. A large open study (no control group) of 1634 women who experienced cyclic mastalgia as part of their PMS reported that 81% of participants rated it as a very good treatment for their mastalgia after 3 months of therapy.[136] In a prospective, multicenter trial using chaste tree in 50 patients with premenstrual cyclic mastalgia, 43 women were treated daily with chaste tree for three consecutive menstrual cycles. By the end of the study period, cyclic mastalgia decreased significantly, along with a smaller degree of improvement even 3 months after stopping the plant. Thirty-eight women rated the effectiveness as moderate to excellent, with five reporting no effect.[137] In a randomized controlled trial, 97 women with cyclic mastalgia showed a significant decrease in the intensity and duration of pain after one or two treatment cycles compared with placebo.[138] In a randomized trial of premenstrual dysphoric disorder, comparing chaste tree with a selective serotonin reuptake inhibitor (SSRI), 58% of patients being treated with chaste tree had an improvement in their cyclic mastalgia, and 68% of patients had improvements in their psychological symptoms.[139] In a randomized, placebo-controlled trial, 170 women were given chaste tree or placebo for three consecutive cycles. The improvement in breast pain was greater in the chaste tree group (52%) compared with the placebo group (24%).[140]

Vitex agnus castus is well tolerated. The most frequent adverse events are nausea, headache, gastrointestinal disturbances, menstrual disorders, acne, pruritus, and erythematous rash; however, all are mild and reversible.[141]

Chamomile *(Matricaria chamomilla)*

A small, randomized placebo-controlled study of chamomile tincture (5 gtts tid) in 60 patients showed a significant reduction of symptoms in women with cyclic mastalgia.[142] Chamomile has been reported to be both a galactogog[143] and to inhibit lactation.[98] The mode of action is unknown; however, *Matricaria chamomilla* has been shown to have antibacterial and antioxidant potential.[144] Chamomile is generally safe, although gastrointestinal side effects have been seen,[145] and allergic reactions and can occur, showing cross-reactivity with echinacea, feverfew, and milk thistle.[146]

Inositol, Betaine, Boswellia

A combination of B vitamins with myo-inositol 200 gm, *Boswellia serrata* 50 mg, and betaine 175 mg (Eumastos) was studied in 76 women in a 2016 randomized controlled study and showed statistically significant improvement in pain relief (56% vs. 17%), breast density reduction (60% vs. 9%), and diminution of size of mass (40% vs. 16%). There were no side effects.[147]

Curcumin

Curcumin, the yellow pigment in turmeric, has the advantage of having both anti-inflammatory and antioxidant properties.[148] It has been shown to have effects on radiation-induced fibrosis as well.[149,150]

Other Considerations

Liver Function

Because FCC may be related to an increased level of and sensitivity to estrogen and the liver is the primary site of estrogen clearance, any factor (e.g., cholestasis, alcohol intake, environmental pollution, or other hepatic compromise) that interferes with proper liver function may lead to an increased estrogen effect and worse symptoms. The previously discussed approaches to lower estrogens should be systematically addressed in these patients.

Colon Function

Breast disease has been linked to the Western diet and bowel function. There is an association between epithelial dysplasia in the nipple aspirates of breast fluid and the frequency of bowel movements. Women having fewer than three bowel movements per week have a risk of FCC that is 4.5 times greater than those having at least one a day.[151]

This association is probably due to reabsorption of deconjugated estrogens; the bacterial flora in the large intestine transforming endogenous and exogenous sterols and fatty acids into various toxic metabolites, and the effect on the gut microbiome.[152] Fecal microorganisms are capable of synthesizing estrone, estradiol, and 17-methoxyestradiol as well as metabolizing estrogen sulfate and glucuronate conjugates, resulting in the absorption of bacteria-derived estrogens and reabsorption of previously conjugated human estrogens. Diet plays a major role in determining colonic microflora, transit time, and the concentration of absorbable metabolites.[153]

Recent studies of the breast microbiome suggest that taking probiotics orally can alter the breast microbiome in beneficial ways and should be considered. (See earlier discussion of the microbiome.)

Women on vegetarian diets excrete two to three times more conjugated estrogens via the gut than those who are omnivorous, who also reabsorb more estrogens.[104] Omnivorous women have 50% higher mean levels of unconjugated estrogens. Supplementation with *L. acidophilus* has been shown to lower fecal β-glucuronidase.[154] Calcium-d-glucarate blocks β-glucuronidase, improving the excretion of estrogens conjugated with glucuronide. Both should be beneficial to women with FCC.

Pharmaceuticals

Pharmaceutical approaches to benign breast symptoms, including oral contraceptives, Tamoxifen, Danazol,[155] Centchroman (ormeloxifene),[156] and Goserelin (luteinizing hormone–releasing hormone [LHRH] analog), are all aimed at reducing estrogen effect. All have significant side effects. Bromocriptine and Lisuride maleate are dopamine agonists aimed at blocking the release of prolactin. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been used by mouth and topically for breast pain.[157] Their anti-inflammatory effects both locally as a cyclooxygenase-2 (COX-2) inhibitor and as an aromatase inhibitor have been reported. Although the reports on some drugs (e.g., Tamoxifen) indicating effectiveness in preventing breast cancer are encouraging, little is reported on reducing cysts or fibrosis.

NONPHARMACOLOGIC THERAPEUTIC APPROACH

Because the origins of FCC are likely related to the causes of fibrosis (inflammation, autoimmune issues, and genetics) in relationship to the environment (breast microbiome, radiation, and trauma) and stimulated by estrogen excess (estrogen/progesterone imbalance, genetics, xenoestrogens), treatment should be aimed at early avoidance of inflammation and improved gut function and ongoing treatments that lower and balance estrogen levels. The use of these approaches is likely to decrease both symptoms problematic to the patient and diagnostic dilemmas problematic to the practitioner.

Some women have noncyclic FCC, and others have cyclic premenstrual breast tenderness and lumpiness, so the therapeutic approach outlined in Chapter 212 may be more appropriate for individual needs.

The therapy recommended here also includes some of the key factors discussed in Chapter 212.

Diet

Dietary changes should be aimed at avoiding the development of obesity[158] and insulin resistance (a known cause of inflammation), improving the microbiome of the gut and the breast, and improving disturbed steroid metabolism. Avoidance of sugar, caffeine, and alcohol at least during the luteal phase of the cycle is helpful. Avoiding gluten in the diet as an inflammagen can be beneficial for some. Avoiding dairy, which contains both high levels of estrogens from the pregnant cows included among the milk suppliers and high level of toxins from the environment, can be useful. The diet should be primarily vegetarian (replete with aromatase inhibitors and phytoestrogens from vegetables, with large amounts of dietary fiber to encourage bowel regularity. All methylxanthines should be eliminated until symptoms are relieved. At that point, methylxanthines can be reintroduced in small amounts because they are tolerated by many patients.

Reducing the saturated fat content of the diet while increasing the consumption of complex carbohydrates has been shown to reduce the severity of premenstrual breast tenderness and swelling as well as the nodularity in some women in one very old study.[159] Reducing the dietary fat intake to 20% of total calories results in significant decreases in circulating estrogens in women with benign breast disease in one study,[160] but other studies have not shown an effect of a diet of increased vegetables and fruit, low fat, and higher grains on benign proliferative breast disease[161] or when breast cancer was the end point.[162] Recommendations on fat intake should emphasize the quality and origins of the fat rather than the total amount, especially in prediabetic women who will likely substitute fat with higher sugar and carbs, to their detriment. Emphasis should be placed on increased vegetable rather than fruit intake.

The diet should emphasize organic, whole, unprocessed foods (whole grains, legumes, vegetables, fruits, nuts, and seeds) to limit food contaminated with herbicides, such as glyphosate, and insecticides, which are xenoestrogens. Patients should be encouraged to drink at least 48 oz of water daily to facilitate the excretion of estrogens and xenoestrogens.

Exogenous estrogens (hormone replacement therapy and environmental toxins)[163,164] should be avoided if possible, as they may exacerbate the condition (hormone replacement therapy[163] and environmental toxins[164]). Birth control pills have been used to lower the ovarian output of estrogen and are helpful in some once the increased estrogen period (first 1–3 months) is past.[165] However, the effect on the breast of the progestins in the pill is likely negative.

Nutritional Supplements

- B vitamins containing 5-methylfolate and B_{12} (preferably in a form not containing cyanide). Doses should be individualized.
- Lipotropic factors: choline 1000 mg and methionine 1000 mg
- Betaine: 175 mg bid
- NAC: 1000 mg/day as an antioxidant
- Indole-3-carbinol (I3C) or Di-indoylmethane (DIM), provided 2OH estrogen metabolites are not already high
- Calcium d-glucarate: 200 to 500 mg bid
- Vitamin E: 400 to 800 IU/day of d-alpha-tocopherol (take care to avoid synthetic dL forms)
- Beta-carotene: 50,000 to 300,000 IU/day
- Iodine (aqueous molecular iodine): 0.07 to 0.09 mg/kg (a prescription item) or Lugol's iodine (95% iodide and 5% iodine 5–10 gtts/d; iodine caseinate [iodized casein I-] 10 mg/d; see earlier precautions)
- Evening primrose oil: 1500 mg twice a day in combination with omega-3 fatty acids
- Omega-3 fatty acids 1000 mg/day of eicosapentaenoic acid (EPA)/docosahexaenoic acid (DHA)
- Probiotics containing a mixture of lactobacillius species with guaranteed live organisms at the date of expiration
- Magnesium: to bowel tolerance for constipation and PMS symptoms other than breast
- Fiber as organic ground flax seeds: 1 to 2 tsp/day

Botanical Medicines

- Vitex (chaste berry): The usual dosage of chaste berry extract (often standardized to contain 0.5% agnuside) in tablet or capsule form is 175 to 225 mg per day. If using the liquid extract, the typical dosage is 2 to 4 mL (½–1 tsp) a day.
- *Boswellia serrata* (resin) standardized to 60%; boswellic acid: 200 mg/day
- Chamomile as tea or extracted
- Curcumin as a spice added to food or a bioavailable supplement (200–600 mg/day)

Mechanical

Breast self-massage can be amazingly helpful in women with painful breasts. A lymphatic massage technique of *gentle* manipulation of the breast from the areola outward and sweeping up into the armpit followed by a circular motion with hands on either side of the breast, usually in the prone position, relieves the congestion of the breast due to hormonal imbalance.[166] Practitioners of thermography have found that this also decreases some of the signs of inflammation and congestion in the tail of the breast and the underarm area (personal communication). Herbalist Susan Weed recommends using essential oils and combining massage with breast self-examination. (http://www.susunweed.com/herbal_ezine/April09/breasthealth.htm). Avoid using progesterone or other hormone creams directly on the breast.

SURGICAL INTERVENTION

Treatment of asymptomatic, fluid-filled cysts with aspiration is no longer recommended.[167] Surgical treatment should be reserved for suspicious dominant masses and used liberally in this situation to avoid failure to diagnose breast cancers. Surgical treatment of fibrocystic breasts with subcutaneous mastectomy should be a last resort and used only when pain is severe and the breast tissue has been almost completely replaced with fibrosis.

Fibromyalgia Syndrome

John Nowicki, ND, and *John C. Lowe*, MA, DC*

OUTLINE

INTRODUCTION

Fibromyalgia diagnosis is a challenging and long process, especially among primary care physicians. There are a variety of factors involved, including the patient's attitude, the patient's personal history, comorbidities, and sociodemographic characteristics (Fig. 170.2). The 13 most common symptoms associated with the pain and tenderness of fibromyalgia syndrome (FMS)[2–4] are listed in Box 170.1.

Diagnostic Summary

- Common: 2% to 13% of population; approximately 80% to 90% women
- Chronic widespread pain involving axial pain and pain on the left, right, upper, and lower parts of body[1]
- Abnormal tenderness at 11 or more of 18 specific anatomical tender point (TnP) sites[1] (Fig. 170.1)

Differential Diagnosis

The purpose of the 1990 American College of Rheumatology (ACR) criteria for FMS was to distinguish patients with a putative primary disorder designated FMS from those with similar symptoms due to other distinguishable medical disorders. The two major criteria for FMS are chronic (longer than 3 months) widespread pain and tenderness.[1] The criteria were established mainly for use in research that would eventually identify the underlying pathological mechanism of the symptoms, but they have come to serve as diagnostic criteria in clinical practice.

Some theorists have argued that widespread pain and tenderness at predictable anatomical sites are features of many medical disorders.[5] Their argument is true only of hypothyroidism and cellular resistance to thyroid hormone, especially when the associated symptoms of FMS are also taken into account. When most patients with hypothyroidism or cellular resistance to thyroid hormone meet the ACR criteria for FMS and are effectively treated with thyroid hormone therapy, they no longer meet the FMS criteria.[6–15] This finding indicates that these patients' FMS symptoms and signs are a distinct clinical phenotype of inadequate thyroid hormone tissue regulation.[16] It also justifies a trial of thyroid hormone therapy to distinguish whether a patient's FMS symptoms and signs are features of hypothyroidism or cellular resistance to thyroid hormone.

BOX 170.1 Most Common Associated Symptoms in Fibromyalgia Syndrome

- Fatigue
- Stiffness
- Headache
- Sleep disturbance
- Irritable bowel
- Depression
- Cognitive dysfunction
- Anxiety
- Coldness
- Paresthesias
- Sicca symptoms
- Exercise intolerance
- Dysmenorrhea

From Lowe JC. *The Metabolic Treatment of Fibromyalgia.* Boulder, CO: McDowell Publishing; 2000; Awad EA. Pathological changes in fibromyalgia. *First International Symposium on Myofascial Pain and Fibromyalgia.* Minneapolis, 1989; Rodolico C, Toscano A, Benvenga S, et al. Myopathy as the persistently isolated symptomatology of primary autoimmune hypothyroidism. *Thyroid.* 1998;8:1033–1038; Lowe JC, Honeyman-Lowe G. Fibromyalgia and thyroid disease. Platelet research in psychiatry. *Experientia.* 1988;44:145–152.

The theorists' argument does not apply to other medical disorders, however, and is refuted by two lines of evidence.[17] First, studies have not established that chronic widespread pain and multiple TnPs are features of other medical disorders. Second, many patients with rheumatoid arthritis, osteoarthritis, Lyme disease, systemic lupus erythematosus, Chiari malformation, and spinal stenosis also meet the ACR criteria for FMS, but when these other disorders are effectively treated, the patients still meet the criteria for FMS.[18–20]

The argument is false, then, that chronic widespread pain and tenderness are features of many medical disorders. Nonetheless, the argument highlights the need to differentiate FMS from other disorders with similar symptoms that may lead the clinician to misdiagnose FMS. The main disorders the clinician should distinguish from FMS are arthritis, myopathy, polymyalgia rheumatica, diabetic polyneuropathy, ankylosing spondylitis, discopathy, cardiac or pleural pain,[21] multiple muscle myofascial pain syndromes,[22] and lupus erythematosus. A given patient may, of course, concurrently meet the criteria for FMS and one or more other disorders with overlapping symptoms. FMS can usually be distinguished from medical disorders other than hypothyroidism and cellular resistance to thyroid hormone by careful pathognomy. However, diagnostic scrutiny will show that the symptoms and signs of most FMS patients are indistinguishable from those of the subclass of hypothyroid and thyroid hormone–resistant patients for whom pain is a predominant symptom.

GENERAL CONSIDERATIONS

Focus of the Conventional Fibromyalgia Research Community

The serotonin deficiency hypothesis is the oldest proposed mechanism of FMS.[23–25] As a research-inspiring concept, it constituted the core theoretical underpinning of the rheumatology paradigm of FMS. This hypothesis proposed that a central nervous system (CNS) serotonin deficiency reduced the efficiency of the brainstem–spinal cord descending antinociceptive system, lowering the threshold for pain perception.[26] By 2000, the serotonin deficiency hypothesis had been effectively refuted[16] by three lines of evidence: First, the only site of low serotonin among FMS patients was their platelets.[26–28] Second, serotonin-increasing drugs were no more effective than placebos[29,30–34] and exacerbated some patients' FMS status.[35] And third, the low brain blood flow of FMS patients[36,37] contradicts a serotonin deficiency; serotonin is a potent vasoconstrictor,[38] and a low CNS level would produce cerebral vasodilation and increased blood flow.

This was further documented in the 2005 publication of the state of that paradigm.[39] The central theoretical viewpoint of the former paradigm had shifted from a serotonin deficiency to a generalized problem of augmented pain processing resulting in a hyperalgesic state,[39,40] which is plausibly explained by the extraordinarily high levels of substance P in patients with FMS.[41] But researchers espousing the former paradigm have failed to address the most plausible mechanism of the patients' high levels of substance P (see the following section). Instead, their main efforts have been in developing pharmaceuticals to manage FMS pain. This has led to the approval of several drugs by the U.S. Food and Drug Administration for FMS and the recommendation that patients undergo education about FMS as well as psychotherapy and aerobic, strength, and flexibility training.[40]

Environmental Toxicants

More than 50% of FMS patients reported adverse reactions to various chemicals. It has been suggested that an elevated total burden of toxic metals, such as cadmium and mercury, may induce worsening of diverse muscle pains with various etiologies. One study evaluated the frequency and clinical relevance of metal allergy in fibromyalgia (FM) patients.[42] Fifteen female FM patients and 10 healthy age-matched women (controls) were included in the study. Metal allergy was measured by a lymphocyte transformation test, MELISA. All FM patients tested positive for at least one of the metals tested. The most frequent reactions were to nickel, followed by inorganic mercury, cadmium, and lead. Some healthy controls responded to inorganic mercury in vitro, but most of the tests were negative. Dental metal restorations and avoidance of known sources of toxic metals were recommended, implemented, and achieved to reduce metal exposure. An objective health assessment was performed 5 years after treatment, which showed that half of the patients no longer fulfilled the FM diagnosis, 20% had improved, and the remaining 30% still had FM. All patients reported subjective health improvement. Additionally, mercury and other toxic elements may interfere with the bioavailability of essential nutrients, which may aggravate symptoms.

Hypometabolism Hypothesis of Fibromyalgia Syndrome

The hypometabolism hypothesis posits that FMS is chronic hyperalgesia and other symptoms and signs of hypometabolism due to hypothyroidism, partial cellular resistance to thyroid hormone, or other metabolism-impeding factors. Among the other factors said to be responsible are pernicious diet, nutritional deficiencies, low physical fitness, and metabolism-impeding drugs. The term *hypometabolism* refers to the global impact on the patient of the underlying factors, most of which are catabolic and inhibitory, although some are anabolic or excitatory.[16]

Considerable evidence indicates that inadequate thyroid hormone regulation (ITHR) due to hypothyroidism or cellular resistance to thyroid hormone is the underlying mechanism of the two main features of FMS: chronic widespread pain and abnormal tenderness. ITHR of metabolic processes in cells of the brainstem–spinal cord descending antinociceptive system can result in chronically enhanced pain perception. Impairment of the antinociceptive system in FMS patients results in the following:

- Spontaneous or ongoing pain
- Tenderness (lowering of the pain threshold to mechanical stimuli)
- Hyperalgesia (increased responsiveness to noxious stimuli)[43,44]

ITHR can impair the antinociceptive system by two mechanisms. First, ITHR can severely increase the production of substance P, which is extremely high in the cerebrospinal fluid (CSF) of tested FMS patients.[41] Substance P is released from the terminals of nociceptive neurons[45] and assists the summation of slow nociceptive signals.[46] This facilitation amplifies the transmission of nociceptive signals in the spinal cord.[47] Thyroid hormone normally inhibits the synthesis and secretion of substance P in many CNS cells. It does so by repressing the transcription of the preprotachykinin-A gene. Preprotachykinin-A is the precursor of substance P and its cognate substance P receptor.[48,49] Lowering thyroid hormone levels by thyroidectomy increased the substance P level in astrocytes,[49] the anterior pituitary,[50–52] many brain nuclei,[53] and, most relevant to pain, the dorsal horns of the lumbar spinal cord. The increase in dorsal horn substance P was highly elevated (100%),[54,55] as in FMS patients.[41] Thyroid hormone treatment lowered the substance P level in the anterior pituitary,[51] brain nuclei,[56] and dorsal horns.[55] Excess thyroid hormone reduced substance P to subnormal levels.[52]

The second mechanism by which ITHR can reduce the effectiveness of the antinociceptive system is by reducing the synthesis and secretion of norepinephrine (NE) in cells of the brainstem locus ceruleus. Adequate NE is essential to the normal function of the descending antinociceptive system.[57,58]

The antinociceptive pathways that descend from the brainstem to the dorsal horns contain two types of neurons: those that secrete serotonin and others that secrete NE.[20,57,59,60] Serotonin secretion by the neurons is tonically augmented by NE secretion. Normal serotonin secretion is therefore dependent on NE secretion.[55] The serotonin stimulates interneurons to secrete opiates.[57,59,61] These then inhibit transmission partly by blocking the release of neurotransmitter substances such as glutamate and substance P from the afferent neurons.[62] They also block calcium influx and potassium efflux from the afferent terminals,[63] mainly those of types C and A delta fibers.[64] The decreased potassium efflux hyperpolarizes terminals, inhibiting the transmission of nociceptive signals to spinothalamic neurons that otherwise would transmit the signals to the brain.[65] Low NE secretion by descending neurons, however, may reduce the secretion of serotonin selectively at dorsal horn interneurons and secondarily reduce opiate secretion. As a result, the transmission of nociceptive signals in the CNS will increase, thus heightening pain perception.

That decreased NE production is involved in the heightened pain perception of FMS patients is indicated by low metabolites of both dopamine and NE in patients' CSF.[27] That inadequate T_3 regulation of locus ceruleus neurons accounts for the low NE production is suggested by the crucial role T_3 plays in the synthesis of both dopamine and NE. The locus ceruleus is the brain site with the heaviest concentration of T_3.[66–68] Thyroid hormone regulates the activity levels of two rate-limiting enzymes in dopamine and NE synthesis.[69] One enzyme, tyrosine hydroxylase, catalyzes the conversion of tyrosine to levodopa, which in turn is converted to dopamine.[70] Tyrosine hydroxylase activity in the noradrenergic neurons of the locus ceruleus is low in hypothyroidism.[71] Low activity of the enzyme and reduced conversion of levodopa to dopamine may be responsible for low dopamine levels in the striatum, hypothalamus, and superior cervical ganglia in hypothyroidism.[69] Thyroid hormone therapy increases the activity of tyrosine hydroxylase.[71] The second enzyme, dopamine-β-hydroxylase, catalyzes the conversion of dopamine to NE. Low activity of the enzyme in hypothyroidism can reduce NE levels.[69] Unfortunately, NE levels in the antinociceptive system and other tissues in thyroid disorders have not been studied extensively[72] enough to support this putative mechanism.

By raising substance P levels and possibly lowering NE levels in the spinal cord, ITHR can thus plausibly heighten FMS patients' pain perception. Patients' pain, however, is probably compounded by other factors. First, most FMS patients are physically inactive because of their pain,[73,74] although low motor drive from low dopamine levels[27] probably contribute to their inactivity. Their low physical activity level may further contribute to the inefficiency of the antinociceptive system.[75–77]

ITHR can also plausibly account for the other symptoms and objectively verified abnormalities of FMS: muscle and joint pain, paresthesias, cognitive dysfunction, depression, cold intolerance, exercise intolerance, weakness and fatigue, dry skin and mucous membranes, constipation, dysmenorrhea and menorrhagia,[78,79] increased platelet α_2-adrenergic receptor density,[80,81] reduced brain blood flow,[82] reduced peripheral blood flow,[83] sleep disturbance,[84] deficient slow-wave sleep,[85] hypotension,[86] blunted sympathetic response to stress,[87] stiffness and swelling,[88] irritable bowel syndrome,[89] excessive urination,[84] high serum hyaluronic acid,[90] low procollagen III,[91] high ground substance proteoglycans,[92] low pyridinoline[93] and hydroxyproline,[94] glycolysis abnormalities,[95] low concentrations of high-energy phosphates in erythrocytes and muscle cells,[96,97] and low growth hormone and somatomedin C levels.[98] The cellular and genomic actions of thyroid hormone can explain the hormone's relationship to all of these factors.[16] Especially important is thyroid hormone's effect on the adrenergic system. If the hypometabolism hypothesis is verified at some point in the future, the definition of fibromyalgia will include an explanation of FMS as a condition of α-adrenergic dominance.

Experimental Support for the Hypometabolism Hypothesis of Fibromyalgia Syndrome

The hypothesis that ITHR is an underlying mechanism of FMS has considerable experimental support.[99] Many researchers have noted the virtually identical features of FMS, hypothyroidism, and the peripheral form of cellular resistance to thyroid hormone.[16,100–115]

Several research groups have used thyroid function testing to determine the incidence of thyroid disease among FMS patients. Each group has reported an incidence higher than in the general population.[100–110] A thorough analysis of all the available evidence indicates that approximately 90% of FMS patients have some form of thyroid disease, either primary or central hypothyroidism or cellular resistance to thyroid hormone.[116,117]

In two studies, 15 female FMS patients had low resting metabolic rates (RMRs) and basal axillary temperatures compared with 15 matched healthy controls. In both studies, the controls' mean RMR was within the reference range predicted by equations. However, in the first study, the mean RMR of FMS patients was 29.2% below normal based on their gender, age, height, and weight.[118] In the second study, FMS patients' mean RMR was 32.5% below normal.[119] In both studies, FMS patients' basal temperatures were significantly lower than those of controls. In the first study,[118] FMS patients' mean basal temperature was 96.95°F (36.08°C). In the second study,[119] the mean temperature of FMS patients was 96.38°F (35.77°C).

Thyroid Supplementation

The only clinical trials in which patients have been fully relieved of FMS have involved orally administered thyroid hormone. It should be noted, however, that in each study patients also used other metabolism-regulating therapies (see later discussion on metabolism-regulating therapies other than thyroid hormone). Euthyroid and hypothyroid FMS patients fully recovered in five open but highly systematic trials[6–10]; three double-blind, placebo-controlled crossover trials[11–13]; and a randomized, double-blind, placebo-controlled trial.[14] In another randomized, double-blind trial, patients with FMS had limited improvement with the use of transdermal

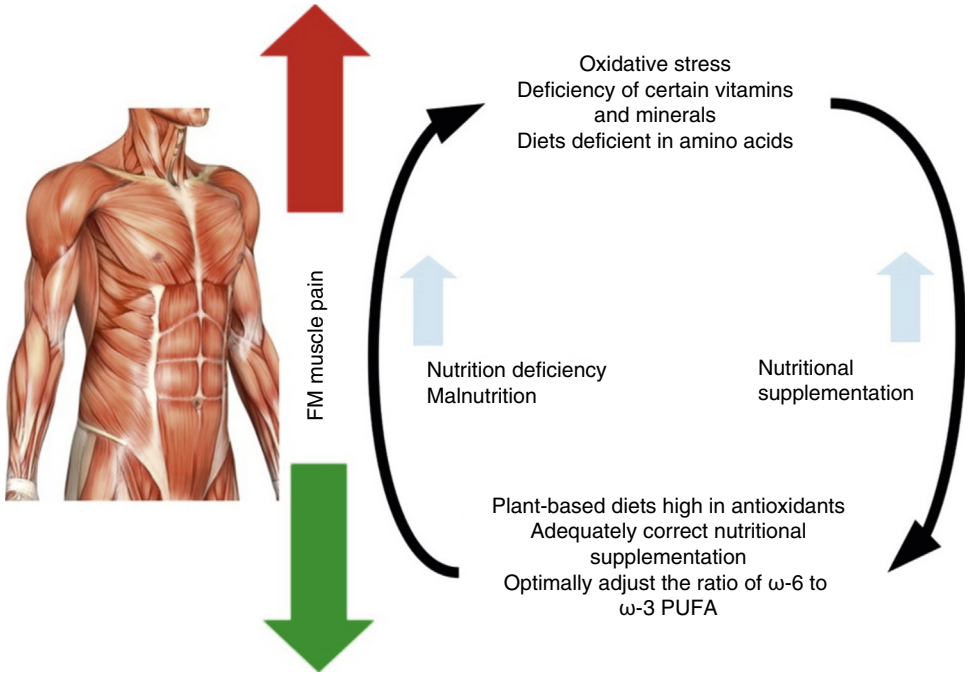

Fig. 170.3 The Relationship Between Nutrition and Fibromyalgia-Related Musculoskeletal Pain. (Bjorklund G, Dadar M, Chirumbolo S, Aaseth J. Fibromyalgia and nutrition: therapeutic possibilities? *Biomed Pharmacother.* 2018;103:531–538. PubMed PMID: 29677539.)

T_3.[120] A 1- to 5-year follow-up study compared the status of control patients with FMS with patients with FMS who had either hypothyroidism or cellular resistance to thyroid hormone and underwent metabolic therapy, including the use of thyroid hormone. Although control patients' FMS status deteriorated, treated patients recovered and maintained their recovery throughout the follow-up period. The results of this study were the first to demonstrate the long-term effectiveness of an FMS treatment.[15]

Metabolism-Regulating Therapies Other Than Thyroid Hormone

Thyroid hormone therapy is necessary in most cases of FMS to ensure recovery, but it is not sufficient. For example, in a study of 77 euthyroid patients with FMS,[6] those who declined to adopt a wholesome diet, take nutritional supplements, and exercise to tolerance were among the 25% who failed to benefit from T_3 therapy. This result is consistent with years of clinical experience supporting the necessity for patients to use other metabolism-regulating therapies in addition to thyroid hormone. A common experience, for example, is a recovered patient stopping the use of B complex vitamins only to suffer a partial recurrence of FMS symptoms. The symptoms are again relieved when the vitamin use resumes.

The most common other metabolism-regulating therapies that patients must use are a wholesome diet, nutritional supplementation, and exercise to tolerance. These therapies are necessary for most patients to recover fully. However, in most cases, they are not sufficient and must be used along with thyroid hormone therapy. This is shown by studies indicating that these therapies alone provide some improvement but that patients do not recover fully (i.e., they continue to meet the criteria for FMS). In addition to the metabolic therapies, most FMS patients also require some physical treatment for full relief of their FMS pain.

Wholesome Diet

Various diets and dietary supplements have been tested as FMS treatments. Mild-to-moderate improvements in FMS status have been reported for vegetarian diets[121,122]; elimination of the excitotoxins monosodium glutamate and aspartame[123]; *Chlorella pyrenoidosa* (a unicellular freshwater green alga rich in proteins, vitamins, and minerals)[124,125]; an uncooked vegan diet consisting of berries, fruits, vegetables, roots, nuts, and germinated seeds and sprouts[126]; and a strict, low-salt, uncooked vegan diet rich in lactobacteria.[127]

Nutritional Therapies

Long clinical experience shows that a wide array of nutritional supplements is necessary if FMS patients are to improve significantly or recover (Fig. 170.3). As the sole treatment, however, supplements provide only mild improvement except for the rare patient.

Studies indicate that vitamins B_1, B_6, B_{12},[56,128–136] C,[137–141] and E and beta-carotene[142] have antinociceptive properties. Other reports indicate that various nutritional supplements improve FMS status: the Myers' cocktail (intravenous formula of B vitamins, vitamin C, calcium, and magnesium)[143]; 5-hydroxytryptophan[144,145]; S-adenosylmethionine[146–149]; magnesium and malic acid[150,151]; combined aloe vera extracts, plant saccharides, freeze-dried fruits and vegetables, *Dioscorea,* and a vitamin/mineral complex[152]; collagen hydrolysat[153]; and a blend of ascorbigen and broccoli powder.[154]

Exercise to Tolerance

The results of studies of exercise in the treatment of FMS have been mixed: some have shown no improvement in FMS status[35,69,155–158] or only minimal improvement.[159–164] Cardiovascular exercise has provided the most improvement,[161–164] especially low-intensity endurance training.[164,165] Endurance exercise is important in reducing the physical limitations associated with FMS.[166] The importance of physical fitness and the high metabolic efficiency it provides[167,168] was shown by deficient slow-wave sleep, inducing FMS-like symptoms in sedentary and not aerobically fit students.[23] This finding suggests that low metabolic efficiency due to ITHR renders some individuals susceptible to FMS.[16]

Vigorous exercise tends to exacerbate patients' FMS symptoms.[72,73] As a result, some patients avoid exercise altogether and consequently are not physically fit.[166,169–171] The most plausible explanation for the exacerbations of vigorous exercise is the high density of α_2-adrenergic receptors on FMS patients' platelets.[172] The platelet density of α_2-adrenergic receptors is a reliable indicator of the receptor density in the CNS.[173] Binding of catecholamines to a high density of the receptors on cells of most tissues inhibits energy metabolism. The inhibition of energy metabolism during vigorous exercise, mediated by the high density of the receptors, appears to worsen symptoms severely. During the early phase of treatment, then, exercise should be mild enough to avoid or minimize catecholamine secretion.[16] With effective thyroid hormone therapy, the density of α_2-adrenergic receptors decreases and the density of β-adrenergic receptors increases, enabling cells to respond appropriately to high levels of catecholamines. The shift away from α_2-adrenergic receptor dominance probably explains, in part, the FMS patient's ability to engage in vigorous physical activity after receiving thyroid hormone therapy.[6,7,8,11–13,15]

Physical Treatment

Extensive clinical experience and clinical trials[7,8,11–13] show that despite the use of integrated metabolic therapies, many patients require physical treatment to fully relieve their FMS pain.[174–177] Several studies have shown that spinal manipulation, soft tissue manipulation, and trigger point therapy provide palliative improvement in some FMS symptoms, especially pain.[178–181]

The most common lesions that exacerbate FMS symptoms are myofascial trigger points and spinal joint fixations.[16,175,182] However, any nociception-generating neuromusculoskeletal lesion may exacerbate FMS patients' pain, probably owing to their high levels of substance P.[40] Neuromusculoskeletal lesions can also disturb sleep.[183–185] This can, in turn, increase FMS symptoms.[23]

It appears, then, that for most FMS patients to improve or recover, integrated metabolic therapies that include the use of thyroid hormone are necessary and sufficient, whereas no single metabolic therapy is sufficient in itself. In addition, physical treatment may be necessary to eliminate most FMS patients' pain completely.

THERAPEUTIC CONSIDERATIONS

As fully discussed previously, because metabolic hypofunction is primarily driven by thyroid dysfunction, fully understanding the patient's cellular thyroid function underlies the therapeutic approach.

Laboratory Testing for Thyroid Status

Thyroid Function Tests

Before beginning the treatment for a patient with FMS, his or her thyroid status should be determined with thyroid function tests. Primary hypothyroidism (thyroid hormone deficiency due to subnormal function of the thyroid gland) in most patients can be determined with the standard thyroid panel:

- Free T_3, free T_4, and thyroid-stimulating hormone (TSH)

In untreated primary hypothyroidism, the TSH is elevated. The recently revised upper limit of the serum TSH reference range is 2.5 μIU/mL.[186]

Thyroid Antibodies

The most common cause of primary hypothyroidism is autoimmune thyroiditis. The presence of this disorder can be determined by the patient's titer of thyroglobulin and thyroid peroxidase (microsomal) antibodies. It is especially important to order tests of antibody levels in patients with FMS. Many patients who have elevated thyroid antibodies have also had thyroid function test results within the reference ranges for many years.[187,188] However, compared with people without chronic widespread musculoskeletal complaints, those with such complaints were found to have a significantly higher incidence of thyroid microsomal antibodies (16% vs. 7.3%, $P < 0.01$). The prevalence of antibodies was also significantly higher in women than men (20.4% vs. 11.6%, $P < 0.02$), but thyroid function test results did not differ significantly between those with and without musculoskeletal complaints.[120] This study indicates that in patients with autoimmune thyroiditis, thyroid hormone levels too low to properly regulate the CNS antinociceptive system and properly inhibit the production of substance P can escape detection by thyroid function tests, including the TSH.

Thyroid Hormone Therapy Based on Initial Thyroid Status

Patients with FMS whose test results indicate hypothyroidism should begin therapy with a thyroid hormone preparation containing both T_4 and T_3. Many hypothyroid FMS patients do not benefit from T_4 alone no matter how high the dosage.[189] Most do benefit, however, from the use of T_4/T_3 preparations in a 4:1 ratio. The dosage range at which most patients improve or recover with T_4/T_3 preparations is that which was used throughout the 20th century, without harmful effects,[190] before TSH assays came into widespread use in the early 1970s: 76 mcgT_4 and 18 mcg T_3 to 152 mcg T_4 and 36 mcg T_3.[16,191]

The thyroid hormone therapy used in studies in which hypothyroid and euthyroid FMS patients recovered[6–14] was not conventional T_4-replacement therapy. Although T_4 was used in some studies,[9,10,14,15] it was T_4/T_3 preparations and T_3 alone used in a way that violated the mandates of T_4 replacement. Specifically, patients were permitted to use thyroid hormone despite laboratory test results indicating that they were euthyroid, and doses were not titrated according to TSH levels but by patients' clinical responses to particular doses.

Effective doses usually suppressed TSH levels. Despite this, patients did not have symptoms of thyrotoxicosis, nor did they have evidence of thyrotoxicosis according to electrocardiography, bone densitometry, or serum and urine biochemical test results.

Patients with FMS whose laboratory test results indicate euthyroidism should begin with T_3. In studies of the thyroid status of FMS patients at intake, approximately 33% were euthyroid according to thyroid function testing.[192,193] Of these patients, approximately 75% have partial peripheral cellular resistance to thyroid hormone according to four criteria[115,116]:

1. The patients are euthyroid (according to laboratory thyroid function test results) before beginning the use of T_3.
2. The patients recover from their hypothyroid-like FMS symptoms and signs with supraphysiological doses of T_3.
3. The patients have high serum-free T_3 levels after beginning T_3 therapy.
4. The patients have no evidence of tissue thyrotoxicosis, according to the results of serial electrocardiograms (ECGs), serum and urine biochemical tests, and bone densitometry.

These patients usually benefit only from immediate-release T_3 (*not* sustained-release T_3) in a single daily dose.[16] They are likely to respond only to supraphysiological doses of T_3. Effective T_3 dosages for most patients are between 25 and 125 mcg. For some patients, however, safe and effective doses are far higher.[16]

Some FMS patients have both hypothyroidism and cellular resistance to thyroid hormone.[8] Most of these patients improve or recover only with T_3 therapy, typically supraphysiological doses.

The Basis of Dosage Adjustments

After a patient's thyroid status has been determined and thyroid hormone therapy has begun, dosage changes should be titrated according to symptom status and physiological measures, not according to thyroid function test results. Thyroid function tests are of no value in finding the safest and most effective dosage for any particular patient.[194] There is no scientific justification for inferring the metabolic status of cells (other than the thyrotrophs of the anterior pituitary) from thyroid function test results. The belief that tissue metabolic status can be accurately inferred from TSH or thyroid hormone levels is a postulate, not a research-derived conclusion. This postulate was found to be false, at least for rats, by studies showing that the levels of T_3 and T_4 in the cells of different tissues cannot be accurately predicted from plasma levels of TSH, T_3, or T_4.[195,196] Moreover, some studies show that TSH levels correlate poorly with measures of the tissue effects of thyroid hormone, such as the speed of the relaxation phase of the Achilles reflex.[197] Conversely, other studies show that the patient's symptoms and signs are far more accurate and reliable indicators of tissue metabolic status than are the results of thyroid function tests.[194,198]

The resting metabolic rate (RMR) measured with indirect calorimetry is the most reliable measurement of oxidative metabolism, which is strongly regulated by thyroid hormone. In a study designed to find a correlation between patients' RMRs and their TSH levels, a significant correlation was obtained only by log-transforming the TSH values.[199] The lack of a significant correlation without log transformation means that the TSH is not a useful tool for determining whether an individual patient's thyroid hormone dosage is providing him or her with sufficient oxidative metabolism. Preferably, clinicians will include indirect calorimetry in their clinical practices. However, this instrument is not necessary for finding patients' safe and effective dosages.

Rehabilitation Model: Data-Driven Clinical Decisions

The clinician should distinguish as clearly as possible all the various factors impairing the individual patient's metabolism. Next, the clinician should provide the patient with an individualized treatment regimen designed to correct, eliminate, or compensate for the causative factors. The treatment regimen that is most effective for guiding the FMS patient to recovery conforms to a rehabilitation model, which requires baseline and repeated monitoring of the patient's clinical status through objective assessment methods. Thus clinical decisions, such as thyroid hormone dosage adjustments, are data driven.

Objective Assessment of Patient Status

In patients with FMS, recovery of normal metabolism, a symptom-free state, and full function occurs gradually over a range of 2 to 6 months. Because of the time involved, it is best for the clinician to quantify the patient's clinical status through objective measures at weekly or biweekly intervals. Scores from these measures should be posted as data points to line graphs after each evaluation. The patient's baseline score on each measure (taken before therapy is begun) is the initial data point on each graph.

Next, a line should be drawn through the data points to create a trend line that makes obvious, on visual inspection, changes in the patient's clinical status. The trend lines of the data points on the graphs thus help the clinician assess the effectiveness of the patient's regimen at any point during treatment. In this way, the lines enable the clinician to make informed, data-driven decisions about any treatment changes needed to optimize clinical results.

The five line graphs in Fig. 170.4 show the changes in FMS measures during metabolic rehabilitation of a euthyroid FMS patient reported by Honeyman-Lowe.[9] Typically, all measures change together in the direction of improvement, no improvement, or worse. The patient's subjective status usually corresponds closely to what the trend lines indicate.

During the course of the rehabilitation process, patients and clinicians often lose sight of the severity of the patient's clinical status before treatment. When patients occasionally experience a brief or mild exacerbation of symptoms, they are especially prone to forget the progress they have made. For some, this state of mind can lead to the false conclusion that they have made no progress at all. This false conclusion is quickly corrected, however, by a review of the patients' graphs, which show visually and objectively their real progress.

The five objective assessment methods that should be used at each patient evaluation are described as outlined in the following discussion. The clinician should also perform a physical examination at each evaluation to further assess the patient's changing tissue metabolic status.

Pain Distribution Body Form

Four studies have shown that the most sensitive indicator for changes in FMS status is the pain distribution as a percentage of the body in pain.[11–13,163,200] This is convenient in that chronic widespread pain is one of the two major criteria for the assessment of FMS status.[1]

Small changes in pain distribution are assessed by using a form containing drawings of the body. The patient precisely shades in where he or she has had aching, pain, soreness, or tenderness since the last evaluation. Next, a template is placed over the patient's shaded form, which shows the body form divided into 36 areas. Each of the 36 divisions has a percentage value.[16,11–13] To obtain the patient's pain distribution, the values of the shaded divisions are totaled. This percentage number is placed on a graph as a data point. The data points for each evaluation are connected by a line showing the trend of the pain distribution over time.

Mean Pressure/Pain Threshold of Tender Point Sites

The second major criterion for the assessment of FMS is the presence of tender point sites (TnPs).[1] A modified version of the TnP examination measures the pressure/pain threshold of TnPs with algometry (numeric values in kilograms per square centimeter). This provides more precise quantification than the 1990 ACR method and enables the clinician to make more objective, evidence-based decisions.[201] The mean of the threshold values is calculated and posted to a line graph.

FibroQuest Symptoms Survey

The FibroQuest Symptoms Survey assessment form consists of 100-mm visual analog scales (VASs), 1 for each of the 13 most common associated FMS symptoms.[2] These symptoms are also characteristic symptoms of hypothyroidism and the peripheral form of cellular resistance to thyroid hormone (see Box 170.1).[16]

The patient estimates the intensity of each symptom by marking the appropriate point on the scale (1–10). The values for each marked symptom are added, and this total symptom intensity is then divided by the number of symptoms the patient marked at intake (baseline). The mean score is then posted to a line graph.

Fibromyalgia Impact Questionnaire

The Fibromyalgia Impact Questionnaire (FIQ)[202] is a measure of the patient's functional status. The total score from the FIQ is posted as a data point to a line graph. The assessment of functional ability is highly pertinent to the care of FMS patients. For example, in a study of the functional abilities of 1735 female FMS patients ages 31 to 78, researchers concluded that the average patient had less ability in activities of daily living than the average community-dwelling woman in her 80s.[203]

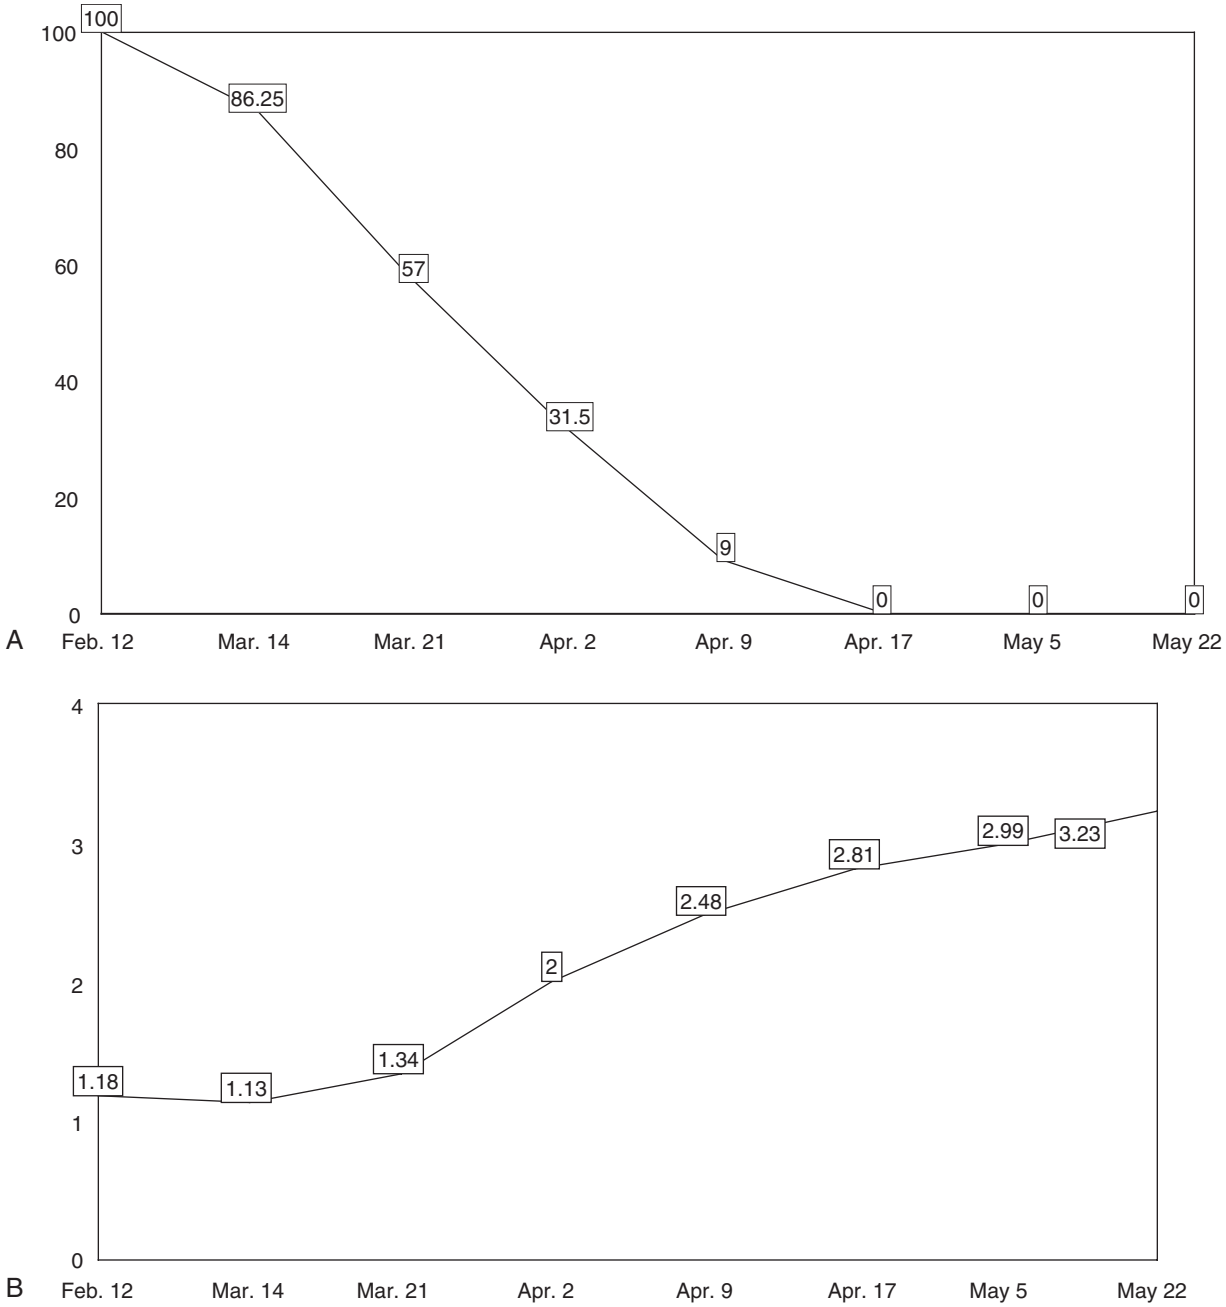

Fig. 170.4 (A) Pain distribution. Scores show the percentage of 36 body divisions containing pain at each evaluation (determined by the patient's pain drawing). At each evaluation, the percentage was posted to the graph. (B) Increases in mean tender point pressure/pain threshold during metabolic rehabilitation.

Zung's Self-Rating Depression Scale

Depression is so common among FMS patients that an assessment specific for the presence and severity of depression is used in addition to the VAS scale for depression. Zung's is one such assessment tool.[204] The score from the depression scale is posted to a line graph.

Physical Examination

When the treatment for the patient with FMS includes thyroid hormone, the five FMS measures should be used in conjunction with physiological tests that assess tissue responses to the hormone. The most convenient physiological tests are the relaxation phase of the Achilles' reflex, basal pulse rate, and basal body temperature. A combination of physiological measurements is a more reliable indicator of tissue metabolic status than are the results of laboratory thyroid function tests.

In the early 20th century, indirect calorimeters came into use to measure patients' RMRs.[205] Based on the patient's measured oxygen consumption, the instrument calculates the patient's estimated 24-hour resting energy expenditure. Thyroid hormone potently and exquisitely regulates oxidative metabolism. Because of this, during the mid-20th century, indirect calorimeters were used as the most relevant instrument for the diagnosis of hypometabolism (subnormal oxidative metabolism) due to hypothyroidism and thyroid hormone resistance. In recent years, handheld and other types of convenient-to-use, affordable, and accurate indirect calorimeters have become available for clinical use. Two studies have shown that patients with FMS have abnormally low RMRs compared with matched controls.[118,119]

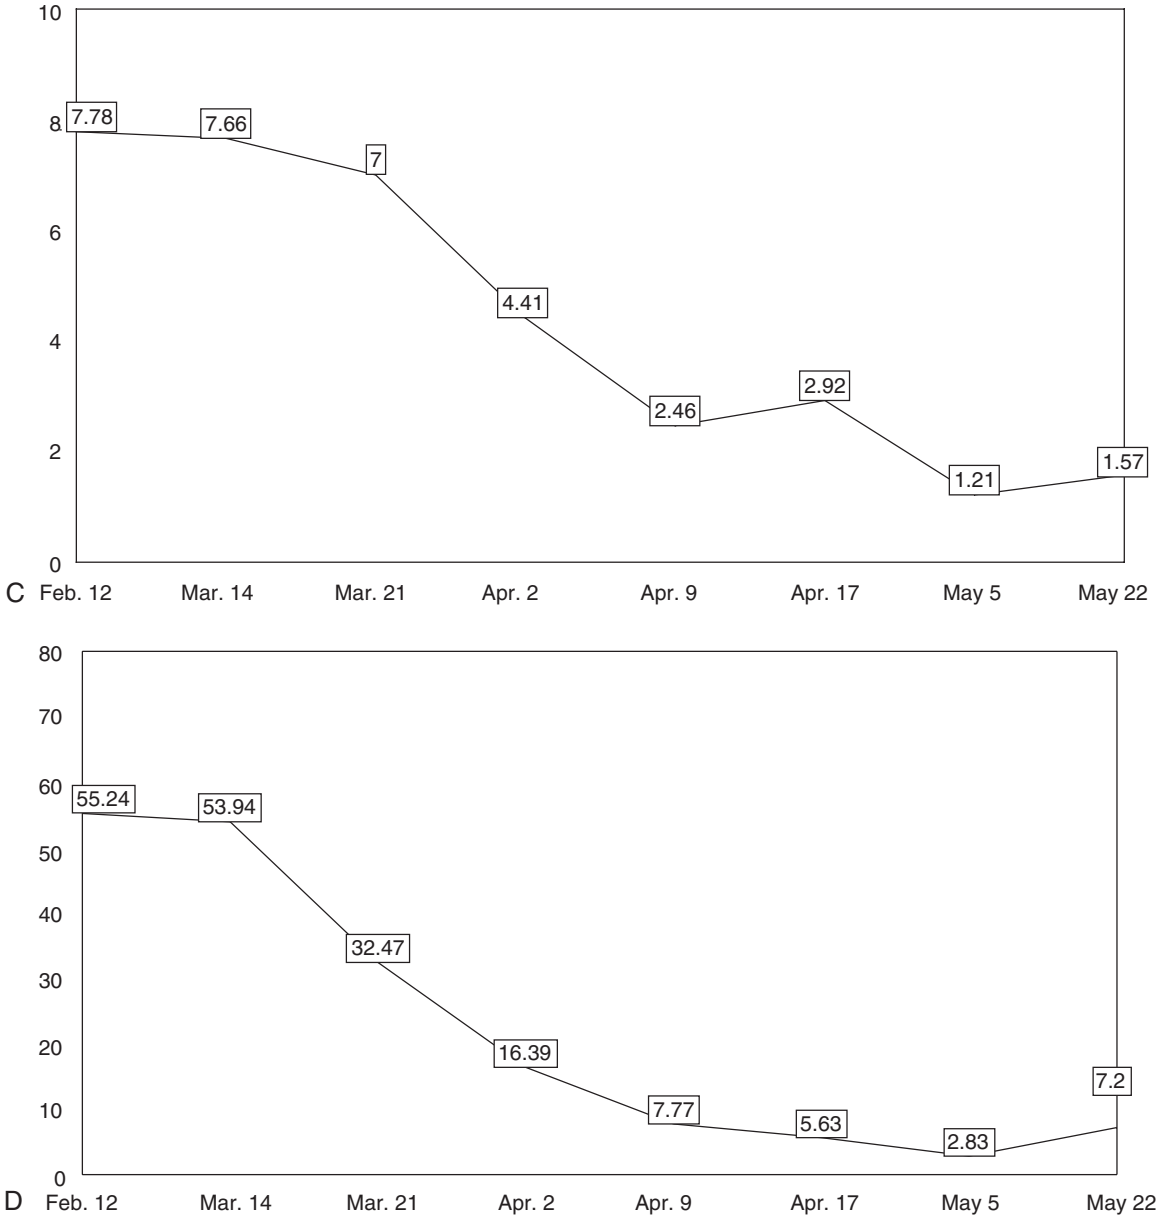

Fig. 170.4, cont'd (C) Decreases in mean intensity of fibromyalgia syndrome symptoms as calculated from the FibroQuest form. (D) Decreasing scores on the Fibromyalgia Impact Questionnaire.

Integrated Metabolic Therapies Essential for All Patients With Fibromyalgia Syndrome

The majority of patients with FMS must control or eliminate at least four metabolism-impeding factors. First, for the approximately 90% of FMS patients who have some form of thyroid disease,[116,117] the proper preparation and dosage of thyroid hormone are necessary for the patient's recovery.

Second, most patients must also modify their diets so that they minimize the intake of arachidonic acid. A high intake of arachidonic acid can increase body levels of both the proinflammatory eicosanoids prostaglandin E2 and leukotriene B4,[206] which can contribute to chronic pain.[207] Patients must also reduce their intake of refined carbohydrate. ITHR of glycolysis, the citric acid cycle, and the electron transport chain results in low production of adenosine triphosphate (ATP) and creatine phosphate. Dysglycemia and insulin resistance due to the intake of refined carbohydrates can worsen the low production of high-energy phosphates due to ITHR.[16]

Third, most patients must take a wide array of nutritional supplements. Various nutrients are synergistic to thyroid hormone in providing optimal intracellular metabolism, and patients must provide themselves with optimal amounts. For example, a deficiency of vitamin B_1 can render patients intolerant of even low dosages of thyroid hormone—dosages too low to be therapeutic.[208] In addition, supplemental thyroid hormone can increase the expenditure of vitamin B_1 in cells. If a patient has a marginal deficiency of the vitamin, supplemental thyroid hormone could induce a frank deficiency. This can result in a beriberi-type of cardiomyopathy.[208]

Fourth, most patients must also exercise to tolerance. Biochemical treatments such as thyroid hormone, optimal diet, and nutritional supplements provide the patient with increased metabolic capacity. Sufficiently vigorous physical activity, however, is necessary for optimizing metabolism in most tissues and for priming the descending nociceptive inhibitory system of the CNS.

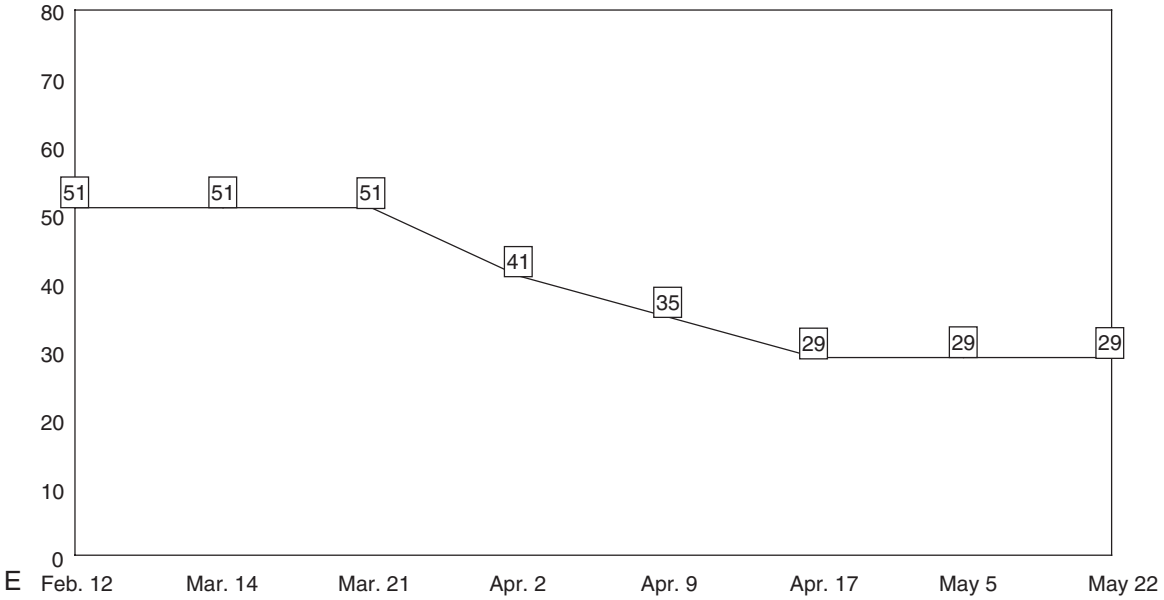

Fig. 170.4, cont'd (E) Decreasing scores on Zung's Self-Rating Depression Scale.

Additional Metabolic Therapies Necessary for Some Patients

Adrenocortical Hypofunction

Some patients must be treated for adrenocortical hypofunction. Low cortisol levels can produce some symptoms that are the same as those associated with FMS. These include weakness, fatigue, exaggerated responses to stress, exercise intolerance, hypotension, and low nociception threshold. Low cortisol levels can also render the patient intolerant of a dosage of thyroid hormone high enough to be fully therapeutic. The reason is that a minimally effective dosage of thyroid hormone is likely to accelerate the hepatic clearance of cortisol.[209] This typically exacerbates the symptoms of cortisol deficiency symptoms.

Metabolism-Impairing Medications

Several classes of medications may be significant in the development or perpetuation of FMS symptoms. Because of this, some patients must cease taking some metabolism-impairing medications, and they must convert from the maintenance to as-needed use of others.

Beta blockers impair metabolism directly by reducing the density of β-adrenergic receptors on cell membranes and rendering α_2-adrenergic receptors predominant in the regulation of cell function, exactly as hypothyroidism does. In some patients, this shift in adrenoceptor isoform balance creates a general mental and physical inhibitory state that may be indistinguishable from hypothyroidism or the associated symptoms of FMS.[210] The shift in adrenergic receptor isoform may also impair the function of the CNS's descending antinociceptive system, resulting in the pain and tenderness characteristic of FMS.

Narcotics, tranquilizers, and muscle relaxants are commonly prescribed as FMS treatments. Patients should be weaned from these as soon as possible because they can render patients disinclined to engage in vigorous physical activity. As the patient's physical fitness level declines, anergia and pain perception increase.

Some antidepressants (also commonly prescribed for FMS) and decongestants can cause tachycardia when they are used simultaneously with exogenous thyroid hormone. Because of this, patients using these drugs must reduce the dosages or stop their use to be able to take a dosage of thyroid hormone high enough to be therapeutic.

THERAPEUTIC APPROACH

Assessment of Fibromyalgia Syndrome Status

The patient's FMS status should be evaluated before treatment is begun and at intervals throughout the course of treatment. Reevaluations are best performed weekly to biweekly and before each increase in thyroid hormone dosage. If patients have taken measurements at home, such as the basal temperature, they should provide the clinicians with a record of these measurements. A physical examination and five FMS measures should be used at each evaluation:

- Pain distribution as the percentage of 36 body divisions containing pain, according to a body drawing
- Mean TnP score in kg/cm^2 measured by algometry
- Symptom intensity estimate according to visual analog scales (FibroQuest Symptoms Survey)
- Functional status according to the Fibromyalgia Impact Questionnaire
- Depression according to the Zung's Self-Rating Depression Scale

Scores for each assessment instrument should be posted to a line graph so that the trend of the scores is obvious on visual inspection. Changes in the patient's individualized treatment regimen should be based on the trend of scores on the line graphs combined with the physical examination and the clinician's and patient's subjective assessments. This process is continued (usually for 2–6 months) until the scores on the line graphs are representative of normal, the patient no longer meets the ACR criteria for FMS, and the patient is symptom-free and fully functional.

Patient Safety

All patients must have an electrocardiogram before beginning metabolic rehabilitation and, if appropriate, at intervals throughout the treatment process. Although dysrhythmic conditions are usually not obstacles to metabolic treatment, it is essential to be aware of them before treatment with thyroid hormone.

Patients should be educated extensively on the possible signs and symptoms of thyrotoxicosis and its management should overstimulation occur. When a patient's history indicates, he or she should

be tested for possible adrenocortical hypofunction. If testing reveals decreased cortisol production, the patient should be treated with physiological doses of cortisol at least temporarily before the use of thyroid hormone is initiated.

Thyroid Hormone Therapy

If the FMS patient is hypothyroid, he or she should begin treatment with 60 mg of desiccated thyroid or a synthetic T4/T3 preparation with a 4:1 ratio. The dosage should be increased by 60 mg of desiccated thyroid at approximately 3- to 4-week intervals until an optimal dosage has been reached.

If the patient is euthyroid, he or she should begin treatment with immediate-release T3, usually with a starting dosage of 50 mcg. The dosage is increased at weekly to biweekly intervals by 12.5 mcg. Dosage increases should continue until the patient is symptom-free, no longer meets the ACR criteria for FMS, is fully functional, and has reference-range physiological measures such as the basal body temperature and basal pulse rate.

Wholesome Diet

If they have not done so already, patients should adopt a diet that both stabilizes blood sugar regulation and insulin levels and reduces pain perception. Such a diet involves lean meats—especially poultry—fish, fruits, vegetables, and minimal intake of whole grains. It also minimizes the intake of foods high in arachidonic acid (which increases the production of the proinflammatory eicosanoids prostaglandin E2 and leukotriene B4[194]) and additive excitotoxins such as monosodium glutamate and aspartame. The author recommends that patients use organic foods and purified drinking water to decrease the quantity of chemical contaminants ingested.

Nutritional Supplements

Patients should take, at minimum, the following nutrients in the approximate dosages given:

High-potency multiple vitamin and mineral
Vitamin B_{12}: 3000 to 5000 mcg a day of methylcobalamin
Vitamin C: 500 mg to 1 g three times a day
Vitamin E (mixed tocopherols): 800 to 1600 IU a day
Carotenoids (mixed): 15 mg a day
Calcium: 2000 mcg a day in divided dosages
Magnesium (preferably as aspartate, citrate, malate, or glycinate): 1000 mg a day in divided dosages
Fish oils: 1000 to 2000 mg EPA+DHA a day

Exercise to Tolerance

Exercise is essential to help normalize metabolism. It is recommended that patients engage in forms of exercise that they enjoy and gradually increase the intensity as their symptoms diminish. Weight-bearing exercise is encouraged because it supports bone health. Aerobic exercise is essential to strengthen the cardiovascular and pulmonary systems. Toning activities build lean muscle mass, which in turn improves metabolism. A combination of these forms of exercise is best. Many patients who have become severely deconditioned owing to their FMS symptoms find warm-water exercise an ideal way to begin.

Physical Treatment

Myofascial therapy to eliminate trigger points in muscles and spinal manipulation to regain flexibility of the spine and other joints are essential for completely eliminating some patients' FMS pain. Both trigger points and spinal lesions can be perpetuated by self-sustaining skeletal muscle contractures. The contractures may result from deficient intramuscular high-energy phosphate production due to ITHR.[20,22,196] Both forms of treatment may raise the nociceptive threshold and increase mobility.

If an examination indicates the need, orthotics should be prescribed to relieve pain-inducing chronic postural muscle tension. The therapeutic aim is to reduce nociceptive input of somatic origin to the CNS.

Gallstones

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- May be asymptomatic or cause biliary colic with irregular pain-free intervals of days or months
- Real-time ultrasonography provides a definitive diagnosis.

GENERAL CONSIDERATIONS

Gallstones are another example of a "Western diet"–induced disease. In the United States, autopsy studies have shown that gallstones exist in approximately 20% of women and 8% of men older than age 40. Conservative estimates suggest that about 20 million Americans (10% of the U.S. population) and 5% to 22% of the population in the Western world have gallstones.[1] Each year, 1 million more develop gallstones. More than 300,000 gallbladders are removed each year in the United States owing to the presence of gallstones.[2–5] Gallstones are also considered a significant risk factor for gallbladder cancer.[6,7]

The bile components include bile salts, bilirubin, cholesterol, phospholipids, fatty acids, water, electrolytes, and other organic and inorganic substances.[8] Table 171.1 shows the characteristics of the major bile components. Gallstones arise when a normally solubilized component of bile becomes supersaturated and precipitates (Fig. 171.1).

Gallstones can be divided into four major categories:

- Pure cholesterol
- Pure pigment (calcium bilirubinate)
- Mixed—containing cholesterol and its derivatives along with varying amounts of bile salts, bile pigments, and inorganic salts of calcium
- Stones composed entirely of minerals

Pure stones, either cholesterol or calcium bilirubinate, are extremely rare in the United States, where recent studies indicate that approximately 80% of the stones are of the mixed variety. The remaining 20% of the stones are composed entirely of minerals, principally calcium salts, although some stones contain oxides of silicon and aluminum.[2–4]

PATHOGENESIS

The formation of gallstones has been divided into three steps:

- Bile supersaturation
- Nucleation and initiation of stone formation
- Enlargement of the gallstone by accretion

Cholesterol and Mixed Stones

The requisite step in the formation of cholesterol and mixed stones is cholesterol supersaturation of bile within the gallbladder. Bile solubility, as well as bile supersaturation, is based on the relative molar concentrations of cholesterol, bile acids, phosphatidylcholine (lecithin), and water. Because free cholesterol is water insoluble, it must be incorporated into a lecithin–bile salt micelle (Fig. 171.2). Using triangular coordinates, it is possible to demonstrate the solubility of cholesterol in bile (Fig. 171.3).

As illustrated in the figures, either an increase in cholesterol secretion or a decrease in bile acid or lecithin secretion will lead the bile to become supersaturated. Once the bile is supersaturated, stone formation is initiated by such factors as biliary stasis, infection, and increased mucin secretion by the gallbladder epithelium. Once the stone begins to form, its radius increases at an average rate of 2.6 mm/year, eventually reaching a size of a few millimeters to more than a centimeter. Symptoms typically occur an average of 8 years after formation begins. Cholelithiasis is present in 95% of patients with cholecystitis.[8]

Risk Factors for Cholesterol and Mixed Stones

The major risk factors for the development of cholesterol and mixed gallstones include the following[2–4]:

- Diet
- Gender
- Race
- Obesity
- High caloric intake
- Estrogens

TABLE 171.1 Characteristics of the Major Bile Components

Component	Percentage of Bile	Water Solubility	Physiochemical Properties
Cholesterol	5	Very poor	Will precipitate from aqueous solutions
Bile salts	69–90	Soluble; have polar and nonpolar regions	Capable of solubilizing cholesterol and phospholipid in aqueous phase
Phospholipid	2–25	Poor	Fits between bile salt molecules, thus increasing their capacity to solubilize cholesterol

Modified from Rubenstein E, Federman DD. *Scientific American Medicine*. New York: Scientific American; 1986;4: VI-1–VI-10.

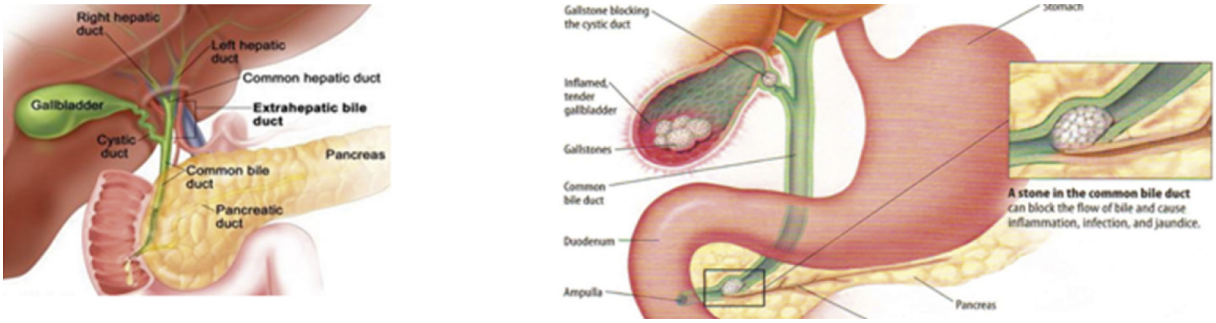

Fig. 171.1 Gallstones.

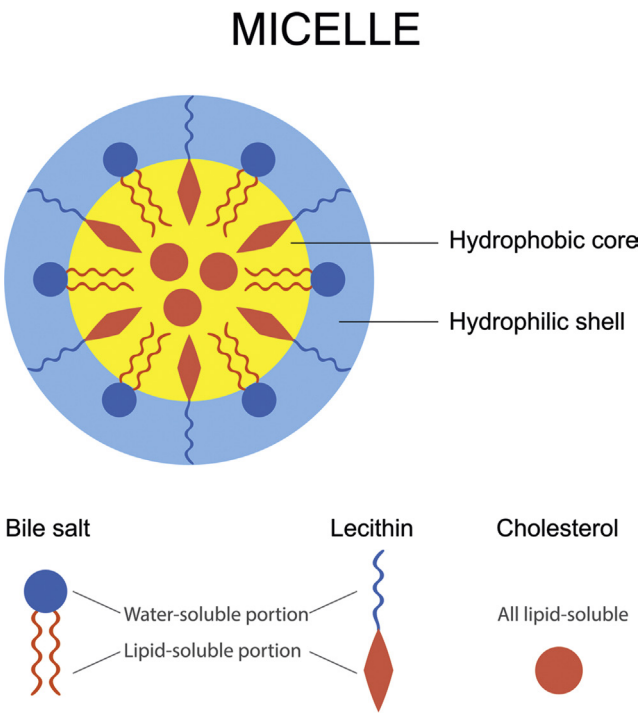

Fig. 171.2 Mixed micelle. (From FancyTapis/iStock.com.)

- Gastrointestinal diseases (especially Crohn's disease and cystic fibrosis)
- Drugs
- Age

The role of a low-fiber, high-fat diet in the development of gallstones, as well as other dietary factors, is discussed later. The other factors are briefly discussed here.

Gender

The frequency of gallstones is two to four times greater in women than in men. Women are thought to be predisposed to gallstones because of either increased cholesterol synthesis or suppression of bile acids by estrogens. Pregnancy, the use of oral contraceptives or other causes of elevated estrogen levels, and tamoxifen use greatly increase the incidence of gallstones.

Genetic and Ethnic

The prevalence of gallstones appears to have some genetic aspects. Gallstones are most common in Native American women over age 30. Nearly 70% of this group have gallstones. In contrast, only 10% of black women over 30 have gallstones. The difference in the prevalence rate between ethnic and genetic groups reflects the extent of cholesterol saturation of the bile. The degree to which dietary factors affect this value probably outweighs genetic factors.[9]

Obesity

Obese subjects are at risk of developing gallstones by being overweight and when initially losing weight.[10] Obesity causes increased activity of 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase, with increased secretion of cholesterol in the bile as a result of increased cholesterol synthesis. Therefore obesity is associated with a significantly increased incidence of gallstones due to biliary cholesterol saturation.

It is important to note that during active weight reduction, changes in body fat and diet can promote gallstone problems. During the first stages of weight loss, biliary cholesterol saturation initially increases.[4] The secretion of all biliary lipids is reduced during weight loss, but the secretion of bile acids decreases more than that of cholesterol. Once the weight is stabilized, bile acid output returns to normal levels, whereas the cholesterol output remains low. The net effect is a significant reduction in cholesterol saturation. In prescribing diet therapies for obese patients with a high risk of gallstones, it should be recognized that prolonged dietary fat reduction can also promote biliary stasis,[1] thus contributing to cholesterol saturation. Studies show that at least 10 g of fat per day is necessary to assure proper gallbladder emptying.[11]

Gastrointestinal Tract Diseases

Malabsorption of bile acids from the terminal ileum disturbs the enterohepatic circulation, thereby reducing the bile acid pool and the rate of secretion of bile. Diseases associated with this phenomenon include Crohn's disease and cystic fibrosis.

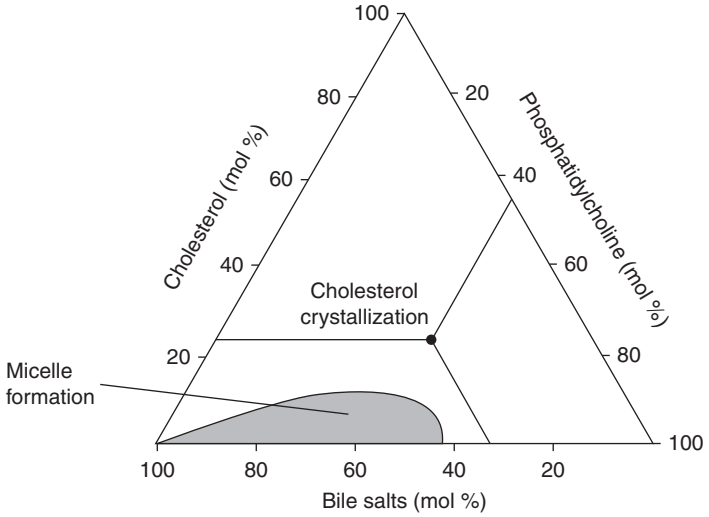

Fig. 171.3 Cholesterol solubility in bile.

Drugs

Tamoxifen treatment in postmenopausal patients with breast cancer greatly increases gallstones. One retrospective cohort study of 703 women demonstrated that after 5 years, the incidence of stone formation in the tamoxifen-treated patients was 37.4%, whereas it was 2% in patients who did not receive tamoxifen.[12] Most gallstones became apparent after 3 years.

In addition to oral contraceptives and other estrogens, other drugs that increase the risk of gallstones include the cephalosporin ceftriaxone, octreotide, HMG-CoA reductase inhibitors,[1] and possibly other lipid-lowering drugs.

Age

Gallstones have been reported from fetal age to extreme old age, but the average patient is 40 to 50 years old. A decline in the activity of cholesterol 7-α-hydroxylase with age[1] leads to an increase in biliary cholesterol hypersecretion[13] and thus cholesterol saturation, with an accelerated formation of gallstones.

Hypothyroidism

Patients with hypothyroidism are more prone to have high serum cholesterol levels. The mechanisms of thyroid hormones on cholesterol are multifactorial, including influencing the synthesis, absorption, and usage of cholesterol. Disturbances in lipid metabolism that occur during hypothyroidism, particularly in the cholesterol pathway, change the rate of bile excretion and lead to the formation of gallstones. In regression multivariate analysis, it has been concluded that the level of serum thyroid-stimulating hormone (TSH) was an independent factor that could be considered a risk factor for the formation of common bile duct stones (odds ratio [OR] = 3.07; 95% confidence interval [CI], 1.51–6.3).[14]

Environmental Pollutants

Metal contamination of both natural and anthropogenic origin has an adverse effect on human health. A study explored the effects of metal contamination on gallstone formation by comparing two environmentally contrasting populations in the Huelva Province of Southwest Spain.[15] The study population resided in an area with high metal abundance derived from the naturally metal-enriched bedrock and historical mining activities in the region of the Iberian Pyrite Belt, whereas the control population resided in the National Park of Sierra de Aracena and Picos de Aroche. The patients from the study group had a higher risk of metal exposure through contaminated soil, particle matter in the air, and consumption of local water and food products. Results demonstrated that metal exposure was related to a higher tendency of forming black-pigment gallstones in the study group compared with the control group, and the gallstones from the study group contained more abundant metal components, such as copper, iron, nickel, and zinc. In addition, a study in India identified a positive correlation between nickel, cadmium, and chromium in water and a high prevalence of gallbladder disease in adjacent villages in Vaishali District, Bihar.[16]

Organochlorine pesticides (OCPs) are persistent organic pollutants (POPs) historically used in the agricultural control of pests. A case-control study from China showed that high levels of p,p′-DDE and p,p′-DDT residues were risk factors for gallstone formation.[17] Because of their lipophilic property, OCPs can accumulate in adipose tissue and other organs. β-HCH and p′,p′-DDE levels in adipose tissues were found to be higher in patients with gallstones and strongly related to gallstone disease.[18]

Risk Factors for Pigmented Gallstones

Risk factors for pigmented gallstones are not related to diet as much as they are to geography, sun exposure, and severe diseases. Pigmented gallstones are more common in Asia because of the higher incidence of parasitical infections of the liver and gallbladder by various organisms, including the liver fluke *Clonorchis sinensis.* Bacteria and protozoa can cause stasis or act as nucleating agents. In the United States, pigmented stones are usually caused by chronic hemolysis or alcoholic cirrhosis of the liver.

THERAPEUTIC CONSIDERATIONS

Gallstones are easier to prevent than to reverse. Primary treatment, therefore, involves reducing the controllable risk factors discussed earlier. Once gallstones have formed, therapeutic intervention involves avoiding aggravating foods and employing measures that increase the solubility of cholesterol in bile. If symptoms persist or worsen, cholecystectomy should be considered.

A number of dietary factors are important in the prevention and treatment of gallstones. Foremost is the elimination of foods that can produce symptoms. Also important are increasing dietary fiber, eliminating food allergies, and reducing the intake of refined carbohydrates and animal protein. There is a protective effect of vegetables and fruits

against gallbladder cancer, and red meat (beef and mutton) was found to be associated with an increased risk of gallbladder carcinogenesis.[19] Because gallstones are a risk factor for gallbladder cancer,[6,7,19] appropriate nonlithogenic dietary practices will protect against both cancer and the development of gallstones.

Other treatment measures involve the use of nutritional lipotropic compounds, herbal choleretics, and other natural compounds in an attempt to increase the solubility of bile.

Biliary cholesterol concentration and serum cholesterol levels do not seem to correlate.[20] Although some authors have reported an inverse correlation between high-density-lipoprotein cholesterol and bile saturation and a direct correlation between low-density-lipoprotein cholesterol and bile saturation,[21,22] more detailed research does not appear to support these correlations.[20] There does, however, seem to be an association between increased levels of serum triglycerides and bile saturation.[23]

Asymptomatic Gallstones

The natural history of silent or asymptomatic gallstones supports the contention that elective cholecystectomy is not warranted. Although there is a cumulative chance of developing symptoms—10% at 5 years, 15% at 10 years, and 18% at 15 years—a patient should never experience discomfort if controllable risk factors are eliminated or reduced.[3]

Diet

Dietary Fiber

The hypothesis that the main cause of gallstones is the consumption of fiber-depleted refined foods has considerable research support.[4,5] As mentioned earlier, in population studies, gallstones are associated with the Western diet. Such a diet, high in refined carbohydrates and fat and low in fiber, leads to a reduction in the synthesis of bile acids by the liver and a lower bile acid concentration in the gallbladder.

Another way in which fiber may prevent gallstone formation is by reducing the absorption of deoxycholic acid.[4,5] This compound is produced from bile acids by bacteria in the intestine. Deoxycholic acid greatly lessens the solubility of cholesterol in bile.

Dietary fiber has been shown both to decrease the formation of deoxycholic acid and to bind deoxycholic acid and promote its excretion in the feces. This greatly increases the solubility of cholesterol in the bile. A diet high in fiber, especially those fibers capable of binding to deoxycholic acid (e.g., predominantly the water-soluble fibers found in vegetables and fruits, pectin, oat bran, and guar gum), is extremely important in both the prevention and reversal of most gallstones.[5]

Interestingly, diets rich in legumes with high concentrations of water-soluble fibers are associated with an increased risk for gallstones.[9] Chileans, Pima Indians, and other North American Indians have the highest prevalence rates for cholesterol gallstones, and all consume a diet rich in legumes. Evidently, legume intake increases biliary cholesterol saturation because of legumes' saponin content.[9] A study conducted in the Netherlands showed just the opposite because legume intake was shown to offer significant protection against gallstones.[24] Until this issue is clarified, it might be best to restrict legume intake in individuals with existing gallstones.

Vegetarian Diet

A vegetarian diet has been shown to protect against gallstone formation.[5,25] A recent study in England compared a large group of healthy nonvegetarian women with a group of vegetarian women. Ultrasound diagnosis showed that gallstones occurred significantly less frequently in the vegetarian group.

Although this may simply be a result of the increased fiber content of the vegetarian diet, other factors may be equally important. Animal proteins, such as casein from dairy products, have been shown to increase the formation of gallstones in animals, whereas vegetable proteins, such as soy, were shown to be preventive against gallstone formation.[4,5,26]

Food Allergies

Since 1948, J. C. Breneman, author of *Basics of Food Allergy,* has used a successful therapeutic regimen to prevent gallbladder attacks: allergy elimination diets. The idea that food allergies cause gallbladder pain has some support in the scientific literature.[27–30] A 1968 study revealed that 100% of a group of patients were free from symptoms while they were on a basic elimination diet (beef, rye, soybean, rice, cherry, peach, apricot, beet, and spinach).[27] Foods inducing symptoms, in decreasing order of their occurrence, were as follows:

- Egg
- Pork
- Onion
- Fowl
- Milk
- Coffee
- Citrus
- Corn
- Beans
- Nuts

The addition of eggs to the diet caused gallbladder attacks in 93% of the patients.

Several mechanisms have been proposed to explain the association of food allergy and gallbladder attacks. Breneman believes that the ingestion of allergy-causing substances causes swelling of the bile ducts, resulting in impairment of bile flow from the gallbladder.

Buckwheat

Buckwheat is a well-known alternative for those avoiding wheat for hypoallergenic purposes. When three groups of eight hamsters were given a buckwheat-, soy-, or casein-based diet, a Japanese research group demonstrated that buckwheat can significantly decrease gallstone formation and reduce the concentration of cholesterol in the gallbladder, plasma, and liver of hamsters compared with the casein diet.[31] Even though soy is a known potent gallstone attenuator itself,[32] these researchers found that the positive effects of buckwheat were far stronger than those of soy. Gallstones were clearly visible in all eight hamsters fed the casein diet, whereas two of seven hamsters fed the soy diet (29%) and none of the buckwheat-fed animals had gallstones. Studies in rats have also corroborated these findings.[33] Rats consuming high-protein buckwheat flour (PBF) had a 33% decrease in serum cholesterol and a significant decrease in liver cholesterol compared with rats consuming casein.[34] In addition, consumption of PBF for 10 days significantly suppressed adipose tissue weight and the hepatic activity of fatty acid synthase in rats fed cholesterol-free diets compared with the consumption of casein, and PBF significantly decreased the incidence of cholesterol gallstones and the lithogenic index in mice fed cholesterol-enriched diets for 37 days. The authors suggest that buckwheat can enhance bile acid synthesis and fecal excretion of steroidal compounds, and PBF has strong activities against hypercholesterolemia, obesity, and gallstone formation. Buckwheat may be useful to treat patients with both high cholesterol and gallstones and may reduce the proliferation of colon cancer cells.[35] The authors also postulated that higher levels of arginine and glycine may play a role in buckwheat's protective function.

Sugar

A 4-year study evaluated 111 cases of biliary tract cancer and compared them with 480 controls for various dietary parameters, including

sugar intake. The major finding was an increased risk associated with the intake of sugars, either monosaccharides or disaccharides, independent of other energy sources. Sugar may be a risk factor for biliary tract cancer based on the relationship among sugars, blood lipids, and gallstone formation. The author also noted an association between the intake of sugar and gallstones. Diets high in refined carbohydrates have been found to be associated with increased cholesterol saturation of the bile.[36,37] A 25-year follow-up study of 860 men, 54 of whom developed symptomatic gallstones, also found a positive association between sugar consumption and gallstones.[38]

Caloric Restriction

In a case-controlled study in which 200 patients with gallstones were compared with 98 controls, total caloric and carbohydrate intake and serum triglyceride levels were higher in the patients with gallstones. Dietary intake of refined carbohydrates was higher in female patients with gallstones, whereas male patients with gallstones had an increased fat intake.[39] In another study, 76 patients whose gallstones were detected by ultrasound were matched to control subjects without cholelithiasis. It was found that high caloric intake of greater than 2500 kcal/day and diets rich in carbohydrates and saturated fats significantly increased gallstone risk.[40] One intriguing note to this study was the finding that alcohol consumption of 20 to 40 g/day was protective.

However, caloric restriction must be instituted carefully, because rapid weight loss[41] and fasting[42] increase the risk of gallstones (see earlier section on obesity). For example, in 179 obese patients, 9% of whom had preexisting gallstones, a low-calorie (605 kcal) diet resulted in 11% of the patients developing gallstones either during or within 6 months of completing the diet.[41] Another study of a 925-kcal diet found that 12.8% of the 47 female patients displayed gallstones at week 17 as determined by sonography. Those who developed gallstones had significantly higher baseline triglyceride and total cholesterol levels than those who did not. They also had a significantly greater rate of weight loss.[43] A 1-year matched cohort study of consecutively enrolled adults in a commercial weight-loss program using very low-calorie diets (VLCDs) or a low-calorie diet (LCD) assessed the risk of symptomatic gallstones requiring hospital care and/or cholecystectomy.[44] During the 6361 person-years, 48 and 14 gallstones requiring hospital care occurred in the VLCD and LCD groups, respectively, and of the 62 gallstone events, 38 (61%) resulted in cholecystectomy. Albeit low, the risk of symptomatic gallstones requiring hospitalization or cholecystectomy was threefold greater with VLCD than LCD during the 1-year weight-loss program.

Coffee

Although coffee can promote symptoms of gallstones, it may also inhibit their formation. In one study, 400 mL of regular coffee and 165 mL of regular and decaffeinated coffee were assessed for their effect on cholecystokinin secretion. Regular coffee at both dosages and decaffeinated coffee caused significant gallbladder contractions compared with the control sodium chloride in six healthy regular coffee drinkers.[45] Another study of 80,898 female nurses between the ages of 34 and 59 years found that drinking four cups of caffeinated coffee per day was associated with a 28% lowered risk of developing symptoms of gallstones. Even one to three cups seemed to have some protective effect.[46] Five prospective cohort studies involving 227,749 participants and 11,477 gallstone disease cases found that coffee consumption was significantly associated with a reduced risk of gallstone disease in a dose–response relationship.[47]

It may be that women who began to drink coffee regularly before or during early gallstone formation were able to either inhibit the development of stones or clear any small stones due to the enhanced gallbladder contractions from multiple daily coffee doses. In women who already have large stones present, increased contractions from coffee may exacerbate their condition and cause untoward symptoms.

Nutritional Supplements

Lecithin (Phosphatidylcholine)

As the main cholesterol solubilizer in bile, lecithin in low concentrations may be a causative factor for many individuals with gallstones. For example, a pure bile salt micelle requires 50 molecules to enclose a single molecule of cholesterol, whereas a mixed bile salt/phospholipid micelle requires only seven molecules.[8] Studies have shown that the ingestion of lecithin can have the direct effect of solubilizing cholesterol.[48] As little as 100 mg of lecithin taken three times a day will increase the concentration of lecithin in the bile, whereas larger doses (up to 10 g) produce even greater increases.[49,50] This is significant because an increased lecithin content of bile usually increases the solubility of cholesterol. However, no significant effects on gallstone dissolution have been obtained using lecithin supplementation alone.

Nutrient Deficiencies

Deficiencies of either vitamin E or C have been shown to cause gallstones in experimental studies in animals.[51,52]

Olive Oil

A popular lay remedy for gallstones is the olive oil "liver flush." There are several variations. A typical one involves drinking 1 cup of unrefined olive oil with the juice of two lemons in the morning for several days.

Many people tell tales of passing huge stones while on the liver flush. However, what they think are gallstones are simply soft, saponified complexes of minerals, olive oil, and lemon juice produced within the gastrointestinal tract.[53]

The olive oil liver flush is undesirable for patients with gallstones for several reasons. First, consuming a large quantity of any oil results in contraction of the gallbladder, which may increase the likelihood that a stone will block the bile duct. This may result in cholecystitis, requiring immediate surgery to prevent death. Second, oleic acid, the main component of olive oil, has been shown to increase the development of gallstones in rabbits and rats by increasing the content of cholesterol in the gallbladder.[54,55] Although this effect has not yet been observed in humans, the animal research suggests that it is unwise to use an olive oil liver flush as a treatment for gallbladder disease.[56] This recommendation is not meant to obviate the use of the liver flush as a viable method of liver detoxification. Rather, it is a caution against its use in patients with gallstones.

Fish Oils

Although human studies appear not to be available at this time, some provocative animal studies exist. For example, one study compared a diet high in lard with a diet high in fish oils in 21 male African green monkeys. One group was fed 0.8 mg cholesterol per kilocalorie and 42% of the calories as fat, with one half of the fat calories derived from lard, whereas the other group was fed a similar diet with an isocaloric substitution of menhaden oil instead of the lard. After 2 to 3 years, necropsies were performed, and it was found that 67% of the animals fed the lard diet had cholesterol gallstones compared with 22% of the animals fed the fish oil. The cholesterol saturation index of the gallbladder bile was also higher in the lard-fed group, although there was no difference in bile acids. There was a significantly greater rate of biliary phospholipid secretion in the fish oil–fed animals compared with the lard-fed animals.[57]

A study found similar effects in a prairie dog model using a diet more typical of human habits: 12 animals consumed a standard control diet, whereas 16 consumed a lithogenic 1.2% cholesterol diet. Half the animals in each group were supplemented with 200 mg/kg/day of omega-3 fatty acids from eicosapentaenoic and docosahexaenoic acids. After 14 days, those fed the diet with added fish oil showed an inhibition of gallstone formation accompanied by a significant decrease in biliary calcium and total protein concentration. This antilithogenic effect may be due to an enhancement in the stability of biliary phospholipid-cholesterol vesicles.[58] In mice, n-3 polyunsaturated fatty acids attenuated gallstone formation through increasing the levels of bile phospholipids and suppressing bile mucin formation.[59]

Lipotropic Factors and Botanical Choleretics

The naturopathic approach to the treatment of gallstones has typically involved the use of lipotropic and choleretic formulas. Lipotropic factors are, by definition, substances that hasten the removal or decrease the deposition of fat in the liver through their interaction with fat metabolism. Compounds commonly employed as lipotropic agents include choline, methionine, betaine, folic acid, and vitamin B_{12}.

These nutritional factors are often used with herbal cholagogues and choleretics. Cholagogues stimulate gallbladder contraction to promote bile flow, whereas choleretics increase bile secretion by the liver.

Many herbal choleretics have a favorable effect on the solubility of bile. Choleretics that are appropriate to use in the treatment of gallstones include *Taraxacum officinale,* silymarin from *Silybum marianum, Cynara scolymus,* and *Curcuma longa.* In addition, *Peumus boldo* contains alkaloids, such as boldine, that are useful in the treatment of gallstones.

One study in rats given a diet that promoted gallstones demonstrated that the animals supplemented with 0.5% dietary curcumin for 10 weeks had only a 26% incidence of gallstone formation compared with a 100% incidence in the group fed the lithogenic diet alone.[60] This effect was found to be dose dependent.

Chemical Dissolution of Gallstones

Several successful nonsurgical alternatives for the treatment of gallstones now exist. These entail using a complex of plant terpenes alone or, preferably, in combination with oral bile acids. Because the formation of the stone depends on either increased accumulation of cholesterol or reduced levels of bile acids or lecithin, decreasing gallbladder cholesterol levels or increasing bile acid or lecithin levels should result in the dissolution of the stone. Chemical dissolution is especially indicated in the treatment of gallstones in the elderly, who cannot withstand the stress of surgery, and in other cases where surgery is contraindicated.

Bile Acids

The use of bile acids, such as ursodeoxycholic acid and tauroursodeoxycholic acid, is effective in dissolving small, uncalcified cholesterol gallstones. About 15% of all patients with cholesterol gallstones meet these criteria. Treatment with bile acids will lead to complete dissolution in about 90% of cases after 6 months of therapy. Once dissolved, it is important to follow the recommendations for gallstone prevention to reduce the risk for recurrence. Bile acid preparations are available by prescription only and represent a safe and effective nonsurgical alternative for many people with gallstones.[60,61] The typical dosage is 12 mg per kg body weight daily.

Terpenes

Gallstone dissolution by a natural terpene combination of menthol, menthone, pinene, borneol, cineol, and camphene has been demonstrated in several studies.[62] This nonsurgical approach to gallstone removal offers an effective alternative to surgery and has been demonstrated to be safe even when it has been implemented for prolonged periods of time (up to 4 years).

Combined Therapy

Although terpenes are effective alone, the best results appear to be achieved when plant terpene complexes are used in combination with bile acid therapy.[63–65] This combined approach offers better results than either bile acids or plant terpenes used alone.[64,65] Furthermore, because a lower dose of bile acid can be used, there is a significant reduction in the risk of complications or side effects and in the cost of bile acid therapy. Because menthol is the major component of this formula, peppermint oil, especially enteric-coated capsules, may offer similar results.

Lifestyle

Sunbathing

Because most cholesterol gallstones contain a central pigmented nucleus with radial or lamellar pigmented bands alternating with layers of crystalline cholesterol, one researcher speculated that activation of the pigmentary system by ultraviolet light might lead to increased concentrations of indole metabolites in the bile, triggering their polymerization. In a case-controlled study of 206 white-skinned individuals, a positive attitude toward sunbathing was associated with twice the risk of cholelithiasis as a negative attitude. When the effect of sunbathing attitude was considered for individual skin pigmentation types, the association was found to be almost entirely restricted to those who always burn after long sunbathing. In this group, the relative risk was a remarkable 25.6% for a positive attitude toward sunbathing versus a negative one.[66]

Social Stress

Using a fish model, one research experiment examined the effect of stress on the gallbladder function. In this work, fish were subjected to prolonged cohabitation with dominant individuals. It was found that this chronic social stress could increase bile retention, increase gallbladder hypertrophy, and inhibit gallbladder emptying.[67] This study suggests that chronic stress may be a predictor of gallbladder dysfunction and eventual gallstone formation.

THERAPEUTIC APPROACH

As is typical of most diseases, gallstones are much easier to prevent than to reverse. The risk factors and causes of gallstones are well known, and in most cases, a healthy diet rich in fiber, with a limitation of excess calories and saturated fats, is adequate prevention.

Once gallstones have developed, measures to avoid gallbladder attacks and increase the solubility of the bile are necessary. To limit the incidence of symptoms, the foods to which an individual is intolerant or allergic must be determined (see Chapter 14) and, along with fatty foods, avoided. The solubility of the bile can be increased by following the dietary guidelines and using the nutritional and herbal supplements recommended here.

Diet

Patients should increase their intake of vegetables, fruits, dietary fiber (especially the gel-forming or mucilaginous fibers such as flaxseed, oat bran, guar gum, and pectin), and buckwheat. They should reduce their consumption of saturated fats, refined carbohydrates, cholesterol, sugar, and animal proteins. All fried foods should be avoided.

An allergy elimination diet can be used to reduce gallbladder attacks.

Water

Consumption of six to eight glasses of water is necessary each day to maintain the water content of bile.

Nutritional Supplements

- Vitamin C: 1 to 3 g/day
- Vitamin E: 200 to 400 IU/day
- Phosphatidylcholine: 500 mg/day
- Choline: 1 g/day
- l-Methionine: 1 g/day
- Fiber supplement (guar gum, pectin, psyllium, or oat bran): minimum of 5 g/day

Botanical Medicines

Choose one or more of the following:

- Dandelion (*Taraxacum officinale)* (three times/day)
  - Dried root: 4 g
  - Fluid extract (1:1): 4 to 8 mL
  - Solid extract (4:1): 250 to 500 mg
- *Pneumus boldo* (three times/day)
  - Dried leaves (or by infusion): 250 to 500 mg
  - Tincture (1:10): 2 to 4 mL
  - Fluid extract (1:1): 0.5 to 1 mL
- Milk thistle *(Silybum marianum)*
  - Sufficient dosage according to form to yield 70 to 210 mg of silymarin three times/day
- Artichoke *(Cynara scolymus)*
  - Extract (15% cynarin): 500 mg three times/day
- Curcumin: 300 mg three times/day

Gallstone-Dissolving Formula

- Menthol: 30 mg
- Menthone: 5 mg
- Pinene: 15 mg
- Borneol: 5 mg
- Camphene: 5 mg
- Cineol: 2 mg
- Citral: 5 mg
- Phosphatidylcholine: 50 mg
- Medium-chain triglycerides: 125 mg
- Chenodeoxycholic acid: 750 mg

The dosage for this formula is to take it three times daily if used in combination with meals.

Note: Peppermint oil in an enteric-coated capsule can be used instead at a dosage of 1 to 2 capsules (0.2 mL per capsule) three times daily between meals.

Gastroesophageal Reflux Disease (GERD)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Burning sensation in the esophagus, regurgitation, teeth erosion
- Symptoms chronic and periodic
- Epigastric tenderness and guarding
- Gastric analysis showing acid in all cases, with hypersecretion in about one half of the patients with duodenal ulcers
- Ulcer crater or deformity, usually occurring at the duodenal bulb (duodenal ulcer) or pylorus (gastric ulcer) on radiography or fiberoptic examination
- Positive test for occult blood in stool

GENERAL CONSIDERATIONS

Gastroesophageal reflux disease (GERD), informally known as heartburn, is a chronic relapsing condition in which repeated exposure of the esophagus to gastric contents provokes symptoms, complications, or histological changes and impairs quality of life. GERD is a common condition, with up to 25% of the general population experiencing symptoms at least one time per month.[1] The incidence of reflux is increasing because of the growing numbers of people with obesity, increased longevity, and the increased use of medications that affect esophageal function.[2] In fact, the prevalence of GERD is 50% higher in the United States in studies carried out after 1995 compared with those carried out before 1995.[3]

The degree of esophageal mucosal injury and the frequency and severity of symptoms are determined by the degree and duration of esophageal acid exposure. However, this is not always the case. A multiple-site, double-blind, randomized clinical trial failed to demonstrate a correlation between the severity of self-reported heartburn symptoms and the presence of endoscopically graded esophagitis.[4] Although there was no correlation between severity and underlying esophagitis, there was a strong correlation between the frequency of heartburn episodes and increasing severity of esophagitis.

Common symptoms include the sensation of burning in the esophagus, chest pain, chronic cough, hoarseness, regurgitation, throat clearing, and teeth erosion. Atypical symptoms such as dysphagia, chronic postnasal drip, laryngitis, dental erosions, and asthma may also be related to GERD and may represent the only clinical presentation of the disease. Other proposed associations include sinusitis, idiopathic pulmonary fibrosis, and recurrent otitis media.[5] In cases of atypical GERD, the cause may be difficult to establish because pH testing does not accurately classify these patients, and placebo-controlled studies with high-dose proton-pump inhibitors (PPIs) show very inconsistent results in this group of patients.[6]

Etiology and Pathogenesis

The pathogenesis of GERD is multifactorial. Mechanisms include (1) motor abnormalities, such as transient lower esophageal sphincter (LES) relaxation, impaired LES resting tone, impaired esophageal acid clearance, and delayed gastric emptying; (2) anatomical factors, such as hiatal hernia; (3) visceral hypersensitivity; and (4) impaired mucosal resistance.[4] Contact between esophageal mucosa with refluxate composed of acid, bile, pepsin, and pancreatic enzymes leads to esophageal injury.

The LES is a segment of smooth muscle at the distal end of the esophagus that acts as a physical barrier preventing gastric contents from refluxing into the esophagus. This sphincter typically opens in response to peristalsis, allowing food and liquids to pass into the stomach. A minority of patients with GERD have a constantly weak, low-pressure LES, which permits reflux every time the pressure in the stomach exceeds the LES pressure (i.e., when LES pressure is <6 mm Hg).[7] In patients with GERD, transient LES relaxations account for 48% to 73% of reflux episodes and thus account for most GERD episodes.[8]

The most common cause of reflux esophagitis is overeating. Other common causes include obesity, cigarette smoking, chocolate, fried foods, carbonated beverages, alcohol, and caffeine. Factors that decrease LES tone include endogenous hormones (e.g., cholecystokinin, progesterone in

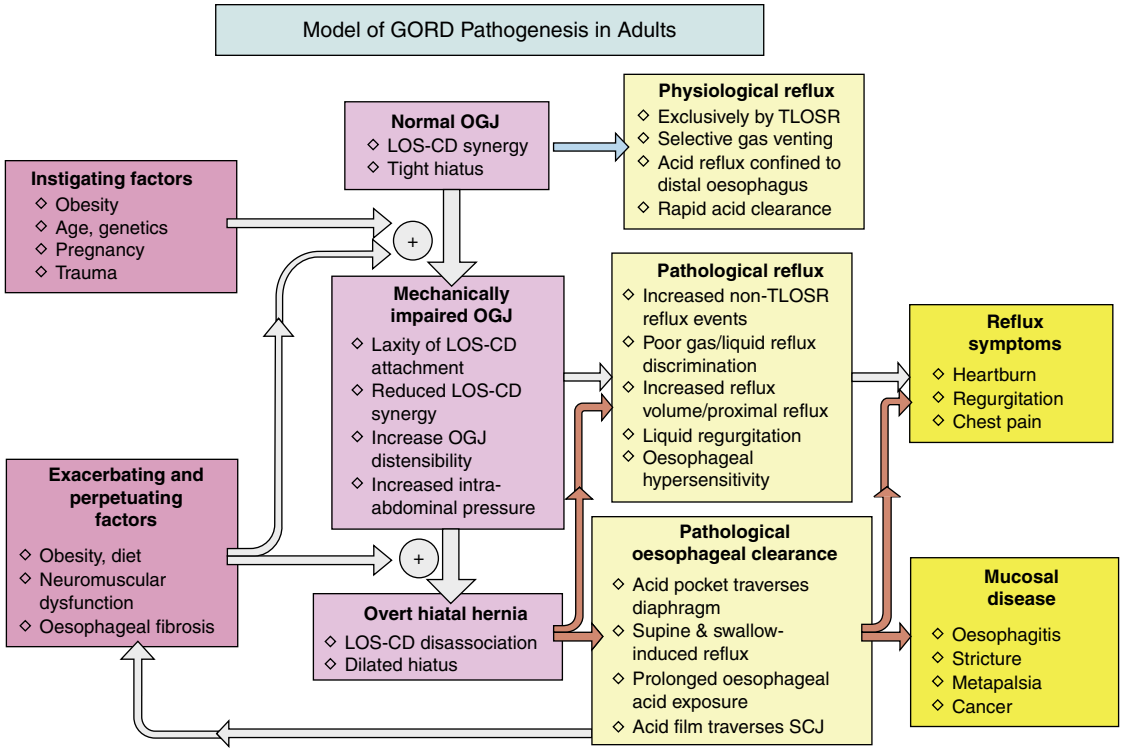

Fig. 172.1 Model of Gastroesophageal Reflux Disease (GERD) Pathogenesis. With the accumulation of these "hits," physiological reflux is transformed into pathological reflux, manifest either symptomatically and/or with mucosal disease. Abdominal obesity plays a dominant role, with its effect mediated through progressive degradation of the OGJ, culminating in the development of overt hiatus hernia. *CD,* crural diaphragm; *LOS,* lower (o)esophageal sphincter; *OGJ,* (o)esophagogastric junction; *TLOSR,* transient lower (o) esophageal sphincter relaxation. (From Boeckxstaens G, El-Serag HB, Smout AJ, Kahrilas PJ. Symptomatic reflux disease: the present, the past and the future. *Gut.* 2014;63[7]:1185–1193. PubMed PMID: 24607936.)

pregnancy); medications (e.g., nitrates, calcium channel blockers); foods (e.g., high-fat meals); and voluntary habits like smoking, caffeine, and alcohol (Fig. 172.1). Symptoms may be particularly bad when the individual is lying down. Studies in healthy volunteers have identified reflux episodes during sleep and the postprandial period resulting from an increased number of inappropriate LES relaxations.[9] During the night, LES relaxation and esophageal reflux occurred only during transient arousals from sleep or when the subjects were fully awake but not during stable sleep. Reduced salivation during or immediately before sleep accounts for markedly prolonged acid clearance times and increased esophageal acid exposure and thus may be a significant causative factor in GERD.[10]

The process of esophageal acid clearance involves peristalsis as well as the swallowing of bicarbonate and is an important protective mechanism against the development of GERD. Impaired esophageal clearance can be caused by an increase in the volume of the refluxate and occasionally by an underlying condition such as scleroderma. In experimentally induced or spontaneous reflux, patients with GERD have been found to present acid clearance times that are two to three times longer than those of subjects without GERD.[11]

Hiatal hernia has been shown to be present in ≥90% of patients with reflux esophagitis.[12] A study assessing the role of hiatal hernia in patients with Barrett's esophagus found a 2-cm or longer hernia in 96% of the patients and 72% of the patients with short segment Barrett's esophagus.[13] It is unclear if hiatal hernias are an initiating factor in GERD. However, hernias clearly play a role in sustaining GERD, accounting for the chronicity of the disease. A hiatal hernia may act as a reservoir for acid-containing material that is subsequently refluxed into the esophagus when the patient swallows, leading to the delayed acid clearance observed in patients with GERD with hiatal hernia.[14]

A traditional naturopathic understanding of reflux suggests that hypochlorhydria (i.e., low stomach acid) is a significant etiological factor in the development of GERD. It is hypothesized that food is inadequately broken down and stays in the stomach for longer periods of time, leading to an increase in gastric pressure and reflux of gastric contents into the esophagus. In many cases, clinical experience has shown that hydrochloric acid supplementation may benefit rather than aggravate GERD.

The ability of the esophageal mucosa to withstand injury is a determining factor in the development of GERD, and the major defense of the epithelium relies solely on the epithelium itself. The epithelial defense consists of three main components: (1) the cell membranes and the intercellular junction complex, which limit the rate of hydrogen ion penetration into the intercellular space or cell cytosol; (2) the presence of cellular and intercellular buffers (e.g., bicarbonate, proteins, phosphate) that neutralize back-diffusing luminal acid; and (3) the presence of cell membrane ion transporters that serve to extrude acid from the cell cytosol when intracellular pH falls to acidic levels.[15] When aggravating factors, such as alcohol, heat, osmolarity, or smoke-derived chemicals, overwhelm the esophageal defense, mucosal injury occurs.

The severity of GERD varies from nonerosive disease to significant esophageal damage. Barrett's esophagus, erosive esophagitis, and esophageal carcinoma are severe complications associated with GERD. Endoscopy reveals that most symptomatic patients do not have mucosal breaks or other esophageal injuries. Therefore the terms "nonerosive reflux disease" and "functional heartburn" have been introduced to redefine and characterize GERD into separate entities rather than a continuous spectrum.[16]

Microbiota

Esophageal inflammation is associated with an altered microbiota in GERD, Barret's esophagus, eosinophilic esophagitis, and cancer. Despite numerous observations by scientists from the late 19th century describing bacteria in the acidic environment of the stomach, there was a widely held view that the gastric secretions of hydrochloric acid and the proteolytic enzyme pepsin, as well as the reflux of bile acids in the stomach, the thickness of the mucus layer, and the effectiveness of gastric peristalsis, ensured a sterile stomach.[17] *Helicobacter pylori* was once believed to be the only species able to colonize the human stomach. *H. pylori* is the most common chronic infection in the world and disrupts the normal gastric physiology and morphology. Research surrounding *H. pylori* has increased the understanding of how it can modify its own microclimate, and further investigations with modern techniques have shown that the microbiota of the stomach involves hundreds of phylotypes with a microbial density between 10^1 and 10^3 colony-forming units (CFU)/g.[18] Similar to the rest of the intestinal microbiome. This is a dynamic situation, with significant fluctuations in microbial density resulting from many factors, including ingestion of foods and gastric pH.

A study of the bacterial flora of the oral cavity and lower esophagus, obtained by esophageal brushings and biopsy samplings, revealed that *Streptococcus viridans* is the most common bacterium, with an occurrence rate of 95% to 98%.[19] The pathogenesis of GERD might be driven by increasing gram-negative bacteria of the esophageal microbiome because lipopolysaccharide upregulates gene expression and increases proinflammatory cytokine production.[20] In patients with severe GERD, histological changes have been reported characterized by T-lymphocyte–predominant inflammation with hyperplasia of papillary and basal cells, suggesting the inflammation may be cytokine mediated rather than the result of the usually attributed acid chemical injury.[21] Bacterial diversity decreases with the transition from nonatrophic gastritis to intestinal metaplasia and then to gastric cancer, with a decrease in the number of *Porphyromonas, Neisseria,* and *Streptococcus sinensis* but with a relative increase in *Lactobacillus coleohominis* and *Lachnospiraceae*.[22] Further study into the microbiota of the stomach and esophagus, including exploration of host immunity and dysbiosis of the microbiota, would be especially productive.

Medications

The use of certain medications can lead to the emergence of GERD and can also exacerbate existing reflux symptoms. For example, the combination of calcium channel blockers and warfarin is an independent risk factor for GERD.[23] Mechanisms by which drugs cause or aggravate reflux include a reduction in LES pressure, delayed gastric emptying, and inducing/facilitating esophageal inflammation and damage (Table 172.1).[24]

TABLE 172.1 Drugs and GERD

Reducing LES Pressure	Inducing/Facilitating Esophageal Inflammation	Delayed Gastric Emptying
• Beta-adrenergic agonists • Alpha-adrenergic antagonists • Anticholinergics • CCBs/nitrates • Benzodiazepines • Estrogen • Progesterone • Theophylline • SSRIs • Tricyclic antidepressants	• Bisphosphonates • Aspirin and NSAIDs • Iron salts • Ascorbic acid • Potassium chloride • Quinidine • Tetracycline • Doxycycline • Clindamycin • Chemotherapeutic agents	• Calcium channel blockers

CCB, Calcium channel blocker; *GERD,* gastroesophageal reflux disease; *NSAID,* nonsteroidal anti-inflammatory drug; *SSRI,* selective serotonin reuptake inhibitor.

DIAGNOSTIC CONSIDERATIONS

The diagnosis of gastroesophageal reflux disease based on subjective evaluation symptoms alone can be difficult. Heartburn is a reasonably sensitive symptom for the diagnosis of GERD, although it does not reliably predict esophagitis. In the absence of alarm symptoms, empiric treatment with acid suppression is warranted. Researchers have developed multiple questionnaires to improve the accuracy of GERD diagnosis, but many have limited sensitivity and specificity.[25] The double-contrast barium swallow has a low sensitivity to diagnose GERD but may be beneficial to identify complications of GERD.[26] The role of esophageal manometry is limited to accurate placement of a pH-measuring device and should not be used to make or confirm a diagnosis of GERD. pH testing has reasonable sensitivity and specificity for the diagnosis of GERD. The sensitivity of upper endoscopy to diagnose GERD is lower than that of pH tests.[27]

THERAPEUTIC CONSIDERATIONS

Most individuals who suffer heartburn and acid reflux self-treat their symptoms, and it is only when the condition becomes intractable or chronic that professional help is sought.[28] A variety of over-the-counter products is currently available in the United States and worldwide for the symptomatic treatment of heartburn, acid indigestion, and acid reflux disorders. These include numerous liquid and tablet antacid formulations, antacid/alginates, histamine H_2-receptor antagonists (H_2RAs), proton-pump inhibitors, and bismuth-containing formulations. Proton-pump inhibitors (PPIs) are the mainstay of both acute and chronic reflux treatment, and they have a clear advantage over H_2RAs because they can increase gastric pH for as long as 15 to 21 hours compared with 8 hours for H_2RAs.[29] Although these products may be necessary when symptoms persist, most individuals improve with diet and lifestyle changes. Natural medicines are worthy of use before implementing additional pharmaceutical interventions.

Diet and Lifestyle Factors

Although it is generally recommended to advise lifestyle changes, the evidence for the efficacy of these recommendations in the management of GERD is mostly anecdotal. Yet many people note symptom aggravation after consuming certain foods, such as chocolate, coffee, alcohol, fatty foods, citrus fruits, spicy foods, and other acidic agents. Considering individual uniqueness, it is prudent to limit recommendations to a generally healthy diet and avoidance of (or limited use of) specific food items or activities that, in the experience of the patient, evoke symptoms.

Weight reduction is an important goal in the treatment of GERD. A structured weight-loss program can lead to complete resolution of symptoms in most overweight individuals with GERD. A decrease in the body mass index (BMI) of as little as 3.5 kg/m^2 has been shown to lead to a nearly 40% reduction in the risk for GERD.[30] A prospective cohort

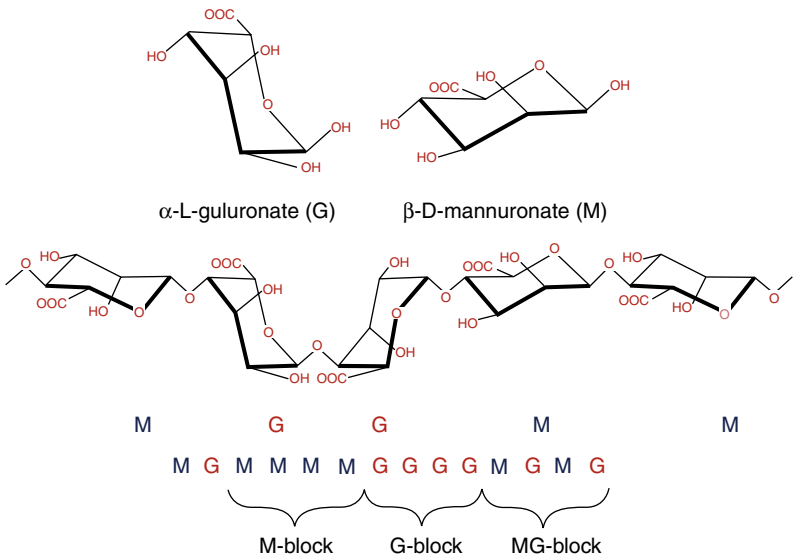

Fig. 172.2 Chemical Structure of Alginate. (From Immunological and technical considerations in application of alginate-based microencapsulation systems. https://www.researchgate.net/Chemical-structure-of-alginate-Linear-block-polymers-of-b-d-mannuronate-M-and_fig3_264826259. Accessed October 2, 2018.)

study measured the effect of weight loss on GERD symptoms in 322 overweight/obese (BMI: 25–39.9 kg/m^2) adult subjects.[31] At 6 months, most of the subjects (97%) lost weight, and compared with baseline, there was a significant decrease in the overall prevalence of GERD and the mean GERD symptom score. Overall, 81% of the subjects had a reduction in GERD symptom scores, 65% had a complete resolution of reflux symptoms, and 15% had a partial resolution of reflux symptoms.

Nutritional Factors

Alginates

Alginates are natural polysaccharide polymers isolated from brown seaweed *(Phacophycae)* and can be classified as dietary fiber. Alginates are block copolymers of L-guluronic and D-mannuronic acid residues connected by 1:4 glycosidic linkages. The relative proportions of D-mannuronic and L-guluronic acids are species dependent and can be influenced by growth conditions (Fig. 172.2).

For decades, formulations containing alginate have been marketed worldwide for the symptomatic treatment of heartburn and esophagitis. Alginate should be combined with calcium carbonate because both the calcium and carbonate serve essential functions in the beneficial effect. When the alginate formulation reaches the acidic environment of the stomach, the alginate forms a pliable gel. At the same time, the calcium carbonate mixes with gastric acid to produce carbon dioxide bubbles that get trapped in the gel, causing it to float to the top of the stomach contents. The free calcium ions released bind with alginic acid, providing strength to raft formation. The resultant alginate complex literally is like a foam raft sitting on top of the stomach contents. Several studies have demonstrated that the alginate raft can preferentially move into the esophagus in place, or ahead, of acidic gastric contents during episodes of GERD.[32] The raft literally acts as a physical barrier to block reflux episodes. The raft-forming process takes less than a minute, and the raft can survive in the stomach for as long as 4 hours.[33] As the alginate complex makes its way through the intestinal tract, the alginate is partially digested and behaves as other dietary fibers until it is finally passed out of the body.

Fourteen human clinical trials and detailed meta-analyses have demonstrated alginate formulations to be a well-proven treatment for GERD. The most recent meta-analysis showed that alginate-based products were clearly more effective than placebo or antacids.[34] Pooling the data from these studies produced a high degree of statistical significance ($P = .001$). Subjects taking alginate were 4.42 times more likely to have complete resolution of their symptoms compared with those taking placebo or antacids. The comparison to stronger acid-blocking medications, such as PPIs and H_2-receptor antagonists, was less clear and did not reach statistical significance largely because most studies were using alginate in conjunction with a PPI. Table 172.2 summarizes the studies used in the meta-analysis.

In one of the more recent double-blind studies, 110 patients with symptoms of GERD were given either alginate chewable tablets or a placebo for 7 consecutive days.[35] The primary endpoint compared the change in overall Reflux Disease Questionnaire (RDQ) symptom score (combined heartburn/regurgitation/dyspepsia). After 7 days, there was a highly statistically significant greater decrease in overall RDQ symptom score in the alginate group compared with the placebo group ($P = 0.0033$), as well as a statistically significant greater decrease for each of the symptoms independently. These results were achieved without any side effects.

When comparing alginate with a PPI, it is important to distinguish between the two basic forms of GERD. The first is characterized by erosion of the esophagus (ERD), and the second involves no esophageal erosion (NERD). The differentiation is important because patients with NERD do not respond well to PPIs. Around the world, the NERD form is the most common. Patients suffering from NERD are ideal candidates for alginate therapy. However, even in the erosive form, alginate is effective. In a detailed open-label study that included patients with either ERD or NERD, alginate, given as the only treatment, was found to be "well-tolerated and effective in reducing heartburn by modifying esophageal acid exposure time, number of acid refluxes and their proximal migration."[36]

A double-blind study evaluated the efficacy and safety of alginate compared with omeprazole (Prilosec) in 195 adult subjects with NERD.[37] Subjects were given either alginate three times a day or omeprazole once daily. The primary efficacy endpoint was the percentage of patients achieving adequate heartburn or regurgitation relief at day 28. Results showed no difference in effectiveness between the two treatments, and although the average symptom score was slightly lower in the alginate group, it was not statistically significant.

Considering the confirmed efficacy, remarkable safety profile, and lack of side effects, alginate therapy should be considered as a first-line approach to symptomatic relief. It is also safe for use during pregnancy.

TABLE 172.2 Characteristics of Studies Included in This Systematic Review

Study	Study Design	GERD Diagnosis and/or Severity	Comparators (*N*)	Duration (Formulation)	Outcome	Results
Placebo or Antacid as Comparators						
Beeley and Warner	Randomized, double blind, three arm, crossover, single center	Typical symptoms and presence of hiatal hernia on barium	Alginate (28) vs. alginate + antacid (28) vs. placebo (28)	2 weeks (tablet)	Improvement in regurgitation	Alginate (19/28) vs. alginate + antacid (25/28) vs. placebo (12/28)
Stanciu and Bennett	Randomized, single blind, three arm, parallel group, multicenter	Typical symptoms	Alginate + antacid (20) vs. antacid (20) vs. placebo (20)	2 weeks (tablet)	Global improvement of symptoms	Alginate + antacid (11/20) vs. antacid (5/20) vs. placebo (7/20)
Barnardo et al.	Randomized, double blind, crossover, single center	Typical symptoms and reflux on barium	Alginate + antacid (26) vs. antacid (26)	6 weeks (tablet)	Global acceptability of treatment	Alginate + antacid (21/26) vs. antacid (5/26)
Chevrel	Randomized, open label, crossover, single center	Typical symptoms and reflux on barium	Alginate (44) vs. antacid (44)	2 weeks (liquid)	Global improvement of symptoms	Alginate (37/44) vs. antacid (10/44)
Lang and Dougall	Randomized, parallel group, multicenter	Reflux dyspepsia of pregnancy	Alginate + antacid (50) vs. antacid (47)	2 weeks (liquid)	Improvement in nighttime reflux symptoms	Alginate (41/50) vs. antacid (36/47)
Chatfield	Randomized, double blind, parallel group, multicenter	Typical symptoms ≥2 days/week	Alginate + antacid (46) vs. placebo (48)	4 weeks (liquid)	Global improvement of symptoms	Alginate + antacid (39/46) vs. placebo (17/48)
Giannini et al.	Randomized, open label, parallel group, multicenter	Typical symptoms ≥3 days/week	Alginate + antacid (87) vs. antacid (92)	2 weeks (liquid)	Complete absence of symptoms	Alginate + antacid (71/87) vs. antacid (68/92)
Lai et al.	Randomized, open label, parallel group, single center	Typical symptoms and EGD without erosions	Alginate (69) vs. antacid (65)	6 weeks (tablet)	Global improvement of symptoms assessed by physician	Alginate (42/65) vs. antacid (18/56)
Thomas	Randomized, double blind, parallel group, single center	Typical symptoms ≥5 days/week	Alginate + antacid (56) vs. placebo (54)	1 week (tablet)	Overall treatment response	Alginate + antacid (47/56) vs. placebo (34/54)
Proton Pump Inhibitor or Histamine-2 Receptor Antagonist as Comparators						
Bennett et al.	Randomized, parallel group, single center	Typical symptoms and positive pH test	Alginate + antacid (19) vs. alginate + antacid + H_2RA (17)	6 weeks (tablet)	Global improvement of symptoms	Alginate + antacid (12/19) vs. alginate + antacid + H_2RA (15/17)
Goves et al.	Randomized, single blind, parallel group, multicenter	Typical symptoms ≥2 days/week	Alginate (337) vs. PPI (333)	2 weeks (liquid)	Complete resolution of symptoms	Alginate (27/337) vs. PPI (90/333)
Poynard et al.	Randomized, open label, parallel group, multicenter	Typical symptoms ≥2 days/week	Alginate (180) vs. 5HTR agonist (173)	4 weeks (liquid)	Global improvement of symptoms	Alginate (158/180) vs. 5HTR agonist (120/173)
Manabe et al.	Randomized, open label, parallel group, multicenter	Typical symptoms ≥2 days/week and EGD without erosions	Alginate + PPI (26) vs. PPI (31)	4 weeks (liquid)	Complete resolution of regurgitation	Alginate + PPI (18/26) vs. PPI (20/31)
Pouchain et al.	Randomized, double blind, parallel group, multicenter	Typical symptoms ≥2 days/week	Alginate (120) vs. PPI (121)	1 week (liquid)	Self-assessed heartburn/pain relief	Alginate (62/120) vs. PPI (74/121)
Chiu et al.	Randomized, double blind, parallel group, multicenter	Typical symptoms ≥2 days/week and EGD without erosions	Alginate (92) vs. PPI (91)	4 weeks (liquid)	Relief of heartburn or regurgitation	Alginate (49/92) vs. PPI (46/91)

EGD, Upper endoscopy; *GERD,* gastroesophageal reflux disease; *H_2RA,* histamine-2 receptor antagonist; *PPI,* proton pump inhibitor; 20 mg omeprazole daily; *5HTR,* serotonin receptor, 20 mg cisapride daily; 400 mg cimetidine four times daily.

Melatonin

Melatonin may block the production of nitric oxide synthase, which may help lower the degree of LES relaxation. Melatonin also stimulates the production of bicarbonate, which protects against the action of gastric acid production.

Several studies suggest melatonin is of therapeutic value in patients with GERD. In one study, 36 individuals with GERD were selected and placed into four groups: control; 3 mg melatonin at bedtime; 20 mg of omeprazole twice daily; and 3 mg of melatonin and 20 mg of omeprazole twice daily for 2 months.[38] After 8 weeks, those using

the melatonin alone had a significant reduction in GERD symptoms, increase in LES pressure (i.e., better LES tone), increase in serum gastrin, a reduction in gastric basal acid output, and an increase in serum melatonin levels. Although omeprazole was also effective in reducing GERD symptoms, it did not significantly alter LES tone.

A randomized clinical trial evaluated the effects of 6 mg melatonin plus vitamin B_6 (25 mg), vitamin B_{12} (50 mcg), folic acid (10 mg), tryptophan (100 mg), methionine (100 mg), and betaine (100 mg) or 1 capsule (20 mg) omeprazole per day in the evening for 40 days in individuals (141 men, 210 women; mean age 44 years) with at least one episode of moderate to severe heartburn.[39] After 40 days, individuals using the natural product combination had a 100% reduction in symptoms as measured by a five-point severity scale, compared with a 65.7% reduction in symptoms in the omeprazole group. As an observation, the 34.3% of the subjects who experienced persistence of their GERD symptoms with the use of omeprazole had complete resolution of their symptoms after 40 days with the natural combination of vitamins, melatonin, and amino acids.

Limonene

D-limonene is a major constituent of citrus oils and is used as a fragrance and flavoring agent in a variety of products. Because of its gastric acid–neutralizing effect and its support of normal peristalsis, it has been used for relief of heartburn and GERD.[40] In a pilot study, 19 patients with GERD or chronic heartburn were given 1000 mg D-limonene daily or every other day. After 14 days, 89% of patients reported a complete remission of symptoms. As a follow-up to this pilot study, 13 participants with GERD or chronic heartburn were randomized to 1000 mg D-limonene once daily, 1000 mg D-limonene every other day, or placebo; 29% of participants in the treatment group experienced significant relief by day 4, and 86% experienced complete relief of all symptoms by day 14.[41]

Botanical Medicines

Demulcent herbs soothe irritated tissue. In the gastrointestinal tract, these substances may help relieve irritation in the esophagus and stomach associated with GERD. Botanical medicines that may help include *Ulmus fulva, Althea officinalis, Plantago major, Pistacia lentiscus, Aloe vera,* and *Glycyrrhiza glabra.*

Glycyrrhiza glabra (Licorice)

Licorice has a mucoprotective effect because it stimulates or accelerates the differentiation of glandular cells and increases mucus formation and secretion from the gastric mucosa.[42] Because glycyrrhizinic acid (GA) has aldosterone-like side effects, a procedure was developed to remove GA from licorice, resulting in deglycyrrhizinated licorice (DGL). Licorice is also anti-inflammatory and prevents ulcer formation. Clinical studies have demonstrated no significant differences in recurrence rates of symptoms between cimetidine and DGL drug regimens.[43] GutsyGum is a chewing gum developed to alleviate the symptoms of GERD that contains calcium carbonate and a proprietary blend of licorice extract, papain, and apple cider vinegar. A double-blind, placebo-controlled crossover study examined the efficacy of GutsyGum in alleviating the symptoms of GERD after a refluxogenic meal compared with placebo gum.[44] Although many of the secondary symptoms, such as pain, nausea, and belching, were lower after GutsyGum, the difference was not statistically significant. However, the primary symptoms of heartburn and acid reflux were significantly lower in GutsyGum than in placebo treatment. The standard dosage for DGL is two to four 380-mg chewable tablets between meals or 20 minutes before meals. DGL therapy should be continued for at least 8 to 16 weeks after a full therapeutic response.

Althea officinalis (Marshmallow)

Although no clinical trials have investigated the effects of marshmallow on GERD, marshmallow contains 5% to 10% polysaccharides that provide a soothing and protective barrier on the mucous membranes of the esophagus and stomach, which may provide benefit.

Ulmus fulva (Slippery elm)

Slippery elm acts as a demulcent that produces a soothing film that extends over mucous membranes as well as acting as an anti-inflammatory agent. The bark of slippery elm is thought to be responsible for the healing effects due to the high percentage of mucilaginous polysaccharides. It is used to alleviate pain from irritated and inflamed mucosa lining the esophagus and gastrointestinal tract.[45]

Pistacia lentiscus (Mastic)

Mastic is a resin obtained from the mastic tree *(Pistacia lentiscus)*. Originally liquid, it is sun-dried into drops of hard, brittle, translucent resin. When chewed, the resin softens and becomes a bright white, opaque gum. The flavor is bitter at first, but after chewing, the gum releases a refreshing, slightly piney or cedar flavor. People in the Mediterranean region have used mastic gum as a medicine for gastrointestinal ailments for several thousand years. Although no human studies are currently available, animal studies have demonstrated that mastic significantly reduced the intensity of gastric mucosal damage induced by pyloric ligation, aspirin, and phenylbutazone.[46]

THERAPEUTIC APPROACH

Physicians should be judicious in prescribing acid-suppressing medications because these medications cause immune dysfunction that persists after discontinuation of the drug.[47] The use of PPIs in infants should be closely monitored in the light of changes in the gut microbiota and the oropharyngeal and respiratory tract colonization, potentially with pathogenic flora.

GENERAL RECOMMENDATIONS

General therapeutic objectives include symptom relief, reducing the risk of Barrett's esophagus and cancer, and improving quality of life. Many individuals experience heartburn nocturnally, when recumbent, and elevating the head of the bed to physically reduce gastroesophageal reflux is a standard medical recommendation in these cases. Lying on the left side while sleeping is also recommended because this position appears to alleviate reflux.

Smoking and alcohol should be eliminated. An exercise program may be implemented, as physical activity has some protective effect.[48]

Diet

Foods that precipitate attacks or aggravate symptoms should be identified and eliminated. The evening meal should be consumed 2-3 hours before retiring, as going to bed with a full stomach increases the likelihood of reflux. Overeating causes the stomach to distend, which may also increase symptoms. If necessary, a weight-reduction program may be implemented.

Supplements

- Alginate preparations are available as liquids and chewable tablets. The general recommendation is that the formula should provide a dosage of 500 to 1000 mg of alginate. The preparation is to be taken after meals and at nighttime as needed up to four times daily. For nighttime use, it is recommended to take 30 minutes before bedtime and avoid lying down for 30 minutes.

- Melatonin: 3 to 6 mg 30 to 45 minutes before bed

Botanicals

- Deglycyrrhizinated licorice: 380 to 760 mg three times a day 20 minutes before meals
- Marshmallow: powder, 1 teaspoon three times per day in cold water
- Slippery elm: powder, 1 teaspoon with food up to 4 times per day in cold water

Glaucoma: Acute (Angle Closure) and Chronic (Open Angle)

Michael T. Murray, ND

OUTLINE

DIAGNOSTIC SUMMARY

Acute Glaucoma

- Increased intraocular pressure, usually unilateral
- Severe throbbing pain in eye, with markedly blurred vision
- Pupil moderately dilated and fixed
- Absence of pupillary light response
- Nausea and vomiting common

Chronic Glaucoma

- Persistent elevation of intraocular pressure associated with pathological cupping of optic discs
- Asymptomatic in the early stages
- Gradual loss of peripheral vision, resulting in tunnel vision
- Insidious onset in older individuals

Normotensive Glaucoma

- Normal intraocular pressure with no pathological cupping of optic discs
- Asymptomatic in the early stages
- Gradual loss of peripheral vision, resulting in tunnel vision
- Insidious onset in older individuals, more common in women than men
- Low blood pressure a common underlying feature

GENERAL CONSIDERATIONS

Glaucoma refers to increased intraocular pressure (IOP) resulting from an imbalance between the production and outflow of aqueous humor. Obstruction to outflow is the main factor responsible for this imbalance in closed-angle glaucoma. Acute glaucoma can occur only with the closure of a preexisting narrow anterior chamber angle, whereas in chronic open-angle glaucoma the anterior chamber appears normal.

In the United States, approximately 3 million people have glaucoma, which is undetected in 25% of them.[1] The chronic open-angle type, for which there appears to be no consistent anatomical basis, accounts for 70% to 75% of these cases. Histologically, however, there is a strong correlation between the content and composition of collagen, glycosaminoglycans, extracellular matrix, and the glaucomatous eye.[2]

Collagen is the most abundant protein in the body, including the eye. In the eye, it provides tensile strength and integrity to the tissues (e.g., cornea, sclera, lamina cribrosa, trabecular meshwork, vitreous). Inborn errors of collagen metabolism (e.g., osteogenesis imperfecta, Ehlers–Danlos syndrome, Marfan syndrome) are often associated with ocular complications: glaucoma, myopia, retinal detachment, ectopia lentis, and blue sclera. Morphological changes in the lamina cribrosa (the scleral area that is pierced by the optic nerve fibers and blood vessels), trabecular meshwork (the connective tissue network through which aqueous humor must pass to reach the canal of Schlemm), and papillary blood vessels in the eye have all been observed in glaucomatous eyes. These changes may result in elevated increased ocular pressure (IOP) readings or, perhaps more significantly, lead to the progression of peripheral vision loss. Changes in collagen structure explain the following:

- Similar peripheral vision loss in patients with normal and elevated IOP
- Cupping of the optic disc even at low IOP levels
- No apparent anatomical reason for decreased aqueous outflow

In some cases, glaucoma develops in people with normal IOP. Referred to as low-tension glaucoma or normotensive glaucoma, this form accounts for approximately 25% to 30% of all cases of glaucoma

in the United States. Because elevated IOP is not a factor in normal-tension glaucoma, other factors must be responsible for the optic nerve damage. Suggested causes include:

- Reduced blood flow
- Early nerve cell death
- Nerve irritation
- Excess glutamate production
- Autoimmune disease

Normotensive glaucoma is more common in women than in men and affects adults averaging 60 years of age. A common risk factor for normotensive glaucoma is low blood pressure.

Toxic Metals

Toxic metals, such as lead, are known to increase the risk of hypertension by multiple mechanisms, including renal and oxidative damage, reducing available nitric oxide, and increasing circulating vasoconstrictive prostaglandins. It has been hypothesized that toxic metals in the blood may accumulate in the eyes, which may result in the elevation of intraocular pressure.[3] A study evaluating the relationship between toxic metals and intraocular pressure found that blood lead and blood mercury levels were associated with a 14% to 21% increase in IOP.[4] A cross-sectional study of 5198 participants older than 19 years of age examined the association between toxic metal levels and open-angle glaucoma (OAG) with low- and high-teen baseline intraocular pressure.[5] After adjusting for potential confounders, the low-teen OAG was positively associated with log-transformed blood cadmium levels (odds ratio [OR] = 1.41; 95% confidence interval [CI], 1.03–1.93). However, in this study, blood lead and blood mercury were not associated with disease prevalence. Although further studies are needed to better assess the significance of toxic metals in glaucoma, the toxic metal body load should be explored as a potential contributing factor in patients with IOP.

DIAGNOSIS

Patients with OAG initially have no symptoms, which is why this disease can be so insidious. Physical examination may reveal slight cupping of the optic disc and narrowing of the visual fields (Fig. 173.1). Tonometry is key to confirmation of the diagnosis.

The primary challenge with acute glaucoma is early recognition because a delay in referral for surgical intervention increases the risk of blindness. Table 173.1 provides an overview of the differential diagnosis of the inflamed eye.

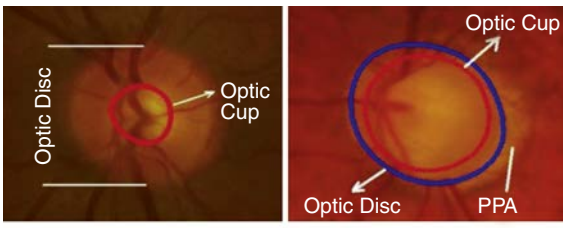

Fig. 173.1 Comparison of the Optic Disc Area of the (A) Normal and (B) Glaucomatous Eye. The cup boundary is shown with the red outline in both images, and the disc boundary is shown with blue outline in (B) only. There is a significantly larger cup in relation to the size of the optic disc in the glaucoma image compared with the normal image. Inferior-sector peripapillary atrophy (PPA) in the glaucoma image (B) is also evident, possibly due to concomitant erosion of the inferior neuroretinal rim tissue. (Haleem MS, Han L, Hemert JV, et al. Regional image features model for automatic classification between normal and glaucoma in fundus and scanning laser ophthalmoscopy [SLO] images. *J Medical Syst.* 2016;40[6]:132. PubMed PMID: 27086033.)

THERAPEUTIC CONSIDERATIONS

Treatment and prevention of both acute and chronic glaucoma depend on the reduction of IOP and improvement of collagen metabolism, particularly in the optic disc and trabecular meshwork.

The optic disc is composed of the lamina cribrosa, optic nerve fibers, and blood vessels. The lamina cribrosa is a meshlike network rich in collagen through which the optic nerves and blood vessels must pass (Fig. 173.2). The morphological changes in the collagen of the eye (i.e., lamina cribrosa, papillary vessels, and trabecular meshwork) precede pressure changes. Therefore primary prevention of the breakdown of the ground substance and collagen framework is important here, as it is in other conditions involving collagen abnormalities (i.e., atherosclerosis, rheumatoid arthritis, and periodontal disease).

Corticosteroids

The importance of collagen destruction in the etiology of glaucoma is apparent in corticosteroid-induced glaucoma.[2] Corticosteroid use should be discouraged in the patient with glaucoma because it is known to inhibit the biosynthesis of collagen and glycosaminoglycans, thereby worsening the patient's glaucoma.[2]

Diet, Supplements, Botanicals, and Lifestyle

Vitamin C

Of foremost importance in achieving collagen integrity are optimal tissue concentrations of ascorbic acid (AA). Furthermore, AA has been demonstrated to lower IOP levels in many clinical studies.[6–9] A daily dose of 0.5 g/kg, whether in single or divided doses, reduces the IOP by an average of 16 mm Hg.[9] Near-normal tension levels were achieved in some patients unresponsive to acetazolamide (a carbonic anhydrase inhibitor) and 2% pilocarpine (a miotic agent).[10] Note, however, that oral supplementation at this dosage will likely cause osmotic diarrhea.

The hypotonic action of AA on the eye is long-lasting if supplementation is continued, and intravenous administration results in an even greater initial reduction in IOP. The patient must be monitored to determine the appropriate individual dose because some patients respond to as little as 2 g/day, whereas others will respond only to extremely high doses (e.g., 35 g/day). Abdominal discomfort as a side effect of high doses is common but usually resolves after 3 to 4 days.[9]

The proposed mechanisms by which AA lowers IOP include the following:

- Increased blood osmolarity
- Diminished production of aqueous fluid by the ciliary epithelium
- Improved outflow of aqueous fluid

However, the role of AA in collagen formation may be the key to its antiglaucomatous action.

Flavonoids

To further aid normal collagen metabolism, flavonoids should be supplemented, particularly anthocyanosides (the blue-red pigments found in berries) and proanthocyanosides. These compounds elicit an AA-sparing effect, improve capillary integrity, and stabilize the collagen matrix by preventing free radical damage, inhibiting enzymatic cleavage of the collagen matrix, and cross-linking with collagen fibers directly to form a more stable collagen matrix.[11] *Vaccinium myrtillus* (European bilberry) extract is particularly rich in these flavonoid and anthocyanidin compounds and has been used in Europe, with good results in reducing myopia, improving nocturnal vision, and reversing diabetic retinopathy.

TABLE 173.1 Differential Diagnosis of the Inflamed Eye

	Acute Conjunctivitis	Acute Iritis	Acute Glaucoma	Corneal Trauma or Infection
Incidence	Very common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect	Slightly blurred	Markedly blurred	Usually blurred
Pain	None	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse, mostly fornices	Circumcorneal	Diffuse	Diffuse
Cornea	Clear	Usually clear	Steamy	Clarity may change
Pupillary size	Normal	Small	Dilated and fixed	Normal
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Normal	Elevated	Normal
Anterior chamber		Normal depth	Very shallow	Normal depth
Iris	Normal	Dull, swollen	Congested and bulging	Normal unless infected
Smear	Causative organisms	No organisms	No organisms	Causative organisms if there is infection

Modified from Distelhorst JS, Hughes GM. Open-angle glaucoma. *Am Fam Physician*. 2003;67:1937–1944.

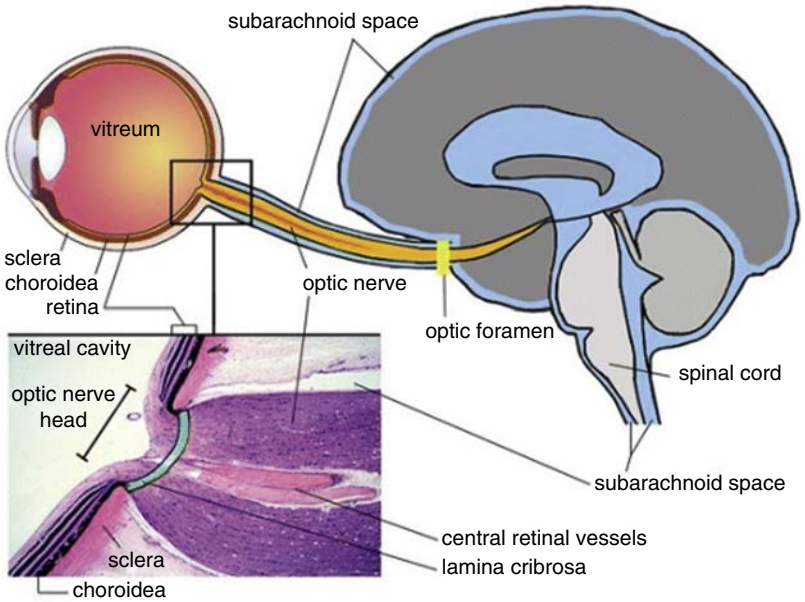

Fig. 173.2 Section of Eye, Optic Nerve Head, and Brain, Illustrating the Subarachnoid Space. The lamina cribrosa *(green)* is a sieve-like structure in the posterior part of the sclera and allows the passage of the retinal ganglion cell axons and the central retinal vessels. The optic nerve is surrounded by cerebrospinal fluid *(blue)* in the subarachnoid space. (Woslyn P, Van Dam D, Audenaert K, Killer HE, De Deyn PP, De Groot V. A new glaucoma hypothesis: a role of glymphatic system dysfunction. *Fluids Barriers CNS*. 2015;12:16. PubMed PMID: 26118970.)

Mirtogenol, a combination of bilberry anthocyanoside extract (160 mg Mirtoselect) and pine bark extract (80 mg Pycnogenol), was studied in 38 asymptomatic subjects with intraocular hypertension. Patients were given either Mirtogenol (20 subjects) or were not treated (18 subjects). After 2 months of supplementation with Mirtogenol, the mean IOP decreased from a baseline of 25.2 to 22.2 mm Hg. After 3 months of treatment with Mirtogenol, the IOP was significantly lowered compared with that of untreated controls ($P < 0.05$) to 22 mm Hg. No further improvement was found after 6 months. Of the 20 patients taking Mirtogenol, 19 had a decreased IOP after 3 months. Only marginal effects on the IOP were found in the 18 control subjects. No side effects were observed. Ocular blood flow (central retinal, ophthalmic, and posterior ciliary arteries) improved both in the systolic and diastolic components as measured by ultrasound. After 3 months of treatment, the improvement in ocular blood flow was significant compared with both baseline and the control group.[10] Rutin has also been demonstrated to lower IOP when used as an adjunct in patients unresponsive to miotics alone.[12]

In patients with normotensive glaucoma (NTG), *Ginkgo biloba* extract (GBE) may be helpful, based on the results of two double-blind studies. In the first study, which comprised healthy human volunteers, GBE (120 mg daily) significantly increased end-diastolic velocity in the ophthalmic artery (23% change), with no change in the placebo group. GBE did not alter arterial blood pressure, heart rate, or IOP.[13] In the second study, patients with NTG received either 40 mg GBE or placebo three times daily for 4 weeks, followed by a washout period of 8 weeks, then 4 weeks of the opposite treatment. After GBE treatment, a

significant improvement in visual field indices was recorded, showing that GBE improves preexisting visual field damage in some patients with NTG.[14]

Allergen Avoidance

The successful treatment of chronic glaucoma by antiallergy measures has been reported in the literature.[15] In one study, many of the 113 patients demonstrated an immediate rise in IOP of up to 20 mm Hg (in addition to other typical allergic symptoms) when challenged with the appropriate allergen, whether foodborne or environmental. The author speculated that the known allergic responses of altered vascular permeability and vasospasm could result in the congestion and edema characteristic of glaucoma.

Magnesium

Because channel-blocking drugs benefit some glaucoma patients, a group of researchers at the University Eye Clinic in Basel, Switzerland, decided to evaluate the effect of supplemental magnesium, which has been referred to as "nature's physiological calcium-channel blocker." The trial included 10 glaucoma patients (6 with primary open-angle glaucoma and 4 with normal-tension glaucoma). All patients had digital cold-induced vasospasm. Magnesium was given at a dose of 121.5 mg twice daily for 1 month. After 4 weeks of treatment, the visual fields improved, as noted by a decrease in the mean defect and square root of loss variance scores. All three nail fold–capillaroscopic parameters improved, as well as digital temperature. These results demonstrate that magnesium supplementation improves the peripheral circulation and seems to have a beneficial effect on the visual field in patients with glaucoma.[16]

To evaluate the effect of oral magnesium therapy on ocular blood flow and visual field perimetry indices in patients with normotensive glaucoma (NTG), 15 patients with NTG (the study group) received 300 mg of oral magnesium (citrate) for 1 month, whereas 15 patients with NTG (the control group) received no treatment. In the study group, significant improvements were noted in visual field measurements (e.g., mean deviation improved from –3.7 at baseline to –2.5 and pattern standard deviation improved from 3.6 baseline to 2.8). There was no change in ocular blood flow, so the exact mechanism of magnesium's effect is not known.[17]

Chromium

A case-controlled study of 400 consecutive eye patients, 52 of whom had ocular hypertension glaucoma, or both, found that primary open-angle glaucoma was strongly associated with a deficiency of erythrocyte chromium and average daily intake of ascorbic acid, and elevations of erythrocyte vanadium, which is chromium's principal antagonist.

Ascorbic acid and chromium potentiate insulin receptors, which help sustain strong focusing activity in the ciliary muscle. Deficiencies of either ascorbic acid or chromium were associated with elevated intraocular pressure, which tends to stretch the normal eye, thereby reducing focusing power.[18]

Fish Oil

In an interesting exploratory study, rabbits were fed food soaked with cod liver oil, resulting in a drop in IOP from 25 to 11 mm Hg. Intramuscular injections of cod liver oil produced a dose-dependent reduction in IOP. When the animals were taken off cod liver oil, their IOP returned to baseline. Control animals given liquid lard or safflower oil experienced no change in IOP.[19] Preliminary studies in humans with docosahexaenoic acid have had encouraging results.[20]

Caffeine

Many physicians instruct patients with glaucoma to avoid coffee, although clinical data supporting this practice are insufficient. To estimate the effect of coffee drinking on IOP, the effects of the consumption of regular coffee (180 mg caffeine in 200 mL of coffee) and decaffeinated coffee (3.6 mg caffeine in 200 mL of coffee) were compared in patients with normotensive glaucoma or ocular hypertension in a double-blind crossover study. IOP was monitored in both groups at 30, 60, and 90 minutes after coffee ingestion. In patients with normotensive glaucoma who drank regular caffeine-containing coffee, the mean changes in IOP at 30, 60, and 90 minutes were 0.9, 3.6, and 2.3 mm Hg, respectively; in those who drank decaffeinated coffee, they were 0.75, 0.70, and 0.4 mm Hg, respectively. The corresponding values in patients with ocular hypertension were as follows: after regular coffee, 1.1, 3.4, and 3 mm Hg; and after decaffeinated coffee, 0.6, 0.9, and 0.5 mm Hg, respectively. This study showed clearly that subjects who drank regular coffee experienced a greater elevation in IOP, which may be clinically significant.[21]

Exercise

Exercise can lead to an immediate and prolonged reduction in IOP. Within 5 minutes of starting exercise, IOP initially increases and then gradually decreases to its lowest level 60 minutes after exercise. The drop in IOP is approximately 23% in normal individuals, whereas people with glaucoma usually experience a greater drop and longer duration of postexercise recovery than do those with normal eyes.[22] Specifically, the drop in IOP for glaucoma patients after walking/jogging and running was 7.2% and 12.7%, respectively, more than the decrease in IOP experienced by persons with normal eyes. Similarly, the mean duration of the IOP-lowering effect after running was approximately 84 minutes in glaucomatous eyes and 63 minutes in normal eyes. The mechanism of acute lowering of IOP is independent of systemic blood pressure and level of sympathetic stimulation but may be partly due to increased serum osmolarity.

Exercise appears to be effective in lowering IOP in sedentary subjects engaging in moderate to heavy exercise but is somewhat less effective in physically fit subjects.[23] However, individuals who are more physically fit tend to have lower IOP. If one stops exercising, the effect wears off in 3 weeks. Although exercise may not be effective in lowering IOP in everyone, it can lead to significant improvements in many. One study found that IOP was lowered by at least 2 mm Hg by exercise in 34% of subjects; however, 57% had no change in IOP, whereas 9% had an IOP elevation.[24]

Coleus forskohlii

In clinical studies, forskolin from *Coleus forskohlii* was shown to greatly reduce IOP when it was applied directly to the eyes (see Chapter 69, *Coleus forskohlii*). Oral administration might prove effective as well. In an open-label pilot study, 16 patients with OAG and stable IOP underwent treatment with different topical drugs and were given a supplement containing 15 mg of forskolin along with rutin (200 mg), thiamin (0.7 mg), and riboflavin (0.8 mg) for 40 days, which produced a further decrease in IOP by roughly 20% of the initial value.[25,26]

Other Factors

Helicobacter pylori

Several studies have found an association between *Helicobacter pylori* infection and OAG.[26] A particularly interesting 2-year study found that successful eradication of *H. pylori* resulted in decreased IOP.[27] See Chapter 198 for a discussion of the treatment of *H. pylori.*

THERAPEUTIC APPROACH

Acute closed-angle glaucoma is an ocular emergency; such patients should be referred immediately to an ophthalmologist or emergency room. Unless adequately treated within 12 to 48 hours, the patient will become permanently blind within 2 to 5 days. An asymptomatic eye with a narrow anterior chamber angle may convert spontaneously to angle-closure glaucoma. The process can be precipitated by anything that dilates the pupil, such as atropine and epinephrine-like drugs. Typical signs and symptoms include extreme pain; blurring of vision; conjunctivitis; and a fixed, dilated pupil.

Agents that dilate the pupils must be strictly avoided in any patient suspected of having glaucoma.

Lifestyle

All patients who are sedentary should be advised to exercise. However, their IOP must be regularly monitored to determine whether they are in the small percentage that will experience an elevation in IOP.

Supplements

- Vitamin C: 0.1 to 0.5 g/kg per day in divided doses
- Bioflavonoids (mixed): 1000 mg/day
- Magnesium: 300 mg/day
- Chromium: 100 mcg/day

Botanical Medicines

For the prevention and treatment of chronic open-angle glaucoma, either bilberry extract or a proanthocyanoside extract, alone or in combination, is indicated as follows:

- *V. myrtillus* extract (25% anthocyanidin content): 160 to 240 mg a day
- Pine bark extract (Pycnogenol) or grape seed extract (95% proanthocyanidin content): 150 to 300 mg a day

  For normotensive glaucoma:
- *Ginkgo biloba* extract: 120 to 320 mg a day

  For open-angle glaucoma:
- *C. forskohlii:*
  - Forskolin: 5 to 10 mg two to three times a day
  - Standardized extract (10% forskolin): 250 mg one to two times a day

Gout

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Acute onset, frequently nocturnal, with typically monoarticular joint pain, involving the metatarsophalangeal joint of the big toe in about 50% of cases
- Elevated serum uric acid level
- Asymptomatic periods between acute attacks
- Identification of urate crystals in joint fluid
- Aggregated deposits of monosodium urate monohydrate (tophi) chiefly in and around the joints of the extremities but also in subcutaneous tissue, bone, cartilage, and other tissues
- Uric acid kidney stones
- Familial disease; 95% males

GENERAL CONSIDERATIONS

Gout is a common type of arthritis caused by an increased concentration of uric acid (the final breakdown product of purine metabolism) in biological fluids. In gout, uric acid crystals (monosodium urate) are deposited in joints, tendons, kidneys, and other tissues, where they cause considerable inflammation and damage.[1] Gout is a condition characterized biochemically by increased serum uric acid levels, leukotriene levels, and neutrophil accumulation. Gout may lead to debilitation owing to the tophaceous deposits around the joints and tendons; renal involvement may result in kidney failure due to either parenchymal disease or urinary tract obstruction.

Gout is associated with affluence and is often called the "rich man's disease." Throughout history, the sufferer of gout has been depicted as a portly, middle-aged man sitting in a comfortable chair with one foot resting painfully on a soft cushion as he consumes great quantities of meat and wine. In fact, the traditional picture does have some basis because meats, particularly organ meats, are high-purine foods, whereas alcohol inhibits uric acid secretion by the kidneys. Gout is primarily a disease of adult males, with more than 95% of sufferers being men older than age 30. The incidence of diagnosed gout cases has been estimated at 2.13% of the 2009 U.S. population, although 10% to 20% of the adult population has hyperuricemia. Gout is a strong predictor of the metabolic syndrome and an increased risk for type 2 diabetes.[1–4]

Causes of Gout

Gout is classified into two major categories: primary and secondary. Primary gout accounts for about 90% of all cases, whereas secondary gout accounts for only 10%. Primary gout is usually idiopathic (i.e., the underlying metabolic defect is unknown). However, there are several genetic defects in which the exact cause of the elevated uric acid is known.[1] The synthesis and degradation of purines are summarized in Fig. 174.1.

The term *secondary gout* refers to those cases in which the elevated uric acid level is secondary to some other disorder, such as excessive breakdown of cells or some form of renal disease. Diuretic therapy for hypertension and low-dose aspirin therapy are also important causes of secondary gout because they cause decreased uric acid excretion.

The increased serum uric acid level observed in primary idiopathic gout can be divided into three categories:

- Increased synthesis of uric acid, found in a majority of individuals
- Reduced ability to excrete uric acid, typical of a smaller group (about 30%)
- Overproduction of uric acid, as well as underexcretion of uric acid—a small minority

Although the exact metabolic defect in gout is unknown in the majority of cases, gout is one of the most controllable metabolic diseases. Box 174.1 summarizes the causes of gout.

About 200 to 600 mg of uric acid is excreted daily in the urine of an adult male. This is two thirds of the amount produced, the rest being excreted in the bile and other gastrointestinal tract secretions. The dietary component of uric acid is usually 10% to 20%, but in an individual with significant hyperuricemia, 1 mg/100 mL may be added to the serum concentration of uric acid through the diet, enough to increase precipitation into the tissues if the individual is near the saturation threshold.

Almost all of the plasma urate is filtered at the glomerulus; only the small amount bound to protein is not filtered. Renal excretion is peculiar in that about 80% of the filtered uric acid is reabsorbed in the proximal tubule of the nephron. Actually, the distal tubule secretes most of the uric acid found in the urine. Distal to this site, some postsecondary reabsorption occurs. These events are summarized in Fig. 174.2.

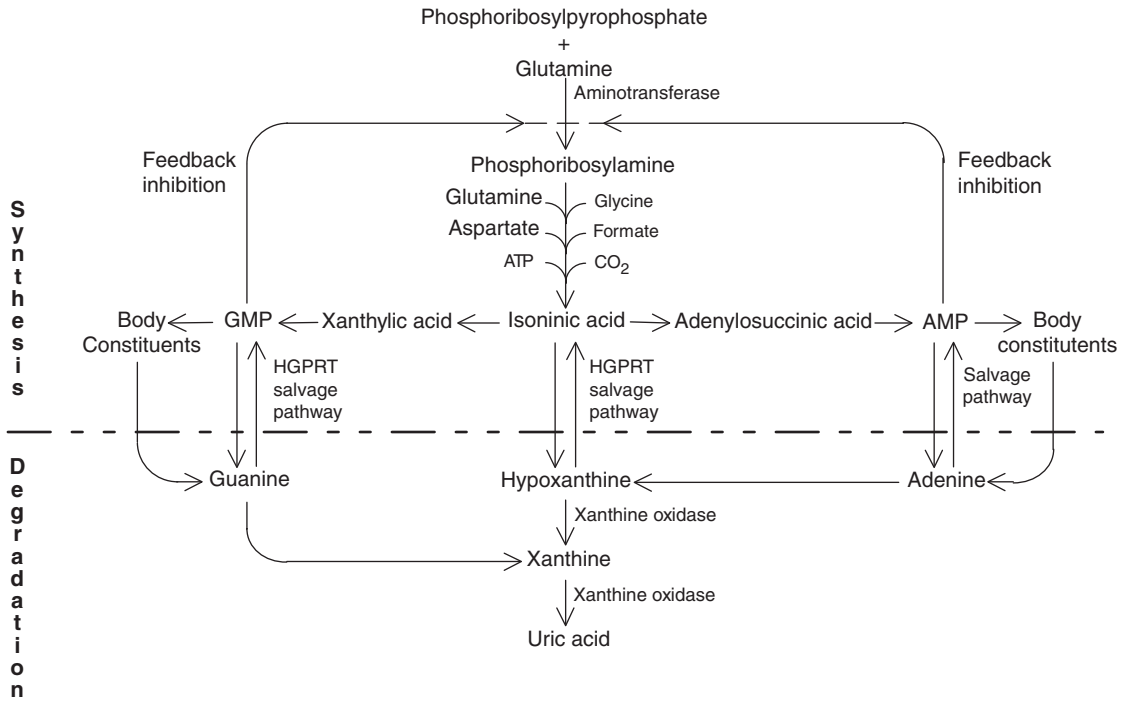

Fig. 174.1 Purine synthesis and degradation. (From Nutrition Foundation. *Nutrition reviews' present knowledge in nutrition*. 5th ed. Washington, DC: Nutrition Foundation; 1984: 740–756.)

BOX 174.1 Causes of Hyperuricemia

Metabolic

- Increased production of purine (primary)
- Idiopathic
- Specific enzyme defects (e.g., Lesch–Nyhan syndrome, glycogen storage disease)
- Decreased enzyme activity (e.g., hypoxanthine-guanine phosphoribosyltransferase is decreased in 1%–2% of adults with gout)
- Increased enzyme activity (e.g., phosphoribosylpyrophosphate synthetase)
- Increased production of purine (secondary)
- Increased turnover of purines
- Myeloproliferative disorders
- Lymphoproliferative disorders
- Carcinoma and sarcoma (disseminated)
- Chronic hemolytic anemia
- Cytotoxic drugs
- Psoriasis
- Increased de novo synthesis (e.g., glucose-6-phosphatase deficiency)
- Increased catabolism of purines
- Fructose ingestion or infusion
- Exercise

Renal

- Decreased renal clearance of uric acid (primary)
- Intrinsic kidney disease
- Decreased renal clearance of uric acid (secondary)
- Functional impairment of tubular secretion
- Drug induced (e.g., thiazides, probenecid, salicylates, ethambutol, pyrazinamide)
- Hyperlacticemia (e.g., lactic acidosis, alcoholism, toxemia of pregnancy, chronic beryllium disease)
- Hyperketoacidemia (e.g., diabetic ketoacidosis, fasting, starvation)
- Diabetes insipidus
- Bartter syndrome
- Chronic lead intoxication
- Glucose-6-phosphatase deficiency

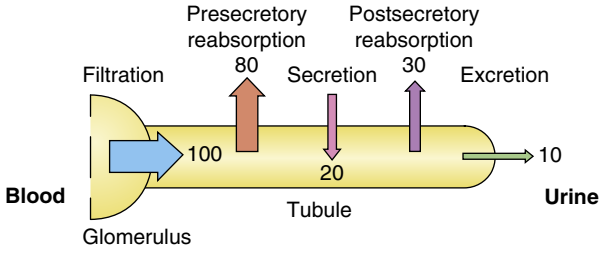

Fig. 174.2 Normal uric acid excretion.

Uric acid is a highly insoluble molecule; at pH 7.4 and body temperature, the serum is saturated at 6.4 to 7 mg/100 mL. Although higher concentrations do not necessarily result in urate deposition (some unknown factor in serum appears to inhibit urate precipitation), the chance of an acute attack is greater than 90% when the level is above 9 mg/100 mL (Table 174.1). Lower temperatures decrease the saturation point of uric acid, which may explain why urate deposits tend to form in areas such as the pinna of the ear, where the temperature is lower than the mean body temperature (Table 174.2). Uric acid is insoluble below pH 6 and can precipitate as the urine is concentrated in the collecting ducts and passed to the renal pelvis.

Signs and Symptoms

The first attack of gout is characterized by intense pain, usually involving only one joint. The first joint of the big toe is affected in nearly one half of the first attacks and is at some time involved in more than 90% of individuals with gout. If the attack progresses, fever and chills will appear. The first attacks usually occur at night and are generally preceded by a specific event, such as dietary excess, alcohol ingestion, trauma, certain drugs, or surgery.

The classic description of gout was offered in 1683 by Sydenham, an English physician who suffered from gout. Little has changed in the clinical picture of gout in more than 300 years. Sydenham's classic description is as follows:

> *The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the great toe;*

TABLE 174.1 Prevalence of Gouty Arthritis by Maximum Urate Level

Serum Urate (mg/100 mL)	Men (%)	Women (%)
<6	0.6	0.08
6–6.9	1.9	3.3
7–7.9	16.7	17.4
8–8.9	25	0
9+	90	0

> *more rarely in the heel, ankle, or instep. The pain is like that of a dislocation, and yet parts feel as if cold water were poured over them. Then follows chills and shivers, and a little fever. The pain which at first was moderate, becomes more intense. With its intensity the chills and fever increase. After a time this comes to a height, accommodating itself to the bones and ligaments of the tarsus and metatarsus. Now it is a violent stretching and tearing of the ligaments—now it is a gnawing pain and now a pressure and tightening. So exquisite and lively meanwhile is the feeling of the part affected, that it cannot bear the weight of bedclothes nor the jar of a person walking in the room. The night is passed in torture, sleeplessness, turning the part affected, and perpetual change of posture; the tossing about of the body being as incessant as the pain of the tortured joint, and being worse as the fit comes on. Hence the vain effort by change of posture, both in the body and the limb affected, to obtain an abatement of pain.*

Subsequent attacks are common, with the majority of such individuals having another attack within 1 year. However, nearly 7% never have a second attack. Chronic gout rarely is an issue, owing to the advent of dietary therapy and drugs that lower uric acid levels. When it does occur, chronic gout is due to poor compliance or inadequate response to treatment, or it may arise in patients with high flare frequency, tophi, and the inability to maintain serum urate levels below 6 mg/dL.[2] Some degree of kidney dysfunction occurs in nearly 90% of subjects with gout, and there is a higher risk of kidney stones.

THERAPEUTIC CONSIDERATIONS

The current standard medical treatment of acute gout is the administration of colchicine, the anti-inflammatory drug originally isolated from the plant *Colchicum autumnale* (autumn crocus, meadow saffron). Colchicine has no effect on uric acid levels; rather, it stops the inflammatory process by inhibiting neutrophil migration into areas of inflammation.

More than 75% of patients with gout show a major improvement in symptoms within the first 12 hours after receiving colchicine. However, up to 80% of patients are unable to tolerate an optimal dose because of gastrointestinal side effects, which may precede or coincide with clinical improvement.

Colchicine may also cause bone marrow depression, hair loss, liver damage, depression, seizures, respiratory depression, and even death. Other anti-inflammatory agents are also used in acute gout, including various nonsteroidal anti-inflammatory drugs (NSAIDs), indomethacin, phenylbutazone, naproxen, and fenoprofen.

Once the acute episode has resolved, a number of measures are taken to reduce the likelihood of recurrence:

- Drugs like allopurinol or febuxostat to keep uric acid levels within a normal range
- Controlled weight loss in obese individuals
- Avoidance of known precipitating factors, such as heavy alcohol consumption or a diet rich in purines or refined carbohydrates
- Low doses of colchicine to prevent further acute attacks

Several dietary factors are known to cause gout: consumption of alcohol, especially beer and hard liquor; foods high in purine content (e.g., organ meats, meat, yeast, poultry); fats; refined carbohydrates, especially high-fructose corn syrup; and overconsumption of calories.[5] Individuals with gout are typically obese; they are prone to hypertension, the metabolic syndrome, and diabetes and are at a greater risk for cardiovascular disease. Obesity is probably the most important dietary factor. Thiazide and loop diuretics are also associated with a higher risk of incident gout and a higher rate of gout flares.[5]

In concept, the naturopathic approach for chronic gout does not differ substantially from the standard medical approach. However, naturopaths focus on dietary and herbal measures to keep uric acid levels within the normal range rather than on the use of drugs. In the conventional medical treatment of gout, drugs that inhibit xanthine oxidase are too often relied upon. Allopurinol, a structural isomer of hypoxanthine (a naturally occurring purine in the body), has been the mainstay treatment for decades. However, in February 2009, the U.S. Food and Drug Administration approved febuxostat (Uloric), another xanthine oxidase inhibitor; it is a more effective treatment for lowering and maintaining serum urate levels.[6] Febuxostat is beginning to supplant allopurinol in the conventional management of gout. Uricosuric agents (probenecid, sulfinpyrazone, and benzbromarone) are used as second-line therapy for patients with underexcretion of uric acid.

Xenobiotics

The risk of hyperuricemia is increased in subjects with higher serum concentrations of organochlorine (OC) pesticides, polychlorinated dibenzodioxins (PCDDs), and dioxin-like polychlorinated biphenyls (PCBs).[7] Chronic low-level arsenic exposure is associated with hyperuricemia and gout. In men, the adjusted odds ratio (OR) for hyperuricemia comparing highest to lowest quartiles of total arsenic was 1.84 (95% confidence interval [CI], 1.26–2.68), and in women, the OR was 1.26 (95% CI, 0.77–2.07).[8] Serum uric acid increases in proportion to body load of perfluorinated hydrocarbons (PFOA and PFOS).[9] Interestingly, low levels of PFOA or PFOS show little effect initially and then rapid elevation of uric acid levels.

An additional item of concern relates to lead toxicity. A secondary type of gout, sometimes called saturnine gout, can result from lead toxicity. Historically, saturnine gout was due to the consumption of alcoholic beverages stored in containers with lead in them. An unexpected and fairly common source of lead appears to be leaded crystal because port wine elutes lead when stored in a crystal decanter.[10] Lead concentration increases with storage time, reaching toxic levels

after several months. Even a few minutes in a crystal glass results in a measurable increase in the level of lead in the wine. Lead promotes hyperuricemia as a result of decreasing renal urate excretion. Among patients in the highest blood lead level (BLL) quartile (mean, 3.95 µg/dL), the prevalence of gout was 6.05% (95% CI, 4.49%–7.62%) compared with 1.76% (CI, 1.10%–2.42%) among those in the lowest quartile (mean, 0.89 µg/dL).[11] Each doubling of BLL was associated with an unadjusted OR of 1.74 (CI, 1.47–2.05) for gout and 1.25 (CI, 1.12–1.40) for hyperuricemia.

Dietary Considerations

The dietary treatment of gout involves the following guidelines:

- Elimination of alcohol intake
- Low purine intake
- Achievement of ideal body weight
- Liberal consumption of complex carbohydrates
- Low fat intake
- Low protein intake
- Liberal fluid intake

Alcohol

Alcohol increases uric acid production by accelerating purine nucleotide degradation; it also reduces uric acid excretion by increasing lactate production (a result of ethanol oxidation), which impairs kidney function. The net effect is a significant increase in serum uric acid levels. This explains why alcohol consumption is often a precipitating factor in acute attacks of gout. Using a 24-hour diet recall, beer consumption was significantly associated with hyperuricemia, with an adjusted OR of 1.28 for men who consumed five or more cans of beer daily compared with those who did not drink.[12] In many individuals, the elimination of alcohol is all that is necessary to reduce uric acid levels and prevent gouty arthritis.

Low-Purine Alkaline-Ash Diet

A low-purine diet has been the mainstay of the dietary therapy of gout for many years. However, with the advent of potent drugs that lower uric acid levels, many physicians lower serum urate levels without subjecting the patient to the inconvenience and deprivation associated with a purine-free diet. However, dietary restriction of purines is recommended to reduce metabolic stress. Foods with high purine levels should be entirely omitted. These include organ meats, meats, shellfish, yeast (brewer's and baker's), herring, sardines, mackerel, and anchovies. Foods with moderate levels of protein should be curtailed as well. These include dried legumes, spinach, asparagus, fish, poultry, and mushrooms. In an analysis of 1247 recurrent gout attacks occurring over a 1-year period in 633 participants, the multivariate OR for recurrent gout attacks for each increasing quintile of purine consumption were 1.17 (95% CI 0.88, 1.55). 1.38 (95% CI 1.02, 1.87), 2.21 (95% CI 1.62, 3.01), and 4.76 (95% CI 3.37, 6.74), respectively.[13]

An alkaline-ash diet is recommended in the dietary treatment of gout because a more alkaline pH increases uric acid solubility. An alkaline-ash diet was shown to increase uric acid excretion from 302 mg/day at pH 5.9 to 413 mg/day at pH 6.5.[14]

Weight Reduction

Excess weight is associated with an increased rate of gout. Weight reduction in obese individuals significantly reduces levels of serum uric acid levels.[15] Weight reduction should involve the use of a low-glycemic diet designed to improve insulin sensitivity. Such a diet also helps manage the elevated cholesterol and triglycerides that are common in obesity.

Carbohydrates, Fats, and Protein

Refined carbohydrates and saturated fats should be kept to a minimum because the former increases uric acid production, whereas the latter increases uric acid retention. In addition, one of the key dietary goals in the treatment of gout appears to be the enhancement of insulin sensitivity.[15] Acute and hypercaloric ingestion of fructose raises serum urate levels via the unregulated phosphorylation of fructose by fructokinase, leading to local ATP depletion and increased AMP production. Exposure to two or more sugar-sweetened beverages (SSBs) per day is associated with a 1.78-fold increased risk of gout in men and a 3.05-fold increased risk in women.[16,17] Fructose consumption is associated with an increased risk of gout (relative risk [RR] = 1.62, 95% CI, 1.28–2.03) when comparing the highest and lowest quantiles of consumption.[18]

Protein intake should not be excessive (i.e., >0.8 g/kg per day) because it has been shown that uric acid synthesis may be accelerated in both normal and gouty patients by a high protein intake. After adjusting for confounders, men in the highest quintiles of total meat and seafood intake have an increased risk of incident gout of 41% and 51%, respectfully.[19] Adequate protein is necessary (0.8 g/kg daily). However, amino acids decrease the resorption of uric acid in the renal tubules, thus increasing uric acid excretion and reducing serum uric acid concentrations.

Fluid Intake

Liberal fluid intake keeps the urine dilute and promotes the excretion of uric acid. Furthermore, dilution of the urine reduces the risk of kidney stones.

Nutritional Supplements

Eicosapentaenoic Acid

Eicosapentaenoic acid (EPA) supplementation may prove useful in the treatment of gout. EPA limits the production of the proinflammatory leukotrienes, the mediators of much of the inflammation and tissue damage observed in gout.

Folic Acid

Folic acid has been shown to inhibit xanthine oxidase, the enzyme responsible for producing uric acid.[20] Research has demonstrated that a derivative of folic acid is an even greater inhibitor of xanthine oxidase than allopurinol, suggesting that folic acid at pharmacological doses may be an effective treatment for gout.[21] Positive results in the treatment of gout have been reported, but the data are incomplete and uncontrolled.[22]

Quercetin

The bioflavonoid quercetin has demonstrated several effects in experimental studies, indicating its possible benefit to individuals with gout.[23,24] Quercetin may offer significant protection by inhibiting the following:

- Xanthine oxidase in a similar fashion to the drug allopurinol[25]
- Leukotriene synthesis and release
- Neutrophil accumulation and enzyme release

One clinical study evaluated the effect of 4 weeks of oral supplementation of quercetin on plasma uric acid levels.[24] Twenty-two healthy males (19–60 years) with baseline plasma uric acid concentration in the higher, but still considered healthy, range (339 (SD 51) µmol/l) were enrolled in the randomized, double-blinded, placebo-controlled, crossover trial. The intervention included one tablet containing 500 mg quercetin daily for 4 weeks, compared with placebo, with a 4-week washout period between treatments. After quercetin treatment, plasma

uric acid concentrations were significantly lowered by –26•5 µmol/l (95% CI, –7•6, –45•5; $P = 0.008$). These results are quite promising and indicate a possible preventive effect against recurrent gout attacks.

For more information on the pharmacology of quercetin, see Chapter 81.

Vitamin C

Megadoses of vitamin C are probably contraindicated in individuals with gout because vitamin C may increase uric acid levels in a small number of individuals. A single large dose (4 gm) of vitamin C resulted in a significant increase in urate excretion, but no change in the serum urate concentration, in 10 patients (5 with gout).[25] Although there are reports that moderate dosages of vitamin C may lower serum uric acid levels by increasing uric acid excretion, neither effect was seen in patients with gout taking vitamin C at a dosage of 500 mg/day. No clinically significant effect was seen on either measurement in either patients taking allopurinol or not.[26]

Niacin

High doses of niacin (i.e., above 50 mg/day) are probably contraindicated in the treatment of gout because niacin competes with uric acid for excretion.[27]

Botanical Medicines

Cherries

Consuming one-half pound of fresh or canned cherries per day has been long recommended in lowering uric acid levels and preventing attacks of gout based upon historical use and early clinical investigation. In a more recent analysis to assess this use, a study was conducted by researchers from the Boston University School of Medicine in 633 people with gout who were recruited and followed online for a year. Participants answered questions about gout onset, symptoms, risk factors, medications, and whether they ate cherries or took cherry extract, and for how long. When the researchers analyzed the participant responses, they found that cherry intake (defined as one-half cup or 10–12 cherries or the equivalent in extract form) over a 2-day period was associated with a 35% lower risk for gout attacks and that cherry extract intake was associated with a 45% lower risk. The risk for gout attacks was reduced by 75% when cherry intake was combined with allopurinol. These benefits persisted even after taking into account factors that can affect gout risk, such as gender, obesity, purine intake (in foods that can increase gout risk), plus the use of alcohol, diuretics, and antigout medications.[28]

These results are consistent with a series of pilot studies conducted by one group of researchers using a cherry juice concentrate.[29] In the first randomized controlled trial (RCT), presented in 2007, patients with gout experienced a significant decrease in the number of acute gout attacks within 4 months of initiating ingestion of the cherry juice concentrate ($P < 0.05$), an effect that was not seen in the control group ingesting pomegranate juice concentrate. Of patients ingesting cherry juice concentrate, 55% were attack-free and stopped their regular intake of nonsteroidal anti-inflammatory drugs within 60 days of initiating consumption of cherry juice concentrate. None of the patients in the group ingesting pomegranate juice discontinued any of their medications. Similar results were shown in the three other trials, leading the researchers to conclude "Our studies suggest that cherry juice concentrate reduces acute attacks of gout when it is consumed over a period of 4 months."[30]

Although some studies have not shown an effect on serum urate levels, one study showed a clear effect on urate metabolism. Researchers measured plasma urate, antioxidant, and inflammatory markers in 10 healthy women who consumed two servings (280 g) of cherries after an overnight fast.[31] Blood and urine samples were taken before the cherry dose and at 1.5, 3, and 5 hours afterward. Plasma urate decreased 5 hours after the cherry consumption by an average of 30 mmol/L. This reduction correlated with an increase in urine urate excretion. Plasma C-reactive protein and nitric oxide concentrations decreased slightly after the 3-hour mark.

Cherries, hawthorn berries, blueberries, and other dark red and blue berries are rich sources of anthocyanidins and proanthocyanidins. These compounds are flavonoid molecules, which give these fruits their deep red-blue color, and are remarkable in their ability to prevent collagen destruction. Anthocyanidins and other flavonoids affect collagen metabolism in many ways:

- They have the unique ability to actually cross-link collagen fibers, resulting in reinforcement of the natural cross-linking of collagen that forms the collagen matrix of connective tissue (e.g., ground substance, cartilage, tendon).
- They prevent free radical damage through their potent antioxidant and free-radical–scavenging action.
- They inhibit enzymatic cleavage of collagen from enzymes secreted by leukocytes during inflammation.
- They prevent the release and synthesis of compounds that promote inflammation, such as histamine, serine proteases, prostaglandins, and leukotrienes.

Zingiber officinalis (Ginger)

Ginger has important anti-inflammatory and analgesic properties (see Chapter 130, *Zingiber officinale* (Ginger)). In a study involving monosodium urate crystal-induced joint inflammation in mice, administration of 6-shogaol, an isolated active principle from ginger, reduced lysosomal enzymes, reduced lipid peroxidation, and decreased the activity of tumor necrosis factor-alpha (TNF-α).[32]

THERAPEUTIC APPROACH

As stated earlier, the naturopathic approach to the prevention and treatment of gout does not differ substantially from the standard medical approach. The basic approach involves the following:

- Dietary and herbal measures that maintain uric acid levels within the normal range
- Controlled weight loss in obese individuals
- Avoidance of known precipitating factors (e.g., heavy alcohol consumption and a high-purine diet)
- The use of nutritional substances to prevent further acute attacks
- The use of herbal and nutritional substances to inhibit the inflammatory process

Diet

Patients should be advised to eliminate alcohol intake, maintain a low-purine diet, increase consumption of complex carbohydrates, decrease consumption of simple carbohydrates, maintain a low-fat intake, optimize protein intake (0.8 g/kg daily), and consume liberal quantities of fluid. Urinary 24-hour uric acid levels can be used to monitor compliance with a purine-free diet (maintained below 0.8 g/day).

In addition, liberal amounts (250–500 g/day) of cherries, blueberries, and other anthocyanoside-rich (i.e., red-blue) berries (or extracts), should be consumed.

Nutritional Supplements

- Fish oils: 3000 mg eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) per day
- Folic acid: 1 to 4 mg/day

Botanical Medicines

Choose one of the following:

- Cherry fruit extract (10:1): 500 to 1000 mg three times a day
- Grape seed extract (>95% procyanidolic oligomers): 100 to 300 mg/day
- Pine bark extract (>90% procyanidolic oligomers): 100 to 300 mg/day
- Anthocyanoside extracts (e.g., *Vaccinium myrtillus*): equivalent to 80 mg anthocyanoside content a day
- Quercetin: 200 to 400 mg three times a day between meals (Note: Consider EMIQ at a dosage of 100–200 mg/day; see Chapter 81 for more information.)

Hair Loss in Women

Michael T. Murray, ND

OUTLINE

INTRODUCTION

In clinical practice, one of the most common complaints from female patients is excessive hair loss. In most cases it is not severe alopecia; rather, it is the perception that hair loss is occurring at an increasing rate. Often these complaints are dismissed because minor hair loss is difficult to quantify, and it is certainly not a life-threatening disorder. However, the patient wants an answer as to why it is happening, so it is important to address it. Physicians should also be careful not to underestimate the emotional impact of hair loss for some patients.

BASIC PHYSIOLOGY OF THE HAIR CYCLE

Between 100,000 and 350,000 hair follicles occupy the human scalp, but not all these hairs undergo cyclic phases of growth and rest. During the growth (anagen) phase, there is active genetic expression of protein synthesis. As the hair matures, it enters a resting stage (telogen). Then the hair bulb migrates outward and eventually is sloughed. It is during this migratory phase that the stage is set for new hair to fill the remaining papilla after the original hair is lost. Age, pathology, and a wide variety of nutritional and hormonal factors influence the duration of the hair cycle. Hair loss is a normal part of aging. By the age of 40 or so, the rate of hair growth slows down. New hairs do not grow in as quickly as old ones fall out.

The hair-pull test can help determine the relative formation of new hair. It involves taking a few strands between the thumb and forefinger and pulling on them gently. Anagen hairs should remain rooted in place, whereas hairs in telogen should come out easily. By knowing approximately how many hairs were pulled and the number that came out, the percentage of hair follicles in a telogen state can be determined. Thus, if 20 hairs were pulled and 2 came out, the frequency of telogen hair follicles is 10%. As a very rough guide, a 10% telogen frequency is excellent, up to 25% is typical, and over 35% is problematic. If after the pull test there are still hairs in the balding areas, it is regarded as a positive test.

DIFFERENTIAL DIAGNOSIS

Hair loss can be broadly divided into two types: focal and diffuse. Diffuse hair loss is most often due to *telogen effluvium*—an umbrella term denoting nonscarring alopecia characterized by diffuse hair shedding, often with an acute onset, caused by a metabolic or hormonal stress or by medications. Generally, recovery occurs when the precipitating factors are dealt with. Women can also experience male- or female-pattern hair loss (previously called androgenic alopecia) (Fig. 175.1). Focal hair loss is most often secondary to an underlying disorder that may cause nonscarring or scarring alopecia. Nonscarring focal alopecia is usually caused by tinea capitis or alopecia areata, although patchy hair loss may also be caused by traction alopecia or trichotillomania. Scarring alopecia is rare and has several causes, most often discoid lupus erythematosus.[1]

CAUSES OF HAIR LOSS IN WOMEN AND THERAPEUTIC CONSIDERATIONS

Six common causes of hair loss in women are discussed here: (1) high levels of androgens, (2) drugs, (3) nutritional deficiencies, (4) hypothyroidism, (5) the presence of antigliadin antibodies; and (6) exposure to environmental toxicants.

Androgenic Female-Pattern Hair Loss

Women can suffer from androgen-related hair loss, just like men.[2–5] The female pattern, however, is more diffuse than the characteristic male pattern, so it was originally referred to as "diffuse androgen-dependent alopecia"; now, however, it is referred to as either female- or male-pattern hair loss.[2] It is a relatively common condition. In fact, one report states that it affects approximately 30% of women before the age of 50.[2] Although genetic factors are clearly significant, androgen excess, insulin resistance, polycystic ovary syndrome, and low antioxidant (i.e., reduced glutathione) status are also associated with female-pattern hair loss.[3–11] Three possible recommendations to help slow down this genetically predisposed process are as follows: (1) improve blood glucose regulation through dietary, lifestyle, and supplementary measures (see Chapter 181); (2) increase antioxidant intake; (3) consider saw palmetto extract; and (4) consider hormone replacement therapy.

Reactive oxygen species have been shown to play a central role (along with testosterone) in male-pattern baldness. Higher levels of these damaging compounds are found in the hair follicles of

Fig. 175.1 Ludwig pattern of hair loss in women. (Vujovic A, Del Marmol V. The female pattern hair loss: review of etiopathogenesis and diagnosis. Biomed Res Int. 2014;2014:767628. PubMed PMID: 24812631.)

men (and presumably women) with male-pattern baldness.[7] This appears to be due to lower levels of glutathione. The use of glutathione-sparing antioxidants like vitamin C and flavonoids seems appropriate.

Saw palmetto extract is a popular recommendation for benign prostatic hyperplasia (BPH). Its effects in BPH occur via several mechanisms, including an ability to inhibit the formation and transport of dihydrotestosterone (DHT). This potent androgen is formed from testosterone by the action of the enzyme 5-α-reductase. The activity of this enzyme is increased in BPH, as well as in both male- and female-pattern baldness.[8] Saw palmetto extract may offer some benefit in androgen-related alopecia by reducing the formation of DHT. This is the same mechanism as the drug finasteride (Propecia), which is often used in the treatment of female-pattern hair loss.[11] Saw palmetto extract also inhibits the transport of DHT to nuclear receptor sites and therefore may prove even more useful. The dosage for the extract standardized to contain 85% to 95% fatty acids and sterols is 320 mg/day.

Drug-Induced Hair Loss

A long list of drugs can cause hair loss, but it should not be assumed that simply because a woman is complaining of hair loss and taking one of these drugs that the drug is the single cause. Some drugs, most notably chemotherapy agents like fluorouracil, are certainly causative because they are such powerful inhibitors of hair growth. When medically appropriate, natural alternatives to the suspected drug or drugs should be employed (Table 175.1).

Nutritional Deficiency

A deficiency of any number of nutrients can lead to significant hair loss. Deficiency of vitamin C manifests as scurvy and can present with corkscrew hairs.[12] Telogen effluvium and alopecia areata have been associated with deficiencies of iron and zinc,[13,14] and generalized hair loss occurs in conjunction with deficiencies in selenium, iron, biotin, and essential fatty acids.[15] In addition, serum vitamin D and folate levels tend to be lower in patients with alopecia areata compared with controls.[16] The patient's nails should be examined for the characteristic white lines indicating poor wound healing of the nail bed even with the most minor of trauma, which may be a sign of a low zinc level. The backs of the arms should be examined for hyperkeratosis, a common sign of vitamin A deficiency. The skin of the elbows and general health of the skin should also be evaluated, looking for the dry skin associated with a deficiency of essential fatty acids. To determine iron status, a serum ferritin evaluation is recommended.

In evaluating serum ferritin levels, it is important to know that many reference laboratories report low ferritin levels (e.g., 10–30 mg/L) to be within the normal range. If the serum ferritin is less than 30 mg/L, iron replacement is indicated. When serum ferritin levels fall below this, hair growth and regeneration are impaired because the body seeks to conserve the remaining iron.[17] There is a very strong association between low body iron stores and diffuse hair loss in women when the serum ferritin level is at or below 30 mg/L.[18,19]

Women with noticeable generalized hair loss typically suffer from deficiencies of all these nutrients. The treatment of hair loss secondary to nutritional deficiency is straightforward—the dietary intake of these nutrients must be increased through appropriate supplementation. One caveat is that many of these women turn out to be hypochlorhydric. In these cases, hydrochloric acid supplementation at meals may be all that is necessary. A general recommendation for women with hair loss related to nutritional status is to take a high-potency multivitamin/multimineral formula that contains iron along with 1 tablespoon of flaxseed oil per day. If their serum ferritin levels are below 30 mg/L, such women can consume iron-rich foods and supplement with additional iron, either 30 mg of iron bound to succinate, fumarate, or other chelate twice daily between meals. If this recommendation results in abdominal discomfort, 30 mg taken with meals three times daily can be suggested. After 2 months, serum ferritin levels should be reassessed. Improvements in serum ferritin often correlate with improved health of the hair and the halting of excessive hair loss.

TABLE 175.1 Classes of Drugs That Can Cause Hair Loss

Class	Examples
Antibiotics	Gentamicin, chloramphenicol
Anticoagulants	Warfarin, heparin
Antidepressants	Fluoxetine, desipramine, lithium
Antiepileptic drugs	Valproic acid, phenytoin
Cardiovascular drugs	Angiotensin converting enzyme inhibitors, beta blockers
Chemotherapy drugs	Doxorubicin, vincristine, etoposide
Endocrine drugs	Bromocriptine, clomiphene, danazol
Gout medications	Colchicine, allopurinol
Lipid-lowering drugs	Gemfibrozil, fenofibrate
Nonsteroidal anti-inflammatory drugs	Ibuprofen, indomethacin, naproxen
Ulcer medications	Cimetidine, ranitidine

Van Neste DJJ, Rushton H. Hair problems in women. *Clin Dermatol.* 1997;15:113–125.

Hypothyroidism

It is well known that hair loss is one of the cardinal signs of hypothyroidism. Using blood levels of thyroid hormones as the criterion, an estimated 1% to 4% of the adult population has moderate to severe hypothyroidism, and another 10% to 12% has mild hypothyroidism.[20] The prevalence of hypothyroidism in American women is estimated to be as high as 20%, even among practitioners of conventional medicine.

Antigliadin Antibodies

The protein gluten and its polypeptide derivative, gliadin, are found primarily in wheat, barley, and rye. It appears that antibodies to gliadin can elicit cross-reacting antibodies that attack the hair follicles, leading to alopecia areata—an autoimmune disease characterized by areas of virtually complete hair loss.[21]

Celiac disease, also known as nontropical sprue, gluten-sensitive enteropathy, or celiac sprue, is characterized by malabsorption and an abnormal small intestinal structure that reverts to normal on the removal of dietary gluten. Evidence is growing that many people with gluten intolerance do not have overt gastrointestinal symptoms. Instead, they may demonstrate gluten intolerance insidiously as hair loss. Rather than testing for antigliadin antibodies in patients with general hair loss or alopecia areata, the test for human antitissue transglutaminase antibodies (IgA anti-tTG) is recommended because it is more sensitive than the test for antigliadin antibodies (see Chapter 157). This recommendation is especially important in the presence of any gastrointestinal symptoms pointing to celiac disease (Box 175.1).

BOX 175.1 Key Diagnostic Features of Celiac Disease

- Bulky, pale, frothy, foul-smelling, greasy stools with increased fecal fat
- Weight loss and signs of multivitamin and mineral deficiencies
- Increased levels of serum gliadin antibodies
- Diagnosis confirmed by jejunal biopsy

Toxicant Exposure

Toxin metal poisoning can also lead to alopecia or thinning of the hair. Excess intake of the trace element selenium can cause increased hair fragility and global hair loss.[22] Hair loss has also resulted from exposure to mercury,[23] arsenic,[24] copper, and lead.[25] Alopecia is often one of the distinctive clinical manifestations of thallium toxicity.[26] A case report of a man who developed severe alopecia during 12 of his 20 years as a glassworker determined the cause to be chronic poisoning by cadmium and bismuth compounds.[27]

CONCLUSION

Hair loss in women should not be dismissed. Although some hair loss is a natural part of the aging process, complaints of excessive or accelerated hair loss should be investigated and treated appropriately. Clinical studies have investigated the psychological impact of increasing hair loss in women and found that it is a significant source of anxiety, fear, and depression.[2,5] Conversely, increasing the health of the hair results in an improvement in the general health, especially the mental health, of these patients.

Hepatitis

Cory Szybala, ND, Mollie Parker Szybala, ND, MPH, and *Peter B. Bongiorno*, ND, MSAc, LAc*

OUTLINE

GENERAL CONSIDERATIONS

Hepatitis refers to inflammation *(-itis)* of the liver *(hepar-)*. Inflammation lasting less than 6 months is known as acute hepatitis, whereas that lasting longer than 6 months is called chronic hepatitis. In people with acute hepatitis who do not progress to chronic disease, all the symptoms, signs, and blood test abnormalities return to normal without permanent or long-term sequelae. People who progress from acute to chronic hepatitis are at risk of progressing to cirrhosis and its complications, such as portal hypertension and hepatocellular carcinoma (HCC). *Hepatitis* is a term that encompasses many inflammatory causes, such as autoimmune liver disease, obesity, alcoholic liver disease, and some medications and herbs. Only hepatitis caused by a virus (viral hepatitis) is potentially infectious to others (Fig. 176.1). This chapter focuses on viral hepatitis A, B, and C.

Hepatitis A is caused by a virus of the *Picornaviridae* family and is transmitted via the fecal–oral (enteric) route by person-to-person contact. Before its identification in 1973, hepatitis A was known as infectious hepatitis. It is the most common cause of acute viral hepatitis in the United States, making up approximately one half of all reported cases of viral hepatitis. The incidence has declined significantly since the implementation of vaccination for those at increased risk of infection. Although infection with the hepatitis A virus (HAV) does not lead to chronic disease, it can relapse up to 6 months after the acute illness has resolved, and it accounted for an estimated 100 deaths each year in the United States in the prevaccine era.[1,2]

Hepatitis B is caused by a virus of the *Hepadnaviridae* family and is transmitted via the parenteral route through blood or blood products, through sexual contact, or from mother–child transmission during pregnancy and childbirth. Before its identification in 1963, it was known as serum hepatitis. Approximately 250 million people worldwide, including an estimated 850,000 to 2.2 million (estimates dependent on the inclusion of immigrants from endemic countries) people in the United States, are chronically infected with the hepatitis B virus (HBV). Chronic carriers are defined through blood work as a positive hepatitis B surface antigen (HBsAg) and a positive hepatitis B core antibody (HBcAb).[3–5]

Hepatitis C is caused by a virus of the *Flaviviridae* family and is transmitted via the percutaneous route through blood-to-blood contact. Current or former intravenous drug users; anyone who received a blood or a blood-product transfusion or donated organ before 1992; anyone who received clotting factor concentrates before 1987; individuals on long-term hemodialysis; individuals born to a mother infected with the hepatitis C virus (HCV); and those who may be at increased risk for exposure to infected blood, such as health care or public safety workers, are at increased risk of infection.[5] Unlike the case with HBV, sexual contact is an inefficient means of HCV transmission. Before its identification in 1989, it was known as non-A, non-B hepatitis. An estimated 185 million people worldwide, 2.4 million of whom are in the United States, have been exposed to and are living with chronic HCV, and approximately 400,000 people per year die of HCV-related liver disease.[6,7]

Symptoms and Signs

Acute viral hepatitis may be asymptomatic or may be an extremely debilitating disease manifesting with jaundice, flu-like symptoms, decreased appetite, abdominal pain, nausea, diarrhea, vomiting, joint pain, and fatigue. Hepatitis A never leads to chronic disease. For hepatitis B, the probability of developing chronic disease in unimmunized individuals is approximately 6% to 10% in older children and adults, 25% to 50% in children aged 1 to 5 years, and greater than 90% in infants. Hepatitis C progresses to chronicity in 75% to 85% of newly infected individuals, with females and children being less likely to progress to chronic diseases than male adults.[5,8,9] The symptoms of chronic hepatitis vary from virtually nonexistent to liver failure or liver cancer, relentless fatigue, and signs and symptoms of decompensated cirrhosis, such as ascites, variceal bleeding, and hepatic encephalopathy.[5]

*Previous edition contributor

Disease	Pathogen	Symptoms	Incubation period	Method of transmission	Diagnostic test
Hepatitis A	HAV, Picornaviridae	Fever, headache, malaise, jaundice	2-6 weeks	Ingestion	IgM antibodies
Hepatitis B	HBV, Hepadnaviridae	Severe liver damage, chronic disease occurs	3-26 weeks	Parenteral, sexual contact	IgM antibodies
Hepatitis C	HCV, Flaviviridae	Same as HBV, more chronic	2-33 weeks	Parenteral	PCR of viral RNA
Hepatitis D	HDV, Deltaviridae	Severe liver damage, high mortality rate	6-26 weeks	Parenteral, when co-infected with HBV	IgM antibodies
Hepatitis E	HEV, Caliciviridae	Pregnant women may be at high risk and show high mortality, not chronic disease	2-6 weeks	Ingestion	IgM antibodies, PCR of viral RNA

Fig. 176.1 Features of different types of viral hepatitis. (From Saleem A, Akhtar MF, Mushtag MF, Saleem M, Muhammad ST, Akhtar B, Sharif A, Peerzada S. Current trends in the treatment of hepatitis C: interventions to avoid adverse effects and increase effectiveness of anti-HCV drugs. *EXCLI J.* 2016;15:578–588. PubMed PMID: 28096788.)

DIAGNOSTIC CONSIDERATIONS

A diagnosis of hepatitis is made via a combination of a thorough history; physical examination; laboratory tests, including serial liver function tests (aspartate aminotransferase [AST] and alanine aminotransferase [ALT], which are known together as transaminases); hepatitis-specific serologies; and in some instances, imaging studies. Because these evaluations typically do not accurately correlate with the extent of damage done to the liver, a liver biopsy is often necessary in chronic cases to determine the grade (degree of inflammation) and stage (degree of fibrosis) of the disease, as well as the need for therapy.[10,11]

Prevention

All people with chronic liver disease or chronic hepatitis of any etiology should receive immunizations for hepatitis A and B if they have not already been exposed to these viruses. The hepatitis A vaccination was first approved by the U.S. Food and Drug Administration (FDA) in 1995, and since its implementation, the incidence has significantly declined. The development of the hepatitis B vaccine represents one of the most important advances in medicine. This is the first and only vaccine in history that can simultaneously prevent liver cancer, cirrhosis, and a sexually transmitted disease, hepatitis B. The FDA approved the hepatitis B vaccine in 1981, and the improved version has been available since 1986. It is considered safe to administer the hepatitis B vaccine to pregnant women if needed. Infants born to HBsAg-positive mothers should receive both the hepatitis B vaccination and the hepatitis B immune globulin (HBIG) within 12 hours of birth. See Box 176.1 for a list of those at increased risk for hepatitis B and who therefore should receive the hepatitis B vaccination.[5,12]

There is currently no vaccine available to prevent HCV. Many barriers exist, slowing the vaccine development, including the not-well-defined immune responses that prevent persistence, the lack of immune correlates, and one of the major barriers, the complex HCV population of mutant strains, known as quasispecies, that can exist in a person infected with hepatitis C.[13]

The hepatitis A virus can be killed by heating foods to 185ºF (85ºC) for 1 minute and by disinfecting surfaces with a 1:100 household bleach solution. It is best to avoid eating raw or partially cooked mollusks (clams, oysters, mussels, and scallops) because these fish often live in HAV-contaminated rivers and seas. When traveling to areas of the world known to have a high incidence of hepatitis A, it is especially important to eat well-cooked foods and to drink only bottled water. Sanitizing diaper-changing tables is also important because hepatitis A–infected infants are typically a silent source for the spread of hepatitis A infection. Meticulous hand washing is of great importance after using the bathroom, before eating a meal, and before preparing food for others.[1]

The avoidance of unprotected sex and injection drug use will greatly reduce the likelihood of infection with HBV or HCV. Employing a barrier such as a condom, dental dam, female condom, or finger cot will decrease the risk of transmission and acquisition of both viruses. Although the risk of sexual transmission of

BOX 176.1 Groups Recommended to Receive the Hepatitis B Vaccination[5]

- All newborns at birth
- Older children who never received a vaccination
- Individuals with multiple sex partners and susceptible sex partners of infected persons
- Individuals who are being evaluated or treated for a sexually transmitted infection (STI)
- Men who have sex with men
- Injection drug users and susceptible sex partners of infected persons
- Susceptible contacts of infected persons
- Health care and public safety workers who may be exposed to blood on the job
- Individuals with chronic liver disease, HIV infection, and end-stage renal disease
- The residents and staff of facilities for developmentally disabled individuals
- Anyone traveling to regions with intermediate or high rates (HBsAg prevalence of ≥2%) of hepatitis B
- Unvaccinated adults between the ages of 19 and 59 with diabetes mellitus
- Any individual seeking long-term protection

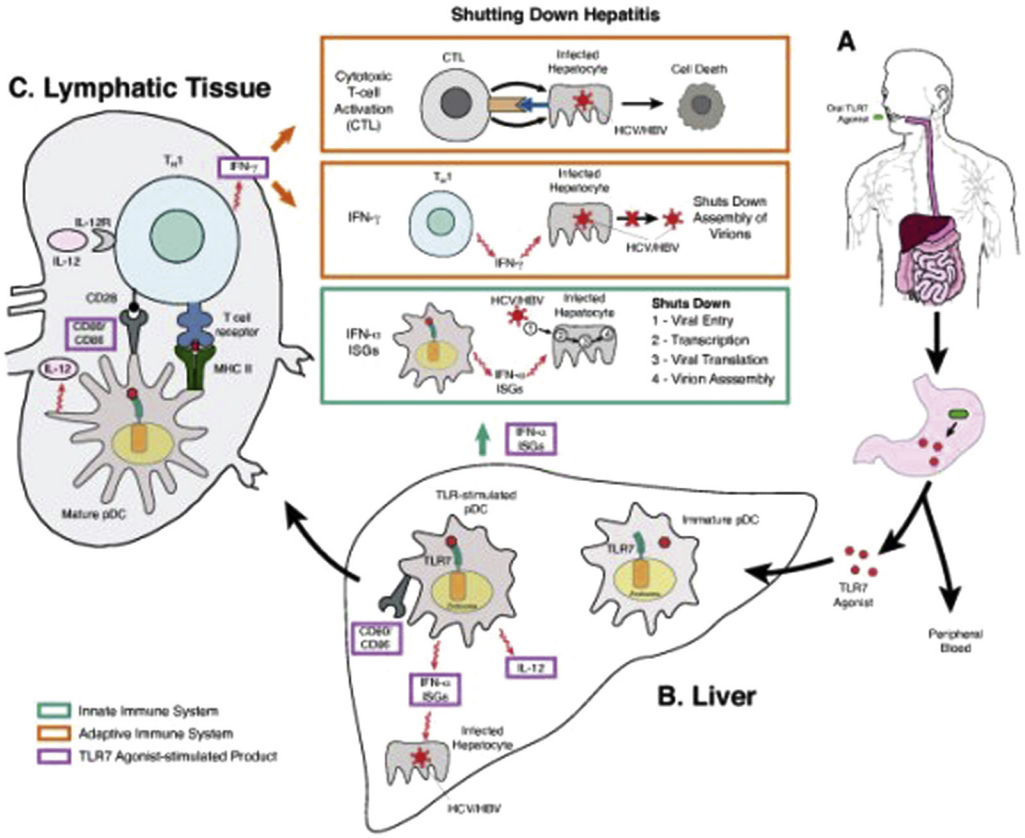

Fig. 176.2 TLR7 stimulation mediates an endogenous type I interferon response. (From Funk F, Kottilil S, Gilliam B, Talwani R. Ticking the TLR7 to cure viral hepatitis. *J Transl Med.* 2014;12:129. PubMed PMID: 24884741.)

HCV is rare, protected sex is recommended if a person engages in anal sex, has multiple sex partners, has frequent prostate infections, has open cuts or sores on the genitalia, or is menstruating. People with hepatitis B or C should avoid sharing anything that may contain even the tiniest amount of their blood, including toothbrushes, needles, razors, and nail clippers. A drop of blood so minuscule that it cannot be seen by the human eye may contain hundreds or even thousands of HBV and/or HCV particles. Even meticulous cleaning may not totally eradicate the virus from a needle. If a person needs unused needles but cannot obtain them, he or she should seek out a needle-exchange program. Alternatively, needle use can be limited to autodestruct syringes, which are designed to self-destruct after one use. Of course, the best advice for a person who continues to use illicit drugs is to discontinue this activity immediately and seek help at a drug rehabilitation center. Also, anyone who intends to get a tattoo or have a body part pierced should deal only with establishments that are clean and that adhere to meticulous sterilization practices.

THERAPEUTIC CONSIDERATIONS

Conventional Therapies

The goals for treatment of chronic hepatitis include sustained viral suppression or total elimination of the virus to slow or prevent progression to cirrhosis, hepatic decompensation, HCC, and to prevent transmission to others. Although not curable, conventional treatment options for hepatitis B include either nucleoside/nucleotide analogs (NAs) or pegylated interferon. Interferons (IFNs) are a family of proteins made naturally by the body that have antiviral, antiproliferative, and immunomodulatory properties (Fig. 176.2). IFN and pegylated IFN have both been shown to be effective in reducing HBV replication and inducing disease remission, although pegylated IFN is preferred due to its increased effectiveness and similar side-effect profile. However, the efficacy of IFN is limited to a narrow population of HBV patients. In addition, its numerous side effects, difficult subcutaneous route of administration, cost, and associated high relapse rate after medication is discontinued have hampered its use for patients with chronic HBV. There are currently five FDA-approved NAs for the treatment of chronic HBV. NAs are quite effective for suppressing HBV replication, induction of disease remission, and the improvement of long-term outcomes. However, the length of time during which patients are treated is not predefined and is determined by specific parameters that may differ from one patient to another, and treatment may be indefinite for some. Furthermore, long-term use of NAs can be complicated by the selection of antiviral-resistant mutations.[4]

In contrast to hepatitis B, hepatitis C can be cured, resulting in improved survival, reduced morbidity, and higher quality of life. The goal of treatment is a sustained virologic response (SVR), or an absence of the virus in the blood 12 weeks after the completion of a treatment regimen. Treatment choice is based on multiple factors, including genotype, efficacy, duration, side-effect profile, drug interactions, history of prior treatment, and stage of fibrosis.[14] The length and success of HCV treatment are also dependent on a variety of factors (Box 176.2). With the approval of new interferon-free regimens in 2014, a major advance in the treatment of HCV occurred, leading to SVR in over 90% of HCV-infected individuals. Interferon-free regimens have helped reduce the number of adverse events (AEs), complex treatment regimens, and the potential for the development of drug-resistance,

- Polymorphisms
- Insulin resistance
- Viral load
- Race
- Statin use

but one barrier still exists: the high price tag associated with each regimen. This change in treatment underscores the need for clinicians to be aware of the effects of natural and integrative therapies on the progression of HCV, potential interactions, and of the potential benefits of these therapies for chronic hepatitis C.[6]

Several nutrients and herbs, discussed later, have been shown to inhibit viral reproduction, improve immune system function, and stimulate regeneration of the damaged liver cells.

Lifestyle Recommendations

Sleep

Experimental studies have demonstrated that sleep deprivation results in poorer immune function, such as reduced natural killer cell activity, suppressed interleukin-2 production, and increased levels of circulating proinflammatory cytokines.[15,16] One study showed that survival was inversely associated with sleep disturbance among 156 patients with cirrhosis. The study's authors suggested that tailored behavioral interventions might help improve overall health-related quality of life and could potentially improve patient outcomes.[17] Sleep problems and chronic fatigue have been reported in patients with chronic hepatitis C, with about 50% to 70% of individuals reporting such complaints. Subjects administered IFN-α demonstrated increased waking after sleep onset, decreased sleep efficiency, and reduced stage 3 and/or 4 sleep.[18,19] Evidence also suggests that impairments in sleep quality exist independent of antiviral therapy with IFN-α and before the advanced stages of liver disease.[20] Sleep deprivation has also been found to attenuate antibody response to hepatitis A and B immunization.[21,22] In terms of sleep duration, individuals with less than 7 hours of regular sleep are approximately three times more likely to develop a cold when exposed to nasally introduced rhinovirus than those with 8 hours or more of sleep.[23] It may therefore be prudent to encourage proper sleep habits and a duration of 8 hours or more to optimize immune and antiviral benefits in the patient with hepatitis as well.

In a 2017 study, resveratrol, at a dose of 19.8 mg/day, was determined to reduce sleep disturbance in patients receiving pegylated-IFN-a-2b and Ribavirin therapy. This was a randomized, double-blind, placebo-controlled study of 60 participants with chronic hepatitis C; 30 receiving resveratrol and 30 receiving a placebo (N-acetylcysteine (NAC) 600 mg and lactoferrin 23.6 g). Addition of resveratrol significantly reduced anxiety; depression; sleep disturbance; serum inflammatory markers, including AST, ALT, C-reactive protein (CRP), tumor necrosis factor-alpha (TNF-α), and interleukin (IL)-6; and histological characteristics, including steatosis and fibrosis. At this time, the mechanism of action for resveratrol is speculative, but it is thought that the phenolic content of resveratrol can alter cellular metabolism to reduce cellular inflammation and improve function. Reduction of inflammatory cytokines likely improves sleep modulation. Consumption of polyphenols likely alters microbial metabolism and alters the composition of microflora, affecting anxiety, depression, and fatigue. It is unknown if resveratrol alone would have the same benefits in the absence of lactoferrin and NAC.[24]

Exercise

Light to moderate exercise has been shown to be well tolerated and beneficial for direct and indirect (extrahepatic) symptoms associated with acute and chronic liver disease.[25,26] Studies demonstrating the incorporation of exercise into the standard of care (SOC) treatment plan for HCV showed that patients can safely participate in an exercise program, create clear changes in the way they perceive their bodies and its capacities, and improve their self-confidence, all of which can lead to far-reaching changes in the way this disease and the constraints of treatment are perceived.[27] Exercise has also been shown to improve symptoms of fatigue, one of the most common and bothersome symptoms affecting people with chronic hepatitis; enhance cardiovascular function; and reduce total body fat, which is important to all people with liver disease. When total body fat is reduced, the fat content of the liver is also reduced, often resulting in a significant reduction in elevated liver enzymes.[27] Thus it is recommended that all patients with chronic hepatitis incorporate an exercise program combining weight training and aerobics into their daily routine, as tolerated, once they have been medically cleared by their physicians.

Diet

Nutritional treatment decisions for hepatitis should be based on modifiable factors associated with accelerated liver disease, including alcohol consumption, obesity, fluid retention, and insulin resistance.[28–30] The most recommended, and researched, dietary pattern for hepatitis is the Mediterranean diet because of its well-documented effects on cardio-metabolic health. Individual components of this diet include reduced carbohydrate intake; increased monounsaturated and omega-3 fatty acid intake; and an increase in whole foods, including whole grains, fruits, and vegetables. The consumption of a diet high in saturated fats, simple carbohydrates (e.g., sugar, white flour, fruit juice, honey), oxidized fatty acids (fried oils), sodium, and animal products has been shown to be detrimental.[31,32] Alcohol should be completely avoided.

The gut–liver–axis (GLA), a relatively novel concept, has been strongly implicated in the progression of hepatitis.[33] The GLA is characterized by the movement of nutrients and metabolites between the small intestine, portal circulation, and bile acid.[33] When there is microbial dysbiosis and disruption of the intestinal barrier, bacteria and their products (including endotoxins) travel to the liver, causing liver damage.[33,34] Elevated bacterial lipopolysaccharide (LPS) causes metabolic endotoxemia and liver inflammation. This both causes and worsens liver disease.[33,34]

HCV infection alters the gut microbial composition.[35,36] It is unknown exactly how this occurs, but it is likely (1) from the direct interaction of HCV and the microbiota and/or (2) mediated via the immune system.[35,36] One study in patients with chronic HBV or HCV has shown that increased microbial translocation and LPS-induced inflammation is predictive of the progression of liver disease[34] The most concerning sequelae of altered GLA function is an increased risk of hepatocellular carcinoma (HCC).[37]

To reduce the risk of HCC by influencing the GLA, it is important to eat a diet that supports the growth of diverse microflora, repairs the intestinal barrier, and decreases LPS levels. Although most research in this field has been performed on mice, eating a high-fat diet (the standard American diet) increases LPS levels and metabolic endotoxemia.[38] Likewise, a high-sugar diet drastically modifies the gut

microbial composition, increases gut permeability, elevates blood endotoxins, and increases liver inflammation.[38,39] Both diets reduce the diversity of the gut flora, which has been linked to a decrease in health.[39–41] To promote the growth of a diverse microflora, eating a diet rich in polyphenols, fiber, and resistant starches is important.[42–44] Probiotic foods including kefir, yogurt, kimchi, miso, and sauerkraut may improve dysbiosis, improve microflora composition, and reduce LPS levels.[45,46] Additionally, the avoidance of xenobiotics in foods should be emphasized.[40]

Patients presenting with liver cirrhosis are likely to be undernourished and sarcopenic.[47] These qualities lead to a decreased quality of life and poor prognosis. Nutritional therapy should support liver regeneration and prevention and correction of nutritional deficiencies. Common nutritional deficiencies with cirrhosis include vitamins A, B, D, E, K, zinc, branched-chain amino acids, and carnitine. Adequate nutrition and prevention of muscle wasting help improve a patient's ability to perform daily activities and reduce complications associated with cirrhosis and HCC.[47]

Flavonoids

Flavonoids are a class of secondary plant metabolites, including common fruits and vegetables, that have been shown to exhibit anti-inflammatory, antithrombogenic, antidiabetic, anticancer, neuroprotective, and antiviral activities. There are a number of ongoing studies looking at the effects flavonoids have on viral infections, including hepatitis B and C.

One such flavonoid, proanthocyandin, found in the blueberry fruit and leaves, has been found to inhibit the replication of HCV,[48] and rats fed diets high in blueberries were protected from developing acute hepatitis.[49] Naringenin, a flavonoid found in grapefruit and other citrus fruits, has been shown to have anti-inflammatory, antioxidant, antiviral, and lipid-lowering properties.[50] Its lipid-lowering properties are specific for very low-density lipoprotein (VLDL) cholesterol; it is suspected that the hepatitis C virus may "hitch a ride" on cholesterol. Studies have demonstrated that naringenin can inhibit or reduce steatosis (the deposition of fat in the liver)[51,52] in addition to inhibiting HCV viral replication.[53,54] It is important to remember that grapefruit contains furanocoumarins and flavonoids, which can inhibit components of the cytochrome P450 drug metabolism pathway, leading to toxic levels of many medications.[55,56]

Caffeine

The mechanisms by which caffeine exerts its hepatoprotective effects are still under investigation, but a growing number of studies are demonstrating a multifactorial etiology, including detoxification, antioxidation, and antifibrinogenesis properties.[57] Although the research is early, there does appear to be dose-dependent response between coffee intake (up to 4 cups daily) and reduced mortality from chronic liver disease. Two population-based studies demonstrated that those who consumed 2 cups of coffee a day were less likely to have elevated serum liver enzymes and were less likely to have chronic liver disease, compared with those who did not drink coffee.[58,59] The protective effect of coffee drinking on the development of cirrhosis and its complications, including HCC, has also been well documented.[60–65]

Higher coffee consumption was associated with less hepatic steatosis, a lower ratio of serum AST/ALT, and lower α-fetoprotein levels in patients with hepatitis C. Patients who drank more than 2 to 3 cups of coffee a day had a lower incidence of disease progression and less fibrosis on histological evaluation compared with patients with HCV who drank less coffee.[60,66] Similar results were not seen in patients who got caffeine from other sources or who consumed decaffeinated coffee. Caffeine may also reduce the fatigue associated with HCV and/or chronic liver disease. Although the exact coffee intake necessary to obtain benefits is unclear, it appears reasonable for patients with hepatitis C to drink 2 to 4 cups of regular coffee daily.

Whey Protein

A by-product of the cheese-making process, whey contains biologically active ingredients that have been shown to enhance immune function, protect against free-radical damage, improve cellular glutathione levels, and reduce overall viral load.[67] A preliminary trial found that 24 g of whey protein daily reduced serum ALT levels and increased plasma glutathione levels in people with hepatitis B but not those with hepatitis C.[68] In a pilot study where whey protein concentrate was supplemented daily in patients with chronic HCV, a significant decrease was noted in viral load, inflammatory markers, and serum ALT and AST. Unfortunately, this study did not disclose an optimal dose, duration, or potential for interaction with ongoing therapy.[67]

Nutritional Supplements

Vitamins C and E

Patients with hepatitis C treated with pegylated interferon and ribavirin were found to have higher SVRs and to be less likely to experience ribavirin-associated anemia when they supplemented this antiviral treatment with vitamins C and E.[69,70] It should be kept in mind that vitamin C increases iron absorption, and many patients with hepatitis C already have elevated iron stores.

Vitamin E levels have been shown to be lower in the serum and liver tissue of people with active hepatitis and those who later develop liver cancer from chronic hepatitis.[71,72] In one preliminary trial of adults with hepatitis C, administering 1200 IU/day of vitamin E for 8 weeks appeared to reduce liver damage.[73] In another study, 544 IU of vitamin E/day for 24 weeks improved the response to interferon/antioxidant therapy, although the results did not reach statistical significance.[74]

Zinc

Zinc is essential to the normal functioning of the immune system and may protect the liver from oxidative damage. Some researchers believe that zinc may protect the body from viruses, including the common cold. A deficiency of this trace element is common in patients with active HCV, HCC, and/or cirrhosis, and serum levels of zinc are inversely correlated with the progression of HCV. Therefore, due to zinc's complex antioxidant effects and the known deficiency state in patients with HCV, zinc supplementation is seen as a viable adjunctive therapy.[75] Oral zinc supplementation (150 mg/day) may slow HCV progression and reduce the incidence of HCC in these patients.[76,77] Zinc supplementation has also been shown to improve functional hepatic reserve, hepatic encephalopathy, and general nutritional status.[47] In addition, zinc supplementation may improve the response to interferon treatment in patients with chronic hepatitis C.[78,79] One study using 17 mg of zinc twice daily (in the form of a zinc complex of L-carnosine) enhanced the response to interferon therapy in patients with chronic hepatitis C.[80] However, it is not clear whether this benefit was due primarily to the zinc or the carnosine. Although daily doses up to 100 mg of zinc may boost the immune system and improve the response to interferon, an excess of this amount may be immunosuppressive. There are also adverse effects associated with excessive zinc consumption, including nausea, vomiting, and diarrhea—all possible side effects of HCV antiviral SOC therapy.

Vitamin D

Patients with chronic hepatitis C often have lower serum levels of 25 hydroxy (OH) vitamin D than individuals without hepatitis C, and approximately one third of these patients are severely vitamin D–deficient.[81] Decreased vitamin D levels have been independently correlated with both the severity of inflammation and hepatic fibrosis on histological evaluation and a reduced incidence of SVRs to therapy with pegylated interferon (PI) plus ribavirin (RBV).[82–85] Additional preliminary findings have suggested that supplementation with vitamin D (1000–4000 IU/day), with the goal of achieving a serum level greater than 32 ng/mL, may improve SVRs in some patients with HCV treated with antiviral therapy. These results suggest that the immunomodulatory properties of vitamin D may act in synergy with this antiviral therapy. Further evaluation revealed that tissue expression of cytochrome P450 25-hydroxylating liver enzymes CYP27A1 paralleled with vitamin D levels and inversely correlated with hepatic necroinflammatory activity. Although further research is expected, because population-based studies have concluded that up to 75% of Americans are deficient in vitamin D,[182] it seems reasonable for all patients with hepatitis C to add vitamin D to their antiviral regimens.

Branched-Chain Amino Acids

In advanced liver disease, such as cirrhosis, patients are often unable to maintain adequate levels of branched-chain amino acids (BCAAs) due to increased demand from ammonia detoxification and energy production.[47] Inadequate BCAA availability causes a reduction of protein synthesis in the liver, resulting in hypoalbuminemia, sarcopenia, edema, and ascites.[86] Supplementing with BCAA has been shown to improve hypoalbuminemia, insulin resistance, immune function, and fatty-acid metabolism; reduce complications of cirrhosis (e.g., esophageal varices, ascites); ameliorate oxidative stress; and inhibit angiogenesis and hepatocarcinogenesis.[47,87] A multicenter randomized controlled trial (RCT) of 622 patients with HCV-related liver cirrhosis showed that oral BCAA supplementation, at a dose of 12 g/day, inhibited hepatocarcinogenesis in obese (body mass index [BMI] >25) patients.[86] The BCAA granules studied contained L-valine, L-leucine, and L-isoleucine at a 1.2:2:1 ratio.[47] General recommendations for the administration of BCAA varies between Japanese, American, and European treatment guidelines.[86]

Acetyl-L-Carnitine

L-carnitine is required for the transportation of fatty acids into the mitochondria of cells. HCV has been found to alter fatty-acid metabolism in hepatocytes by inducing adipogenesis, enhancing lipid droplet formation, and then using these lipids for viral assembly.[88] In vitro studies have shown the inhibition of lipid droplet formation using L-carnitine, suggesting it may have antiviral properties and inhibit the HCV replication process. Additionally, L-carnitine is a well-known antioxidant that has been proven to help decrease hepatocyte damage from HCV.[88] A 2008, placebo-controlled, randomized, double-blind study of 125 cirrhotic patients with chronic hepatitis B or C showed that L-carnitine is able to reduce serum ammonia levels and improve neuropsychological functions compared with placebo.[89] Studies by the same group have demonstrated additional benefits of acetyl-L-carnitine supplementation in patients with HCV, including reduction of fatigue and depression, improved cognition, and an increase in quality of life.[90–92]

Selenium

Selenium is an essential trace element that plays a pivotal role in immune function, including activation of the enzyme glutathione peroxidase, a well-known mediator of oxidative stress. In a deficient state, general immune dysfunction, cancer, and liver cirrhosis have all been documented, the latter showing a proportional decline with the severity of liver injury.[93,94] These findings help confirm that selenium supplementation may be an important addition to current viral hepatitis therapies.[95]

Whole-blood and plasma selenium levels in 59 patients with chronic liver pathologies, including alcoholic and viral liver cirrhosis, were found to be significantly lower than in healthy controls.[96] Another study of hepatocellular carcinoma cell lines reveals that liver cancer cells are able to acquire a selective survival advantage that is prominent under conditions of selenium deficiency and oxidative stress.[97] Oxidative stress is a well-known feature in late-stage cirrhotic liver disease, and subsequent studies have found it to occur much earlier than previously thought.[98] Yu and colleagues found that selenium deficiency correlated with the development of HCC in patients with chronic hepatitis B, and those who supplemented with 200 mcg of selenium daily were less likely to develop HCC compared with nonsupplemented individuals.[99,100] Given this information and the safety of selenium, it is reasonable to employ a supplementary dose of 50 to 100 mg of selenium/day in a hepatitis protocol.[101]

S-Adenosyl Methionine

S-adenosyl methionine (SAMe) functions mainly as a methyl group donor but is less known for its regulation of hepatocyte growth, death, and differentiation. It has been hypothesized that lower hepatic methionine adenosyltransferase (MAT) activity may play a role in the pathogenesis and progression of cirrhosis as well as predisposition to HCC.[102] In a mouse model, SAMe has been shown to enhance interferon's antiviral properties.[103] In a small pilot study performed on G1 HCV nonresponders to pegylated interferon plus ribavirin, it was demonstrated that those patients who were retreated with the same regimen but supplemented with 400 mg SAMe tablets per day displayed both improved early viral kinetics and interferon signaling. This led to enhanced interferon responsiveness and resulted in a higher percentage of patients achieving SVR.[104]

SAMe, at an oral dose of 1600 mg/day, has also been shown to subjectively reduce pruritis and fatigue related to intrahepatic cholestasis due to viral hepatitis.[105]

Probiotics

Probiotics and the gut microbiota seem to be playing a larger role in liver health than previously thought. The GLA, a relatively new concept, helps us better understand the pathophysiology of several hepatopathies, including viral hepatitis. Studies have demonstrated a direct relationship between HBV and HCV and an overproduction of proinflammatory cytokines and hepatic inflammation. One study demonstrated the direct effects of lactitol, a prebiotic known to increase the number of beneficial bacteria species (e.g., *Bifidobacterium* and *Lactobacillus*), on the reduction of endotoxins in patients with hepatitis B or C.[106] Another study looking at the GLA found that those infected with HCV had an increased risk for intestinal permeability, the inciting factor of gut dysbiosis and the proinflammatory effects of liver cirrhosis and HCC.[107] More research is needed to completely understand the effects of probiotics on liver disease, but the link between gut dysbiosis and endotoxemia has been well documented, and any therapies used to treat dysbiosis should be considered when treating those patients with hepatitis.[108]

Glandulars

Liver Extracts

The oral administration of liver extracts has been used in the treatment of many chronic liver diseases since 1896. Numerous investigations

into the therapeutic efficacy of liver extracts have demonstrated that these extracts promote hepatic regeneration and are quite effective in the treatment of chronic liver disease, including chronic active hepatitis.[109–111] For example, in one double-blind study, 556 patients with chronic hepatitis were given either 70 mg of a liver extract or a placebo three times daily.[111] At the end of 3 months, the group receiving the liver extract had far lower liver enzyme (aminotransaminase) levels, suggesting that liver extract may have an anti-inflammatory effect on the liver. This study must be interpreted with caution because the cause of chronic hepatitis was not clearly stated.

Thymus Extracts

The effectiveness of orally administered bovine thymus in viral hepatitis is reflective of broad-spectrum immune system enhancement, presumably mediated by improved thymus gland activity. Several double-blind studies in both acute and chronic hepatitis B have shown thymus extracts to be moderately effective at best. In these studies, a therapeutic effect was noted by accelerated decreases of liver enzymes (transaminases), elimination of the virus, and a higher rate of seroconversion to anti-HBe[112,113] (see Chapter 136 for additional information on the thymus gland).

Botanical Medicines

The use of botanical medicine, in conjunction with other forms of complementary and alternative medicine (CAM), has been increasing among patients with liver disease even though long-term clinical trials have yet to confirm the safety and efficacy of many of these treatments. It is due to this increased public interest, as well as known historical uses and lack of quality research, that the scientific community has taken an interest in botanical medicine. Unfortunately, among the several hundred plants that have been examined, there are only a handful of quality studies looking at safety, therapeutic effectiveness, and mechanisms of action. Of all those herbs studied, the most promising for the treatment of viral hepatitis include licorice *(Glycyrrhiza glabra),* silymarin (the flavonoid complex from milk thistle, *Silybum marianum*), and an ayurvedic herbal combination Liv-52 (containing *Capparis spinosa, Cichorium intybus, Soalnum nigrum, Terminalia arjuna, Cassia occidentalis, Achillea millefolium, Tamarix gallica,* and *Phyllanthus amarus*).[114–116,183]

Glycyrrhiza glabra (Licorice Root)

Many hepatitis trials have looked at the triterpenoid saponin, glycyrrhizin, found in the roots of the licorice plant. Licorice, and its main constituent glycyrrhizin, has been suggested to exert many pharmacological actions beneficial to the treatment of acute and chronic hepatitis, including antioxidant, antihepatotoxic, choleretic, antiviral, and immune-modulating actions. These actions have been proven to reduce serum alanine transaminase and aspartate transaminase values, inhibit immune-mediated cytotoxicity against hepatocytes, suppress hepatitis B surface antigen (HBsAg) secretion, and antagonize nuclear factor-kappa B (NF-κB), a transcription factor that activates genes encoding inflammatory cytokines.[80,115,116]

Licorice has been shown to stimulate the production of the body's natural supply of interferon. This may account for its popularity in Japan, where it has been used in the treatment of chronic viral hepatitis for more than 20 years.[117–122] When used intravenously, licorice has been demonstrated to lower liver enzymes, suggesting a potential benefit in the treatment of hepatitis C, and decrease the risk of HCV-associated HCC.[123–125] A product by the name Stronger Neominophagen C (SNMC) consists of 200 mg of glycyrrhizin, 100 mg of cysteine, and 2000 mg of glycine in 100 mL of physiological saline. When administered intravenously, liver enzymes were decreased in approximately 40% of patients, but with little to no change in HCV load.[117–121] Furthermore, the beneficial effect of SNMC on the reduction of liver enzymes was short-lived: after discontinuation of this supplement, ALT elevations returned. A similar outcome was found by others.[123]

In a study of 453 Japanese patients diagnosed with chronic hepatitis C, 84 were treated with SNMC at a dosage of 100 mL/day for 8 weeks, followed by treatments two to seven times weekly for periods up to 16 years. The rates of cumulative HCC and cirrhosis in year 10 were 7% and 12%, respectively; in year 15, they were 12% and 21%, respectively. And in a cohort of patients with HCV who were unresponsive to interferon therapy, intravenous glycyrrhizin decreased the risk of progression to HCC.[126] Unfortunately, the beneficial results of glycyrrhizin in hepatitis are not consistent. When lower doses of oral glycyrrhizin were used, significant reductions in ALT levels were not observed. Many have concluded that although licorice may reduce ALT elevations, long-term beneficial effects on HCV-associated fibrosis have not been shown.[127]

The main adverse effect of licorice administration is the production of its aldosterone-like effects, including fluid retention, hypokalemia, and hypertension; thus, licorice should be avoided in patients with a history of ascites, hypertension, or renal failure and those using digitalis preparations.[115,116]

Silybum marianum (Milk Thistle)

The origins of the effects of milk thistle on the liver can be traced back to ancient Roman times when Pliny the Elder (AD 23–79) referred to the milky juice of this plant as being excellent for "carrying off bile." John Gerard, a 16th-century British herbalist, recommended milk thistle for "expelling melancholy," a symptom attributed to liver disease during that era. In Germany, during the 19th century, doctors commonly treated jaundice and other liver diseases with an extract from milk thistle seeds. In 1949 German researchers found that milk thistle appeared to protect the livers of animals exposed to high doses of carbon tetrachloride, a potent hepatotoxin.[128]

In 1968 it was found that the active ingredients in milk thistle, a mixture of flavolignans and a flavonoid, are in the seed and consists of silybin, silydianin, and silychristin, collectively referred to as silymarin. Due to its cytoprotectant, antioxidant, anti-inflammatory, and antifibrotic properties, silymarin is the most used natural compound for hepatic disorders worldwide.[129] In the United States, milk thistle is most commonly used for treating viral hepatitis and cirrhosis of the liver. Unfortunately, the trials that have been completed have produced conflicting results, even with the standardization (between 70% and 80%) of silymarin.[130] It is hypothesized that silymarin's hepatoprotective properties come from the following:

- Acting as an antioxidant and reducing reactive oxygen species
- Increasing the intracellular content of glutathione, superoxide dismutase, and catalase
- Inhibiting the formation of leukotrienes and cellular damage
- Stimulating hepatocyte regeneration

Silymarin has been used to treat both acute and chronic hepatitis of varying etiologies. In a study with 29 patients with acute viral hepatitis, those treated with silymarin showed greater improvements in serum levels of bilirubin and liver enzymes compared with the placebo group.[131]

Other investigators specifically evaluating the antiviral effect of silymarin on patients with hepatitis C concluded that improvements in some symptoms occurred when silymarin was administered orally but that it failed to exert an antiviral effect or result in significant reductions in ALT or improvements in ultrasound abnormalities related to hepatitis C.[132–134]

In humans, flavonoids have a low bioavailability, owing to extensive first-pass metabolism; thus, the plasma levels needed to exert an antiviral effect may not be possible. Discrepant results reported by various investigators may be due to a lack of homogeneity among doses and routes of administration.

A newer form of silymarin that binds it to phosphatidylcholine (referred to as silymarin phytosome) may provide greater benefit. A growing body of research indicates that phosphatidylcholine-bound silymarin is better absorbed and produces better clinical results than the unbound variety.[135–140] These benefits were demonstrated in a study involving 232 patients with chronic hepatitis (viral, alcoholic, or chemically induced) treated with silymarin phytosome at either 120 mg twice a day or 120 mg three times a day for up to 120 days.[140] Liver function returned to normal faster in patients given silymarin phytosome compared with both the commercially available silymarin and a placebo.

Intravenous silibinin is capable of the greatest suppression of hepatitis C viral replication. The first study that provided clear evidence of the antiviral effects of silymarin in humans with hepatitis C was published in 2008 by Ferenci and colleagues.[141] These investigators found that such patients who were nonresponders to SOC treatment were able to achieve undetectable HCV RNA levels after intravenous administration of silibinin for 15 days. Although these results proved to be temporary, the antiviral effect of intravenous silibinin was permanent for one patient with hepatitis C who received this treatment for 2 weeks after liver transplantation. This suggests that silibinin may be capable of preventing graft reinfection with HCV.[142] Further studies are needed to confirm these promising results.

Phyllanthus amarus

Phyllanthus amarus is an important herb in the Ayurvedic system of medicine commonly used for liver disorders. An array of phytochemical studies looking at this herb demonstrated a wide spectrum of pharmacological activities, including antiviral, antibacterial, anti-inflammatory, antimicrobial, anticancer, antioxidant, and hepatoprotective.[143] A preliminary report from 1988 demonstrated that 59% of patients with hepatitis B had lost the hepatitis B surface antigen when tested 15 to 20 days after treatment with a preparation of *P. amarus* (200 mg of the dried, powdered, sterilized plant in capsules three times a day).[144] In a 2011 in vitro study looking at the correlation between *P. amarus* (root and leaf) extracts and HCV replication, there were two HCV enzymes that were shown to be inhibited by the extracts, therefore also inhibiting HCV replication.[143] At this time, these results have not been confirmed by other researchers, indicating the need for more research in this field.[145–148]

Combination Approach with Antioxidants and Botanical Therapy

It has been well documented that the pathogenesis of chronic HCV is associated with a suboptimal immune response and intrahepatic oxidative stress. Therefore the addition of antioxidant therapies in the treatment of HCV may have beneficial effects on the prognosis and outcome of this disease.[149,150]

A report by Berkson describes three patients with advanced cirrhosis, portal hypertension, and esophageal varices secondary to chronic hepatitis C infection who were effectively treated with a low-cost combination program. Although these patients were originally given extremely poor prognoses, all "recovered quickly," showed improved liver enzymes, and were able to resume their normal daily activities. One patient revealed a substantial improvement in her condition within only 2 weeks. The other patients progressed to health within 4 to 7 months.[151]

Berkson's regimen was composed of oral supplementation of α-lipoic acid (600 mg/day in two divided doses), selenium (as selenomethionine at 400 mcg/day in two divided doses), and silymarin (900 mg/day in three divided doses). The subjects were also asked to take a B-complex vitamin, eat a diet high in fruits and vegetables, consume 4 oz or less of meat per meal, and drink eight glasses of water per day. They also took between 1000 and 6000 mg of vitamin C daily and 400 IU/day of vitamin E. They were encouraged to walk 1 mile three times a week. Only the α-lipoic acid/selenium/silymarin portion of the protocol was verified, and it is not known how strictly the other nutritional and lifestyle suggestions were followed.[151]

Although this protocol is documented in only three cases, it makes reasonable sense from a naturopathic standpoint, given the excellent safety record, reasonable cost, and known efficacy of the individual treatment options and is certainly worth trying, especially in patients failing to respond to conventional therapies. It is hoped that stringent clinical trials of this type of multiantioxidant/lifestyle combination protocol will be conducted soon.

One such study, by Melhem et al., in which 50 patients with chronic HCV were treated with oral (glycyrrhizin, schisandra, silymarin, ascorbic acid, lipoic acid, l-glutathione, and alpha-tocopherol) and intravenous preparations (glycyrrhizin, ascorbic acid, l-glutathione, b-complex) demonstrated an enhanced response rate when looking at HCV RNA levels, liver enzymes, liver histology, and quality of life.[152]

Acupuncture and Chinese Medicine Herbs

The Chinese medicine diagnosis for hepatitis often includes consideration of damp heat in the liver and spleen channels. Acupuncture points and herbal formulas are often directed at clearing heat and damp to cool and drain these channels. Often efforts are made to also nourish liver blood and tone the liver and spleen.

In a study of 60 patients with hepatitis B, 30 were prescribed 30 minutes of acupuncture once a day for 4 to 6 weeks, whereas the other 30, the control group, continued their conventional treatment. Those in the treatment group had significantly shorter recovery times, greater symptom improvement, and lower interleukin-8 levels.[153] Studies have also investigated the use of acupuncture to improve secondary and comorbid symptoms, such as depression and myalgias. One 6-week trial categorized 28 patients: group 1 comprised 13 patients with high depression and myalgia scores, group 2 was made up of 11 patients with low depression but high myalgia scores, and group 3 consisted of 4 patients with high depression but low myalgia scores. Compared with baseline levels, significant improvement was shown in end-treatment depression and myalgia scores.[142] Although no positive outcomes regarding improved viral load using acupuncture have been shown, acupuncture may help other symptoms, improve immune balance, and lower comorbidities in patients with hepatitis. In a meta-analysis done by Zhao et al. in 2011, a positive correlation was found between interferon along with the use of Chinese herbal formulas and a higher sustained virologic response.[154] More studies are needed, but given the possible benefit and low risk, acupuncture and Chinese herbs may be reasonable therapies for patients with viral hepatitis.

Because the standard operating procedure for acupuncture mandates the use of clean-needle technique, the risk of hepatitis from acupuncture is considered extremely low.[155] Acupuncture may help improve symptoms and hepatic function. A patient should look for a practitioner who uses only disposable needles as opposed to resterilized needles.

Sho-saiko-to or "Xiao Chai Hu Tang"

Sho-saiko-to (named Xiao Chai Hu Tang in Chinese) is a botanical formulation containing seven herbs traditionally used to treat liver

and gastrointestinal disorders.[156] This formula has been shown in animal models to prevent liver injury and promote liver regeneration by inhibiting oxidative stress on lipid peroxidation in hepatocytes and hepatic stellate cells[157,158] and, in human trials, to prevent the progression of cirrhosis to HCC.[159] One prospective study of 260 patients also found that it increased the survival of those with chronic viral hepatitis by reducing progression to HCC.[160–162]

A Phase II trial at Sloan-Kettering Cancer Center showed that shosaiko-to may improve liver pathology in patients with HCV who are unable or choose not to receive interferon therapy.[163] In this open-label trial, 24 subjects were given 2.5 g granulated powder, three times daily, for 12 months. After 12 months of treatment, 38% of subjects had improved liver histology on fine-needle biopsy, 67% had reduced AST levels, and 75% had reduced ALT levels. Of note, this treatment is contraindicated with interferon drug therapy because there is an increased risk of pneumonitis,[164] and Sho-saiko-to has been reported to cause acute hepatitis.[165]

Hepatotoxic Supplements

The use of nutritional and herbal supplements has dramatically increased in popularity since the 1990s, especially in certain subgroups, including affluent societies, elderly individuals, nonsmoking females, and those with higher education levels. With such an increase in supplementation and limited oversight from either the FDA or practitioners, there is also more concern for toxicity due to unknown additives, dosage, and incorrect or off-label uses.[166]

Niacin, a supplement used mostly for hyperlipidemia, known to cause flushing, headache, and stomachache, may cause hepatotoxicity, depending on form and dosage. Immediate-release, or crystalline, niacin at doses above 500 mg and/or sustained-release forms at doses of 2 g/day or higher have been shown to contribute to hepatotoxicity and should be avoided in patients with hepatitis.[167–169] Other forms of niacin, including extended release (ER) and niacinamide, appear less likely to induce hepatic abnormalities and may be considered safer options.[170,171]

Vitamin A belongs to a group of compounds known as retinoids. About 80% to 90% of total-body stores of retinoids are found in hepatic stellate cells. Excessive consumption of vitamin A (acute doses of over 100,000 IU or chronic doses of 25,000–100,000 IU daily for over a year) may cause hypervitaminosis A; individual tolerability may vary. Hypervitaminosis A has been well documented to cause hepatotoxicity, including elevation of serum liver enzymes, cholestatic hepatitis, noncirrhotic portal hypertension, fibrosis, and cirrhosis.[166,172] Vitamin A's potential to cause liver toxicity has been shown to be enhanced with increased alcohol consumption, excessive intake of other fat-soluble vitamins, and vitamin C deficiency.

Iron has been demonstrated to generate reactive oxygen species, leading to point mutations, chromosomal damage, and inactivation of tumor-suppressor genes such a p53; therefore it is a direct hepatotoxin. Unless a patient is found to be iron deficient, iron supplementation should be avoided because iron has been shown to speed the progression and worsen the course of many liver diseases. This is especially true for alcoholic liver disease because alcohol and excess iron have been shown to have an additive harmful effect on the liver.[173]

Hepatotoxic Botanicals

Given the pharmacological nature of plant medicines, it is important to remember that some commonly used botanicals may be hepatotoxic and should be avoided in patients with hepatitis. Perhaps the most researched is *Symphytum officinale* (comfrey), which contains hepatotoxic pyrrolizidine alkaloids (PAs), such as lasiocarpine and symphytine, and their related N-oxides.[174] Although *Symphytum* is most commonly used as a topical vulnerary, the PAs may still be absorbed through the skin, and their use should be avoided in patients with liver disease. *Piper methysticum* (kava kava) has also been implicated in hepatic liver damage.[175] A number of these reported cases of kava toxicity seemed to involve poor documentation, preexisting conditions, kava overdose, or concomitant polypharmacy. Although considered safe at normal doses for people without liver disease, those with hepatic conditions should avoid kava kava as a precaution.[176]

There is a long list of other potentially hepatotoxic botanicals that should be discussed due to past and emerging research (Box 176.3). Many of these herbs are found in formulas that are known to be hepatotoxic, and others have been included based on constituent actions. Until more quality research is done to confirm the role of these botanicals in the pathophysiology of liver damage/disease, they should be used with caution in those with hepatitis.[177,178]

BOX 176.3 Botanicals Associated With Liver Damage[177,178]

- *Borago officinalis*
- *Camellia sinensis*
- *Larrea tridentata*
- *Hypericum perforatum*
- *Lycopodium serratum*
- *Valeriana officinalis*
- *Atractylis gummifera*
- *Chelidonium majus*
- *Cimicifuga racemosa*

THERAPEUTIC APPROACH

During the contagious phase (2–3 weeks before symptoms appear to 3 weeks after), good hygiene and avoiding close contact with others is important. Once a diagnosis has been made, work in a daycare center, restaurant, or other similar employment is not recommended. Chronic hepatitis requires a multifactorial, integrative approach that will include lifestyle and dietary measures, as well as possibly a combination of nutrients, botanicals, and conventional pharmaceuticals, as needed on an individual basis.

Lifestyle

In the acute phase, bed rest is important, with a slow resumption of activities as health improves. At least 8 hours of sleep is recommended during the acute and recovery phases. Exercise is recommended at the level of intensity safest for each patient, a level that may vary from person to person. Strenuous exercise should be avoided. Weight loss is recommended for those who are overweight or obese. Smoking tobacco and drinking alcohol should be completely avoided.[179,180]

Diet

A low-caloric, whole-foods, high-fiber diet low in saturated fats, oxidized fatty acids (fried oils), and simple carbohydrates (e.g., sugar, white flour, and fruit juice) is recommended.[179] Consumption of vegetable broths, diluted vegetable juices (diluted with 50% water), and herbal teas is helpful to avoid dehydration, especially in the presence of diarrhea. Foods such as flavonoid-rich blueberry, coffee, and grapefruit (if there are no interactions with medication) may be beneficial to the patient with chronic hepatitis. Prebiotic and probiotic foods should be emphasized to improve the GLA and reduce liver inflammation.[181]

Nutritional Supplements

Vitamin C: to bowel tolerance (10–50 g/day) in acute cases; 1000 mg three times/day in chronic cases. Caution in cases of iron overload when taken with iron sources.
Vitamin D: 1000 to 4000 IU a day
Vitamin E (mixed tocopherols): 1200 IU a day
Selenium: 50 to 200 mcg a day
Whey protein: for hepatitis B at 24 g a day
Liver extracts: 70 mg three times a day
Thymus extracts: equivalent to 120 mg pure polypeptides with molecular weights of less than 10,000 or roughly 750 mg of the crude polypeptide fraction a day

Botanical Medicines

Glycyrrhiza glabra (Licorice)

Powdered root: 1 to 2 g three times daily
Fluid extract (1:1): 2 to 4 mL (1–2 g) three times daily
Solid (dry powdered) extract (5% glycyrrhetinic acid content): 250 to 500 mg three times daily.
Intravenous administration may be the most effective form.
Note: chronic licorice administration may call for an increased intake of potassium-rich foods.

Silybum marianum (Milk Thistle)

Standardized extract: 70 to 210 mg three times daily, based on its silymarin content.
The best results are achieved at higher dosages (i.e., 150–300 mg three times daily). For this reason, standardized extracts are preferred.
Silybin bound to phosphatidylcholine: 120 mg two to three times daily between meals. Intravenous silibinin may be the most effective form.

Berkson Combination Antioxidant Approach

See the earlier section on antioxidant/botanical therapy for this specific protocol.

Herpes Simplex

Michael Traub, ND, DHANP, FABNO

OUTLINE

DIAGNOSTIC SUMMARY

- Acute or recurrent viral infection of the skin or mucous membranes characterized by the appearance of grouped vesicles on an erythematous base, frequently occurring about the mouth (herpes gingivostomatitis), lips (herpes labialis), genitals (herpes genitalis), and conjunctiva and cornea (herpes keratoconjunctivitis)
- Incubation period of 2 to 12 days, average of 6 to 7
- Positive culture or polymerase chain reaction (PCR), with the latter being more sensitive
- Regional lymph nodes sometimes tender and swollen
- Outbreak may follow minor infections, trauma, hormonal fluctuations, stress (emotional, dietary, and environmental), and sun exposure
- Viral shedding, leading to possible transmission, during primary infection, recurrences, and (asymptomatically) between recurrences (Fig. 177.1)

GENERAL CONSIDERATIONS

More than 70 viruses compose the *Herpesviradae family*. Of these, four are important in human disease: herpes simplex virus (HSV), varicella zoster virus, Epstein–Barr virus, and cytomegalovirus. Serological methods have distinguished two types of HSV, which have been designated HSV-1 and HSV-2. HSV-1 is frequently acquired in early childhood. More than one third of the world's population has recurrent HSV. Although 80% of seropositive individuals do not have clinically apparent recurrences, the virus is still shed asymptomatically. The prevalence of HSV-1 infection has declined steadily from 60% when first measured between 1979 and 1980. The most pronounced decline was among 14- to 19-year-olds, in whom the prevalence fell from 39% to 30% ($P < 0.01$) from 1999 to 2004 and from 2005 to 2010, respectively. HSV-2 prevalence also declined from 21% between 1988 and 1994 to 16% between 2007 and 2010. However, racial disparities in HSV-2 prevalence have widened, as this decline did not occur among black individuals. Thus rates of HSV-2 infection were highest among black women (50%), followed by black men (32%), white women (15%), and white men (7%). These differences were found to exist at every level of sexual activity and thus do not reflect individual behaviors. In all, 87% of HSV-2 seropositive persons did not know they had genital herpes.[1]

Previously, HSV-1 was primarily isolated from extragenital sites, whereas genital infections were caused primarily by HSV-2. By the year 2000, however, HSV-1 had replaced HSV-2 as the primary cause of genital lesions, likely due to orogenital contact.[2] A retrospective review of genital HSV isolates collected in a university student health service showed that HSV-1 accounted for 78% of all genital isolates in this population by 2001, compared with 31% of isolates in 1993.[3] Individuals who are exposed to HSV and have asymptomatic primary infections may experience an initial clinical episode of genital herpes months to years after becoming infected.

Herpes outbreaks on the hands and fingers (herpes whitlow) is increasingly recognized, probably as result of digital–genital contact.

Recurrence Rate

After the resolution of the primary infection, HSV probably becomes a dormant inhabitant within sensory or autonomic trigeminal or lumbosacral ganglia or both (Fig. 177.2). Recurrences develop at or near the sites of primary infection and may be precipitated by many different stimuli:

- Sunburn
- Sexual activity
- Menses
- Stress
- Food allergy
- Drugs
- Certain foods

Patients with primary genital HSV need to be counseled that recurrence is expected. The frequency of recurrence depends on the severity and duration of the initial episode, the infecting serotype, and the host. In one series of 457 patients with HSV-2 primary infection, 89% had one recurrence during a follow-up of 391 days.[4] Furthermore, 38% of patients had as many as 6 recurrences, and 20% had more than 10. Recurrent infection is more common with HSV-2 than HSV-1. The magnitude of this effect was evaluated in a prospective study of 137 patients with a first symptomatic episode of genital herpes. The likelihood of recurrence was much higher with HSV-2 infections (60% vs. 14% with HSV-1).[5]

Herpes viruses: life cycle

- Virus can bind several host receptors
  - Envelope fuses with plasma membrane
- Capsid moves to nucleus
  - Uses host polymerse to replicate
- Lytic infection
  - mRNA moves to cytoplasm
  - Proteins built, assembled
  - Virus exocytosed from plasma membrane

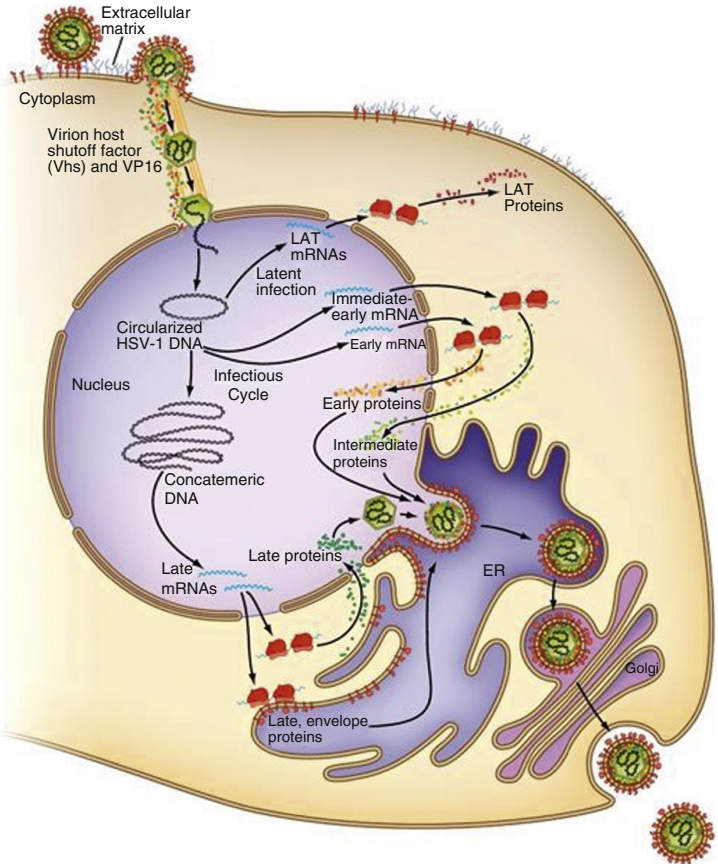

Fig. 177.1 Life Cycle of Herpes Simplex Virus.

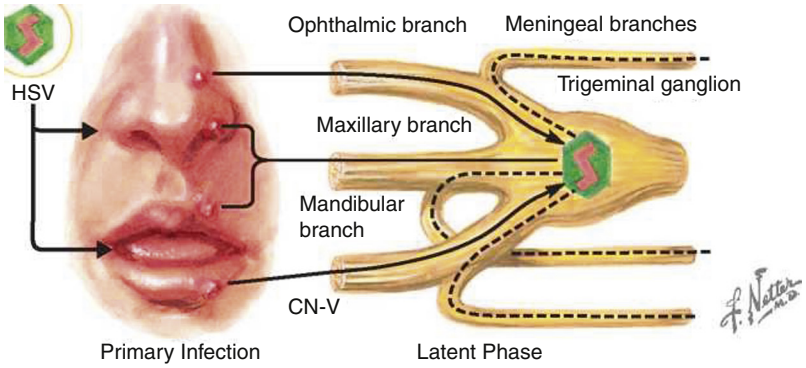

Fig. 177.2 Herpes Simplex Virus in Trigeminal Ganglion.

Immunological Aspects

Because not everyone exposed to HSV develops clinical infection, it appears that host defense mechanisms are paramount in protecting against infection. Chronic, persistent labial and genital infections are seen in immunosuppressed individuals. The cell-mediated immune system is undoubtedly the major factor in determining the outcome of herpes exposure—that is, whether it leads to resistance, latent infection, or clinical disease.

DIAGNOSIS

Isolation of HSV from tissue scrapings is the gold standard for diagnosis. The availability of type-specific serology using surface glycoproteins (gG2 and gG1 for HSV-2 and HSV-1, respectively) to distinguish HSV-1 and HSV-2 enables the clinician to determine whether the patient is at risk of acquisition or has evidence of prior infection with either subtype.[5] A positive serology indicates present or past infection. Positive serological testing for HSV-2 indicates anogenital infection,

but positive serological testing for HSV-1 can be consistent with either anogenital or orolabial infection.[6]

THERAPEUTIC CONSIDERATIONS

Prevention of recurrent herpes is recommended to decrease the number and severity of outbreaks, reduce asymptomatic viral shedding, and prevent transmission to a partner and/or fetus. Three or more people may benefit when one person takes preventive measures. Education regarding transmission and asymptomatic viral shedding is imperative.

Enhancement of the host's immunological status is a key goal in the control of herpes infection. In addition to general immune support (for a complete discussion, see Chapter 136), one of the key natural measures to strengthen cell-mediated immunity is the use of polypeptide-rich bovine thymus extracts. These have been shown to be effective in preventing both the number and severity of recurrent infections in immune-suppressed individuals.[7] Thymus extract appears to increase the lymphoproliferative response to HSV, natural killer cell activity, and interferon production, thus preventing viral activation by potentiating these cell-mediated immune responses. To date, no clinical trials have been published on thymus extract and the prevention or treatment of HSV infections.

Nutritional Supplements

Zinc

Oral supplementation with zinc (50 mg/day) has been shown to be effective in laboratory studies.[8] Although zinc is an effective inhibitor of HSV replication in vitro, its effect in vivo is probably related to its role in enhancing cell-mediated immunity. The topical application of 0.01% to 0.025% zinc sulfate solutions has also been shown to be effective in both ameliorating symptoms and inhibiting recurrences of HSV infection.[9]

Vitamin C

Both the oral consumption and topical application of vitamin C increase the rate of healing of herpetic ulcers. In a randomized, double-blind study, an ascorbic acid–containing pharmaceutical formulation (Ascoxal) applied with a soaked cotton-wool pad three times daily for 2 minutes resulted in patients reporting fewer days with scabs and fewer cases of worsening of symptoms. Cultures yielded herpes complex viruses significantly less frequently in the treatment group.[10] In another study, 20 patients with herpes labialis were treated with a complex of 600 mg of water-soluble bioflavonoids and 600 mg of vitamin C given orally in equal increments three times daily. Twenty episodes of herpes labialis were treated with a complex of 1000 mg of water-soluble bioflavonoids and 1000 mg of vitamin C in equal increments five times daily. Ten episodes were treated with a lactose preparation. This approach was maintained for 3 days after the recognition of symptoms. The water-soluble bioflavonoid–vitamin C complex was shown to reduce vesiculation and to prevent disruption of the vesicular membrane. The therapy was most beneficial when it was initiated at the beginning of the disease. Those treated with the 1000-mg regimen saw their blisters heal in 4.4 days, compared with 10 days for the placebo group. Optimal remission of symptoms was observed in 4.2 ± 1.7 days with the 600-mg dosage of the water-soluble bioflavonoid/ascorbic acid complex.[11] Vitamin C has also been employed intravenously with benefit in the treatment of patients with HSV infection, including patients with AIDS.[12]

Lysine and Arginine

A lysine-rich/arginine-poor diet has become a popular treatment for HSV infections. This approach came from research showing that lysine has antiviral activity in vitro because of its antagonism of arginine metabolism.[13] HSV replication requires the synthesis of arginine-rich proteins, and arginine itself is suggested to be an operon coordinate inducer.[14] A preponderance of lysine over arginine is believed to act as either an allosteric enzyme inhibitor or an operon coordinate repressor.

Double-blind studies on the effectiveness of lysine supplementation with uncontrolled avoidance of arginine-rich foods have shown inconsistent results.[14–17] These outcomes may be due to the relatively low levels of lysine used (1200 mg/day) and the severity of the cases in some of the studies (placebo and treated groups had lesions for 40% of the time in one negative study).[14,15] In one study, lysine was given at a larger dosage (1 g three times daily) along with the dietary restriction of nuts, chocolate, and gelatin.[16] At 6 months, lysine was rated as effective or very effective by 74% of those receiving lysine compared with only 28% of those receiving the placebo. The mean number of outbreaks was 3.1 in the lysine group compared with 4.2 in the placebo group.

Theoretically, this approach should be effective because in vitro studies have shown that HSV replication depends on adequate levels of arginine and low levels of lysine.[17] As dibasic amino acids, they compete with each other for intestinal transport, and rats fed a lysine-rich diet displayed a 60% decrease in brain arginine levels, although there was no change in serum levels.[12] Because HSV is believed to reside in the ganglia during latency, lysine supplementation seems appropriate. In some patients, withdrawal from lysine is followed by relapse within 1 to 4 weeks.[17] However, there are no published data to support the avoidance of arginine-rich foods to prevent or treat HSV. In fact, in one study, the opposite was shown to be true: arginine inactivated HSV-2 and inhibited genital HSV infection in mice.[18]

Topical Preparations

Melissa officinalis

One of the most widely used topical preparations in the treatment and prevention of herpes outbreaks is a concentrated extract (70:1) of *Melissa officinalis* (lemon balm). Rather than a single antiviral chemical, *Melissa* contains several components that work together to prevent the virus from infecting human cells. When *Melissa* cream was used in patients with an initial herpes infection, results from comprehensive trials in three German hospitals and a dermatology clinic demonstrated that there was not a single recurrence.[19] In other words, by using the cream, not a single patient with a first herpes outbreak developed another cold sore.

Furthermore, it was noted in these studies that the *Melissa* cream produced an interruption of the infection and promoted healing of the herpes blisters much faster than normal. The control group receiving other topical creams had a healing period of 10 days, whereas the group receiving the *Melissa* cream healed completely within 5 days.

The *Melissa* cream was also studied in patients suffering from recurrent cold sores. Researchers found that if subjects used this cream regularly, they would either stop having recurrences or experience a tremendous reduction in the frequency of recurrences (an average cold sore–free period of >3.5 months).[20]

The *Melissa* cream should be applied to the lips two to four times daily during an active recurrence.[20] It can be applied fairly thickly (1–2 mm). Detailed toxicology studies have demonstrated that it is extremely safe and suitable for long-term use. Extracts of other species of the *Lamiaceae* family have also shown in vitro efficacy against the adsorption, but not replication, of HSV-1 and HSV-2, including *Mentha piperita, Prunella vulgaris, Rosmarinus officialis, Salvia officinalis,* and *Thymus vulgaris.*[21]

Salvia officinalis

A combination of topical *Salvia officinalis* extract and rhubarb root extract proved to be as effective as topical acyclovir cream in a German double-blind, comparative, randomized trial of 149 patients with herpes labialis, and the herbal combination was more effective in relieving HSV-associated pain.[22]

Glycyrrhiza glabra

Another popular ingredient for the topical treatment and prevention of herpes outbreaks is glycyrrhetinic acid. This triterpenoid component of *Glycyrrhiza glabra* (licorice root) inhibits both the growth and cytopathic effects of herpes simplex as well as vaccinia, Newcastle disease, and vesicular stomatitis viruses.[23] Topical glycyrrhetinic acid has been shown in clinical studies to be helpful in reducing the healing time and pain associated with cold sores and genital herpes.[24–26]

Resveratrol

Resveratrol (3,5,4′-trihydroxy-transstilbene) is a natural component of certain foods such as grape skins; it has been shown to have anti-HSV activity in vitro. Intriguing research in mice has shown that the topical application of a cream rich in resveratrol (12.5%–25%) effectively blocked replication of the virus and stopped lesion eruption if applied early and frequently.[5,27] No human studies have been reported; however, subsequent in vitro studies have yielded data indicating that resveratrol suppresses HSV-induced activation of nuclear factor (NF)-kappaB within the nucleus and impairs the expression of essential immediate-early, early, and late HSV genes and the synthesis of viral DNA.[28]

Vitamin E and Other Antioxidants

In two uncontrolled trials, topical vitamin E decreased pain and healing time in oral herpes. Lesions responded best when the content of a vitamin E capsule was applied every 4 hours.[29] In a clinical trial, a combination of oral acyclovir with alpha-tocopherol, selenium, L-methionine, and coenzyme Q_{10} induced significantly faster healing with significantly reduced incidence of relapse compared to the control group that received acyclovir alone, confirmed by decreased viral load and increased antiviral cytokine and peroxynitrite plasma levels. Plasma antioxidant capacity was also significantly higher in the combination group.[30]

THERAPEUTIC APPROACH

The therapeutic aim is to shorten the current attack and prevent recurrences. Support of the immune system is of primary importance, necessitating control of food allergens and the optimization of nutrients necessary for cell-mediated immunity. Inhibition of HSV replication through lysine supplementation may be useful. Strengthening the immune system can be effective in reducing the frequency, duration, and severity of recurrences.

Diet

A diet that avoids major food allergens and is rich in antioxidants is recommended.

Supplements

- Vitamin C: 2000 mg/day
- Bioflavonoids: 1000 mg/day
- Zinc: 25 mg/day
- Lysine: 1000 mg three times daily
- Vitamin E 400 iu, selenium 200 mcg, coenzyme Q_{10} (ubiquinol) 100 mg

Topical Treatments

- Sunblock
- Ice: 10 minutes on, 5 minutes off during prodrome
- Zinc sulfate solution: 0.025% solution applied three times a day
- *Melissa* cream: applied twice a day
- Glycyrrhetinic acid: applied twice a day
- Vitamin E: applied every 4 hours

HIV/AIDS: Naturopathic Medical Principles and Practice

Steven C. Milkis, ND, and *Kevin L. Conroy, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- A diagnosis of human immunodeficiency virus–positive (HIV+) infection is most commonly made after a positive HIV 1/0/2 antigen/antibody (fourth-generation) test to identify HIV antibodies by enzyme-linked immunosorbent assay (ELISA) and/or HIV-1 p24 antigen. A positive result is reflexed to distinguish between HIV-1 and HIV-2 infection.
- Primary HIV infection (acute retroviral syndrome) resembles common influenza. Most persons experience this syndrome 2 to 6 weeks after initial inoculation with the virus; it often goes unnoticed and undiagnosed as HIV owing to its similarity to the flu. Signs and symptoms can include fever, lymphadenopathy, skin rash, pharyngitis, myalgia, arthralgia, headache, diarrhea, and oral ulcerations. Laboratory findings might include leukopenia, thrombocytopenia, and elevated transaminases. Primary infection is also characterized by a high level of virus production, high concentrations of viral particles and RNA in plasma, and a rapid and steep decline in CD4+ T-helper cells. Peak viral titers can reach 10^7 virions per milliliter during this phase. Viral production can range up to 10 billion copies per day. After the initial viremia, high levels of viral p24 antigen appear.
- An insidious onset of HIV infection may manifest as an acquired immunodeficiency syndrome (AIDS); associated opportunistic infection (OI); or unexplained progressive fatigue, weight loss, fever, diarrhea, or generalized lymphadenopathy. It is often something that is discovered after other possible causes for illness are ruled out, resulting in delayed diagnosis.
- AIDS, for an individual aged 6 or older, is diagnosed after positive serology and either a CD4+ T-cell count below 200/mm^3 or the presence of a designated AIDS-indicator condition (from the Centers for Disease Control and Prevention [CDC] guidelines of 2014).
- The lower the CD4+ count and the higher the viral load, the higher the risk of contracting OIs, neoplasms, or neurological abnormalities, and the higher the mortality rate.
- Groups at high risk for contracting HIV include injection drug users who share needles, homosexual and bisexual men, hemophiliacs and others receiving transfused blood or other blood products (highest risk to recipients before May 1985, when regular screening of the blood supply began), regular sex partners of people in the aforementioned groups, heterosexual individuals with greater than one sex partner in the past 12 months, and those who have had unprotected sex during the previous 6 months.

INTRODUCTION

HIV has been described as a retrovirus containing two identical single strands of RNA. It enters the body via the transfer of body fluids and subsequently binds to and infects CD4-expressing cells of the human immune system (T-helper lymphocytes, blood monocytes, tissue macrophages, Langerhans cells in the skin, and microglial and multinucleated cells in the central nervous system). AIDS is a secondary syndrome typically resulting from long-term HIV infection. AIDS is defined by the following: levels of CD4+ cells or the presence of certain specific indicator conditions or secondary malignancies known to be associated with HIV. Many theories exist as to what causes AIDS, ranging from HIV itself to multifactorial (environmental and infectious) assaults on the immune system. In this science's infancy, there is no definitive answer, but current medical thinking is that AIDS is caused by HIV.

Focus and Goals of Chapter

This chapter is written for the naturopathic physician, although conventionally trained physicians and other holistic practitioners may find

the perspective, treatment principles, and some of the treatment suggestions helpful. The field of HIV/AIDS medicine is rapidly changing. HIV/AIDS was only first reported to the CDC in 1981, and it has since exploded into an international pandemic. Highly active antiretroviral drug therapy (HAART), introduced in 1996, is the use of multiple drugs in combination, with the goal of decreasing viral load and increasing CD4+ T-cell counts, thereby prolonging life and preventing the onset of complicating conditions related to the immune system decline. Although this innovation resulted in a dramatic slowing in the death rate from AIDS, with it came complicated drug side effects, drug interactions, and unique symptoms that require frequent follow-up between the patient and physician and affect the quality of life of individuals on those regimens. These complications from HIV treatment have become less and less common over the past several years with the advent of new, safer, and more effective medications. In addition, changing treatment guidelines that include starting treatment on diagnosis (vs. the older guideline of waiting until the CD4+ count drops to a low level) have resulted in patients being in a much healthier state and making actual AIDS diagnoses less and less common.

Studies indicate that more than 79% of HIV+ persons are using some form of complementary/alternative medicine (CAM) in their treatment, resulting in improvements in their quality of life and better outcomes.[1] The goal of this chapter is to help the physician better understand the condition and to appropriately guide this affected population with unique and complicated health issues.

BIOLOGY OF HIV

Two types of HIV have been identified. HIV-1 is found throughout the world. The majority of infections in the United States are caused by HIV-1. HIV-2 was first identified in West Africa in 1986 and has been found to have a genetic sequence approximately 50% similar to HIV-1. HIV-2 is considered less virulent than HIV-1 and shows lower rates of sexual and perinatal transmission and a lower viral load with a slower rate of CD4 cell decline. This results in a slower rate of disease progression in infected people.[2] Research shows that the virus is mutating, and multiple subtypes or clades are spreading throughout the world.[1] The existence of multiple clades raises the theoretical possibility that a single individual could become infected with multiple subtypes of the virus. Research has not conclusively demonstrated the existence of a "superinfection," but the possibility of this phenomenon would significantly enhance virulence as well as increase resistance to present treatments.

Existing research has failed to isolate an intact HIV entity, although fragments believed to belong to the HIV virus have been isolated and identified. Despite this shortcoming, the virus is believed to consist of a bilayer lipid envelope covered with envelope glycoproteins (gp120 receptor and gp41 transmembrane), a viral core containing two single strands of RNA and the reverse transcriptase enzyme (needed to translate the viral RNA into DNA that can affect human cells), and structural core proteins (p24 capsid protein and p18 matrix protein). It is believed that HIV binds to CD4-expressing cells of the immune system and, through a series of steps, is brought into the cell, replicates itself, and incorporates its genome into the host cell's genome.

The various classes of antiretroviral medications have been developed to interrupt viral replication during various steps in this process. The key to understanding the mechanisms of action of the various medications is to understand those steps.

Fusion is the process by which the HIV particle contacts and binds to the target cell. This occurs through the interaction of the viral gp120 and gp41 transmembrane proteins with CD4 and chemokine receptors on the cell's membrane. Entry inhibitors are designed to inhibit this process by altering the cellular receptor sites or the process that takes the virion into the cell.

Transcription occurs when the viral reverse transcriptase enzyme translates the viral RNA into a double strand of DNA. Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) and nonnucleoside reverse transcriptase inhibitors (NNRTIs) are designed to disrupt this process.

Integration occurs when the double strand of proviral DNA migrates to the cell's nucleus and is inserted into the host's chromosome via the integrase enzyme. The provirus is then permanently integrated into the host DNA. It can remain essentially dormant (equilibrium of viral production and destruction) or become activated and initiate the production of large chains of new viral RNA subunits independent of the host cell's replication process. Integrase strand transfer inhibitors (ISTIs) prevent the integrase enzyme from inserting the viral DNA into the host DNA; thus it is unable to produce new virus material.

After a period of normal cell function, the infected cell becomes activated, initiating *transcription* of the proviral DNA into mRNA, which is then *translated* in the cytoplasm to produce long chains of viral polypeptides. *Cleavage* occurs when the protease enzyme cuts up these viral polypeptides. The pieces are then joined together to form new retroviruses. Protease inhibitors block the action of the protease enzyme and thereby prevent the reassembly of new viral polypeptides.

Packaging is a poorly understood step in this process, where the new RNA viruses are wound up tightly and encapsulated into new viral particles. *Budding* occurs when the HIV nucleocapsid containing the new viral RNA moves to the host cell's membrane and binds to the inside of the membrane. It is then enveloped by the membrane as it leaves the cell. As of yet, there are not any approved medications that target these steps of viral replication.

TRANSMISSION

HIV has been found in body fluids and tissues that contain lymphocytes. This includes blood and blood products, semen, vaginal fluids, breast milk, cerebrospinal fluid, synovial fluid, pleural fluid, amniotic fluid, and infected tissues. It has also been found in small amounts in saliva, tears, feces, and urine. According to the CDC, the only documented cases of transmission are via blood, semen, vaginal secretions, breast milk, and transplanted organs from an infected person. Variables affecting transmission rates include the infectivity of the source partner (higher viral load), the presence of sexually transmitted diseases (STDs) (especially with ulcerations), and the type of contact (increased risk with anal intercourse or vaginal intercourse during menses because blood is present).

The most significant routes of transmission are via sexual contact (vaginal, anal, and less frequently, oral intercourse), intravenous drug use (sharing contaminated needles and syringes), transfusion of blood or blood products (highest risk before May 1985 when screening of the blood supply in the United States for HIV began), and from an HIV-infected mother to her baby (before or during birth or through breastfeeding). Transmission can also potentially occur via percutaneous needlestick, mucous membrane exposure, or exposure of infected fluid into an open wound. Studies show the risk of seroconversion after a needlestick from an HIV+ source to be 0.25% per exposure. They also show that there have been no known seroconverters after splash exposure. The CDC has identified one documented case of transmission from acupuncture.

There is no evidence that HIV can be transmitted via air, water, insects, or dried body fluids. Universal infection control precautions as developed by the CDC should always be employed by health care

workers to minimize the risk of HIV transmission in the health care setting. Always assume that all blood and body fluids are potentially hazardous and that all patients are potentially infected.[3]

THE IMMUNE SYSTEM'S RESPONSE

Both the humoral and cellular immune systems have a role in the body's response to HIV infection. The humoral response involves the initial production of transient immunoglobulin M (IgM) antibodies to viral core and envelope proteins. Permanent immunoglobulin G (IgG) antibodies are subsequently established (this may take several weeks) to core p24 and envelop gp160, gp120, and gp41, corresponding to the resolution of clinical symptoms. The development of these IgG antibodies results in a rapid decrease in circulating virions and p24 antigen titers. *Seroconversion* occurs when the body starts making antibodies to HIV antigens and those antibodies become detectable by conventionally used laboratory tests (enzyme-linked immunoassays).

There is a window of time between initial infection (when patients remain antibody-negative or seronegative as measured by EIA tests) and when seroconversion (antibody-positive or seropositive by EIA) occurs. The length of this window varies depending on the individual and can range from 10 to 14 days to 6 months. The cellular immune response is characterized by the elevation of various cytokines (including interferons and tumor necrosis factor), CD4+ lymphopenia, and CD8+ lymphocytosis. Cytotoxic T cells reduce the plasma viremia, whereas natural killer (NK) cells may be involved with killing infected T cells.

CLINICAL PROGRESSION TO AIDS

The progression of HIV in an untreated state is broken down into three stages: stage 1 is acute HIV infection, stage 2 is clinical latency (or HIV inactivity/dormancy), and stage 3 is AIDS.

The overall natural progression of HIV infection can be broken up into three types: rapid (AIDS develops within 3 years of infection and seroconversion), intermediate (AIDS develops more slowly, between 3–10 years after infection), and long-term non-progression (AIDS does not develop for >8–10 years after infection).

Assuming no antiretroviral treatment, a typical scenario of HIV infection might unfold as follows: Starting with stage 1, within 2 to 3 weeks of initial infection with the virus, an acute retroviral syndrome occurs. This resembles a common flu and is often missed in individuals without obvious risk factors or awareness about HIV. Recovery and seroconversion usually follow in 2 to 3 weeks. After recovery from the initial acute syndrome, HIV plasma concentrations decline to a viral "set point," and equilibrium is established between the production and destruction of CD4+ cells, which denotes the beginning of stage 2 or clinical latency. The level of viral replication after acute infection and seroconversion coupled with the CD4+ count is predictive of long-term prognosis. A lower level of replication with a higher CD4+ count indicates a longer asymptomatic course. Conversely, a higher level of replication with lower CD4+ counts generally indicates a shorter asymptomatic course. Over time, a gradual decline in T-cell numbers begins with a concurrent gradual increase in the amount of virus in the body. This period can last 5 to 15 years. Eventually there are not enough T cells for the body's immune system to function properly, and stage 3 or AIDS is the result. This is when the risk of OIs and other so-called AIDS indicator conditions increases, with the ultimate result being death.[4]

There are two unique groups of patients that do not follow this typical scenario. The first group is termed *long-term non-progressors*. These individuals are thought to make up less than 5% of the total HIV+ population. They are antiretroviral naïve, their viral load remains <5000 copies/mm^3, and CD4 count remains in a normal range, and they never manifest any AIDS-defining illness or OI. The second group is a subset of the long-term non-progressors called *elite controllers*. These individuals maintain even lower viral loads and higher CD4 counts and are thought to number approximately 1 in 200 HIV+ individuals. The reasons for why these individuals are able to maintain this status are unclear (and may even be different between the two groups), but they likely involve some sort of interplay between genetic factors in the individual host and the genetics of the specific virus. Both of these groups are getting considerable attention from researchers who are working on finding a cure for HIV.

Box 178.1 lists the CDC's 2014 revised surveillance case definition of AIDS for adults and children (6 years of age or older). Note that the criteria are different both for children less than 1 year old and children who are 1 to 5 years old. This definition creates stages of HIV infection based on CD4+ cell counts/percentages and/or clinical symptoms. The primary criterion used is positive serology (i.e., positive for antibodies to HIV or the presence of p24 antigen via fourth-generation HIV 1/0/2 antigen/ antibody test and/or positive HIV antigen detection via polymerase chain reaction [PCR] or another specific HIV antigen test). Given a positive serology, a diagnosis of stage 3 HIV or AIDS is given when CD4+ counts fall below 200/mm^3 (<14%), any of the noted AIDS-defining conditions occurs, or both.[5]

Clinically, patients tend to be susceptible to certain complications (both infectious and noninfectious) on the basis of their CD4+ cell counts.[6] Although there is always individual variation, these data are helpful in predicting probable clinical presentations. Generally, lower CD4+ cell count and/or a higher viral load represents a greater risk for complications and should always be factored into any such consideration. It is notable that these issues are becoming less and less common, given the current standard of care and the use of antiretroviral medications by most patients.

- When the CD4+ cell count is greater than 500/mm^3, a patient could manifest acute retroviral syndrome, candidal vaginitis, persistent generalized lymphadenopathy (PGL), Guillain–Barré syndrome, myopathy, or aseptic meningitis.
- When the CD4+ count is between 200 and 500/mm^3, possible complications include pneumococcal or other bacterial pneumonia, pulmonary tuberculosis, herpes zoster, oropharyngeal candidiasis/thrush, cryptosporidiosis (self-limited), Kaposi sarcoma, oral hairy leukoplakia, cervical and anal dysplasia/cancer, B-cell lymphoma, anemia, mononeuritis multiplex, idiopathic thrombocytopenic purpura, Hodgkin's lymphoma, or lymphocytic interstitial pneumonitis.
- When the CD4+ count is below 200/mm^3, complications might include *Pneumocystis jirovecii* pneumonia (previously known as PCP pneumonia), disseminated histoplasmosis and coccidioidomycosis, miliary/extrapulmonary tuberculosis, progressive multifocal leukoencephalopathy (PML), wasting, peripheral neuropathy, HIV-associated dementia, cardiomyopathy, vacuolar myelopathy, progressive polyradiculopathy, or non-Hodgkin's lymphoma.
- When the CD4+ count is below 100/mm^3, complications might include disseminated herpes simplex, toxoplasmosis, cryptococcosis, chronic cryptosporidiosis, microsporidiosis, or candidal esophagitis.
- When the CD4+ count is below 50/mm^3, complications might include disseminated cytomegalovirus (CMV), disseminated *Mycobacterium avium* complex (MAC), or central nervous system lymphoma.

BOX 178.1 Centers for Disease Control and Prevention (CDC) Revised Surveillance Case Definition for HIV Infection—United States, 2014

For adults and children aged 6 years and older:

Stage 0: When a previous negative or indeterminate HIV test result has been documented within 180 days of the first confirmed positive HIV test of any type

Stage 1: CD4+ T-lymphocyte count of ≥500/microliter (μl) or ≥26%; no AIDS-defining condition present

Stage 2: CD4+ T-lymphocyte count of 200 to 499/μL or 14% to 25%; no AIDS-defining condition present

Stage 3 (AIDS): CD4+ T-lymphocyte count <200 /μL or <14% or documentation of an AIDS-defining condition

Stage unknown: no information of CD4+ T-lymphocyte count or percentage; no information on presence of AIDS-defining conditions

NOTE: There are separate CD4+ T-lymphocyte–based criteria for children <1 year old and 1 to 5 years old.

The specific AIDS-indicator conditions include the following:

Bacterial infections, multiple or recurrent (only among children <6 years old)

Candidiasis of esophagus, bronchi, trachea, or lungs

Cervical cancer, invasive

Coccidioidomycosis, disseminated or extrapulmonary

Cryptococcosis, extrapulmonary

Cryptosporidiosis, chronic intestinal (>1 month's duration)

Cytomegalovirus disease (other than liver, spleen, or lymph nodes), onset at age >1 month

Cytomegalovirus retinitis (with loss of vision)

Encephalopathy, attributed to HIV

Herpes simplex with chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi sarcoma

Lymphoma—Burkitt's, immunoblastic, primary (of brain)

Mycobacterium avium complex or *Mycobacterium kansasii,* disseminated or extrapulmonary

Mycobacterium tuberculosis of any site, pulmonary, disseminated, or extrapulmonary

Mycobacterium, other species, or unidentified species, disseminated, or extrapulmonary

Pneumocystis jirovecii (previously known as *"Pneumocystis carinii"*) pneumonia

Pneumonia, recurrent

Progressive multifocal leukoencephalopathy

Salmonella septicemia, recurrent

Toxoplasmosis of brain, onset at age >1 month

Wasting syndrome attributed to HIV—involuntary weight loss >10% of baseline plus chronic diarrhea (>2 loose stools/day for >30 days) or chronic weakness and documented enigmatic fever >30 days

[a]In all stages laboratory confirmation is required.

From Selik RM, Mokotoff, ED, Branson B, et al. Revised surveillance case definition for HIV infection—United States, 2014. *MMWR Morb Mortal Wkly Rep.* 2014, April 11;63(RR03):1–10.

BOX 178.2 Revised Recommendations for HIV Testing of Adults, Adolescents, and Pregnant Women in Health Care Settings as of 2006

Screening for HIV Infection

- Routine testing for all patients 13 to 64 years old (at least once in their life; more frequently if risk factors are present)
- Pregnant women
- All patients initiating treatment for tuberculosis
- All patients seeking treatment or evaluation at clinics treating sexually transmitted diseases
- All persons with signs or symptoms consistent with HIV or with an opportunistic infection consistent with HIV/AIDS

Repeat Screening

- Annual screening (minimally) for persons in high-risk groups (includes injection-drug users and their sex partners, persons who exchange sex for money or drugs, sex partners of HIV-infected persons, and men who have sex with men [MSM] or heterosexual persons who themselves or whose sex partners have had more than one sex partner since their most recent HIV test)
- Potential screening every 3 to 6 months for persons with ongoing high risks
- Patients and their prospective partners before initiating a new sexual relationship
- Any person whose blood or body fluid is the source of an occupational exposure to a health care provider should be informed of the incident and tested at the time of the exposure

Data from Branson BM, Handsfield HH, Lampe MA, et al. Revised recommendations for HIV testing of adults, adolescents, and pregnant women in health-care settings. *MMWR Morb Mortal Wkly Rep.* 2006, September 22;55(RR14):1—17; DiNenno EA, Prejean J, Irwin K, et al. Recommendations for HIV Screening of gay, bisexual, and other men who have sex with men—United States, 2017. *MMWR Morb Mortal Wkly Rep.* 2017, August 11;66(31):830–832.

DIAGNOSIS AND WORKUP

Diagnostic Testing

Box 178.2 lists the most recent CDC guidelines for HIV testing (from 2006 and 2017).[7,8] These guidelines advise routine HIV screening of adults, adolescents, and pregnant women in health care settings in the United States. The recommendations also call for reducing barriers to HIV testing. In April 2013 the U.S. Preventive Services Task Force issued similar recommendations.

Standard serological testing for the presence of HIV begins with the fourth-generation HIV 1/0/2 antigen/antibody test that uses synthetic peptide or recombinant protein antigens to detect IgM and IgG antibodies (via enzyme-linked immunoassay technique) and monoclonal antibodies to detect the presence of p24 antigen. If this is positive, then a reflex test is done to distinguish HIV-1 from HIV-2 infection. The inclusion of p24 antigen detection in HIV screening has allowed for a positive result to be found 3 to 5 days before seroconversion (when HIV-specific antibodies begin to appear), thus allowing for earlier detection of an infection than was previously possible with the earlier test methods. This test has a sensitivity of between 99.76% and 100% for HIV-1 and 100% for HIV-2.[9]

A number of rapid HIV tests have been developed and are currently approved for use by the U.S. Food and Drug Administration (FDA). They all use similar technology to detect antibodies and vary in category assigned by the Clinical Laboratory Improvement Amendments (CLIA) from "waived" to "moderately complex." Options include Chembio DPP HIV-1/2, Chembio Sure Check HIV1/2 Assag, Clearview HIV 1/2 Stat-Pak, Determine HIV-1/2 Ag/Ab Combo Test, INSTI HIV-1/HIV-2 Rapid Antibody Test, MedMira Reveal G3 Rapid HIV-1 Antibody Test, OraQuick Advance Rapid HIV-1/2 Antibody Test, and Uni-Gold Recombigen HIV.[10,11] Additionally, there are self-administered tests that have been FDA approved. Home Access

Health Corp. (www.HomeAccess.com/shop) produces a kit to detect HIV-1 where the specimen is self-obtained at home and mailed in for analysis. Results are available by phone as soon as the next business day. The OraQuick In-Home HIV Test provides results at home in 20 minutes. These tests use either whole blood, serum, plasma, or oral fluids and have sensitivity and specificity rates of 99% to 100%.[12–14]

If an HIV screening test is negative and risk factors suggest likely infection, the test should be repeated at 6-week, 3-month, and 6-month intervals. There is no reason to repeat if one of those tests comes back positive.

Although routine testing is now recommended, HIV testing remains voluntary and should be performed only with the patient's knowledge and understanding. Patients should be informed either orally or in writing of testing recommendations and that testing will be performed unless they decline (termed "opt-out" screening). A patient's decision to decline an HIV test should be documented in the medical record. It is recommended that HIV screening consent be incorporated into the patient's general informed consent for medical care form in the same way other screening or diagnostic tests are. A separate consent form for HIV testing is not recommended. Risk screening should be incorporated into routine primary care and risk reduction counseling offered as applicable. All states require that newly diagnosed cases of HIV/AIDS be reported to local health departments and that providers have case reporting forms available.

Medical History

Initiation of care of an HIV+ patient should begin with a standard medical history, including a detailed diet history, exercise patterns, and a complete review of systems. A number of additional historical details should be obtained as well (Box 178.3).

BOX 178.3 Historical Data Recommended for HIV-Positive Patients

- Dates of infection and subsequent diagnosis, as well as probable source of infection (IV drug use, sexual contact, transfusion). If date of infection is unknown, the naturopathic physician should determine whether there was any history of acute retroviral syndrome. Additionally, past and current risk factors for HIV exposure should be determined. This information helps estimate overall health and vital force and long-term prognosis.
- Vaccination history and adverse reactions to past vaccines.
- History of other sexually transmitted diseases. This information should include date and duration of infection as well as therapies (efficacy, adverse reactions, and duration of treatment). Particular infections to screen for include syphilis, gonorrhea, *Chlamydia,* herpes simplex (all types), hepatitis (A, B, and C or E), and HPV (skin, genital, or anal).
- Chronological history of HIV-related problems, including history of OIs or cofactor viruses/infections (mononucleosis, EBV, molluscum contagiosum, CMV, or yeast infections—vaginal, gastrointestinal, skin), skin rashes or other lesions, oral lesions or tongue coating, lymphadenopathy, fevers, night sweats, weight loss, diarrhea, anorexia, fatigue, malaise, shortness of breath, or cough.
- Specific for females, history of abnormal Pap smears and frequency of gynecological examinations.
- HIV viral load and trend of CD4 count (both currently and historically if known); good indicators of the patient's susceptibility to OIs, indication for and effectiveness of HAART, as well as long-term prognosis.
- History of all past and present HAART, history of any prophylactic antibiotic prescription medications, and all other current medications and supplements, with duration of treatment, response and side effects, intolerance, and allergies.
- Family history of chronic disease, with particular emphasis on cardiovascular disease (including lipid problems), diabetes, and cancer.
- History of psychoemotional trauma and issues (abuse history, anxiety, depression).
- Patients' spiritual lives and support systems, life goals, and meaning of HIV in their lives.
- Clear identification of complete medical care team as well as reasons for seeking naturopathic medical care.
- The initial physical examination must be both comprehensive and appropriately focused as directed by the history. In addition, all patients should have particularly thorough examinations of the mouth and throat, skin, and genitalia. If a full pelvic examination and Pap smear cannot be done on a new female patient at the initial evaluation, these should be scheduled for shortly thereafter (the exception being if one of their other providers does this at appropriate intervals).

CMV, Cytomegalovirus; *EBV,* Epstein–Barr virus; *HAART,* highly active antiretroviral drug therapy; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *IV,* intravenous; *OI,* opportunistic infection.

Laboratory Assessment and Monitoring

Basic initial screening tests for all HIV+ patients should include a complete blood count (CBC) and a fasting serum chemistry panel (to monitor liver, kidney, and pancreatic function; electrolytes; blood proteins; glucose; and lipids). The baseline serum albumin level can serve as an independent predictor of prognosis in HIV+ women.[15] Additional testing should include a urinalysis, screening for STDs (syphilis, herpes simplex, *Chlamydia,* and gonorrhea—including oral/urinary/rectal areas), hepatitis (A, B, and C), toxoplasmosis, tuberculosis, and varicella (if unknown history of chickenpox or shingles). An optional test is glucose-6-phosphate dehydrogenase (based on risk factors).[13] Female patients should have regular Pap smears with initial testing for human papillomavirus (HPV) because there is a significant increase in cervical cancer rates in HIV+ women.[16] A recent development is the use of the anal Pap smear in male patients engaging in anal sex. Anal squamous cell cancer is similar to cervical cancer in that it is caused by HPV infection, and rates are significantly increased in HIV+ men compared with the general population. Currently, there continues to be controversy about the use of this test, with no clear consensus on whether to make it part of routine screening.[13] Studies are ongoing, which should help clarify this. One such study is the multicenter Anchor Study, begun in 2017 and involving 5058 participants over an 8-year study period. The goal of the study is to determine whether routine anal screening, detection, and removal of high-grade squamous intraepithelial lesions (HSILs) will reduce the occurrence of more severe anal cancers in HIV+ men.[17]

HIV-specific testing includes measurement of viral load and T-cell counts as part of the initial evaluation and then at 3- to 6-month intervals. The viral load test detects the presence of viral RNA in the plasma or DNA in white blood cells (WBCs) and uses PCR branched-chain DNA (bDNA) or nucleic acid sequence–based amplification technology. A number of viral load tests exist, with varying levels of sensitivity. The most sensitive test currently available detects virus to 20 copies per cubic millimeter of plasma.[18] Below any specific test's threshold, the viral load is deemed "undetectable." This means that the virus may still exist but in concentrations in the blood below the ability of the given test to detect. Additionally, note that these assays are not reflective of viral presence or concentration in body compartments beyond the blood (e.g., tissues, cerebrospinal fluid, breast milk, seminal fluid, vaginal fluid).

Other key tests involve T-cell counts. CD4+ helper cells and CD8+ suppressor cells are quantified (absolute numbers and relative

percentages), along with the CD4:CD8 ratio. These tests are known as CD4:CD8 ratio panels. This information is used to stage HIV, predict susceptibility to various OIs, and monitor response to antiretroviral therapy. Many factors can influence CD4+ cell counts, including total WBCs, acute infection, certain medications (e.g., corticosteroids, interferon), and other medical conditions. There are also seasonal and diurnal variations in these counts.

In 2014, the guidelines on HIV-specific testing were altered as a reflection of the success of HAART. Once a person's CD4+ count is above 500 cells/mm^3, his or her immune system is thought to be fully reconstituted and functional. As long as the CD4+ count has remained above 500 cells/mm^3 and he or she has had an undetectable viral load for 2 years, then continuing to check the CD4+ count is now considered optional. From this time on, all that is now checked is HIV viral load once yearly, and as long as this remains undetectable, then the CD4+ is expected to stay stable and in a safe range. If the viral load becomes consistently detectable, then it would become necessary to check CD4+ cell counts again.[19]

Resistance to antiretroviral medications is a growing problem in treatment-naive patients and remains a potential problem in patients already undergoing this therapy. Therefore resistance testing is now recommended at the time of diagnosis as part of baseline screening as well as before changing therapy because of the failure of a current regimen. Two types of tests are available: genotypic and phenotypic. There are advantages and disadvantages to each, but in general, this testing can help identify antiviral medications that the patient might be either resistant or susceptible to and thereby allow the physician to formulate the most effective medication regimen.[13]

THERAPEUTIC CONSIDERATIONS

Medical Management of HIV and AIDS

The medical understanding and treatment of HIV/AIDS continue to evolve. AIDS is a complex, multifactorial disease that has both immunodeficiency and autoimmune inflammatory aspects involving virtually every system of the body. HIV enters the body and infects CD4+-expressing cells of the immune system. It inserts itself into cellular DNA and can lie dormant indefinitely. Those cells can be activated for the reproduction and multiplication of HIV virions by antigens, oxidative stress, proinflammatory cytokines, and overstressed liver detoxification and immune systems.

Conventional medical management of HIV/AIDS revolves around the following treatment principles:

- Frequent monitoring, including laboratory and physical examination
- Vaccinations administered as appropriate (may include hepatitis A, hepatitis B, influenza, mumps-measles-rubella [MMR], pneumonia tetanus-diphtheria, varicella, HPV, and travel-related vaccines)[13]
- HAART for inactivation or slowing HIV replication and increasing CD4+ cell counts
- Antibiotic prophylaxis for patients with abnormally low CD4 lymphocyte counts
- Antimicrobial treatment of OIs
- Symptomatic care of HIV- or HAART-induced adverse drug reactions
- Radiation, chemotherapy, or both for HIV-related neoplasms
- Psychosocial support via counseling, clinical social work, and medication

Up-to-date resources should always be consulted before making any management decisions. The AIDS information website, administered by the U.S. Department of Health and Human Services (https://aidsinfo.nih.gov), provides an excellent resource for understanding all aspects of HIV/AIDS, including determining the most up-to-date conventional treatment guidelines as well as information on prevention, FDA-approved and investigational drugs, clinical trials, and vaccinations. Another fine resource is the Johns Hopkins HIV Guide (https://www.hopkinsguides.com/hopkins/index/Johns_Hopkins_HIV_Guide). This HIV guide provides detailed information on the diagnosis and management of HIV and its associated OIs, medications, and resistance. Note that some areas of the site require a subscription for access. Johns Hopkins University School of Medicine/Knowledge Source Solutions LLC also publishes a helpful text called the *Medical Management of HIV Infection* (2012, 16th ed, by J. G. Bartlett, J. E. Gallant, and P. A. Pham). It can be ordered online. Excellent resources also exist for both clinician and patient education. These include the websites www.positivelyaware.com, www.poz.com, and www.thebody.com. These sites each have their strengths, but all have valuable information on various aspects of HIV, including signs, symptoms, conventional treatments, detailed drug information, some patient-centered complementary treatments, as well as future possibilities for treatment.

HIV Prevention Strategy and the Continuum of Care

Over the past several years, with the success and availability of HAART medications throughout the world, there has been a shift in focus in HIV care and management from how to cope with so many very sick people to thinking about how we can prevent of the further spread of HIV. This has resulted in a strategy known as "treatment as prevention." It is based on recent studies showing that if a person's HIV viral load is undetectable, then there is an extremely low risk of that person having enough free virus in his or her system to infect someone else.[20] Worldwide, the strategy for prevention of HIV spread is known as "90/90/90," and the goal is to have it implemented by the year 2020. This means that 90% of people who are HIV+ will know it. And of those, 90% will be on antiretroviral therapy. And of those, 90% will have an undetectable viral load. Therefore those HIV+ individuals who are being treated and undetectable will not be vectors for the further spread of the disease. This will ultimately result in far fewer new infections.

In the United States this prevention strategy is effectively being implemented by targeting at-risk populations with education about transmission, getting at-risk people tested regularly (to identify individuals who are positive), and then getting into care when there is a positive test result. The National HIV Care Continuum has identified and monitors the steps required from the time a person is diagnosed with HIV to achieve viral suppression. It involves testing to achieve the diagnosis; linking them to care; and making sure they are engaged in and retained in care, that they are prescribed and take antiretroviral therapy, and they get to the point where they are virally suppressed and remain that way.[21]

The other key piece of the worldwide prevention strategy is the use of pre-exposure prophylaxis (PrEP). In the United States the CDC first issued guidelines about PrEP use in 2012, and they have since gone through some minor revisions, but the principle and use are unchanged. The concept is that a person who is HIV negative but at risk for contracting HIV takes a daily antiretroviral medication (initially approved with Truvada and now Descovy is an option as well; both are discussed in the section on antiretroviral therapy that follows) that prevents them from becoming infected should they be exposed to the virus. This implementation of this strategy was initially based on four key studies, the iPrEx, TDF2, Partners PrEP, and Bangkok Tenofovir studies.[22–25] These studies variously followed both heterosexual and homosexual discordant couples and men and women using intravenous drugs in multiple locations. All the studies showed a significant

reduction in risk of acquiring a new HIV infection—up to 92%, with the best results coming with rigorous adherence to the regime of daily use. Based on this, PrEP has become a key HIV prevention recommendation in high-risk individuals. The CDC maintains excellent resources with regard to PrEP for both consumers and providers. This includes detailed instructions on how to administer Truvada and how to monitor patients.[24] Note that regular HIV testing (every 3 months) is part of the process because it is critical that any individual who has contracted the virus despite the PrEP be identified so that they can be placed on effective HAART treatment (Truvada alone is insufficient and is likely to lead to resistance issues). Note also that the use of barrier methods such as condoms is still recommended to protect against other sexually transmitted infections as well as further lower the risk of HIV transmission.

On October 3, 2019 the FDA approved a second medication, Descovy, for PrEP. Descovy is similar to Truvada in that it contains two similar medications but with one of them being a safer variant. The approval was based on preliminary data from the ongoing DISCOVER trial. In this multi-year phase 3 trail, 5300 HIV at-risk cisgender men having sex with men and transgender women having sex with men were provided with PrEP with either Truvada or Descovy. After 96 weeks, Descovy was found to be non-inferior to Truvada in preventing HIV infection. Efficacy was strongly correlated with daily dosing. Note that Descovy also has advantages over Truvada in areas of renal safety and bone density. While Truvada will end up being more economical than Descovy due to its age, Descovy could be an excellent option for any individual with renal or bone density issues.[26]

For the naturopathic physician, practical actions toward prevention can include the following:

- Talk to patients about sex to determine risk factors, educate about how HIV and other sexually transmitted infections are transmitted, and educate about safer sex practices.
- Recommend HIV testing at appropriate intervals based on individual risk factors and CDC guidelines.
- Recommend PrEP as appropriate. This includes helping patients to access the medication should they desire to use it.

Naturopathic Management of HIV and AIDS

The naturopathic medical management of HIV and AIDS revolves around a number of treatment principles that should guide the physician in helping patients to optimize their health, slow disease progression, improve their quality of life, and improve immune function.

Specific goals include the following:

- Enhance overall integration with primary care physicians and build a caregiving team.
- Complement and enhance the positive effects of conventional medical treatment and minimize the negative effects.
- Establish a foundation of health and wellness on the basis of naturopathic principles.
- Establish a core nutrient protocol:
  - Replace nutrient deficiencies known to exist with HIV.
  - Provide other nutrients to support optimal immune function.
- Provide therapies to address constitutional symptoms, medication side effects, and symptoms of immunosuppression.
- Provide specific antiviral therapy and immunomodulation using other, nondrug treatments.

Enhance Overall Integration With Primary Care Physicians and Build a Caregiving Team

In the area of HIV, naturopathic physicians should lead the effort to optimize integrated care. A holistic provider who identifies advantages of all available treatments and encourages positive relationships with all available providers creates a unique and trusting relationship with patients who have often experienced lifetimes of fear, discrimination, victimization, and abuse. Naturopathic medicine offers an important opportunity to empower HIV+ patients.

One of the first priorities is to ensure that each HIV+ patient has a complete care-providing team beginning with a conventional Western medicine HIV specialist. HIV specialists ensure the accessibility of HAART and have the greatest familiarity with the multitude of signs, symptoms, adverse reactions, and other issues unique to the HIV+ population. A growing body of literature reports that HIV+ patients have better objective indices of health (low viral load and high CD4 counts), better compliance with medications, and better long-term survival when they work with HIV specialists.[27,28]

The specialist's obligations constitute a full-time job, precluding many other aspects of care that have demonstrated efficacy for the overall health of HIV+ patients. Additional providers can support HIV+ patients with general health and lifestyle promotion, specific nutrient and other nondrug recommendations, social services, psychoneuroimmunological support, counseling, personal empowerment, and end-of-life care. In fact, although naturopathic physicians might be legally able to prescribe prophylactic antimicrobial therapy and HAART in a growing number of states, the greater need is to provide nondrug holistic care in the areas just mentioned.

Complement and Enhance the Positive Effects of Conventional Medical Treatment and Minimize the Negative Effects

One of the paradigms of natural/preventative/holistic medicine is to minimize the need for higher-force (drug, surgery, radiation) interventions. This goal remains valid in the care of patients with HIV, but there are no therapies known to be as effective as HAART in suppressing viral load or increasing CD4 T-lymphocyte cell numbers. CAM providers may be the best practitioners to teach HIV+ patients that there are no realistic s"alternatives" to HAART.

Some HIV+ patients may never need HAART, and others may be resistant to HAART, but the option of HAART should always be considered, and its use is the current standard of care; therefore it should not be discouraged. With or without HAART, there is significant evidence that HIV+ patients receive many benefits from nondrug therapies.[29] Naturopathic physicians must actively understand, integrate, and use the entire therapeutic order (most subtle, lower-force through most high-force, often-invasive therapies) to ensure that each patient has the best options to maximize his or her quality of life as well as length of life. Finally, physicians working with HIV must stay current with the global effort to find solutions for this pandemic to provide the best possible treatment options to match patients' short-term needs while also including strategic health goals and future possibilities.

Factors to be considered in the holistic care of HIV+ patients include complications (from immune suppression) of health challenges that existed before HIV infection. In addition, the social, psychological, and spiritual challenges that exist with the diagnosis of HIV create a need for health care that extends far beyond the best drug or nutrient necessary for optimal health. Holistic physicians have a vital role in the care of each patient with HIV.

The majority of HIV+ patients in North America are using HAART. Many of those same patients are also using CAM therapies. Therefore one of the first priorities of the naturopathic provider should be to ensure that the patient is safe from adverse drug–nutrient interactions. To

ensure safety, it is necessary to understand the mechanisms of HAART as well as those of common nutrients being used by HIV+ patients.

Conventional Treatment: Highly Active Antiretroviral Therapy

The use of HAART has been the standard of care in HIV treatment since 1996 when multiple classes of medications came into existence and it was found that using multiple drugs of multiple classes was more effective at suppressing HIV virus as well as preventing resistance issues than single drug/class regimes.

In terms of when to start HAART, the risks of OIs and other serious complications increase exponentially when CD4 cell counts drop below 200/μL. Until 2015, the standard of care was to initiate HAART when the CD4 count dropped below 350/μL in asymptomatic patients, those with an AIDS-defining illness (regardless of CD4 count), pregnant women, patients with HIV-associated nephropathy, or hepatitis B coinfection (when treatment of the hepatitis is indicated). HAART initiation could be considered when CD4 cell counts are greater than 350/μL in discordant relationships (one partner is HIV+ and the other HIV−), rapid CD4 decline, advanced age, or high viral load (more than 100,000 copies per milliliter).[30]

In September 2015, the World Health Organization (WHO) published new guidelines on the treatment and prevention of HIV infection (http://www.who.int/hiv/pub/guidelines/earlyrelease-arv/en/). The main outcome of these new recommendations is that HAART should be initiated in most patients upon diagnosis. This was based on two studies, the START Study (Strategic Timing of Anti-Retroviral Treatment Trial) and the HPTN 052 Trial (HIV Prevention Trials Network 052 study).[20,31,32] These were large studies at multiple sites around the world. The START study concluded that immediate initiation of antiretroviral therapy significantly reduced both AIDS-related and non–AIDS-related adverse events in that population. The HPTN 052 study concluded that antiretroviral therapy is highly effective at preventing heterosexual transmission of HIV if viral suppression is achieved and maintained in the positive partner. From this, the WHO issued the new guidelines recommending HAART be initiated in everyone upon diagnosis (with some case-specific caveats). The U.S. guidelines (published July 14, 2016) made similar recommendations for HAART initiation.[33]

The choice of specific antiretrovirals for either initial regimens or the modification of existing therapy is complex, and there are many factors to consider. Additionally, the guidelines change frequently. The best resource for the most current recommendations is the "Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents Living with HIV," available on the AIDS information website https://aidsinfo.nih.gov/guidelines/html/1/adult-and-adolescent-arv/0. The most recent guidelines were updated as of May 30, 2018.

Six main classes of HAART are currently being used in the care of HIV+ patients in various combinations designed to disrupt the life cycle of the virus at multiple junctures.[30] These include the following:

- Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs, or "nukes")
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs, or "non-nukes")
- Protease inhibitors (PIs)
- Entry inhibitors (including fusion inhibitors, CCR5 inhibitors, and monoclonal antibodies)
- Integrase strand transfer inhibitors
- Pharmacokinetic enhancers

Over the past several years, a number of single-tablet, fixed-dose, multiclass formulations have been developed. This has helped to simplify dosing and decrease pill burden for patients using HAART. These single-tablet regimens (STRs) are rapidly becoming the most commonly used forms of HAART as of 2019.

As a result of the rapidly evolving resistance of HIV to specific drugs, there has historically been great pressure to quickly develop and approve new medications. As a result, many HAART medications have been generally fast-tracked through the FDA approval process. Therefore new drugs have been typically prescribed as soon as they are approved and usually before the full extent of their adverse reactions are known. Because the adverse drug reactions and interactions with HAART are myriad and potentially quite harmful, the clinician is advised to consult up-to-date resources to determine specific issues with each individual medication.

Nucleoside/nucleotide reverse transcriptase inhibitors. NRTIs were the first class of antiretroviral drugs approved for use in the United States by the FDA. These drugs work during the transcription phase of the HIV life cycle by competitive inhibition of HIV reverse transcriptase (RT), leading to DNA chain termination. Nucleoside (or nucleotide) analogues act as substrates and bind to the active site of the RT enzyme. Then they are added to the new chain of DNA. Once they have been inserted, the normal links between pieces of the chain will not form, and the viral chain will be terminated without being inserted into the cell's DNA.

The following is a list of NRTIs; all are nucleoside analogues except tenofovir, which is the only nucleotide analogue that is FDA-approved:

- 3TC: lamivudine (Epivir)
- ABC: abacavir (Ziagen; patient must be HLA-B*5701 negative if used)
- AZT: azidothymidine, zidovudine (Retrovir; the first FDA-approved HIV medication in 1986)
- DDC: zalcitabine (Hivid; no longer manufactured)
- DDI: didanosine (Videx, Videx EC)
- D4T: stavudine (Zerit)
- FTC: emtricitabine (Emtriva)
- TDF: tenofovir disoproxil fumarate (Viread, a nucleotide)
- TAF: tenofovir alafenamide (a "prodrug" form of TDF)

As of 2019, it is extremely rare to see AZT, DDC, DDI, or D4T used because there are many safer and easier-to-use alternatives.

There are several combination formulations of NRTIs in existence:

- Trizivir: 3TC, AZT, and ABC (no longer in use)
- Combivir: 3TC and AZT (no longer in use)
- Epzicom: 3TC and ABC
- Truvada: FTC and TDF
- Descovy: FTC and TAF
- Cimduo: 3TC and TDF

Truvada and, as of October 2019, Descovy have both been approved for use as PrEP for individuals in high-risk categories of exposure to HIV. Either one is given as a single tablet once daily. Daily use is important for maintaining efficacy.

In April of 2016 the FDA approved tenofovir alafenamide (TAF) for use. It is a "prodrug" form of TDF that is used in much lower doses and becomes activated once it's inside individual cells. It has a reduced profile of adverse effects versus its predecessor, TDF, which can affect kidney function as well as create problems with bone mineral density. The TAF form alleviates these issues. TAF is not available as a stand-alone but is found along with FTC as Descovy (as well as some specific single-tablet formulations). It is approved for the same uses as Truvada in HIV infection but is not approved for PrEP or post-exposure prophylaxis (PEP).

NRTIs have effectively become the "backbone" of all HAART regimes. Unless there are resistance issues, every regime will contain Truvada, Descovy, or Epzicom, either directly or as part of an STR.

The NRTIs are fairly well tolerated after introduction (initial mild to severe nausea usually resolves), with minimal long-term adverse

effects. Exceptions include AZT and the remaining "D" drugs (DDI and D4T). A common side effect of AZT is bone marrow suppression, leading to macrocytic anemia.[34] The D drugs are less commonly used today except in the case of multidrug resistance. They have been associated with mild to severe peripheral neuropathy and, of greater concern, pancreatitis.[35] These side effects manifest secondary to neural inhibition of mitochondrial DNA polymerase and reduced mitochondrial DNA content.[36] Therefore patients who have been on D drug therapy should be provided with ample mitochondrial support. Acetyl-L-carnitine, coenzyme Q_{10} (CoQ_{10}), essential fatty acids (EFAs), α-lipoic acid, and B vitamins have been shown to decrease signs or progression of these side effects when taken in large doses.[37–41] Additionally, the thymidine analogues (d4T, ddI, AZT) have been associated with lipoatrophy, also as a result of mitochondrial toxicity. Because the NRTIs have been on the market longer than the other drugs, it is no surprise that they are backed with the greatest amount of research regarding nutrient interactions. Although there are no studies indicating that vitamins or other nutrients deplete AZT, there is evidence that AZT may deplete cellular levels of carnitine, copper, zinc, and vitamin B_{12}.[42,43] With the exception of carnitine, these nutrients can be found in a good hypoallergenic multivitamin/multimineral supplement. In addition to deficiency caused by NRTI drugs, carnitine deficiency has been found in HIV+ patients not on HAART. Further, there are many other indications for carnitine in patients with HIV, making this nutrient a high priority for supplementation.

Some nutrients have been found to enhance the efficacy of NRTIs when taken in combination with these drugs, including vitamin E, zinc, and folate.[44–46] These nutrients are easily supplemented through a nutritious diet full of whole grains, colorful vegetables, and fruits and a good multivitamin/multimineral supplement.

Overall, NRTIs are fairly well tolerated, and some have the additional benefit of being active against hepatitis B virus (3TC, FTC, TDF).[47–49]

Nonnucleoside reverse transcriptase inhibitors. The second class of HAART comprises the NNRTIs. NNRTIs also affect the transcription process and work by allosterically binding to HIV-1 reverse transcriptase and inhibiting both RNA- and DNA-directed DNA polymerase functions of the RT enzyme.

The following is a list of the NNRTIs:

- EFV: efavirenz (Sustiva)
- ETV: etravirine (Intelence)
- DLV: delavirdine (Rescriptor; rarely used)
- NVP: nevirapine (Viramune XR)
- DOR: doravirine (Pifeltro)
- RPV: rilpivirine (Edurant)

NNRTI drugs are also fairly well tolerated after introduction, with low long-term toxicity. Other than an initial transient mild to severe skin rash, typical side effects (depending on the specific drug) include insomnia, abnormal dreams, elevated liver enzymes, and gynecomastia (all manageable with naturopathic support).[50–52] Resistance to this class of HAART can occur easily if the viral load is unsuppressed, so this type of medication may not be an optimal choice for someone who is inconsistent with taking medications. No nutrients are known to be depleted by NNRTIs or to enhance their efficacy.

Large randomized, double-blind, placebo-controlled studies have shown that when used in combination with NRTIs, NNRTIs produce sustained reductions in plasma viral loads and improvements in immunological responses.[53–56] The advantages of this type of protocol include the fewest number of side effects, excellent long-term viral suppression, and ease of dosing (fewer pills).

Protease inhibitors. The third class of HAART is the PIs. PIs intervene during the cleavage part of the viral life cycle by binding competitively to the substrate site of the viral protease (the enzyme responsible for the posttranslational processing), resulting in inhibition of the enzyme and the production of immature virus particles.

The following is a list of the PIs:

- ATV: atazanavir (Reyataz)
- DRV: darunavir (Prezista)
- FPV: fosamprenavir (Lexiva)
- IDV: indinavir (Crixivan)
- LPV-r: lopinavir + ritonavir (Kaletra; fixed-dose combination)
- NFV: nelfinavir (Viracept)
- SQV: saquinavir (Invirase)
- TPV: tipranavir (Aptivus)

Although PIs are effective at viral suppression, they are associated with the greatest number and most significant adverse drug reactions, and as of 2018, with the availability of equally effective classes with much fewer adverse reactions, they are being used less frequently. Adverse reactions include chronic and persistent gastrointestinal (GI) abnormalities; lipodystrophy and lipoatrophy; elevations of cholesterol and triglycerides; insulin resistance leading to diabetes; and liver, kidney, and musculoskeletal complaints.

Note that PIs are typically used in a "boosted" form. That is, they are given along with another class of HAART called a pharmacokinetic enhancer that inhibits the enzyme responsible for their metabolism and thereby raises their blood levels and their effectiveness. They have traditionally been given as two separate medications; however, there are three single-tablet combinations available. Kaletra (lopinavir + ritonavir) is the oldest example of this. Newer options include Evotaz (atazanavir + cobicistat) and Prezcobix (darunavir + cobicistat).

In understanding these "boosted" forms of HAART, it is essential to realize that NNRTIs and PIs work by inhibiting cytochrome P450 3A4 enzyme metabolism. Inhibition of this enzyme slows down the metabolic breakdown of the drug and effectively prolongs higher blood levels, which results in better viral suppression. Many foods, nutrients, and botanicals have been known to upregulate this enzyme function, and two have gained noteworthy attention. Some small studies (of fewer than 25 subjects) in healthy HIV-negative (HIV−) individuals as well as in vitro studies have demonstrated that garlic and St. John's wort decrease NNRTI and PI drug levels. In the human trials, subjects initiated NNRTI or PI therapy to establish the drug levels theoretically necessary to suppress viral load. Garlic or St. John's wort was then introduced at levels typically used for therapeutic effect. Blood levels were then measured and found to be lower than the levels believed to be necessary to maintain optimal viral suppression. Garlic or St. John's wort was then discontinued and NNRTI or PI blood levels subsequently measured and found to be back in the therapeutic range.[57–60] Although these studies certainly do not conclusively demonstrate that garlic and St. John's wort interfere with HAART viral suppression (small number of participants, single antiretroviral vs. typical multidrug HAART protocol, HIV− vs. HIV+, drug-naive vs. long-term HAART), these therapies should be avoided in patients with HIV on HAART. The lesson learned from these studies is to be intimately aware of the mechanisms of action when adding new non-drug therapies intended for patients on multidrug treatments. The potential for drug–nutrient interactions also should encourage and reinforce the use of the multitude of low-force interventions (e.g., diet, lifestyle, homeopathy, physical medicine, counseling) for conditions commonly treated by garlic or St. John's wort to avoid potentially decreasing NNRTI or PI blood levels and risking increases in drug resistance.

Milk thistle may be considered for the treatment of significant gastrointestinal (GI) and liver complications with PIs. To date, there have been several studies investigating the drug interactions of this herb. In one with 10 HIV−, drug-naive patients taking milk thistle at 175 mg three times daily, investigators concluded that milk thistle did not significantly alter blood levels of indinavir despite a decrease of as much

as 25% in trough levels.[61] Another study showed no effect on indinavir levels in healthy subjects.[62] Yet another tested cellular uptake of ritonavir in the presence of various herbal substances including milk thistle (silybinin) and found no change in the efflux of ritonavir or any effect on CYP 3A4.[63] An in vivo study with coadministration of nifedipine and silymarin in 16 healthy male volunteers concluded that silymarin is not a potent CYP 3A4 inhibitor in vivo.[64] Silymarin was also found to be safe with other PI combinations.[65]

The best study to date involved 15 HIV+ individuals taking darunavir and ritonavir as it is actually used in practice (600/100 mg twice daily) and giving them silymarin (150 mg three times daily) for 14 days. High-performance gas-liquid chromatography was used to measure serum concentrations of the darunavir before and at regular intervals after its ingestion through to 12 hours after taking it. Values were compared between day 0 and day 14. This study's findings showed no effect on the serum concentrations of darunavir from the silymarin. Therefore it was concluded that coadministration of silymarin with darunavir/ritonavir was safe and no dose modifications were necessary.[65]

Currently, there is no evidence suggesting that milk thistle should be avoided by HIV+ patients on HAART. No nutrients are known to be depleted by PIs or to enhance their efficacy. However, if GI side effects are present, it could lead to micro- and macronutrient deficiencies.

Entry inhibitors. There are now three classes of entry inhibitors: fusion inhibitors, chemokine coreceptor antagonists (CCR5 inhibitors), and monoclonal antibodies. They are designed to prevent the HIV virion from initially entering the CD4+ cell through its membrane.

The following is a list of the entry inhibitors:

- ENF: T-20 or enfuvirtide (Fuzeon)
- MVC: maraviroc (Selzentry)
- IBA: ibalizumab (Trogarzo)

ENF, T-20, or enfuvirtide (Fuzeon), is a fusion inhibitor that was approved by the FDA in 2003. It blocks the fusion of the virus with the target-cell membrane by binding with cell receptor gp41 proteins and thereby preventing the virus from entering the cell. This drug is unique because it is the only HAART medication administered via injection (two subcutaneous injections per day into the upper arm, thigh, or abdomen). Because of its cost and difficulty of use, Fuzeon was used only as "last resort" or salvage therapy during the mid-2000s in heavily treatment-experienced individuals in the presence of extensive viral resistance and is not designed to be used alone. With the approval of numerous new medications, Fuzeon is no longer used. It was fairly well tolerated, with the exception of injection-site irritation, allergic reactions, and an increased risk of bacterial pneumonia. There are no known drug–nutrient interactions of any clinical significance.

MVC, or maraviroc (Selzentry), is a chemokine coreceptor antagonist (CCR5 inhibitor) approved by the FDA in 2007. After HIV binds to CD4 receptors on the T-cell membrane, it then binds to one of two coreceptors, CCR5 or CXCR4. MVC is an antagonist that specifically blocks CCR5 coreceptors and prevents HIV from binding to them so that it cannot enter the cell. The limitation with this drug is that different viruses may express various coreceptors: CCR5, CXCR4, or both. A relatively expensive test called a tropism assay must be run in any individual in whom the use of MVC is being considered. This test determines whether the specific virus present binds to CCR5, CXCR4, or both types of receptors. MVC will be effective only in a patient with a CCR5-tropic virus. Significant possible side effects include an allergic reaction (rash) and liver toxicity. Other side effects can include cough, fever, cold, muscle/joint pain, stomach pain, and dizziness. If MVC is used, doses of other medications may have to be adjusted (including but not limited to NNRTIs, PIs, oral contraceptives, certain other antimicrobials). Another potential issue is that other cells of the immune system exhibit CCR5 receptors, and MVC may affect them and potentially increase the risk of other infections and cancers. As of the date of writing, this has not been seen in clinical trials.

IBA or ibalizumab (Trogarzo) is a monoclonal antibody approved for use in HIV by the FDA in March 2018. It is the first of this type of biologic medication approved for use as a treatment for HIV. It was specifically approved for use in individuals with multiple resistances to other HIV medications. It is not approved for use other than in this multidrug-resistance scenario. It works by binding to CD4 receptors on the T-lymphocytes and interferes with HIV from properly binding to those same receptors, thus blocking HIV's entry into the cell. Notably, it does not interfere with the CD4 lymphocyte's normal functioning. It is administered by intravenous infusion, with a single initial loading dose of 2000 mg, followed by 800 mg infusions every 2 weeks. It must be combined with other oral antiretrovirals, and resistance testing is imperative to identify those medications with at least some anti-HIV activity to ensure success. The main common side effects include diarrhea, dizziness, nausea, and rash. It can also trigger immune reconstitution inflammatory syndrome (IRIS). The most common laboratory abnormalities include creatinine and bilirubin elevations. There are no known drug interactions between Trogarzo and other medications (including the HIV antiretrovirals).

Integrase strand transfer inhibitors. ISTIs are one of the newer classes of antiretroviral medications, first approved for use by the FDA in 2007. These drugs disrupt the integrase enzyme, which facilitates the incorporation of HIV DNA into human DNA in the T cell and thereby prevents viral replication at that site.

Four ISTIs currently exist:

- RAL: raltegravir (Isentress)
- DTG: dolutegravir (Tivicay)
- EVG: elvitegravir (Vitekta; no longer available as a stand-alone; found only in the STRs Genvoya and Stribild)
- BIC: bictegravir (approved by the FDA in February 2018 as part of a new STR medication; it will likely not be approved as a stand-alone)

Both RAL and DTG are used quite extensively in many multidrug regimes.

ISTIs are relatively well tolerated, are easy to take, and have demonstrated a remarkable ability to increase CD4 counts and drop viral load to undetectable levels in highly treatment-experienced patients with significant resistance issues. They are now part of many first-line initial regimes based on this effectiveness and tolerability. The most common side effects include diarrhea, nausea, headache, and fever. Some other possible issues may include hypersensitivity reaction, anemia, and liver toxicity. They are metabolized by glucuronidation, and there is no interaction with the CYP450 system. Care should be taken with any drug that affects glucuronidation. Divalent cations (calcium, magnesium, zinc, iron) can bind ISTIs and can potentially interfere with absorption and activity. This includes vitamins, minerals, and antacids containing any of these minerals, and it is recommended that ISTIs not be taken with 2 hours of any of these formulations.

Pharmacokinetic enhancers. The PKs are medications that have no inherent anti-HIV activity but are used in low doses in combination with other classes of medications to boost their blood levels and make them more effective. This mechanism was previously mentioned with regard to "boosted" PIs. The PKs work by inhibiting CYP-3A4, which is a key enzyme in the detoxification pathway of certain antiretroviral medications. Because they affect CYP-3A4, there are significant interactions between any medication, herb, or nutritional supplement that involve this enzyme. Caution is therefore advised.

- RTV: ritonavir (Norvir) has been in use for the longest and has traditionally been used with protease inhibitors. It has previously been

categorized as a protease inhibitor but is included here because this most closely describes its function. It is not particularly well tolerated, with significant GI side effects, and is rarely used anymore.

- COBI: cobicistat (Tyboost) is the newest of this class and is typically better tolerated. It can raise serum creatinine and decrease creatinine clearance, an effect that is reversible when stopped. It is used in some STRs (Stribild and Genvoya) and two boosted PIs (Evotaz and Prezcobix).

Single-tablet regimens. Over the past several years, there has been a trend in the medical treatment of HIV toward the use of multiclass combination STRs. The STRs are single tablets that are taken once daily and consist of a full complement of fixed doses of the medications needed to effectively suppress HIV replication. These formulations have allowed for the simplification of HIV treatment, resulted in a decrease in issues with adverse effects, and significantly reduced the daily pill burden for those individuals taking them. The STRs are now commonly used as initial treatment as well as an alternative for patients who have been on other, more complicated regimes. Side effects and interactions are all related to the individual drugs that make up each single tablet, and it is recommended that each be researched. As previously mentioned, all STRs (with the sole exception of Juluca) have as their backbone NRTIs, to which some other class of medication is added. In some instances, a PK is included; others do not include a PK.

NRTI- and NNRTI-based STRs include the following:

- Atripla: FTC, TDF, EFV
- Complera: FTC, TDF, RPV
- Delstrigo: 3TC, TDF, DOR (approved by the FDA August 2019; note that it contains TDF rather than the safer TAF)
- Odefsey: FTC, TAF, RPV
- Symfi and Symfi Lo: 3TC, TDF, EFV (both approved by the FDA in 2018)

NRTI- and ISTI-based STRs include the following:

- Biktarvy: FTC, TAF, BIC (approved by the FDA in November 2017 as maintenance therapy in already virally suppressed individuals; now used as an initial regime)
- Dovato: DTG, 3TC (approved by the FDA in April 2019 as an initial regime in individuals where ABC, TAD, TAF cannot be used)
- Genvoya: FTC, TAF, EVG, COBI
- Stribild: FTC, TDF, EVG, COBI

NNRTI: and ISTI based:

- Juluca: DTG, RPV (approved by the FDA in November 2017 for maintenance therapy in an already virally suppressed individual)

NRTI- and PI-based STRs include the following:

- Symtuza: FTC, TAF, DRV, COBI (the first of the PI-based fixed-dose single-tablet treatments; FDA approved on July 17, 2018)

New Approaches. One promising new approach to antiretroviral therapy involves the use of long-acting injectable medications as an alternative to daily oral regimens. These are given at predetermined intervals and alleviate the need for patients to take daily medications. The Latte 2 trial is a Phase IIb trial that used an investigational ISTI (cabotegravir) with an existing NNRTI (rilpivirine). Once the study subjects were virally suppressed on an oral medication regime, they were switched to the injectable medication combination at either 4- or 8-week intervals, with another group maintaining the oral regime as controls. After 32 weeks, 94% of the 4-week group, 95% of the 8-week group, and 91% of the oral group maintained viral suppression. At the 96-week mark, 87% of the 4-week group, 94% of the 8-week group, and 84% of the oral group maintained viral suppression. The main side effects were site reactions and pain, both of which were more pronounced in the 4-week versus 8-week group. The patients involved in the study reacted quite favorably to it.[66,67] The results at 96 weeks for the 8-week study group are quite impressive, and the use of injectable antiretrovirals may prove to be a viable strategy for treating individuals who are in situations where they cannot effectively maintain a daily oral regimen.

Establish a Foundation of Health and Wellness on the Basis of Naturopathic Principles

The naturopathic standard of incorporating healthy diet and lifestyle practices cannot be overemphasized for HIV+ individuals. These patients are likely to be taking a large number of medications, nutritional supplements, or both, resulting in additional biochemical stress on the body. Therefore each patient should be clearly encouraged and continually reminded to maintain dietary habits designed to ensure optimal GI health and nutritional intake.

The most important recommendation is to encourage a high intake of filtered or safe water and fiber so as to decrease oxidative stress and reduce the toxic load of the HIV and medications.[68] These patients should also be encouraged to maintain an optimal intake of protein.[69,70] Protein requirements can be as high as 100 to 150 g per day, particularly when patients are experiencing malabsorption and/or diarrhea; it may be necessary to provide supplemental protein to prevent weight loss. Studies using large doses of whey protein and amino acids (L-glutamine, L-arginine) have proved effective in reversing or preventing HIV-induced wasting.[71–73] Essential fatty acids (EFAs) have also been found to be deficient in HIV+ patients. Studies have demonstrated that HIV+ patients consuming generous amounts of EFAs have an increased body cell mass and a decreased risk of progression to AIDS[74–76] as well as improved symptoms of depression.[77]

HIV+ patients and healthy subjects ingesting fruit juices or a fruit-vegetable concentrate on a long-term basis were found to have higher micronutrient and antioxidant levels.[78,79] From this, it can be concluded that HIV+ patients should be continually encouraged to include colorful vegetables and fruits in their diets to help maintain levels of essential micronutrients and fiber.[80,81]

HIV+ patients commonly require appetite stimulation, digestive enzyme support, or both to combat the adverse effects of HIV, HAART, and prophylactic antibiotics on the GI system.[82,83] Further, with high oxidation already present in the digestive system, all patients should be strongly encouraged to avoid additional GI stressors such as high-sodium foods, high-fructose corn syrup in processed foods, alcohol, caffeine, fried foods, and cigarette smoke. Raw eggs, unpasteurized milk, undercooked meat or fish, and potentially contaminated foods must also be avoided to decrease the risk of gastrointestinal OIs and parasites.

Naturopathic physicians should exercise extreme caution in considering allergy-elimination diets in HIV+ patients owing to the likelihood of nutrient deficiencies, maldigestion, and malabsorption caused by HIV itself and HAART medications. A safer alternative is to recommend replacement of common food allergens one food at a time to make sure that patients can maintain replacement diets without decreasing caloric and nutrient intake over time. Removing food vices and irritating foods may be one of the most challenging aspects of moving HIV+ patients toward optimal wellness because there are so many other higher-priority challenges and a vital need to maintain body mass.

Lifestyle factors should be part of the naturopathic foundation with each HIV+ patient. Aerobic exercise has been demonstrated to provide benefit to individuals with immunodeficiency diseases, particularly through stress alleviation and mood enhancement. HIV+ individuals had increases in CD4, CD8, and NK cells immediately after aerobic exercise, and long-term exercise has demonstrated increases in immune parameters.[84,85] HIV+ individuals practicing Tai qi demonstrated a greater overall perception of health and significant improvements in several measures of physical function compared with

controls.[86] Other patients practicing yoga demonstrated an increased quality of life (QOL)[87,88] and reported increased self-confidence, reduced blood pressure,[89] and a quicker return to athletic activities after medical interventions.[90]

All patients should be encouraged to create an optimal sleeping environment and to sleep 8 to 10 hours each night. Sleep is essential for the repair and rebuilding of tissues and has been demonstrated to increase circulating NK cells and lymphocytes.[91,92]

Screen for obstructive sleep apnea. Uncontrolled sleep apnea can result in a host of adverse health issues that can be alleviated if the issue is identified and treated. Simple in-office screening can be done using the STOP-BANG questionnaire (http://www.stopbang.ca/osa/screening.php). Based on a patient's answers and situation, a score is obtained that gives a low, intermediate, or high likelihood of the presence of obstructive sleep apnea. If there is intermediate or high risk, clinicians should consider referring the patient for further evaluation with a qualified sleep medicine specialist.

HIV+ patients involved with group activities have better prognoses as well as decreased stress and anxiety. Anecdotal evidence links long-term AIDS survival with one or more of the following: having a positive attitude toward the illness, participating in health-promoting behaviors, engaging in spiritual activities, and taking part in activities that support the HIV+ community. Structured, brief group intervention for bereavement due to the loss of loved ones has been shown to decrease plasma cortisol and improve several immune markers in patients with HIV.[93,94] Other forms of stress relief and management have proved effective for HIV+ patient health care. Cognitive-behavioral stress management is a guided form of relaxation training. It has been shown to improve the quality of life in HIV+ women, decrease herpes simplex 2 antibody titers in HIV+ men, improve HIV laboratory values, and have lasting effects on quality of life and psychological well-being of patients.[95–100] Mindfulness-based stress reduction was able to demonstrate increased mean CD4 counts in patient HIV+ ART-naïve patients.[101]

Engaging in prayer, including distance healing, has demonstrated fewer new AIDS-defining illnesses, decreased illness severity, significantly fewer doctor visits, fewer hospitalizations, and significant improvements in mood.[102,103] For individuals not on HAART, participation in spiritual activities (prayer, meditation, affirmations, psychic healing, visualizations) resulted in a reduced risk of death over a 1-year period.[104] Finally, laughter has been associated with improvement in WBC values and decreased stress.[105]

Establish a Core Nutrient Protocol

Replace known nutrient deficiencies caused by HIV. Vitamin and mineral replenishment has been demonstrated to be efficacious in HIV+ patients.[106–109] A double-blind placebo-controlled study involving 1078 pregnant Tanzanian women infected by HIV reported that taking vitamin A (preformed vitamin A and beta-carotene) and a low-cost multivitamin (vitamins B, C, and E) resulted in delayed progression to AIDS as well as a delay in the requirement to initiate antiretroviral therapy. Adding the low-cost multivitamins was statistically significant versus placebo or vitamin A alone.[110] Numerous vitamin and mineral deficiencies have been identified with HIV disease progression.[111] These deficiencies are likely due to loss, poor absorption, or rapid use and consumption.

Box 178.4 summarizes the nutrients that have been found to be deficient in patients with HIV. Typical daily doses required to replete deficiencies taken in divided doses throughout the day are noted in parentheses followed by the rationale or benefits.

Nutrient deficiencies (beta-carotene, vitamin D, acetyl-L-carnitine, dehydroepiandrosterone [DHEA], testosterone, reduced glutathione, and catalase) not commonly included in a multivitamin/multimineral supplement must be replaced through specific dietary regimens or through additional supplementation. Natural forms of beta-carotene should be used because evidence suggests that synthetic forms can increase the risk of lung cancer in individuals who smoke.[112] Consider acetyl-L-carnitine as a high-priority nutrient, despite its high cost, on the basis of the number of benefits.

Provide other nutrients to support optimal immune function. Box 178.5 summarizes nutrients that have been found to replace or reduce other nutrient deficiencies or have beneficial action in patients with HIV, their daily doses divided throughout the day, and effects of supplementation.

All these nutrients have benefits, but they significantly increase the overall cost and pill burden. Further, despite the positive evidence and outcomes demonstrated integrating CAM with HIV, there have been a few recent studies, including a systemic review, that have reported CAM therapies potentially interfering with HAART.[113–116] In these negative studies, the antiretroviral therapies referenced are no longer commonly being prescribed outside of less developed regions of world, the forms (chelates) of CAM that were used were often inferior forms, the populations being studied were often nutritionally unique (African), and many of the findings were debatable. These negative studies clearly emphasize the need to understand the mechanisms and interactions for the best integration of CAM and HAART.

With pill burden and efficacy in mind, it is suggested that priority be given to the most essential (EFAs and DHEA) and lower-cost (vitamin C) nutrients or to address specific symptoms, as described in the next section.

Provide Therapies to Address Constitutional Symptoms, Medication Side Effects, and Symptoms of Immunosuppression

The following are some approaches for specific health conditions and OIs. The naturopathic physician should endeavor to identify and remove the cause, tonify systems, and treat each patient individually.

Candida albicans/Oral Thrush. Overgrowth of this fungal organism may occur as a result of HIV itself (a low CD4+ count, reducing the body's immune capacity) or secondary to prophylactic antibiotic treatment. Orally, it can cause pain and make eating difficult, which can lead to reduced caloric intake and subsequent problems. In the intestines, it can cause inflammation and compromise nutrient absorption. In the esophagus, it can cause pain and should be dealt with swiftly via antifungal pharmaceuticals.

For treatment, patients should avoid foods that promote yeast growth, such as simple carbohydrates, sugar, baked goods, and starchy vegetables. These options should be considered:

- Probiotics: Provide and support healthy flora via the consumption of fermented foods as well as using supplements with at least 8 billion colony-forming units (CFUs), best taken with food. Beneficial species include *Lactobacillus acidophilus/bifidus; Lactobacillus* GG, a well-researched strain from Germany; and *Saccharomyces boulardii,* which is best for antibiotic-induced colitis and can help displace pathogenic flora.[117–121]
- Garlic (4 g/day, approx. = 1 clove, best taken before meals): Garlic is a potent antifungal found to spare nonpathogenic flora; note that patients on HAART should not take supplemental garlic.[122] Consider incorporating it into the diet.
- Oregano oil (300 mg best taken away from food): This is also a potent antifungal.[123]
- Nystatin, clotrimazole, and fluconazole: These are pharmaceutical antifungals.

BOX 178.4 Nutrient Deficiencies in HIV Patients

- Vitamin A (15,000–30,000 IU taken with food) slows progression to AIDS and decreases mortality, improves growth in infants, decreases stunting associated with chronic diarrhea, and prevents GI deterioration in mothers and infants.[253–256] May increase the risk of HIV transmission by breastfeeding but has no effect on mortality by 24 months.[257] Deficiencies can be due to decreased dietary intake, poor GI absorption, high urinary loss, impaired hepatic protein synthesis, and increased needs due to chronic infection.
- Beta-carotene (60–120 mg/150,000 IU taken with food) replenishment increased CD4+ count, CD4/CD8 ratios, and total lymphocyte count and decreased mortality.[258–260] Deficiency found in all HIV+ patients is likely due to poor digestion, decreased free-radical elimination, and high lipid peroxidation.[261]
- Folate (400 mcg) normalized cell differentiation. Deficiency is most likely due to malabsorption; AZT-induced deficiency may increase the risk of bone marrow toxicity.[262,263]
- Vitamin B_1 (50 mg) replenishment is associated with increased survival in HIV+ patients and decreased progression to AIDS.[264–266]
- Vitamin B_6 (50 mg) is essential in nucleic acid and protein metabolism and cellular and humoral immune responses.[267,268] Vitamin B_6 repletion both alone and in conjunction with CoQ_{10} increased circulating IgG, CD4+ cells, and CD4/CD8 ratios.[269]
- Vitamin B_{12} (1000 mcg hydroxy-, methyl- or cyanocobalamin best taken via intramuscular injections 3 times a week—alternate form is daily 1000 mcg sublingual) is important in several parameters of immune function, in proper cell differentiation and nerve function, and in decreasing homocysteine levels. Vitamin B_{12} repletion can improve lymphocyte counts, CD4/CD8 ratios, and NK-cell activity.[270] Supplementation has also been found to reverse AIDS dementia complex when associated with low levels.[271] Deficiency has been associated with an increased risk of progression to AIDS and with HIV disease in general.[272–274]
- Vitamin D (5000 IU) deficiency commonly found in urban HIV-infected men with suppressed viral load and CD4 >200; tobacco use was correlated with severe deficiency.[275] Undetectable levels of vitamin D in HIV+ patients correlated with more advanced HIV infection, lower CD4 count, and higher levels of TNF-α.[276] Repletion of vitamin D decreased bone turnover markers[277] and improved some clinically important HIV immune markers in children and young adults.[278] Lower bone-mineral density was found in HIV patients using tenofovir/emtricitabine combination (TDF, FTC).[279] Recently, it was determined that switching from combination therapy to Darunavir/ritonavir monotherapy resulted in significant improvements in vitamin D.[280] Vitamin D with calcium was also demonstrated to minimize bone loss with the initiation of therapy.[281]
- Vitamin E (800 IU daily—mixed tocopherols taken with food) is indicated to decrease lipid peroxidation, protect against AZT-induced oxidative damage to cardiac mitochondria, normalize immune function, and slow progression to AIDS.[282–287] Deficiency is found in most HIV+ patients with wasting and in progression to AIDS.[288]
- Copper (2 mg) can inhibit HIV protease and viral replication.[289] Deficiencies of copper are associated with AZT therapy and AIDS.[290,291]
- Magnesium (300 mg) deficiency is found in AIDS patients.[292,293]
- Selenium (400 mcg) to suppress the progression of HIV-1, decrease viral burden, and provide indirect improvement of CD4 count as well as reducing the rate of decline.[294,295] Selenium has been found to decrease HIV-associated mortality, decrease anxiety in HIV+ recreational drug users, and decrease hospitalizations and costs of caring for HIV+ patients.[296–299] The severity of deficiency in patients progressing to AIDS may be due to decreased calorie and protein intake, malabsorption, and various infections.[300]
- Zinc (15 mg—optimal intake levels have not been determined) has been found to decrease the frequency of OIs.[301,302] Deficiency is noted in all HIV+ patients progressing to AIDS.[303] Higher pre-ART Zn levels were associated with significant increases in CD4% at 48 weeks.[304] Zinc was also found to decrease diarrhea and upper respiratory tract infections in HIV+ infants.[305]
- Acetyl-L-carnitine (2–6 g, best taken away from other proteins to optimize absorption) is essential for proper energy supply as well as critical metabolic functions. Deficiency is common in HIV+ patients and increases the risk for alterations in fatty-acid oxidation.[306–308] Repletion has also been linked with a reduction in serum triglycerides, decreased risk of wasting, increase in CD4 cells and reduced apoptosis, increased levels of serum insulin-like growth factor, reduction in mitochondrial neurotoxicity, and treatment of peripheral neuropathy.[309–314] It has also been demonstrated as an effective treatment for NRTI-induced lactic acidosis.[315]
- DHEA (15–50 mg taken with food) repletion helps increase CD4 count, stimulate immune function, and improve quality of life.[316,317]
- Testosterone (intramuscular injection weekly) is indicated if serum levels are low to decrease the loss of lean body and muscle mass.[318]
- Glutathione/GSH (increased through selenium and N-acetyl-cysteine or whey protein powder) has been found to decrease disease progression and mortality.[319–322] Cysteine with glycine increased insulin sensitivity, body composition, and muscle strength in older HIV-infected patients.[323] Deficiencies are found in both symptom-free HIV+ and AIDS patients.[324,325]
- Many of these nutrients can be replenished through the use of a highly nutritious diet and a good multivitamin. A few multivitamins have been specifically developed to replace the deficiencies of HIV+ patients and include high doses of carotenoids, B vitamins, antioxidants, and sometimes digestive enzymes. Taking one multivitamin designed specifically for HIV reduces pill burden and enhances compliance. Conversely, it is generally more cost-effective to use a basic multivitamin and supplement individually with additional nutrients.

AIDS, Acquired immunodeficiency syndrome; *ART,* antiretroviral therapy; *AZT,* azidothymidine/zidovudine; *CoQ_{10},* coenzyme Q_{10}; *DHEA,* dehydroepiandrosterone; *GI,* gastrointestinal; *GSH,* growth-stimulating hormone; *HIV,* human immunodeficiency virus; *NK,* natural killer; *NRTI,* nucleoside/tide reverse transcriptase inhibitors; *OI,* opportunistic infection; TNF-α, tumor necrosis factor-alpha.

Cardiovascular disease. The issue of cardiovascular disease is becoming increasingly problematic and prevalent, particularly in the aging HIV+ population. The adverse effects on serum lipids and glucose that accompany the use of HAART medications (specifically PIs and D-type NRTIs) significantly promote cardiovascular disease, particularly in patients already at high risk (where there are predisposing factors such as a positive family history).

All patients on HAART should be encouraged to institute a preventive diet, adopt a healthy lifestyle, and implement exercise recommendations to promote cardiovascular health. Exercise in particular has been demonstrated to increase functional aerobic capacity, eliminate functional aerobic impairment, and improve measures of exercise performance (improved peak oxygen consumption, oxygen pulse, tidal volume, ventilation, and leg power).[124,125] Garlic should be avoided owing to its adverse interaction with HAART medications. The following specific nutrients should be considered:

- Acetyl-L-carnitine (2–6 g best taken away from other proteins to optimize absorption) repletion has also been linked with a reduction in serum triglycerides.
- CoQ10 (100–300 mg) may enhance cardiovascular function.[126]
- Arginine (7.4 g taken away from food) decreases atherosclerosis.[127]

BOX 178.5 Nutrients That Have Been Found to Replace or Reduce Other Nutrient Deficiencies or Have Beneficial Actions in HIV Patients

- *Silybum marianum*/milk thistle (300 mg standardized extract away from HAART) is indicated for all patients on HAART to improve liver function, decrease liver damage, and increase the antioxidant activity of blood cells.[326]
- NAC (2–8 g best taken away from other nutrients but may need to be taken with food to decrease GI distress) is indicated to prevent loss of sulfur-containing amino acids, increase GSH, decrease TNF-α activity, and increase CD4 cell count.[327–329]
- CoQ_{10} (100–300 mg) optimized mitochondrial function and replaced deficiency.[330,331] Repletion with CoQ_{10} increased circulating IgG, CD4+ cells, and CD4/CD8 ratios.[332,333]
- Vitamin C (2–6 g) when combined with vitamin E significantly lowered oxidative stress and has demonstrated a trend toward lowered viral load.[334]
- Alpha-lipoic acid (600 mg) protected the liver, inhibited viral replication, increased intracellular GSH, increased CD4/CD8 ratios, and potentially decreases peripheral neuropathic pain by its antioxidant effect on nervous tissue.[335–340]
- L-arginine (7.4 g taken away from food) improved lean body mass and increased NK-cell activity. Must be used with caution because large amounts of arginine can aggravate herpesvirus outbreaks. Prophylactic L-lysine may prevent or reduce this effect.
- EFAs (5 g taken with food; best from fish oil) improved lean body mass,[341] improved outcomes from ART,[342] increased NK-cell activity, and were beneficial as adjuvant therapy in patients with tuberculosis.
- L-Methionine (1000 mg taken away from other proteins) slowed the decline of CD4 cells.[343]
- Phosphatidylcholine-containing food or supplements can offer protection against HAART-induced hepatoxicity.[344]

ART, Antiretroviral therapy; *CoQ_{10},* coenzyme Q_{10}; *EFAs,* essential fatty acids; *GSH,* growth-stimulating hormone; *HAART,* highly active antiviral therapy; *IgG,* immunoglobulin G; *NAC,* N-acetylcysteine; *NK,* natural killer; *TNF-α,* tumor necrosis factor-alpha.

- EFAs (up to 6 g daily taken with food) have been clearly demonstrated to lower triglycerides and markers of inflammation including, IL-6 and TNF-α,[128–130] as well as lower lipids.[131]

Diarrhea. Diarrhea is a common complaint and an issue that can greatly affect quality of life. An HIV+ person might develop diarrhea for numerous reasons; the specific etiology guides the choice of treatment. Causes might include HIV-associated enteropathy, HAART side effects (see specific medications—this is particularly an issue with PIs), antibiotic side effects, GI infections, and food allergies or intolerances. An osmotic-type diarrhea can also result from the consumption of too many indigestible gel caps (from medications and supplements) building up in the intestinal lumen.

The first treatment priority is to remove the cause if at all possible. There is an increased incidence of gluten intolerance in HIV+ individuals.[132] Lactose intolerance and irritable bowel syndrome are also possibilities. Food allergies/sensitivities should be cautiously ruled out, with consideration given to the patient's general nutritional status to ensure the safety of trial food eliminations. Stool cultures and testing for ova and parasites should be considered to screen for suspected infectious causes, and patients should be treated as indicated for each microbial etiology. All nutrient supplementation may be stopped on a temporary basis to screen for an osmotic cause and then reintroduced one at a time to determine potential causes.

Steps for prevention include avoiding unfiltered tap water, unpasteurized milk or dairy products, ice made from unfiltered tap water, raw fruits and vegetables unless they can be peeled personally or washed with appropriate antimicrobial agents, raw or rare meat and fish, meat or shellfish that is not hot when served, and food from street vendors. Dehydration can be prevented by replacing electrolytes; broths, soups, fruit and vegetable juices, and high-nutrient drinks should be included.

Prevent malnutrition; if diarrhea is present, malabsorption of nutrients is a likely consequence. Ensure adequate micro- and macronutrient intake with a multivitamin/multimineral supplement and maintain adequate protein intake (requirements may increase to 100–150 g/day). Initial dietary intervention may include simplifying the diet (BRAT diet: *b*ananas, *r*ice, *a*pplesauce, *t*oast) or using 1 tbsp tomato juice combined with 1 tbsp sauerkraut juice (a protocol taught by Dr. John Bastyr to two generations of naturopathic students and used with considerable clinical success by the senior editor to facilitate electrolyte replacement and promote enterocyte healing). Carob powder is an astringent that can help symptomatically. Begin with 1 tsp in applesauce and increase up to 6 tsp/day as needed.

Consider these additional supplements:

- Provide and support healthy flora as described earlier in the care of candidal infection.[117–121]
- L-Glutamine (9–40 g best taken away from other proteins) is an amino acid that provides fuel for small intestinal enterocytes. Using a powder is most efficient and cost-effective. Start with 3 g three times daily. This can be increased up to 40 g daily if necessary. This high dose can lead to psychoses, so the patient should be monitored closely.[133]
- Diphenoxylate and atropine (Lomotil), loperamide (Imodium), and psyllium husk (Metamucil) are common pharmaceutical interventions.

Herpes simplex virus/herpes zoster/shingles. All conditions with a herpes-type virus etiology are considered together because the treatment approach is similar for each. The sequelae of herpesviruses tend to manifest on the skin in a dermatomal pattern of distribution. These symptoms can occur secondary to various types of stress, hormonal fluctuations, or a poor immune system response. First and foremost, try to identify and remove causes of stress (including dietary, emotional, and sunlight exposure) and support immune function. Secondarily, address the symptoms (most often, pain is at the forefront).

Naturopathic physicians should consider the following:

- Dietary suggestions include eliminating foods high in L-arginine (promotes herpes replication), such as chocolate, nuts, and peanuts, and increasing foods high in L-lysine (antagonizes L-arginine), such as whole grains, dairy, fish, lima beans, and soy.
- L-lysine: 1000 mg three times daily away from food during an outbreak; 500 mg three times daily away from food prophylactically.[134]
- Monolaurin: this antiviral, taken at 300 to 600 mg three times daily, is effective against encapsulated DNA viruses.[135]
- *Melissa officinalis:* an antiviral botanical used topically.[136]
- *Glycyrrhiza glabra:* an antiviral oral and topical botanical.[137]
- Acyclovir/valacyclovir: pharmaceutical antiviral therapy.

Kaposi sarcoma. Kaposi sarcoma (KS) is an HIV-associated neoplasm of vascular origin that tends to occur when CD4+ counts fall below 500/mm^3. KS is rarely found outside of the HIV+ population and is an issue that is becoming far less common in this era of early treatment through HAART. The etiology of AIDS-associated KS is poorly understood, but several factors are thought to contribute, including the presence of human herpesvirus (HHV) type 8, a compromised immune response, and hormones (it rarely occurs in women, and androgen therapy causes increased proliferation of the tumors). It is most commonly found in iron-rich geographical areas.

Interestingly, 90% of AIDS-related cases in the United States occur in homosexual men, making it rare in heterosexual men, women, and intravenous drug users.

KS begins as macules or elevated papules and can progress to large plaques or nodules. The color ranges from pink to purple or brownish-black. The lesions may be round or oval and do not blanch when pressure is applied to them. The lesions often appear first on the skin of the upper body or mucosal surfaces. In their aggressive form they can become widely disseminated and can manifest anywhere on the skin, mucous membranes, lymph nodes, or viscera (including the GI tract from the mouth to anus, lungs, liver, spleen, or pancreas).

KS tumors secrete increased amounts of angiogenic growth factors, TNF-α, IL-6, basic fibroblast growth factor, platelet-derived growth factor, and oncostatin-M.[138–143]

The level of immunosuppression of an affected person determines the clinical course of KS in AIDS. Currently, there are no known cures; the various local and systemic approaches are aimed at palliation.

Treatment may involve the use of chemotherapeutic agents such as doxorubicin as well as standard HAART. Surgical excision can successfully remove a lesion, but there is a high rate of recurrence at the affected site. Other researched options that have produced varying results include radiation therapy, cryotherapy with liquid nitrogen, and electrical stimulation with direct current.

The following treatments should also be considered:

- Topical and systemic retinoids[144]
- Topical vitamin D (1, 25-dihydroxyvitamin D3)[145]
- Iron has been shown to stimulate the growth of KS cells in vitro, whereas iron chelators reduced their growth.[146,147] Given this information, it may be sensible to limit iron intake and ensure that serum iron and ferritin levels are at the low end of normal.
- The use of various cytokine inhibitors and antiangiogenesis compounds might have a benefit for reducing the proliferation of these vascular tumors.
- Because there are no known curative therapies and the palliative treatment of KS is difficult at best, naturopathic physicians have an opportunity to be creative and contribute in this area. Given the association between KS and HHV type 8, it may be beneficial to use antiherpetic therapies if a patient is known to be herpes simplex virus–positive.[148] Topical application of a medicinal peat preparation has resulted in remission of topical KS lesions in several patients. Glutathione (NAC as a precursor) could be helpful in the treatment of KS lesions as well.[149–151]

Lipodystrophy. Lipodystrophy is a redistribution of adipose tissue from the extremities to the trunk. It often manifests with a Cushingoid "buffalo hump" over the upper thoracic region of the back or with truncal obesity. Self-image issues are often most significant for patients experiencing this condition. Lipodystrophy can occur as a result of alterations in lipid metabolism secondary to HAART or simply chronic HIV infection (greater than 15 years).[152] Given the appearance of the buffalo hump, it is possible that adrenal abnormalities contribute to the problem. Increases in serum cortisol lead to increases in insulin release from the pancreas, which drives blood glucose into storage in adipose cells. This leads to increased truncal obesity,[153–156] a physiological mechanism that bears consideration in the therapeutic approach as well as in future research. Lipodystrophy has also been found to increase with lack of exercise.[157] In addition to correcting dietary nutrient insufficiencies, supplementing nutrients as per the general protocol, increasing exercise, and ensuring that blood glucose is appropriately regulated, the use of the following can be considered:

- L-Glutamine (10 g in divided doses away from food)[158,159]
- Acetyl-L-carnitine (2–6 g away from food) to optimize mitochondrial function[160–162]
- Uridine (36 g three times daily for 10 consecutive days per month) to normalize subcutaneous fat[163]
- Testosterone (10 g of testosterone gel daily) in HIV+ men with abdominal obesity and low testosterone; decreased whole-body, total, and abdominal fat mass; and increased lean body mass[164]
- Nandrolone decanoate (150 mg intramuscularly [IM] every 2 weeks) may increase lean body mass more effectively than testosterone.[165]
- Tesamorelin (Egrifta), a growth hormone–releasing factor analogue (2 mg per subcutaneous injection given daily), decreases visceral adipose tissue and triglycerides without aggravating glucose.[166]
- Dimethyl sulfoxide (DMSO)/bromelain (5% bromelain compounded by the Key pharmacy in DMSO gel applied two to three times daily). Topical applications have resulted in the reduction of Cushingoid adipose deposits.
- Conventional treatment may include surgical removal of the truncal adipose deposits. Although this may not be the most desirable approach owing to its invasiveness, patients who undergo this procedure tend to be happy afterward because of their more positive self-image.
- Buccal injections of polylactic acid (PLA/Nufill) have been found to be safe and can reduce the cosmetic signs and depressive symptoms of lipodystrophy and wasting.[167]

Macrocytic anemia. Macrocytic anemia can be a secondary effect from the malabsorption of nutrients or a side effect of HAART (AZT causes bone marrow toxicity; PIs may cause malabsorption).[168,169] The following treatments can be considered:

- Vitamin B_{12} (hydroxocobalamin/methylcobalamin/cyanocobalamin 1000 mcg/mL given IM three times a week) is an important nutrient for proper cell division and differentiation.[170] If an IM injection is unavailable, sublingual tablets at 1000 mcg/day can be used to bypass intestinal absorption issues.
- Folic acid (activated form recommended) and vitamin B complex (both found in a good multivitamin supplement) are indicated for proper cell division, differentiation, and improved vascular reactivity.[171–173]

Neuropathy. This is usually manifested in the periphery, particularly in the feet. It can work its way proximally as it increases in severity. It is most often seen either as a result of long-term HIV infection or as a side effect of the D-type NRTIs and their toxic effect on the mitochondria in neurons.[174,175] Diabetes mellitus type 2 can also be a factor, as can overdoses of vitamin B_6 (greater than 200 mg/day).[176]

The following treatments can be considered:

- Acetyl-L-carnitine (2–6 g best taken away from other proteins to optimize absorption) decreases the risk for alterations in fatty-acid oxidation and energy supply, improves critical metabolic functions, and decreases pain.[177]
- EFAs (5 g/day with food) are anti-inflammatory agents and components of healthy cell membranes.[178]
- Vitamin B_{12} (1000 mcg/mL IM three times weekly) is an important nutrient for proper cell division and differentiation.
- Vitamin B complex (1 mL IM three times weekly) is indicated for proper cell division and differentiation.[179,180]
- CoQ_{10} (100–300 mg) is indicated to optimize mitochondrial function.[181,182]
- Alpha-lipoic acid (600 mg/day) may decrease pain.[183]

Psychological conditions. Issues such as depression, anxiety, posttraumatic stress disorder, sexual dysfunction, and substance abuse are extremely common in the HIV+ population. These problems potentially have physiological as well as psychological components but may not be adequately addressed by other providers.

Suicidal ideations and suicide attempts can also be an issue for this population. As quality of life deteriorates, the burden of ongoing

BOX 178.6 AIDS Wasting Syndrome Criteria

AIDS wasting syndrome must meet one of the following criteria:
Unintentional weight loss of >10% over 12 months
Unintentional weight loss of >7.5% over 6 months
BCM loss of <5% over 6 months
Men: BCM <35% of TBW and BMI <27 kg/m^2
Women: BCM <23% of TBW and BMI <27 kg/m^2
BMI <20 kg/m^2

BCM, body cell mass; *BMI,* body mass index; *TBW,* total body weight.

medical treatment increases, and close friends die, the desire to live can wane. It is critical that practitioners always be vigilant for signs of suicidal thinking or loss of hope in patients. These signs should be taken seriously, and there should be no hesitation in bringing in experienced professional help to assist these patients.

In contemplating the treatment of any psychological issue in this patient population, extreme caution must be exercised owing to issues of polypharmacy and drug–nutrient interactions. Many of these patients are taking a substantial number of pharmaceutical medications. Interactions among many nutrients and these medications and even among the medications themselves are likely. Before instituting any treatment, all potential interactions must be researched, identified, and considered.

An example of this problem is the potential use of St. John's wort, a commonly used herbal antidepressant. As previously discussed, St. John's wort is an inducer of the cytochrome P-450 detoxification enzyme 3A4 in the liver and has been found to reduce serum levels of various HAART medications. Therefore it can theoretically reduce the effectiveness of those medications and potentially lead to increased issues with resistance. The use of St. John's wort should be avoided in any patient who is undergoing HAART.

Modalities such as counseling, lifestyle modification, and homeopathy can be quite useful in treating these psychological conditions. Meditation and mindfulness have been found to be effective for psychological health. For example, a mindfulness-based stress reduction meditation program showed stabilization of CD4+ T-lymphocyte counts independent of antiretroviral medication use.[184] In another study, mantra repetition—a word or phrase with spiritual associations repeated silently throughout the day—was found to reduce anger as well as to increase spiritual faith and spiritual connectedness; it was inversely associated with non-HIV-related intrusive thoughts and positively associated with quality of life, total existential spiritual well-being, and meaning/peace.[185,186] Additional therapies to consider are as follows:

- Multivitamin supplementation (B complex, C, and E) resulted in a reduction in the risk of elevated depressive symptoms and improvement in quality of life.[187]
- Androgens (DHEA 50 mg or testosterone—in supraphysiological doses of 300 mg IM weekly) can improve mood, quality of life, and overall survivability and also decrease fatigue.[188,189]
- Amino acids (if levels are found to be low by specialty laboratory analysis) should be prescribed in combinations tailored to replenish deficiencies.[190,191]
- Zinc (25 mg/day) can serve to normalize levels and improve the efficacy of antidepressants.[192]
- EFAs (5 g/day with food) have been found to be useful as adjunctive treatment in depressive disorders.[193,194]
- SAMe (1600 mg/day) has been shown to be as effective as imipramine (150 mg) in treating major depression and is better tolerated.[195]

Wasting. In 1987, the CDC defined HIV-associated wasting syndrome as an involuntary weight loss of greater than 10% of baseline body weight accompanied by chronic fever, weakness, or diarrhea. A more complete definition is available in *The AIDS Reader*[196] (Box 178.6).

Body cell mass (BCM) can be measured via bioimpedance assay. Research shows that BCM is a better predictor of survival than CD4 counts. Key issues to be addressed with patients include perceived weight loss, changes in appetite, diarrhea, energy level, and difficulties in performing activities of daily living.

The etiology of wasting is most likely multifactorial in nature; some possible etiologies include the following[197]:

- Decreased food intake—anorexia (decreased desire to eat or loss of appetite with corresponding decrease in food intake) or nausea secondary to medications, systemic illness, or GI pathology; finances; dependence on others; poor food choices.
- Malabsorption/chronic diarrhea—results in decreased nutrient intake; influenced by many pathologies and dysfunctions (affecting any part of the GI tract: oral, esophageal, stomach, pancreatic, biliary, hepatic, and small and large intestine); problems might include infections, medication side effects, enzyme deficiencies, and malignancies; all might result in the inability to absorb macro- and micronutrients.
- Alterations of metabolism—studies show that resting energy expenditure (REE) is higher in HIV/AIDS patients than in HIV– controls; studies also show the REE does not downregulate if anorexia or malabsorption is present (therefore the combination of decreased caloric intake with a metabolic rate that does not adjust to that state would result in a negative energy balance and weight loss).[198]
- Cytokine abnormalities—not well understood; TNF and IL-1 may induce anorexia and affect lipid, protein, and carbohydrate utilization; an example is cachexia in cancer.
- Endocrine abnormalities—thyroid abnormalities, adrenal insufficiency (cortisol, DHEA), hypogonadism (testosterone), growth hormone deficiency.
- Alcohol abuse—studies show that progression to AIDS is much quicker in HIV+ patients who consume large amounts of ethyl alcohol (ETOH) versus normal expectations; ETOH can stimulate HIV production, suppress immune defenses (lower CD4 cell counts), and deplete tissue micronutrients (specifically, antioxidants).

As per general recommendations, the naturopathic physician should endeavor to remove the cause if it is identifiable and removal is feasible. Then he or she should identify and remove possible food allergies/intolerances (gluten and dairy in particular) and ensure adequate and appropriate nutritional intake via dietary counseling; patients should also be helped to access social service assistance if necessary. Patients are likely to need superdoses of nutrients. Protein intake should be increased to 100 to 150 g/day. Patients should be active and engage in daily exercise.

The following therapies can be considered:

- EFAs (5 g/day with food), which are essential in a healthy diet[199]
- Acetyl-L-carnitine (2–6 g/day) to optimize fatty acidic metabolism[200]
- L-Glutamine (10–40 g), an essential amino acid for enterocytes[201,202]
- DHEA (50 mg) to promote lean body mass[203]
- Melatonin (20 mg at bedtime) to decrease cachexia and TNF[204]
- Cannabis (four times daily) or oral dronabinol (5–10 mg four times daily) to increase daily caloric intake and body weight[205]
- Megastrol acetate (a synthetic hormone similar to progesterone; 400 mg) to decrease cachexia[206]

BOX 178.7 Botanicals That Have Demonstrated Efficacy in Treating HIV

- *Glycyrrhiza glabra*/licorice (1500 mg) inhibited HIV fusion and viral transcription.[345–347] It should not be used in patients with a history of hypertension or with renal or cardiac problems.
- *Curcuma longa*/tumeric (1200 mg) inhibited HIV integrase and proteases and viral transcription and decreased nuclear factor-kappa B.[348–350]
- *Olea* sp./olive leaf extract (2–6 g) increased NK-cell function and was effective against HIV and herpesviruses.[351,352]
- *Phyllanthus amarus* (1200 mg) demonstrated in vitro and ex vivo HIV-1 inhibition of reverse transcriptase, receptors, and proteases and is also effective against HBV.[353]
- *Lentinus edodes*/shitake mushrooms (1–5 mg IV twice weekly) inhibited reverse transcriptase, increased CD4 counts, and decreased p24 (surface marker).[354,355]
- *Andrographis paniculata* (1500 mg) inhibited fusion, viral replication, and HIV-1 cell-to-cell transmission. It also stimulated objective measures of immune function, increased the effectiveness of AZT, protected against liver damage, and decreased diarrhea.[356] Toxicity questions remain; further study is necessary.
- *Silybum marianum*/milk thistle (300 mg extract) improved liver function and antioxidant activity of blood cells.
- *Hyssopus officinalis*/hyssop (1- to 4-mL tincture) exhibited anti-HIV activity and inhibited the integration of proviral genome into host genome.[357,358]
- *Prunella vulgaris*/self-heal (10 mg/mL IV) inhibited HIV replication and binding and prevented cell-to-cell infection.[359,360]
- *Rosmarinus officinalis*/rosemary (use liberally in food) decreased HIV replication and protease activity.[361]
- *Momordica charantia*/bitter melon (6 oz fresh juice) normalized CD4+/CD8+ ratios and inactivated viral DNA.[362]
- *Spirulina platensis*/blue-green algae (use liberally in food) reduced fusion and viral production.[363]
- *Scutellaria baicalensis*/skullcap (6–15 g whole root) inhibited HIV-1 reverse transcriptase.[364]
- *Podophyllum* resin (25% solution as a single topical application) resulted in resolution of hairy leukoplakia.[365]
- *Melaleuca leucadendron*/tea tree oral solution was effective for fluconazole-refractory oropharyngeal candidiasis in patients with AIDS.[366]
- *Hypericum perforatum*/St. John's wort (900 mg) inhibited protein kinase C and viral uncoating, fusion, and assembly.[367] Do not use in patients on NNRTI or PI.
- *Allium sativa*/garlic (4 g fresh garlic) selectively killed HIV-1 infected cells in vitro.[368] It should not be used in patients on NNRTI or PI.

AIDS, Acquired immunodeficiency syndrome; *AZT,* azidothymidine/zidovudine; *HBV,* hepatitis B virus; *HIV,* human immunodeficiency virus; *IV,* intravenous; *NK,* natural killer; *NNRTI,* nonnucleoside reverse transcriptase inhibitor; *PI,* protease inhibitor.

- Testosterone in hypogonadal men to increase lean body mass and muscle strength[207]
- Anabolic steroids (nandrolone decanoate, oxandrolone, oxymetholone) to increase lean body mass[208,209]
- Thalidomide, a cytokine modulator, to increase BCM and extracellular fluid[210]

Provide Specific Antiviral Therapy and Immunomodulation Using Other Nondrug Treatments

This section summarizes the botanical, homeopathic, and physical medicine studies that have been found to have potential for patients with HIV. They are not substitutes for HAART. This list is intended to assist health providers in finding additional nondrug solutions that resonate with the unique needs of individual HIV+ patients. Further, the majority of the following studies are based on initial or empirical findings encouraging additional areas for research and exploration.

Botanical Medicines

Box 178.7 includes botanicals that have demonstrated efficacy in treating HIV. Care must be taken to understand the constituents and metabolism of these substances to ensure that there are no interactions with the patient's medications or other treatments.

Homeopathy

Homeopathy may offer a most interesting possibility in the care of HIV+ patients. The *British Journal of Homeopathy* published a report on the use of constitutional homeopathic remedies (30C-1M doses) given to 129 asymptomatic HIV+ patients in India. As a result, 12 patients became ELISA negative after 3 to 16 months.[211] In another study, 100 HIV+ patients between 17 and 50 years of age (71% men) were randomized to receive either a single homeopathic remedy or a placebo. The experimental group receiving remedies showed statistically significant increases in CD4+ T cells after 6 months.[212]

Other studies in homeopathy have demonstrated success with symptom care in HIV.[213] For example, Bissuel and colleagues[214] reported on the use of homeopathic sulfamethoxazole and trimethoprim (Bactrim) in preventing the hypersensitivity reaction commonly associated with this drug. In a randomized, double-blind, placebo-controlled trial of 24 HIV+ adults with baseline CD4+ counts between 125 and 500/mL, as reported by Brewitt and colleagues,[215] oral doses of homeopathic growth hormone resulted in statistically significant improvements in CD4 cells, CD8 cells, erythrocyte sedimentation rate (ESR), weight gain, and viral load; reduced occurrences of OI; and increased platelet counts.

The use of constitutional homeopathy should be considered an essential aspect of the care of all HIV+ patients considering the amazing potential, minimal side effects, and overall affordability.

Physical medicine and acupuncture. Physical medicine is another low-cost therapy that HIV+ patients can seek through a naturopathic provider. A growing body of evidence suggests that these therapies also play a pivotal role in the care of HIV+ patients:

- Whole-body hyperthermia (twice weekly at 108°F for 20 minutes) may elevate CD4 count, but extreme caution must be used in heat-intolerant individuals.[216]
- Ozone (rectal and aural insufflation) may inactivate HIV-1.[217–219]
- Acupuncture and moxibustion (three treatments weekly) have been demonstrated to decrease diarrhea, decrease nausea, and decrease cravings for illicit drugs (cocaine and heroin).[220–223] Acupuncture has also been found to be clearly effective in reducing attrition and decreasing pain in peripheral neuropathy.[224]
- Electroacupuncture (by continually stimulating acupuncture/conductance skin points associated with nervous and immune systems) has been demonstrated to ameliorate the complications of HIV-related peripheral neuropathy, raise CD4+ counts, and raise other lymphocyte counts.[225,226]
- Massage therapy has been demonstrated to increase NK cells, CD3 and CD4 cell counts, and CD4:CD8 ratios; improve quality of life; decrease health care costs; and decrease anxiety and symptoms of depression.[227–230]
- Reiki therapy with music has been found to reduce stress, anxiety, and depression.[231] Other studies have demonstrated increased

growth and development and overall behavior in HIV-exposed newborns as well as improved immune preservation in HIV+ children in the absence of antiretroviral therapy.[232,233]
- Therapeutic touch can reduce anxiety in children.[234]
- Cranioelectrical stimulation (microcurrent 0.1 mA at 100 Hz to alligator clips attached to the earlobes 20 minutes twice daily) can decrease anxiety, insomnia, and depression.[235]
- Movement therapies may also be useful:
  - Aerobic exercise has been demonstrated to provide benefit to individuals with immunodeficiency diseases, particularly through stress alleviation and mood enhancement. One exercise study demonstrated that HIV+ individuals had significant improvements in both CD8 and NK cells.[236–239]
  - Tai chi has demonstrated a greater overall perception of health and significant improvements in all functional measures in 13 HIV+ individuals compared with controls.[240]
  - Yoga has shown improvements in self-confidence and a return to athletic activities after the intervention.[241,242]

Provide Education and Guidance to Patients Seeking Alternatives to Conventional Treatment

As mentioned earlier, there are currently no known therapies as effective as HAART in suppressing viral load or increasing CD4 lymphocyte cell numbers, thereby supporting normal immune function. CAM providers must avoid the temptation to allow their patients to believe otherwise. Additionally, as HAART has proven to be so efficacious in reducing the incidence of AIDS and other HIV-associated adverse events, it is now the standard of care that it should be started upon diagnosis.

If a patient is aware of the risk of a high HIV viral load, low CD4 count, or both, yet still does not desire to initiate HAART or antibiotic prophylaxis, ensure that this patient has access to a conventional Western HIV specialist. This specialist can provide clear education on conventional Western medical approaches to HIV and help diagnose and treat OIs should they arise. Concurrently, initiate a foundation of care that includes a healthy diet and lifestyle, nutritional support, and additional therapies as described earlier. Furthermore, ensure that the patient is scheduled for frequent follow-ups with health care providers to regularly screen for and monitor potential or existing OIs.

If a sole practitioner is treating a patient who refuses to undergo conventional Western medical and pharmaceutical intervention, specific use of the following therapies should be considered to decrease viral load and increase CD4 cell count:
- *Curcuma longa*/turmeric (1200 mg) to inhibit HIV integrase, proteases, and viral transcription
- *Olea* sp./olive leaf extract (2–6 g) to increase NK-cell function and oppose HIV and herpesviruses
- *Phyllanthus amarus* (1200 mg), which has been shown to inhibit HIV-1, reverse transcriptase, receptors, and proteases in vitro and ex vivo
- *Lentinus edodes*/shiitake mushrooms (1–5 mg IV twice a week), which can increase CD4 and decrease p24 (a surface marker)
- Ozone (rectal and aural insufflations), which may inactivate HIV-1

For patients seeking advice on the discontinuation or interruption of HAART (a structured treatment interruption [STI] or "drug holiday"), naturopathic physicians should ensure that patients clearly communicate this desire to their primary care physicians and HIV specialists. Treatment interruptions may be indicated in the following situations[30]:
- Severe or life-threatening toxicity, unexpected inability to take oral medications, or lack of availability of antiretroviral medication (a short-term interruption)
- Where the patient has to be relieved of the inconvenience, toxicity, and cost of antiretroviral therapy
- Where the response to salvage therapy (treatment regimens used in patients who have failed other HAART regimens) can be improved by allowing the re-emergence of wild-type virus (the predominant virus type in a given individual as unaffected by HAART therapy)

Potential problems with treatment interruptions include viral rebound, immune decompensation, and clinical progression of HIV. Multiple studies have been done over time to examine strategies for discontinuing and reintroducing HAART as well as to evaluate the safety of such discontinuations; however, there has been no clear resulting consensus.[243–249] The most recent studies include the SMART, TRIVACAN, and DART trials, which have not had positive outcomes.[250–252] The SMART study was the largest, with more than 5000 subjects, and interrupted HAART when the CD4 cell count was greater than 350/mm^3 and reinitiated treatment when it fell below 250/mm^3. This trial was discontinued when there was a clearly increased risk of disease progression and death compared with the arm on continuous HAART. The current recommendation of the Department of Health and Human Services is that HAART interruptions should not be recommended except in the case of clinical trials or an acute problem.[13]

THERAPEUTIC APPROACH

HIV is a chronic disease with no known cure; naturopathic physicians are encouraged to apply the principles of naturopathic medicine in the search for treatments and refinements of care. In addition, naturopathic physicians must be familiar with all aspects of this disease because HIV+ patients are actively seeking treatment options unique to naturopathic medical training. Naturopathic medicine already offers important possibilities in the care of HIV, and all fields in health care must collaborate to find solutions for this worldwide health problem. Each patient should have a complete and appropriate caregiving team, including an infectious disease expert, primary care physician, and specialist providing psychosocial support.

Diet

A natural, whole-foods diet and a high caloric intake are recommended. This diet should be low in simple carbohydrates (e.g., sugar, white flour, fruit juice, honey, processed foods), low in natural and synthetically saturated fats, and low in oxidized or trans fatty acids. It should also be high in protein, fiber, and filtered water. Patients should abstain from alcohol, nicotine, and caffeine. Digestive stimulation is recommended if appropriate. Broad-spectrum allergy-elimination diets should generally be avoided (dependent on an individual's nutritional status).

Lifestyle

Aerobic or mind–body exercise (e.g., tai qui, yoga) and 8 to 10 hours of sleep each night are optimal. Rule out obstructive sleep apnea if suspected. Prayer, spiritual activities, and activities that support the HIV+ community, guided forms of stress relief, and relaxation training are beneficial.

Nutritional Supplements

Potential interactions with HAART must always be investigated in considering the use of any nutritional or botanical supplement.

- A high-potency hypoallergenic multivitamin/multimineral supplement, preferably designed specifically to replace known nutrient deficiencies of HIV
- Beta-carotene (150,000 IU/day best taken as food)
- Vitamin D (5000 IU/day best taken with food)
- DHEA (15–50 mg/day best taken with food)
- Acetyl-L-carnitine (2–6 g/day in divided doses best taken away from other proteins)
- EFAs (5 g/day taken with food)
- Probiotics (8–12 billion CFU a day taken with meals)
- Botanical medicines:
  Silybum marianum/milk thistle extract (300 mg/day) for all patients on HAART
- Homeopathic medicines:
  Constitutional intake and remedy for each patient
  Acute remedies as indicated
- Physical medicine and acupuncture:
  Whole-body hyperthermia—use extreme caution in patients with heat intolerance or peripheral neuropathies.
  Movement therapies—as indicated
  Acupuncture and electroacupuncture—as indicated

Hypertension

Michael T. Murray, ND

OUTLINE

DIAGNOSTIC SUMMARY

- Elevated blood pressure: 120 to 129/<80 mm Hg
- Stage 1 hypertension: 130 to 139/80 to 89 mm Hg
- Stage 2 hypertension: 140 and higher/90 and higher mm Hg

GENERAL CONSIDERATIONS

Elevated blood pressure (BP) is a major risk factor for a heart attack or stroke. In fact, it is generally regarded as the most significant risk factor for stroke. More than 70 million Americans have high BP, including more than half (54.3%) of all Americans 65 to 74 years of age and almost three-quarters (71.8%) of all African Americans in the same age group (Box 179.1). Additionally, 37% of U.S. adults have a blood pressure of 120 to 139/80 to 89 mm Hg, which is associated with a greater likelihood of developing not only hypertension and cardiovascular disease but also diabetes and cognitive impairment.[1]

Individuals with a normal diastolic pressure (<80 mm Hg) but elevated systolic pressure (>140 mm Hg), meaning an increased pulse pressure (>60 mm Hg), usually suffer from decreased compliance of the aorta (arteriosclerosis) and have a twofold increased risk of cardiovascular death compared with those whose systolic pressure is normal (<120 mm Hg).[2] Increased stroke volume due to aortic regurgitation, thyrotoxicosis, fever, and so on can also be a cause of increased pulse pressure.

Hypertension is also classified as to the cause. However, more than 90% of patients with hypertension are classified as suffering from essential hypertension, in which no discernible cause is given. Patients with essential hypertension are further divided into groups based on the level of renin, an enzyme secreted by the juxtaglomerular cells of the kidneys and linked with aldosterone in a negative feedback loop. Renin plays a central role in vascular reactivity through its effects in generating the vasoconstricting peptide angiotensin II. Renin secretion is influenced primarily by the individual's fluid-volume status and salt intake.

Patients with low-renin essential hypertension have low renin activity. In these patients, aldosterone production is not being suppressed, leading to a mild degree of hyperaldosteronism, with its resulting increased sodium retention, fluid volume, and BP. The same phenomenon occurs in patients with normal-renin hypertension, indicating that such patients may be at the end of a continuum of those with essential hypertension. Patients with low renin levels can also display an increased sensitivity to angiotensin II.

Patients with normal-renin essential hypertension typically are insulin resistant and display abdominal obesity. However, several studies have found that hyperinsulinemia and insulin resistance are present even in lean hypertensive patients without non–insulin-dependent diabetes mellitus, suggesting that there is a strong relationship between insulin sensitivity and BP. Several theories have been suggested to explain this connection. The most plausible states that because insulin

BOX 179.1 Classification of Blood Pressure

Optimal
- Systolic <120 mm Hg
- Diastolic <80 mm Hg

Prehypertension
- Systolic 120 to 139 mm Hg
- Diastolic 80 to 89 mm Hg

Stage 1 Hypertension
- Systolic 140 to 159 mm Hg
- Diastolic 90 to 99 mm Hg

Stage 2 Hypertension
- Systolic 160 and higher mm Hg
- Diastolic 100 and higher mm Hg

BOX 179.2 Classifications of Hypertension

I. Essential hypertension (>90% of all cases of hypertension)
  A. Low renin
  B. Normal renin
  C. High renin
II. Renal etiology
  A. Chronic pyelonephritis
  B. Acute and chronic glomerulonephritis
  C. Polycystic renal disease
  D. Renovascular stenosis or renal infarction
  E. Most other severe renal diseases (e.g., arteriolar nephrosclerosis, diabetic nephropathy)
  F. Renin-producing tumors
III. Endocrine etiology
  A. Adrenocortical hyperfunction
  B. Cushing's disease and syndrome
  C. Primary hyperaldosteronism
  D. Congenital or hereditary adrenogenital syndromes (17-hydroxylase and 11-hydroxylase defects)
  E. Pheochromocytoma
  F. Myxedema
  G. Acromegaly
IV. Neurogenic etiology
  A. Psychogenic
  B. Diencephalic syndrome
  C. Familial dysautonomia (Riley–Day)
  D. Polyneuritis (acute porphyria, lead poisoning)
  E. Increased intracranial pressure (acute)
  F. Spinal cord section (acute)
V. Miscellaneous
  A. Toxemia of pregnancy
  B. Acute intermittent porphyria
  C. Coarctation of aorta
  D. Increased intravascular volume (excessive transfusion, polycythemia vera)
  E. Polyarteritis nodosa
  F. Hypercalcemia
  G. Medications (e.g., glucocorticoids, cyclosporine, oral contraceptives)

modifies ion transport across the cell membrane, insulin insensitivity can lead to decreased cytosolic magnesium levels and increased cytosolic calcium levels within the vascular smooth muscle, resulting in increased vascular reactivity. Patients with normal-renin essential hypertension typically do not respond to sodium restriction.

Patients with high-renin essential hypertension make up approximately 15% of patients with essential hypertension. The elevation in renin (and associated high BP) is thought to be secondary to an increase in sympathetic nervous system activation.

The categorization of BP by renin level does not remain constant in each patient. For example, a patient might be labeled as having low-renin essential hypertension due to insulin resistance secondary to obesity. If the patient lost weight, regained insulin sensitivity, and yet the BP did not normalize, he or she would then be categorized as having normal- or high-renin essential hypertension. The categories based on renin level are primarily useful in identifying possible therapeutic interventions, as shown in Box 179.2.

White-Coat Hypertension

White-coat hypertension has been defined as the persistent elevation of BP at the clinic or office only. Its prevalence may be as high as 20% to 45% of people diagnosed as hypertensive.[1] It appears to be more frequent in women, older patients, and persons with stage 1 hypertension. White-coat hypertension should not be confused with the *white-coat effect,* which signifies the difference in BP between the office and daytime ambulatory BP and occurs in patients with white-coat hypertension as well as in those with other causes of hypertension. The current conventional wisdom among naturopathic physicians is to treat white-coat hypertension as if it were essential hypertension. The reason for this stance is that current data suggest that the pressor response elicited mirrors real-life reactions to stress; that is, studies have suggested that white-coat hypertension is not an innocent phenomenon.[3,4] In regard to the latter, in a 21-year study comprising 536 men, those with a white-coat effect had a significantly higher rate of mortality than normotensive men and were nearly twice as likely to develop sustained hypertension.[4]

Ambulatory BP monitoring is a clinically useful tool for assessing suspected white-coat hypertension and cardiovascular risk.[5] In patients with confirmed white-coat hypertension, drug treatment is usually not indicated; instead, treatment should consist of lifestyle and dietary modifications, weight reduction, regular exercise, smoking cessation, and correction of glucose and lipid abnormalities.[1] In addition, semiannual or annual follow-up with ambulatory BP monitoring is advised.

Etiology

Essential hypertension is most likely the result of any number of factors that disrupt the regulation of arterial pressure and fluid volume. Vascular, hormonal, renal, and neurological factors function in a complex interrelationship to maintain normal BP; disruption of any single facet disrupts the entire system and creates a cascading effect on regulatory mechanisms. Although genetic factors play a role, dietary, lifestyle, psychological, and environmental factors are the underlying causes in most cases of essential hypertension. Dietary factors include obesity; high sodium-to-potassium ratio; a low-fiber, high-sugar diet; high saturated fat and low omega-3 fatty acid intake; and a diet low in calcium, magnesium, and vitamin C. Important lifestyle factors that may cause high BP include stress, lack of exercise, and smoking. The dietary factor that has received the greatest attention is salt intake. Between 40% and 60% of patients with hypertension are salt sensitive. This factor is discussed later in the chapter under "Therapeutic Considerations."

Exposure to toxic metals, such as lead, mercury, cadmium, and arsenic, may also be a significant factor in some patients. The kidneys are end-organ targets of several toxins. Although studies of blood lead levels have not consistently shown an association, it is important to point out that blood lead levels reflect primarily acute exposure.[6–8] Studies looking at bone lead, for example, have upheld that exposure to heavy metals is associated with an increased risk of hypertension.[9] Specifically, the data suggest that lead has an acute effect on BP via either a recent exposure or cumulative dose. These associations were demonstrated in a cross-sectional analysis of 2001 to 2002 data from a community-based cohort in Baltimore, Maryland, of 964 men and women aged 50 to 70 years (40% African American, 55% white, 5% other race/ethnicity). Both blood lead and tibial lead were determined, along with systolic and diastolic BP. Blood lead was a strong and consistent predictor of both systolic and diastolic BP in models adjusted and not adjusted for race/ethnicity and socioeconomic status. Tibial lead was also associated with hypertension status before and after adjustment for race/ethnicity and socioeconomic status.[10]

THERAPEUTIC CONSIDERATIONS

Because more than 90% of patients with higher-than-optimal blood pressure have either prehypertension or stage 1 hypertension, most can be brought under control through changes in diet and lifestyle.[11] In fact, in head-to-head comparisons, many nondrug therapies, such as diet, exercise, and relaxation therapies, have proved to be superior to drugs in cases of prehypertension and stage 1 hypertension. For stage 2 hypertension, pharmacological therapy may be necessary. Ideally, drug treatment should be used only until the dietary, lifestyle, and supplement strategies take hold. However, long-term drug therapy is sometimes required.

Pharmacotherapy of Hypertension

For many years, the first drug of choice for high BP was a thiazide diuretic alone or in combination with a beta blocker. Because of the questionable effectiveness of this combination in reducing the cardiovascular death rate and the side effects noted in numerous studies, this approach has somewhat fallen out of favor but is still quite popular. The most common treatment is a diuretic used alone or in combination with newer medications designed to relax the arteries, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, and calcium channel blockers.

The use of a diuretic or any of the previously mentioned other drugs alone is referred to as a "step 1" therapy. Thiazide diuretics are still the most popular step 1 drugs but may soon be displaced by calcium channel blockers or ACE inhibitors. Beta blockers are not suitable step 1 drugs because of their known side effects.[12] Step 2 therapy comprises two medications, step 3 uses three, and the step 4 approach involves four. Physicians are instructed to use single therapies before going on to the combinations, unless compelling indications are present, such as diabetes or heart failure.[13]

Other types of BP-lowering medications that can be used in step 3 or 4 approaches include those that act on the central nervous system, such as clonidine, methyldopa, and reserpine, as well as some that are potent dilators of the blood vessels, like nitroprusside sodium, hydralazine, prazosin, minoxidil, and hydralazine. However, these drugs have fallen out of favor with the development of the newer calcium channel blockers and ACE inhibitors. Nonetheless, they may be appropriate in certain situations.

Overview of Dietary and Lifestyle Factors

Hypertension is closely related to lifestyle and dietary factors. Some of the important lifestyle factors linked to hypertension include smoking, stress, and lack of exercise. The most important dietary factors include obesity; high sodium-to-potassium ratio; low-fiber, high-sugar diet; high saturated fat and low essential fatty acids (EFAs) intake; a diet low in calcium, magnesium, or vitamin C; and excessive alcohol or caffeine intake (Fig. 179.1).

Several of these dietary and lifestyle factors are also discussed in Chapter 148 because the health of the arteries is critical to maintaining normal BP.

Stress

Stress can be the causative factor of hypertension in many instances, although, as in other health conditions, it has more to do with the response to and processing of stress than with stress itself. Relaxation techniques such as deep-breathing exercises, biofeedback, autogenics, transcendental meditation, yoga, progressive muscle relaxation, and hypnosis have all been shown to have some value in lowering BP.[14] Although the effect is only modest, a stress reduction technique is a necessary component of a natural BP-lowering program.

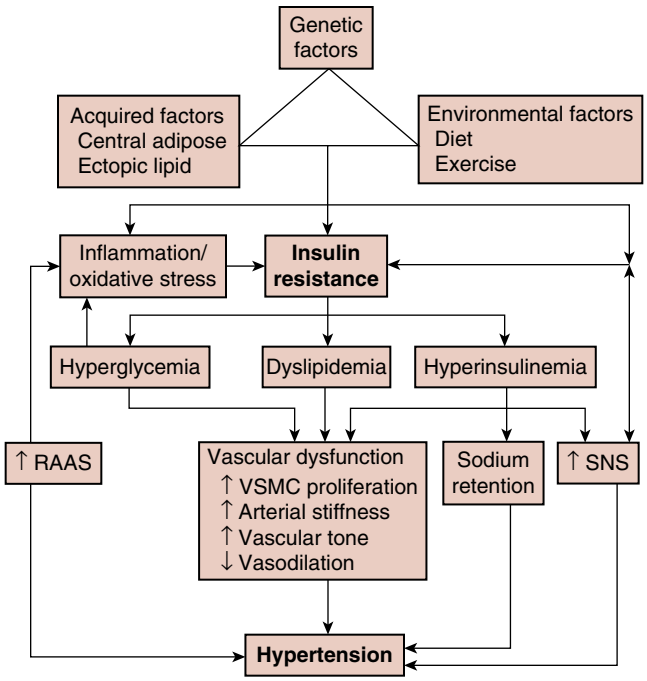

Fig. 179.1 Summary of putative pathophysiological mechanisms in the development of hypertension. (From Mugo MN, Stump CS, Rao PG, et al. Hypertension and diabetes mellitus. In: Black HR, Elliott WJ, editors. Hypertension: A Companion to Braunwald's Heart Disease. Elsevier; 2007. p. 409.)

One of the most powerful methods of producing less stress and more energy in the body is diaphragmatic breathing. Regular short exercise sessions of slow, regular diaphragmatic breathing have also been shown to lower BP in hypertensive individuals in several studies.[15,16] One study in particular has shed light on the effect of breathing in hypertension.[17] Volunteers with normal BP were taught shallow breathing. Measurement of the amount of sodium and potassium then excreted in their urine indicated that shallow breathing led to the retention of sodium in the body. It was suggested that this breathing pattern may play a causative role in some cases of hypertension as a result of the retention of sodium. However, slow breathing (six breaths per minute) has also been shown to improve oxygen saturation, exercise tolerance, and baroreflex sensitivity.[18]

RESPeRATE is a medical device that interactively guides the user toward slow, regular breathing by synchronizing voluntary respiration to musical tones. When used for 15 minutes daily, this device can lead to a significant reduction in BP. In one 8-week study, systolic BP was reduced by 10.0 mm Hg and diastolic BP by 3.6 mm Hg, but not in the controls, and greater BP reduction was observed in those who demonstrated increased compliance with the device.[19]

Exercise

Epidemiological studies have consistently demonstrated an inverse association between physical activity (or fitness) and hypertension. In addition to this evidence, clinical trials in hypertensive patients have clearly established that regular exercise is an effective treatment for high BP.[20,21] Although it is generally thought that the greater the intensity of aerobic exercise, the greater the hypotensive effect, it has been shown that even mild to moderate aerobic exercise in as few as three exercise sessions per week with durations as short as 20 minutes produces a hypotensive effect.[21] The degree of BP reduction from a regular exercise program is typically in the range of 5 to 10 mm Hg for both the systolic and diastolic readings. Patients with prehypertension and stage

1 hypertension can typically bring their BP readings into the normal range with regular exercise.

Dietary Recommendations

Obesity is the major dietary cause of hypertension, and achieving their ideal body weight is the most important therapeutic goal for most patients with any form of hypertension. From prehypertension to chronic renal failure, weight loss can lead to complete elimination of the health issue, significant improvement, or at least a reduction in the number of prescriptions needed.[22,23]

Vegetarians generally have lower BP levels and a lower incidence of hypertension and other cardiovascular diseases than nonvegetarians.[25]Although dietary levels of sodium do not differ significantly between these two groups, a vegetarian diet typically contains more potassium, complex carbohydrates, EFAs, fiber, calcium, magnesium, and vitamin C and less saturated fat and refined carbohydrates, all of which have a favorable influence on BP.

An increased intake of fruits and vegetables has been shown to lower BP.[24] This effect may be due to increased antioxidant concentrations. Hypertensive patients have been shown to have increased oxidative stress, and antioxidants have been shown to block angiotensin II–induced increases in BP as well as to promote proper nitric oxide synthesis.[25,26]

The most useful foods for people with hypertension include the following:

- Celery
- Garlic and onions
- Nuts and seeds or their oils for their EFA content
- Cold-water fish (e.g., salmon, mackerel)
- Green leafy vegetables for their calcium and magnesium
- Whole grains and legumes for their fiber
- Foods rich in vitamin C, like broccoli and citrus fruits
- Foods rich in active flavonoids, including berries, cherries, grapes, and small red kidney beans

Celery contains 3-n-butyl phthalide, a compound that has been found to lower BP. In animals, a small amount of this compound lowered BP by 12% to 14% and cholesterol by about 7%.[27] The equivalent dose in humans can be supplied in about four to six ribs of celery. The research was prompted by the father of one of the researchers, who, after eating a quarter pound of celery daily for 1 week, observed that his BP had dropped from 158/96 to 118/82.

Garlic and onions are also important foods for lowering BP. Although most research has focused on the cholesterol-lowering properties of these vegetables, both have also been shown to lower BP in hypertension.[28] In addition, commercial garlic supplements may be of benefit. The usual response to the use of garlic is fairly modest, a reduction of roughly 8 to 11 mm Hg for the systolic and 5 to 8 mm Hg for the diastolic BP (see Chapters 62 and 63 for a full discussion and dosages).

Dietary Approaches to Stop Hypertension (DASH)

Clinical studies of Dietary Approaches to Stop Hypertension (DASH) were funded by the National Heart, Lung, and Blood Institute (NHLBI) to evaluate the efficacy of a system of dietary recommendations in the treatment of hypertension. The DASH diet is rich in fruits, vegetables, and low-fat dairy foods and low in saturated and total fat. It is also low in cholesterol; high in dietary fiber, potassium, calcium, and magnesium; and moderately high in protein.

The first study showed that a diet rich in fruits, vegetables, and low-fat dairy products can reduce BP in the general population and people with hypertension.[29] The original DASH diet did not require either sodium restriction or weight loss—the two traditional dietary tools to control BP—to be effective.[30] The second study from the DASH research group found that coupling the original DASH diet with sodium restriction is more effective than dietary manipulation alone.[31] In the first trial, the DASH diet produced a net BP reduction of 11.4 and 5.5 mm Hg systolic and diastolic, respectively, in patients with hypertension. In the second trial, sodium intake was also quantified at a "higher" intake of 3300 mg/day, an "intermediate" intake of 2400 mg/day, and a "lower" intake of 1500 mg/day. Compared with the control diet, the DASH diet was associated with a significantly lower systolic BP at each sodium level. The DASH diet with the lower sodium level led to a mean systolic BP that was 7.1 mm Hg lower in participants without hypertension and 11.5 mm Hg lower in participants with hypertension. These results are clinically significant and indicate that sodium intake below the recommended level of 2400 mg daily can significantly and quickly lower BP.

Table 179.1 lists a brief description of the components of the DASH eating plan on the basis of a 2000-calorie daily diet.

Potassium and Sodium

Considerable evidence indicates that a diet low in potassium and high in sodium is associated with hypertension and plays a major role in the development of cancer and cardiovascular disease (e.g., heart disease, hypertension, stroke).[32,33] In regard to hypertension, there is overwhelming evidence that dietary sodium chloride (salt) is a major cause of raised BP and that a modest reduction in salt intake can lower BP, which is predicted to reduce cardiovascular disease because there is a direct relation between salt intake and cardiovascular risk.[34] In advising a patient to decrease salt consumption, one must ensure that he or she is getting enough iodine from alternative sources. Conversely, a diet high in potassium and low in sodium is protective against cardiovascular diseases. In the case of hypertension, as evident from the second DASH study and others, this type of diet can be therapeutic.

It is a well-established fact that excessive consumption of dietary sodium chloride coupled with diminished dietary potassium is a common cause of high BP, especially in "salt-sensitive" individuals. However, numerous studies have shown that in many cases, sodium restriction alone does not significantly improve BP control—it must be accompanied by high potassium intake. In a typical Western diet, only 5% of sodium intake comes from the natural constituents in food. Prepared foods contribute 45% of the sodium intake, 45% is added during cooking, and another 5% is added as a condiment.

Most Americans have a potassium-to-sodium (K:Na) ratio of less than 1:2. Epidemiological and experimental research suggests that a dietary K:Na ratio of greater than 5:1 (as was apparently typical of human evolutionary diets) is necessary to maintain health. However, even this level may not be optimal. A natural diet rich in fruits and vegetables can produce a K:Na ratio greater than 100:1 because most fruits and vegetables have a K:Na ratio of at least 50:1.

Nutritional Supplements

Potassium

Many studies have shown that increased dietary potassium intake can lower BP.[35] In addition, several studies have shown that potassium supplementation alone can produce significant reductions in BP in hypertensive subjects. Results from 33 randomized controlled trials (2609 participants) in which potassium supplementation was the only difference between the intervention and control conditions were used in one meta-analysis. Using a random-effects model, potassium supplementation was associated with a significant reduction in mean systolic and diastolic BP of 4.44 and 2.45 mm Hg, respectively. The effects of potassium supplementation appeared to be enhanced in subjects who had a high intake of sodium, indicating that this is an important recommendation for the prevention and treatment of hypertension in those who are unable to reduce their intake of sodium. The dosage of potassium typically used in the studies ranged from 2.5 to 5 g/day.

TABLE 179.1 Basic Components of the DASH Diet (2000 Calories a Day)

Food Group	Daily Servings	Serving Sizes	Examples	Significance of Each Food Group to the Dash Diet Pattern
Grains and grain products	7–8	1 slice bread ½ cup dry cereal ½ cup cooked rice, pasta, or cereal	Whole-wheat bread, English muffin, pita bread, bagels, cereals, grits, oatmeal	Major sources of energy and fiber
Vegetables	4–5	1 cup raw leafy vegetables ½ cup cooked vegetables 6 oz vegetable juice	Tomatoes, potatoes, squash, broccoli, turnips, greens, collards, kale, spinach, artichokes, sweet potatoes, beans	Rich sources of potassium, magnesium, and fiber
Fruits	4–5	6 oz fruit juice 1 medium fruit ¼ cup dried fruit ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, oranges, orange juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or nonfat dairy foods	2–3	8 oz milk 1 cup yogurt 5 oz cheese	Skim or 1% milk, skim or low-fat yogurt, part-skim mozzarella cheese, nonfat cheese	Major sources of calcium and protein
Meats, including poultry and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4–5 weekly	5 oz or 1⁄3 cup nuts ½ oz or 2 tbsp seeds ½ cup cooked legumes	Almonds, filberts, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils	Rich sources of energy, magnesium, potassium, protein, and fiber

DASH, Dietary Approaches to Stop Hypertension.

In one study, 37 adults with hypertension received either 2.5 g/day of potassium, 2.5 g/day of potassium plus 480 mg/day of magnesium, or a placebo for 8 weeks; then they were crossed over to receive one of the other treatments for another 8 weeks; and then they were crossed over again in another 8 weeks.[36] The potassium supplementation lowered systolic BP an average of 12 mm Hg and diastolic BP an average of 16 mm Hg. Interestingly, the additional magnesium offered no further reduction in BP; nonetheless, magnesium supplementation has been shown to be helpful in other studies (discussed later).

Potassium supplementation may be especially useful in the treatment of hypertension in persons above age 65, who often do not fully respond to antihypertensive drugs. In one double-blind study, 18 untreated elderly patients (average age 75 years) with a systolic BP of greater than 160 mm Hg, a diastolic BP of greater than 95 mm Hg, or both were given either potassium chloride (2.5 g of potassium) or a placebo each day for 4 weeks.[37] After this relatively short treatment period, the group receiving the potassium experienced a drop of 12 mm Hg in their systolic BP and 7 mm Hg in their diastolic BP. These results compare quite favorably with the reduction of BP produced by drug therapy—and without the negative effects and side effects.[38]

Potassium supplements are available by prescription and over the counter (OTC). However, the U.S. Food and Drug Administration (FDA) restricts the amount of potassium available in OTC potassium supplements to 99 mg per dose because of problems associated with high-dosage prescription potassium salts. Salt substitutes such as the popular brands NoSalt and Nu-Salt are, in fact, potassium chloride and provide 530 mg of potassium per 1⁄6 tsp. The prescription and OTC supplements are either potassium salts (chloride and bicarbonate), potassium bound to various mineral chelates (e.g., aspartate, citrate), or food-based potassium sources. Potassium chloride preparations are the most popular by prescription and are available in a vast array of formulations (e.g., timed-release tablets, liquids, powders, and effervescent tablets) and flavors. Potassium salts are commonly prescribed in the dosage range of 1.5 to 3 g/day. However, potassium salts can cause nausea, vomiting, diarrhea, and ulcers when given in pill form at high dosages. These effects are not seen when potassium levels are increased through the diet only. This difference highlights the advantages of using foods or food-based potassium supplements rather than pills to meet the human body's high potassium requirements.

Potassium supplementation is relatively safe except for patients with kidney disease. Their inability to maintain appropriate potassium homeostasis may result in heart arrhythmias and other consequences of potassium toxicity. Potassium supplementation is also contraindicated if used in combination with a number of prescription medications, including digitalis, potassium-sparing diuretics, and the ACE inhibitor class of antihypertensive drugs.

Magnesium

Potassium interacts with magnesium in many body systems, and low intracellular potassium levels may be the result of low magnesium intake. It is therefore appropriate to supplement magnesium (400–1200 mg/day in divided doses) along with potassium. This may also lower BP.

A meta-analysis of 14 clinical trials that tested the effects of magnesium supplementation on hypertension demonstrated clear dose-dependent BP reductions—a drop of 4.3 mm Hg systolic and 2.3 mm Hg diastolic for each 10 mmol/day increase in magnesium dose.[39]

In one double-blind clinical study, 21 male patients with hypertension were given 600 mg/day of magnesium (as magnesium oxide) or placebo.[40] Mean BP (the average between the systolic and diastolic) decreased from 111 to 102 mm Hg. The patients who responded best were those with reduced red blood cell (RBC) potassium. After therapy with magnesium, the levels of intracellular sodium, potassium, and magnesium normalized, suggesting that one of the ways in which magnesium lowers BP is through activation of the cellular membrane pump moving sodium out of the cell and potassium into the cell.

Considerable evidence indicates that a high intake of magnesium is associated with lower BP in population studies. The principal source of magnesium in early studies was water. Water that is high in minerals like magnesium is often referred to as "hard water." Numerous studies have demonstrated an inverse correlation between water hardness and high BP.[41]

In the Honolulu Heart Study, systolic BP was 6.4 mm Hg lower and diastolic BP 3.1 mm Hg lower in the group with the highest magnesium intake compared with that having the lowest magnesium intake.[42]

Studies of magnesium supplementation in the treatment of hypertension have yielded mixed results. Although the overall results in a meta-analysis of the data are quite favorable, it appears that the hypertensive patients who respond are those taking a diuretic who have a high level of renin, with low RBC magnesium, or with elevated intracellular sodium or a decreased intracellular potassium.

The recommended daily intake for magnesium in hypertensive patients appears to be approximately 6 to 10 mg/kg body weight.

Magnesium is available in several forms. Although most are equally well absorbed, magnesium bound to aspartate or the Krebs cycle intermediates (malate, succinate, fumarate, and citrate) is usually preferable to magnesium oxide, gluconate, sulfate, or chloride. Absorption studies indicate that magnesium is easily absorbed orally, especially when it is bound to citrate (and presumably aspartate and other members of the Krebs cycle).[43,44] In addition, magnesium bound to aspartate or Krebs cycle intermediates may also help with fatigue. Aspartate feeds into the Krebs cycle, the final common pathway for the conversion of glucose, fatty acids, and amino acids to chemical energy (adenosine triphosphate, or ATP), whereas citrate, fumarate, malate, and succinate are actual components of the Krebs cycle. Minerals chelated to the Krebs cycle intermediates are better absorbed, used, and tolerated compared with inorganic or relatively insoluble mineral salts, including magnesium chloride, oxide, or carbonate. In addition, although inorganic magnesium salts often cause diarrhea at higher dosages, organic forms of magnesium generally do not.

In general, magnesium is well tolerated. Magnesium supplementation can sometimes cause a looser stool, particularly magnesium sulfate (Epsom salts), hydroxide, or chloride. Magnesium supplementation must be used with great care in patients with kidney disease or severe heart disease (such as high-grade atrioventricular block).

Calcium

Population-based studies have suggested a link between hypertension and a low intake of calcium.[36] However, the association is not as strong as the one for magnesium and potassium. In addition to the epidemiological data, several clinical studies have demonstrated that calcium supplementation can lower BP in hypertension, but the results have been inconsistent.[45]

To clarify the effectiveness of calcium supplementation in patients with hypertension, a double-blind, placebo-controlled crossover study was performed on 46 patients with either salt-sensitive or salt-resistant hypertension.[46] During the calcium supplementation phase, patients received 1.5 g/day of calcium (as calcium carbonate) for 8 weeks. The calcium supplementation was found to effectively reduce BP in black patients and in salt-sensitive patients but not in those having salt-resistant hypertension. Better results have been found for calcium citrate versus calcium carbonate.[47]

Another group that appears to respond to calcium supplementation is elderly patients with hypertension. One study used 24-hour monitoring of BP to evaluate the effect of calcium supplementation on essential hypertension in elderly hospitalized patients. The mean systolic and diastolic BPs over a 24-hour period declined by 13.6 mm Hg and 5 mm Hg, respectively, in patients whose diets were supplemented with 1 g of elemental calcium.[48]

Vitamin C

Population-based and clinical studies have shown that the higher the intake of vitamin C, the lower the BP. The results from two double-blind trials have confirmed a modest BP-lowering effect with vitamin C supplementation in people with mild elevations of BP.[49,50] One of the key findings of these studies was that a daily dose of 500 mg produced the same benefit as higher doses (i.e., 1000 and 2000 mg daily). Vitamin C supplementation can produce decreases of up to 4.5 mm Hg in the systolic and 2.5 mm Hg in the diastolic BP.

One of the mechanisms by which vitamin C exerts this antihypertensive effect is by promoting the excretion of lead. Chronic exposure to lead from environmental sources, including drinking water, is associated with hypertension and increased cardiovascular mortality. Areas with a soft water supply have an increased lead concentration in drinking water due to the increased acidity of the water, and people living in these areas may be predisposed to hypertension. It should be noted that soft water is also low in calcium and magnesium, two minerals that have also been shown to protect against hypertension.

Vitamin C is likely to be more effective when it is used with other antioxidant nutrients. The combination of 500 mg of vitamin C, 600 mg of α-tocopherol, 200 mg of zinc sulfate, and 30 mg of beta-carotene daily produced mild reductions in the systolic BP compared with the placebo phase both in subjects receiving antihypertensive therapy and those who were normotensive.[51]

Folic Acid and Vitamin B_6

Folic acid and vitamin B_6 reduce plasma homocysteine levels—a known contributor to atherosclerosis. A 2-year trial of folic acid and vitamin B_6 therapy to lower homocysteine was associated with a reduction of 3.7 mm Hg in systolic BP and a reduction of 1.9 mm Hg in diastolic BP.[52] Vitamin B_6 supplementation alone has also been shown to lower BP. In one study, vitamin B_6 supplementation at a single daily oral dose of 5 mg/kg for 4 weeks in 20 people with hypertension demonstrated significant reductions in systolic and diastolic BPs as well as serum norepinephrine levels.[53] The effects on BP were significant; systolic pressure dropped from 167 to 153 mm Hg, and the diastolic pressure dropped from 108 to 98 mm Hg.

Omega-3 Oils

More than 60 double-blind studies have demonstrated that fish oil supplements are effective in lowering BP.[54,55] Typically, fish oils produced a reduction of 2.1 mm Hg in the systolic BP and 1.6 mm Hg in the diastolic BP at a dose of 3000 mg of omega-3 (EPA/DHA) daily. In one double-blind, placebo-controlled, randomized clinical trial, healthy men and women consumed a control oil or fish oil providing 0.7g or 1.8g EPA + DHA per day (intakes achievable through diet), in random order, each for 8 weeks to examine the effect of fish oil on systolic and diastolic BP.[56] Findings indicated that in adults with isolated systolic hypertension, daily doses of EPA + DHA as low as 0.7 g showed clinically meaningful BP reductions. Flaxseed oil may also lower BP. In one study, along with reducing the intake of saturated fat, 1 tbsp/day of flaxseed oil reduced both the systolic and diastolic readings by up to 9 mm Hg.[57] Another study found that for every absolute 1% increase in body alpha-linolenic acid content, there was a decrease of 5 mm Hg in the systolic, diastolic, and mean BPs.[58]

Arginine

Arginine, an amino acid, is important in the formation of nitric oxide. This compound plays a central role in determining the tone of blood vessels and renal function. Specifically, it exerts a relaxing effect on

blood vessels, thereby improving blood flow as well as renal plasma flow and the glomerular filtration rate. Normally the body makes enough arginine even when the diet is lacking. However, in some instances, the body may not be able to keep up with increased requirements, in which case supplementation may prove useful. In high BP, even in mild cases, there appears to be a derangement of endothelial nitric oxide production, especially in the kidneys.

Low levels of NO are associated with impaired endothelial function. Asymmetrical dimethylarginine (ADMA), an analog of L-arginine, is a naturally occurring product of metabolism found in human circulation. Elevated levels of ADMA inhibit NO synthesis and therefore impair endothelial function and thus promote atherosclerosis and hypertension. Experimental data from cell culture and animal experiments and cross-sectional studies in humans suggest an association between elevated ADMA concentrations and cardiovascular diseases.

In a randomized, double-blind, placebo-controlled study investigating endothelial function as measured by brachial artery flow-mediated dilatation (FMD), serum ADMA and serum L-arginine levels in 49 hypercholesterolemic individuals were compared with those of individuals with normal cholesterol levels.[59] People with hypercholesterolemia had impaired endothelial function, increased ADMA levels, and decreased L-arginine/ADMA ratios. ADMA levels were inversely correlated to the endothelial-dependent vasodilatation, and intravenous infusion of L-arginine normalized the L-arginine/ADMA ratio as well as the endothelial function.

A 2005 study investigated the relationship between ADMA plasma levels and endothelium-dependent vasodilation in 36 patients with never-treated essential hypertension and 8 normotensive healthy subjects.[60] Subjects with hypertension had impaired brachial artery FMD, increased ADMA levels, and increased L-arginine plasma concentrations compared with normotensive controls. These measures were inversely correlated with ADMA levels, independently accounting for 34% of the interindividual variability in peak flow-mediated dilatation. Infusion of L-arginine improved the endothelial function.

Arginine supplementation has been shown to be beneficial in several cardiovascular diseases, including hypertension. By increasing nitric oxide levels, arginine supplementation improves blood flow, reduces the formation of blood clots, and improves blood fluidity. In hypertension, the degree of improvement offered by arginine supplementation can be quite significant in some cases.[61,62] In general, however, a dosage of 4 g three times daily will produce only modest decreases (e.g., 5 mm Hg) in systolic BP with little meaningful change in diastolic BP.[63] Arginine supplementation may prove to be most beneficial in younger subjects with essential hypertension because older adult patients with hypertension appear to have a derangement in NO-dependent renal mechanisms. In a study comparing the renal response with an intravenous infusion of arginine in young and aged patients with essential hypertension, arginine induced a significant increase in renal plasma flow, arginine glomerular filtration rate, and natriuresis and kaliuresis in the younger subjects, without changes in filtration fraction.[64] These effects were not observed in older subjects.

One trial investigated the influence of a combination of L-arginine with the vitamins B_6, folic acid, and B_{12} (TELCOR Arginin plus) on endothelial dysfunction in subjects aged 40 to 65 years with mild to moderate BP elevation not treated with antihypertensive drugs.[65] Individuals were randomly assigned to either the dietetic product ($n = 40$) or a matching placebo ($n = 41$) for 3 months with open follow-up for a further 3 months. The primary efficacy analysis demonstrated a statistically significant superiority of the combination of L-arginine with B vitamins over placebo in improving and restoring impaired endothelial function and lowering BP in patients with mild to moderate blood pressure elevation.

Anti-ACE Peptides

Various naturally occurring peptides have been shown to inhibit ACEs, including peptides from milk, chicken, and fish. The best-studied are composed of a purified mixture of nine small peptides (proteins) derived from muscle of the fish bonito (a member of the tuna family).[66–68] Anti-ACE bonito peptides do not appear to produce the side effects typical of ACE inhibitors (according to human safety studies) and do not lower BP in people with normal BP, even when administered at levels 20 times greater than the dose level that lowers BP in people with high BP. A possible reason is that its mechanism of action in inhibiting ACEs is different from that of the drugs. Research bears out this theory. The drugs indiscriminately block ACEs by interfering with their action, whereas the bonito anti-ACE peptides interact much differently. ACEs convert angiotensin I to angiotensin II by cleaving off a small peptide. Drugs work by directly blocking this action. Naturally occurring anti-ACE peptides work differently; ACEs actually react with the peptides instead of angiotensin. In addition to competing with angiotensin via this effect, anti-ACE peptides are transformed into even more potent inhibitors of ACEs. Technically speaking, the bonito anti-ACE peptides are considered a "prodrug" because the transformed peptides exert an 800% greater activity level.

Four clinical studies have shown that fish-derived anti-ACE peptides (three with the bonito peptides and one with a dipeptide from sardine) exert significant BP-lowering effects in people with high BP.[67–69] The degree of BP reduction in these studies was quite significant, typically reducing the systolic BP by at least 10 mm Hg and the diastolic BP by 7 mm Hg in people with hypertension. Greater reductions are seen in people with higher initial BP readings.

Coenzyme Q_{10}

Coenzyme Q_{10} (CoQ_{10}), also known as ubiquinone, is an essential component of the mitochondria. Although CoQ_{10} can be synthesized within the body, deficiency states have been reported. In hypertension, CoQ_{10} deficiency has been shown to be present in 39% of patients. This finding alone suggests a need for CoQ_{10} supplementation. However, CoQ_{10} appears to provide benefits beyond the correction of a deficiency.

The majority of studies exploring CoQ10 in the treatment of high BP have been uncontrolled or have used CoQ10 in combination with conventional antihypertensive medical treatments, making these studies difficult to interpret. A Cochrane review on CoQ_{10} in the treatment of hypertension (12 clinical trials, 362 patients) concluded that in hypertensive patients, CoQ_{10} has the potential to lower systolic and diastolic BP without significant side effects.[70] Among all included studies, decreases in systolic BP ranged from 11 to 17 mm Hg and in diastolic BP from 8 to 10 mm Hg. In 3 of the 12 studies, CoQ_{10} was given in addition to existing antihypertensive medication, and in one of these, more than 50% of the patients were able to cease taking at least one antihypertensive medication during the trial. These results are consistent with some of the uncontrolled studies. For example, in one uncontrolled study, the dose of CoQ_{10} was adjusted in 109 patients with essential hypertension according to clinical response and blood CoQ_{10} levels (the aim was to attain blood levels >2 mg/mL). The average CoQ_{10} dose was 225 mg/day in addition to these patients' usual antihypertensive regimen. The need for antihypertensive medication declined gradually; after a mean treatment period of 4.4 months, about half of the patients were able to discontinue between one and three of their drugs.[71]

It is important to remember that the antihypertensive effect of CoQ_{10} is usually not seen until after 4 to 12 weeks of therapy. Thus CoQ_{10} is not a typical BP-lowering drug; rather, it seems to correct some metabolic abnormality, which in turn has a favorable influence on BP. For more information, see Chapter 79.

L-Citrulline

Supplementation with citrulline, an NO-boosting agent, has shown promise as a BP-lowering intervention in adults with hypertension, with animal evidence for atherogenic-endothelial protection. The cardiovascular health benefits of L-citrulline are largely predicated on the capacity for citrulline to increase L-arginine availability for NO biosynthesis. In spontaneously hypertensive rats, L-citrulline treatment prevents hypertension by increasing the L-arginine/ADMA ratio.[72] In obese men with prehypertension or stage 1 hypertension, those treated with watermelon extract containing 6 g/day of L-citrulline/L-arginine, compared with placebo, for 6 weeks exhibited reduced ankle and brachial systolic blood pressure (–12 ± 4 and –15 ± 3 mm Hg, respectively), ankle and brachial diastolic blood pressure (–8 ± 2 and –8 ± 2 mm Hg, respectively), and carotid wave reflection, which may suggest improved arterial function.[73] A pilot study of middle-aged, prehypertensive men and women evaluated the effects of watermelon supplementation (L-citrulline/L-arginine, 2.7g/ 1.3g per day) on aortic BP and arterial function in individuals with prehypertension.[74] Compared with placebo, 6 weeks of watermelon extract supplementation improved peripheral vascular tone (decreased augmentation index and pulse wave velocity) and led to a significant reduction in aortic systolic blood pressure (–9 ± 3 vs. –2 ± 3 mm Hg) and nonsignificant reductions in brachial artery systolic blood pressure (–9 ± 7 vs. –3 ± 7 mm Hg).

Forty volunteers consumed 6 g of watermelon extract daily ($n = 20$; age 48.7 ± 1.9 years, 10 men) or a placebo ($n = 20$; age 47.4 ± 1.2 years, 11 men) in a 6-week randomized, double-blind, experimental, and placebo-controlled study to evaluate the effect of supplementation with watermelon extract on the BP and sympathovagal balance of individuals with prehypertension or hypertension.[75] BP and cardiac autonomic modulation were measured. Although there was no significant change in sympathovagal balance from the beginning (1.7 ± 0.1) to the end of the study (1.7 ± 0.4), watermelon extract promoted a significant reduction in systolic (137.8 ± 3.9–126.0 ± 4.0 mm Hg, $p < 0.0001$) and diastolic (79.2 ± 2.2–72.3 ± 2.0 mm Hg, $p < 0.001$) BP.

Accumulating human clinical trials provide evidence that L-citrulline and watermelon extract reduce peripheral and central (aortic) BP and improve resting BP and arterial stiffness in adults with prehypertension and those with hypertension.[76] In addition, L-citrulline appears to promote adaptations to physiological and environmental stressors to reduce vessel wall stiffness and attenuates any sympathetic-mediated hypertensive response.[77]

Caffeine

Caffeine consumption from coffee or tea can produce an immediate, short-lived increase in BP, and regular coffee drinking has been associated with slight increases in BP. However, it is generally thought that a tolerance to the hypertensive effects of caffeine develops in habitual coffee or tea drinkers.[78–79] Yet some studies have shown that with repeated administration of caffeine, a persistent pressor effect is produced. For example, in 11 short-term trials looking at the pressor effect of caffeine consumption (ranging from 14 to 79 days), the average dose of five cups of coffee per day was associated with an increase of 2.4 mm Hg in systolic BP and an increase of 1.2 mm Hg in diastolic BP.[80] Although the overall benefit of long-term avoidance of caffeine (from coffee, tea, chocolate, cola drinks, and some medications) on BP is unclear, it appears that some patients seem to respond quite favorably to caffeine avoidance. It should therefore be attempted in patients with hypertension.

Botanical Medicines

Crataegus Species

Extracts of hawthorn berries as well as of the flowering tops are widely used by physicians in Europe because of their cardiovascular effects. Several studies, including double-blind trials, have demonstrated that hawthorn extracts are effective in lowering BP and improving heart function.[81,82] However, the BP-lowering effect of hawthorn is mild. It typically takes 2 to 4 weeks before this agent begins to exert any effect. For more information, see Chapter 82.

Olive *(Olea europaea)*

The leaves of the olive tree (*Olea europaea* L.) have been used since ancient times to combat high BP, and this agent has significant support in animal and human studies both as an antihypertensive and in lowering cholesterol. The active substances are oleuropein (a polyphenolic iridoid glycoside),[83] oleacein, and oleanolic acid, which act as natural calcium channel blockers. Hydroxytyrosol is a metabolite of oleuropein that exerts antioxidant effects. Olive extracts are often standardized for hydroxytyrosol, but this compound is devoid of any significant antihypertensive effect. Oleuropein is also found in the olive's fruit and oil but in significantly smaller quantities than the leaf.

In an initial small double-blind study of patients with essential hypertension, 12 consulting for the first time and 18 currently on antihypertensive drugs, olive leaf extract at a dose of 400 mg four times daily for 3 months produced a modest yet statistically significant decrease in BP, with no side effects.[84]

Additional studies have used Benolea (EFLA943), standardized to oleuropein (16%–24%), and polyphenols. In a preliminary clinical study, 20 monozygotic adult twin pairs with mild hypertension received either a dose of 500 or 1000 mg daily for 8 weeks or a placebo. After 8 weeks, BP remained unchanged from baseline in the placebo group and the 500-mg/day group but was significantly decreased for the group receiving 1000 mg/day (137 vs. 126).[83]

In another study with Benolea, 232 patients with hypertension were given either the olive leaf extract (500 mg twice a day) or captopril (12.5 mg twice daily). The mean BP at baseline was 149.3/93.9 mm Hg in the group receiving olive leaf extract and 148.4/93.8 mm Hg in the group on captopril. Mean reductions in systolic BP from baseline to the end of the study were 11.5 and 13.7 mm Hg in the olive leaf extract and captopril groups, respectively, with parallel reductions in diastolic BP of 4.8 and 6.4 mm Hg, respectively.[85]

Allium Sativum and *Allium Cepa*

A meta-analysis of published and unpublished randomized controlled trials of garlic preparations was conducted to determine the effect of garlic on BP relative to placebo.[28] Eight trials (seven double blind, one single blind) were identified as meeting analytic criteria. In total, 415 subjects were included in the analysis. All trials used a dried garlic powder standardized to contain 1.3% allicin at a dose of 600 to 900 mg daily (corresponding to 7.8 and 11.7 mg, respectively, of allicin or the equivalent of approximately 1.8–2.7 g of fresh garlic daily). The meta-analysis concluded that garlic preparations designed to yield allicin can lower systolic and diastolic BP over a 1- to 3-month period. The typical drop from pooled data was 11 mm Hg in the systolic BP and 5 mm Hg in the diastolic BP.

Hibiscus Sabdariffa

Hibiscus tea and extracts prepared from the dried flowers (calyces) of *Hibiscus sabdariffa* have demonstrated antihypertensive properties in clinical trials. The active components are anthocyanidin glycosides. A systematic review and meta-analysis of randomized controlled trials

indicated a significant effect of *H. sabdariffa* supplementation in lowering both systolic blood pressure (weighted mean difference –7.58 mm Hg) and diastolic blood pressure (weighted mean difference –3.53 mm Hg).[86]

One double-blind, placebo-controlled clinical trial was conducted in 65 prehypertensive and mildly hypertensive adults 30 to 70 years of age who were not taking antihypertensive medications. They were given either three 240-mL servings per day of brewed hibiscus tea or a placebo beverage for 6 weeks. At 6 weeks, hibiscus tea was found to have lowered systolic BP compared with placebo (by 7.2 vs. 1.3 mm Hg). Diastolic BP was also lower, although this change did not differ from placebo. Participants with higher systolic BP at baseline showed a greater response to the hibiscus treatment.[87]

In another double-blind study, the effect of hibiscus tea was compared with that of black tea in 60 patients with diabetes and hypertension who were not taking antihypertensive or lipid-lowering drugs. The mean systolic BP in the hibiscus group decreased from 134.4 mm Hg at the beginning of the study to 112.7 mm Hg after 1 month, whereas it increased from 118.6 to 127.3 mm Hg in the group drinking black tea. The intervention had no statistically significant effect on the mean diastolic BP in either group.[88]

Another study with hibiscus tea did show an effect on diastolic BP (reducing it by 10.7%), as well as systolic BP (reducing it by 11.2%), after 12 days of treatment.[89]

Two clinical studies featured the use of a standardized extract of hibiscus in patients with high BP. In one double-blind study, 193 patients with hypertension were given either hibiscus extract (250 mg of total anthocyanins daily) or 10 mg of lisinopril (control group). The results showed that the hibiscus extract decreased BP from 146.48/97.77 to 129.89/85.96 mm Hg, reaching an absolute reduction of 17.14/11.97 mm Hg. The hibiscus treatment showed a therapeutic effectiveness of 65.12% as well as tolerability and safety of 100%. BP reductions and therapeutic effectiveness were lower than those obtained with lisinopril. Hibiscus treatment lowered plasma ACE activity from 44 to 30 U/L.[90]

Similar effects on BP were shown in another double-blind study with a standardized hibiscus extract (a daily dose of 9.6 mg of total anthocyanins) compared with captopril (50 mg/day). Hibiscus extract decreased the systolic BP from 139.05 to 123.73 mm Hg and the diastolic BP from 90.81 to 79.5 mm Hg.[91]

Viscum Album

Viscum album, or mistletoe, exhibits hypotensive action in animal studies. The crude extract of *V. album* possesses smooth-muscle–relaxant effects mediated through the voltage-dependent Ca(++) channel blockade, which may explain its spasmolytic and vasorelaxant activity.[92] *V. album* has been shown to inhibit the excitability of the vasomotor center in the medulla oblongata and to possess cholinomimetic activity.[87]

Its hypotensive activity may depend on the form in which the mistletoe is administered and the host tree from which it was collected. Studies indicate that aqueous extracts are more effective; the highest hypotensive activity was demonstrated by a macerate of leaves of mistletoe parasitizing on willow and gathered in January (see Chapter 134 for further discussion).

THERAPEUTIC APPROACH

Elevated Blood Pressure (120–129/<80 mm Hg) or White-Coat Hypertension

- Reduce excessive weight (see Chapter 192 for more information).
- Substantially reduce or eliminate salt (sodium chloride) intake.
- Follow a healthy lifestyle. Avoid alcohol, caffeine, and smoking. Exercise and use stress-reduction techniques.
- Follow a potassium-rich diet that is high in fiber and consistent with either the Mediterranean or DASH diet.
- Increase dietary consumption of celery, garlic, and onions.
- Reduce or eliminate the intake of animal fats while increasing the intake of monounsaturated vegetable oils.
- Supplement the diet with the following:
  - A high-potency multivitamin and mineral formula
  - Vitamin C: 500 to 1000 mg three times a day
  - Magnesium: 600 to 1200 mg/day
  - Fresh garlic: the equivalent of 4000 mg/day
  - Omega-3 fatty acids such as flaxseed oil, 1 tbsp/day, or fish oils, 3 g total EPA/DHA content per day

If BP has not returned to normal after following these recommendations for a period of 3 months, the recommendations for stage 1 hypertension, given next, may be followed.

Stage 1 Hypertension (130–139/80–89 mm Hg)

- Employ all the measures mentioned earlier, plus the following:
  - CoQ_{10}: 100 mg two to three times a day
  - Anti-ACE peptides from bonito: 1500 mg/day
  - L-citrulline: 3 g/day to 10 g/day
  - Take one of the following:
    - Hawthorn extract (10% procyanidins or 1.8% vitexin–4%-rhamnoside): 100 to 250 mg three times a day
    - Olive leaf extract (17%–23% oleuropein content): 500 mg twice a day
    - Hibiscus: three 240-mL servings a day or an extract providing 10 to 20 mg anthocyanidins a day

These guidelines should be followed for 1 to 3 months. If the BP has not dropped below 135/85, the patient may have to be placed on antihypertensive medications.

Stage 2 Hypertension (140+/90+ mm Hg)

Drug intervention is required. All the measures mentioned previously should be employed. When satisfactory control over the high BP has been achieved, the patient can taper off the medications gradually.

Hyperthyroidism

Alan G. Christianson, NMD, and *Michael T. Murray, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Weakness; sweating; weight loss; nervousness; loose stools; heat intolerance; irritability; fatigue; tachycardia; warm, thin, moist skin; stare; tremor
- Diffuse nonpainful goiter
- Increased T4, free T4, and free T4 index
- Failure of thyroid suppression with T3 administration
- In Graves' disease: goiter (often with bruit), ophthalmopathy

GENERAL CONSIDERATIONS

Hyperthyroidism, also known as thyrotoxicosis, denotes a group of clinical disorders characterized by increased levels of tetraiodothyronine (T4) and/or triiodothyronine (T3). The autoimmune disorder Graves' disease accounts for up to 85% of all cases of hyperthyroidism. It is more common in women than men (ratio 8:1) and typically begins between the ages of 20 and 40. Diffuse, nonpainful goiter with hyperthyroidism is the most common presentation of Graves' disease. Less common signs and symptoms include exophthalmos, pretibial myxedema and other skin changes, nail changes (acropachy), and, in some groups, paralysis. The exophthalmos and skin changes can progress independently from thyroid dysfunction (euthyroid Graves' disease), making it difficult to predict the course of the disease. Ophthalmopathy and pretibial myxedema are caused by thyroid antibodies that cross-react with antigens in fibroblasts and adipocytes behind the eye (Fig. 180.1). Although no single immunological abnormality explains all the clinical features of the disease, the common denominator is the presence of antibodies against thyroid-stimulating hormone (TSH) receptors.

Disease Risk

Gender

The majority of original cases described by Parry, von Basedow, and Graves occurred in women. The female-to-male ratio in published series is 7:1 to 10:1, but the ratio in those with ophthalmic complications is about 1:1.

Stress

Recent stress has been recognized as a precipitating factor since Graves' disease was first recognized. In fact, the most common precipitating event is an "actual or threatened separation from an individual upon whom the patient is emotionally dependent."[1] Studies support the long-held observation that the onset of Graves' disease often follows emotional shock, specifically some sort of loss, such as divorce, death, or difficult separation.[2]

Genetics

Graves' disease is statistically more prevalent in some human leukocyte antigen (HLA) haplotypes, such as HLA-B8 and HLA-DR3 in Caucasians, HLA-Bw35 in Japanese populations, and HLA-Bw46 in Chinese populations.[1] HLA identical twins have a 50% chance of presenting with Graves' disease if one twin is affected, and there is a 9% chance for fraternal twins.[3] Some haplotypes appear to offer protection from manifesting Graves' disease. Genetic haplotype does not seem to affect the clinical course of Graves' disease or the response to treatment.

Smoking

Smoking is known to raise the risk and severity of ophthalmopathy among patients with Graves' disease.[4,5] Germline polymorphisms of detoxification genes and genes belonging to the major DNA

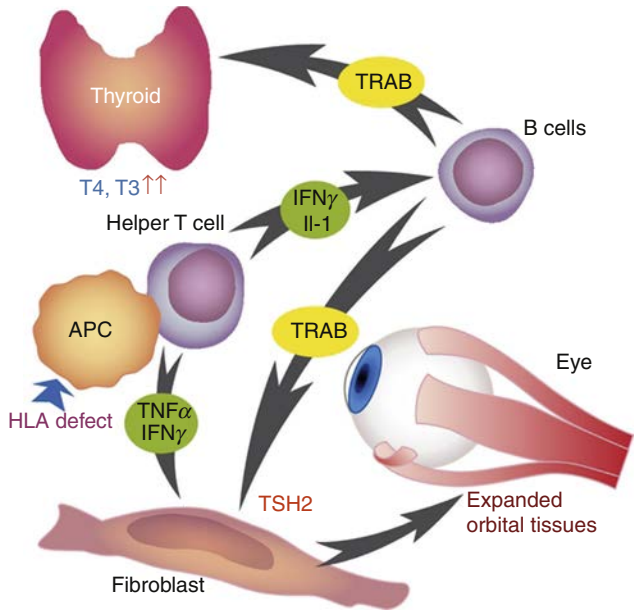

Fig. 180.1 Schematic representation of the cascade of events in the pathogenesis of Graves' ophthalmopathy. (From Duntas LH. The evolving role of selenium in the treatment of Graves' disease and ophthalmopathy. *J Thyroid Res.* 2012:736161. PubMed PMID: 22315699.)

repair-apoptosis pathways might have an important role in disease susceptibility, and because some of these genes are regulated by thyroid hormones, they may affect the patient outcomes. One prospective case-controlled study aimed to assess the influence of the GST, CYP, and TP53 gene polymorphisms in the risk of Graves' disease.[6] The authors concluded that GSTP1, CYP1A1, and TP53 germline polymorphisms may be associated with smoking-related Graves' disease susceptibility and configure a risk profile for the disease. However, these polymorphisms did not influence the patients' response to treatment.

Iodine Supplementation

An interesting study evaluated the effects of mandatory consumption of iodized salt in a whole population of 267,330 inhabitants of Galicia.[7] The incidence of thyrotoxicosis, diagnosed as elevated T4 and suppressed TSH levels, increased throughout the whole study period, with 4.89 new cases per 100,000 population. The rate of increase among females (8.03) was much greater than that among males (1.34). The increased incidence of thyrotoxicosis comprised both nodular and diffuse goiters. The authors concluded that dietary iodine supplementation in iodine-sufficient areas can increase the incidence of thyrotoxicosis in susceptible individuals.

Globally, similar scenarios have occurred. When a population's intake of iodine suddenly increases, even to appropriate levels, many individuals lapse into hyperthyroid states. This is more common among the elderly, those with positive thyroid antibodies, and those with marginal selenium status. Iodine from other sources in doses above 600 mcg can trigger Graves' disease and toxic multinodular goiter. Common sources include potassium iodide, an iodine/potassium iodide (Iodoral) supplement, medications such as amiodarone, and imaging contrast agents.[7]

Infection

The TSH receptor antibodies in Graves' disease share a similar structure with antibodies against several known pathogens. It has been shown that cases of Graves' have started during or shortly after acute infection with *Yersinia enterocolitica* and *Borrelia burgdorferi*.[8]

Drugs

In older patients with hyperthyroidism, a toxic reaction to prescription drugs must be considered. Exposure to iodine-containing contrast agents during medical procedures is a common scenario. Some sources recommend TSH screening before administration of iodine-containing contrast agents.[9] Another drug-induced cause of hyperthyroidism in the elderly is the use of amiodarone, an antiarrhythmic drug.[10]

Toxins

Workers exposed to 2,3,7,8-TCDD, a dioxin contaminant of chlorophenoxy herbicides, have significantly higher free T4 levels.[11] Children with high perinatal exposure to PCDD/Fs show no change in thyroid hormone levels at age 1 or 2 but have significantly elevated T3 levels at age 5.[12] A similar elevation of FT4 was noted at birth in babies exposed to dioxins in utero and through breast milk.[13] The elevation of FT4 in the exposed infants reached statistical significance at week 1 and week 11. By week 11, TSH concentrations were also statistically higher in the children receiving dioxin with their breast milk.

Perchlorate is known to competitively inhibit iodide uptake at the sodium iodide symporter and has been used in the past in the diagnosis and treatment of thyrotoxicosis.[14] Workers in an ammonium perchlorate production plant were found to have a 38% reduction in 14-hour thyroid radioactive iodine uptake.[15]

Other

Other factors that may initiate Graves' disease include corticosteroid use and local trauma to the thyroid. In addition, symptoms of hyperthyroidism vary somewhat in older adults, with apathy, tachycardia, and weight loss being more common. This response is more probable in those with subclinical hyperthyroidism (lack of symptoms, normal T4, but low TSH).

DIAGNOSIS

Clinical Presentation

The typical clinical presentation of Graves' disease is a young adult female complaining of the following:

- Nervousness
- Irritability
- Sweating
- Palpitations
- Insomnia
- Tremor
- Frequent stools
- Unexplained weight loss
- Metrorrhagia

Physical examination often reveals a smooth, diffuse, nontender goiter; tachycardia, especially after exercise; loud heart sounds (often a systolic murmur); mild proptosis, lid retraction, lid lag, and tremor; and exaggerated deep tendon reflexes.

Other signs and symptoms may include muscle weakness and fatigue, anxiety, heat intolerance, and pretibial myxedema. However, in atypical cases, especially in elderly patients, any or all of the previously mentioned symptoms may be absent. This presentation is known as apathetic thyrotoxicosis and has been known to present in the elderly, with the only symptom being depression. Special care must be taken to avoid missing the diagnosis with this presentation. A screening laboratory test for suppressed TSH is helpful in these patients. Also, it is useful to keep in mind that an increase in thyroid hormone can present as a worsening of already present cardiac symptoms such as angina pectoris, congestive heart failure, and atrial fibrillation.

TABLE 180.1 Relative Frequency of Primary Causes of Hyperthyroidism

Etiology	Relative Frequency[a]
Graves' disease	70%–85%
Toxic multinodular goiter	5%–15%
Toxic uninodular goiter	3%–30%
Thyroiditis (including so-called hashitoxicosis)	4%–23%
Drug induced	Commonly in the elderly; rare in the young except in cases where iodine is administered to a population
Postradiation	

[a]Overall frequency and relative frequency may be altered in certain populations (e.g., the elderly, individuals living in regions of endemic goiter).

The skin can show characteristic changes, becoming moist, warm, and finely textured. Perspiration increases as a response to the increased body temperature. Pigment changes such as vitiligo can be associated with Graves' disease, as well as increased pigmentation of areas such as skin creases and the knuckles. Hair may thin or fall out in patches or altogether (alopecia). Nails may separate prematurely from the nail bed (onycholysis). Localized, nonpitting edema typically occurs along the shins (myxedema) but may occur elsewhere, generally on the extensor surfaces, and is often pruritic and red.

Additional symptoms associated with Graves' disease, include glucose intolerance, dyspnea, polyuria and polydipsia, myopathy, paralysis, parkinsonian, and others.[16,17]

Although in severely hyperthyroid states symptoms are predictable, some symptoms can be paroxysmal, manifesting in both mild hyperthyroid and hypothyroid states. These include anxiety, palpitations, weight gain, fatigue, and insomnia. This is relevant in managing patients for either hypothyroidism or hyperthyroidism because it is not safe to assume that patients have increased or decreased levels of thyroid hormone based solely on symptoms.

Differential Diagnosis

Graves' disease is the most common diagnosis of hyperthyroidism, but several other conditions present with a similar symptom picture. The second most common cause is toxic nodular goiter, which includes toxic adenoma and multinodular goiter. Other causes of hyperthyroidism include early Hashimoto's thyroiditis (also known as hashitoxicosis), painless thyroiditis, and radiation thyroiditis. Hyperthyroidism can also result from exogenous causes, including iatrogenic hyperthyroidism, factitious hyperthyroidism (often seen in dieters who are taking thyroxine for weight loss), and iodine-induced hyperthyroidism (Jod–Basedow disease).

Rare causes of hyperthyroidism include thyroid carcinoma, ectopic hyperthyroidism, trophoblastic tumors (e.g., hydatidiform mole, choriocarcinoma, embryonic carcinoma of the testis), excessive TSH (e.g., pituitary adenoma, nonneoplastic pituitary secretion of TSH), and struma ovarii.

Table 180.1 indicates the relative frequency of the various causes of hyperthyroidism.

Laboratory Diagnosis

The laboratory is where the definitive diagnosis is made, and several tests are available to assess thyroid function and functional anatomy (Table 180.2).

In most cases, serum TSH will be suppressed below 0.2, and free T3 and free T4 may be elevated. Hyperthyroid morbidity and mortality risks are present even with TSH suppression alone. The autoimmune activity associated with Graves' disease involves both B and T lymphocytes and is directed at four specific thyroid antigens: the sodium/iodide symporter (NIS), thyroglobulin (Tg), thyroid peroxidase (TPO), and the thyrotropin receptor (TSH-R). TSH receptor antibodies (TSH-R Ab) or thyroid-stimulating immunoglobulins (TSIs) are present in 80% of cases of Graves' disease.

TABLE 180.2 Thyroid Function Tests in Hyperthyroidism

	Serum TSH	Serum T4	Serum T3	Free T4	24-h Radioiodine Uptake (Thyroid)
Hyperthyroidism, untreated	Low	High	High	High	High
Hyperthyroidism, toxicosis	Low	Normal	High	High	Normal

If a nodule or diffuse swelling is present on palpation or ultrasound, a thyroid uptake scan should be performed to guide treatment and rule out malignancy. The determination of serum antibodies can also be useful in ruling out cancer in patients with firm lobular goiters. High antibody levels suggest chronic thyroiditis in these cases. The presence of a nodule in the absence of abnormal thyroid function tests always warrants ultrasound and possible biopsy. Iodine scans show diffuse heightened iodine uptake in Graves' disease and localized heightened iodine uptake, also known as "hot" nodules, in toxic nodular goiter. "Cold" nodules on scans are regions of poor iodine uptake and are assumed to be cancerous until proven otherwise.

THERAPEUTIC CONSIDERATIONS

The objective of the natural treatment of Graves' disease and hyperthyroidism is to reduce symptoms while trying to reestablish normal thyroid status. Few treatments besides antithyroid drugs (ATDs), radiation, or surgery will have a significant effect on the immediate severity of hyperthyroid symptoms. Nonetheless, adjunctive treatments and Naturopathic lifestyle recommendations can lower the dose or duration of ATDs or increase the likelihood of disease remission when combined with conventional treatment.

Practical steps include reduction of risk factors (e.g., stress, smoking, excess iodine intake) and increased rest. Stress control is the single most important action the patient can take to assist normalization of the thyroid. The patient should avoid anything that will excite him or her and increase agitation. Counseling may be incorporated to prevent a return to a stress-generating lifestyle. Rest should also be increased.

Comorbidities

Patients with autoimmune thyroid disease are more likely than the general population to suffer from the following[18]:

- Celiac disease
- Osteoporosis
- Mitral valve prolapse
- Type 1 diabetes

CONVENTIONAL TREATMENT OF HYPERTHYROIDISM

Conventional first-line treatment of hyperthyroidism in the United States focuses on radioactive iodine ablation. Advantages include a high rate of response and lack of ongoing suppression. Disadvantages include progression to hypothyroidism and an elevated risk of nonlocalized cancers and parathyroid disease.

Surgery to remove all or part of the gland is less commonly used for hyperthyroidism. It is a consideration when the patient is very young or pregnant and iodine or ATDs are less preferred. It can also be considered when the gland is enlarged enough to create anatomical impingement on adjacent structures or cosmetic concerns. Disadvantages include laryngeal nerve damage, parathyroid abnormalities through localized trauma or inadvertent removal, and general surgical complications.

Globally, ATDs are more commonly relied on as mainstays of treatment for hyperthyroidism. Most cases can be given a trial of an ATD for 18 to 24 months; these individuals may not need ongoing treatment afterward. The disadvantage is that they can have hepatic and hematologic toxicities and monitoring is required.

ATDs work by entering the thyroid via active transport mechanisms, accumulating inside the thyroid, and inhibiting binding of iodine to tyrosine, thus disrupting hormone synthesis. In Europe and Japan, ATD treatment is considered a first-line approach for Graves' and Plummer's diseases. Most cases are known to resolve within 18 months, and most remain euthyroid or hypothyroid for life. In the United States, radioactive iodine (RAI) is considered first-line therapy, with ATDs only being used for initial management.[19] However, according to a recent study examining the frequency of antithyroid drug prescription in the United States, methimazole has become the most frequently prescribed antithyroid drug, indicating a shift toward pharmacological treatment as the primary treatment option in Graves' disease.[20]

Fluoride in the form of sodium fluoride is a natural compound with antithyroid properties significant enough to allow for its use instead of conventional ATD or in conjunction with ATDs allowing for lower doses of medications. Historically, sodium fluoride and fluorotyrosine were used as oral antithyroid agents before propylthiouracil (PTU) and methimazole. Common doses of PTU used to manage adult hyperthyroidism range from 200 to 450 mg/day in divided doses and 5 to 20 mg/d in divided doses for methimazole. Fluoride is listed as a pregnancy category C agent and is known to cause gastrointestinal side effects at doses starting at 3 mg/kg and toxicity at doses starting at 5 mg/kg.

In the early management of hyperthyroidism, 4 to 6 weeks of ATD are needed to see clinical benefit because of the high amount of protein-bound iodine already stored within the thyroid gland. Excess levels of both T4 and T3 are known to be reabsorbed through enterohepatic recirculation. It has been shown that cholestyramine can speed the elimination of thyroid hormone by blocking enterohepatic recirculation.[18] It is plausible that dietary fibers such as rice bran or ground flax may have similar properties.

Diet

Balanced, Whole-Foods Diet

Small, frequent, high-calorie meals should be consumed to compensate for the increase in metabolism. Protein should be supplemented if the patient is nutritionally depleted. Caffeine-containing foods and other stimulants should be avoided. In mild cases, consumption of large amounts of raw *Brassica* family foods and raw soy products may be adequately combined with restricted iodine consumption to control symptoms.

Dietary Goitrogens

Some foods contain goitrogenic substances that prevent the utilization of iodine. These compounds are primarily isothiocyanates that are similar in action and structure to propylthiouracil. They are found in such foods as turnips, cabbage, rutabagas, mustard, cassava root, soybeans, peanuts, pine nuts, and millet. However, these foods are unreliable in the treatment of hyperthyroidism for the following reasons:

- The goitrogen content is quite low and has minimal beneficial effect on hyperthyroidism.
- Cooking inactivates goitrogens.
- No substantial documentation exists that these naturally occurring goitrogens interfere with thyroid function to any significant degree when dietary iodine levels are adequate.

Because iodine is found in kelp and other seaweeds, vegetables grown near the ocean, seafood, iodized salt, and some nutritional supplements should be avoided.[21] Great care must be exercised when using this approach because results are inconsistent, and a delay in effective treatment can harm the patient. If the patient does not respond within a few weeks of treatment, conventional intervention is required.

NUTRITIONAL SUPPLEMENTS

Iodine

Worldwide, iodine deficiency continues to be a problem, but in developed countries, iodine excess is more common. Sources of iodine include additives to food products (e.g., salt and iodine used to sterilize pipes in dairies) and in medical products (e.g., povidone/iodine washes, iodine-containing drugs such as amiodarone, radiographic dyes).

The effects of iodine in patients with hyperthyroidism include the following:

- Large doses of iodine temporarily reduce symptoms by stopping hormone synthesis (Wolff–Chaikoff effect).
- The thyroid can remain suppressed or can eventually resume hormone synthesis at a reduced, former, or even increased rate (escape from Wolff–Chaikoff).[22]
- Excess iodine can trigger hyperthyroidism (Jod–Basedow disease) in a euthyroid person or can trigger an overactive thyroid to return to normal.

From the brief descriptions of these three possibilities, aside from the initial suppression of thyroid function, the action of iodine is unpredictable.

- Iodine intake should be kept on the low end of the normal therapeutic range; 150 to 250 mcg/day for adults.

L-Carnitine

L-Carnitine is a ubiquitous nutrient in tissues, where it plays an important role in energy metabolism and may be beneficial in cases of hyperthyroidism.[23] Carnitine is already known for its important implications for cardiovascular disease, Alzheimer's disease, acquired immunodeficiency syndrome, and several other conditions (see Chapter 63).

Calcium

Calcium metabolism is altered in hyperthyroidism, and patients with Graves' disease are more susceptible to osteoporosis.

Selenium

Emerging research is showing that selenium deficiency influences the generation of free radicals, the conversion of T4 to T3, and the autoimmune thyroid process. Selenium administration may be effective and safe in patients with Graves' disease and with mild forms of Graves' orbitopathy.

A prospective, case-control study of 198 patients from Australia aimed to determine whether serum selenium levels are reduced in patients with Graves' disease with orbitopathy compared with those without orbitopathy.[24] Results showed that mean serum selenium levels were significantly lower in individuals with Graves' orbitopathy than in those without orbitopathy. In addition, mean selenium levels appeared to decrease in parallel with increasing severity of orbitopathy.

One randomized, double-blind, placebo-controlled trial compared the effect of selenium (an antioxidant agent) or pentoxifylline (an anti-inflammatory agent) in 159 patients with mild Graves' orbitopathy.[25] The patients were given selenium (100 μg twice daily—a very modest dosage), pentoxifylline (600 mg twice daily), or placebo (twice daily) orally for 6 months. Selenium, but not pentoxifylline, was shown to improve quality of life, reduce ocular involvement, and significantly slow the progression of the disease. Moreover, a 6-month follow-up confirmed the benefits of the 6-month selenium treatment.

Antioxidants

Oxygen free radicals and cytokines play a pathogenic role in Graves' disease as well as in the development of Graves' orbitopathy. Patients with Graves' disease who received supplementation with a mixture of antioxidants (selenium, beta-carotene, vitamin C, and vitamin E) in addition to therapy with methimazole achieved euthyroidism faster than patients taking methimazole alone.[26] A prospective, nonrandomized, comparative study of patients with mild or moderately severe, active, newly diagnosed Graves' ophthalmopathy found that 82% of patients treated with oral antioxidants showed improvement in symptoms compared with only 27% of the control group.[27] Although the sample size was small, the encouraging results warrant further prospective studies.

Vitamin D

Low serum vitamin D status is associated with the development of autoimmune diseases, including hyperthyroidism and new-onset Graves' disease. A quantitative meta-analysis of t20 case-control studies found that patients with autoimmune thyroid disease had lower levels of 25(OH)D and were more likely to be deficient in 25(OH)D compared with controls.[28] Subgroup analyses results showed that patients with Graves' disease and Hashimoto's thyroiditis also had lower 25(OH)D levels and were more likely to have a 25(OH)D deficiency. In addition, considering the increase in metabolic rate and systemic functioning, vitamin D supplementation is recommended to maintain bone mineral density and to maintain circulating vitamin D concentrations.

Vitamin A

Vitamin A is vital for proper thyroid function, and deficiency is common in thyroid disorders. In a study of 190 patients with goiter, serum levels were significantly decreased in those with hyperthyroidism or hypothyroidism.[29]

Botanical Medicines

Table 180.3 lists medicinal plants that have traditionally been used in the treatment of hyperthyroidism. Unfortunately, these plants have not been adequately evaluated in clinical studies.

Lycopus Species, *Lithospermum officinale,* and *Melissa officinalis*

Aqueous freeze-dried extracts of *Lycopus* species, *Lithospermum officinale,* and *Melissa officinalis* have been studied both in vivo and in vitro, with preliminary results supporting their use in the treatment of Graves' disease. However, additional research is necessary before these plants can be relied on clinically.

Effects noted for these three plants include an ability to inhibit the effects of exogenous TSH on the thyroid glands of rats, block the effects of TSH on the TSH receptor sites located on thyroid membranes, inhibit the peripheral deiodination of T4 to T3, and block the effects of antithyroid immunoglobulins on TSH receptors.[30–32]

Eight isolated compounds, mainly oxidation products of derivatives of 3,4-dihydroxycinnamic acid, were found to be responsible for most of these effects.[33] The blocking effects of the isolated compounds of the TSH receptors were reversible, and none of the compounds combined irreversibly, damaged, or altered the TSH receptors in situ.

TABLE 180.3 Medicinal Plants Traditionally Used in the Treatment of Hyperthyroidism

Medicinal Plant	Traditional Indications
Valerian officinalis	Nervine effect
Scutellaria lateriflora	Nervine effect
Cactus grandiflorus	Heart tonic; used with elevated pulse
Iris versicolor	Traditionally used for hyperthyroidism
Fucus spp.	To be used with caution because a high iodine content can improve symptoms at first and then later cause aggravation
Lycopus spp.	Blocks the TSH receptors; blocks peripheral conversion of T4 to T3
Lithospermum officinale	Blocks the TSH receptors
Melissa officinalis	Blocks the TSH receptors

TSH, Thyroid-stimulating hormone.
Data from Felter HW. *The Eclectic Material Medica, Pharmacology and Therapeutics.* Portland, OR: Eclectic Medical Publications; 1985 (first published Cincinnati, 1922); Hoffman D. *The New Holistic Herbal: A Herbal Celebrating the Wholeness of Life.* Rockport, MA: Element;1990.

An alcohol extract of *Lycopus europaeus* administered orally to rats caused a long-lasting decrease in T3 levels, presumably due to reduced peripheral T4 deiodination. A pronounced reduction in TSH was also observed 24 hours later, as were declines in luteinizing hormone and testosterone.[34] Water extracts did not have as strong an effect, explaining the lack of results in some earlier studies. This finding is consistent with the observation that the active constituents are the unoxidized phenolic compounds, which are not present in the aqueous extract.

Although these findings support the traditional use of these plants for patients with hyperactive thyroids, there is no research on the clinical use of these plants or documented guidelines for dosage recommendations. Anecdotally, most who have attempted to use botanical medication to treat Graves' disease have found it to be ineffective.

THERAPEUTIC APPROACH

Acute Graves' disease is not easily treated by naturopathic methods. In most cases, there is no guarantee that natural treatments will alleviate the symptoms. Thyroid storm is a potentially fatal complication and should be treated aggressively with antithyroid drugs, radio ablation, or thyroidectomy. In mild cases, natural therapeutics can manage the symptoms well but must be monitored carefully to avoid sudden exacerbation of the illness. Patients will often do well for a time and then relapse. Mild cases should be treated symptomatically and allowed to return to a euthyroid status if possible. Rarely are natural antithyroid treatments adequate as monotherapies. If iodine is used, then ablative treatment should also be scheduled, as the risk of escape, with a potential for a return to even more intense symptoms, increases with time.

The allopathic treatment of Graves' disease is unusual in that there are three relatively equal treatments from which to choose. As physicians, it is best to educate patients about the advantages and disadvantages of each treatment option and work together to decide which treatment best fits their needs. Importantly, decision making is difficult while patients are in a thyrotoxic state. For these individuals, symptomatic relief must be rendered before a decision is made.

Antithyroid medications can manage symptoms indefinitely while waiting for a possible return to euthyroid status. The main consideration is they can have immunosuppresant and hepatotoxic effects.

Monitoring is required and changing therapies may be needed. If these drugs are not well tolerated, then ablative therapies must be considered. Surgery has a higher rate of euthyroid results than radioactive iodine but carries a greater risk of serious complications. Regardless of the treatment selected, supportive treatment should be rendered.

Diet

A whole-foods diet with increased levels of calories, micronutrients, and protein is recommended to meet the increased metabolic needs of the patient with hyperthyroidism. In mild cases, consumption of large amounts of raw *Brassica* family foods and raw soy products may be adequately combined with restricted iodine consumption to control symptoms.

Supplements

- Fluoride: 3 to 10 mg/day
- Indole 3 carbinol: 200 to 600 mg/day
- Selenium: 60 to 200 µcg/day

Botanical Medicines

- *Lycopus* species, *L. officinale,* or *M. officinalis*
- Dried herb: 1 to 3 g or by infusion three times a day
- Tincture (1:5): 2 to 6 mL three times a day
- Fluid extract (1:1): 1 to 3 mL three times a day

Hypoglycemia

Michael T. Murray, ND

OUTLINE

DIAGNOSTIC SUMMARY

- Blood glucose level at or below 40 to 50 mg/dL
- A normal response curve during the first 2 to 3 hours of a glucose tolerance test (GTT), followed by a decrease of 20 mg or more below the fasting glucose level during the final hours of the test, with symptoms developing during the decrease

INTRODUCTION

Both low and high blood glucose levels can cause significant physiological dysfunction. Normally, the body maintains blood sugar levels within a narrow range through the coordinated effort of several glands and their hormones (Fig. 181.1). If these control mechanisms are disrupted, hypoglycemia (low blood sugar) or hyperglycemia (high blood sugar) may result.

The beta cells of the pancreas respond to the rise in blood glucose levels after meals by secreting the hormone insulin, which lowers blood glucose by increasing the rate at which glucose is taken up by cells throughout the body. Reductions in blood glucose, as occur during food deprivation or exercise, cause the release of the hormone glucagon by the alpha cells of the pancreas. Glucagon stimulates the release of glucose stored in body tissues as glycogen, especially the liver. Rapidly falling blood sugar levels, anger, fright, and stress may stimulate the release of epinephrine and corticosteroids by the adrenal glands. These hormones provide a quicker breakdown of stored glucose for extra energy during a crisis or increased need.

Americans overstress these control mechanisms through improper diet and lifestyle. As a result, diabetes and hypoglycemia are common diseases.

Hypoglycemia can be divided into two main categories: reactive hypoglycemia and fasting hypoglycemia. Reactive hypoglycemia, the most common, is characterized by the development of symptoms of hypoglycemia 3 to 5 hours after a meal and may herald the early onset of type 2 diabetes.

Despite this rather straightforward designation into reactive and fasting hypoglycemia, there are underlying factors that can lead to more precise designations. Hypoglycemia can further result from insulinoma, noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS), postbariatric surgery, dumping syndrome, insulin autoimmunity, or postprandial syndrome.[1] Reactive hypoglycemia may also result from the use of oral hypoglycemic drugs (Box 181.1).

Some researchers suggest that reactive hypoglycemia should instead be termed *idiopathic postprandial syndrome*. Although symptoms exist and are related to rapid drops in blood glucose, the absolute glucose levels are not reliable indicators of the syndrome. Many asymptomatic controls have glucose levels below 50, and many symptomatic patients have normal postprandial glucose levels.[2–4] Fasting hypoglycemia is rare because it usually appears only in severe disease states, such as pancreatic tumors, extensive liver damage, prolonged starvation, autoantibodies against insulin or its receptor, various cancers, or from excessive exogenous insulin in patients with diabetes. Pregnant women with diabetes who use insulin or oral glycemic medications also have a high incidence of asymptomatic hypoglycemic events.[5]

Hypoglycemia can promote untoward physiological changes in the body. Insulin-induced hypoglycemia is known to increase the levels of C-reactive protein (CRP), a known cardiac risk factor.[6] Glucose is the primary fuel for the brain, and thus low levels initially affect the brain. Symptoms of hypoglycemia can range from mild to severe and may include the following:

- Headache
- Depression, anxiety, irritability, and other psychological disturbances
- Blurred vision
- Excessive sweating
- Mental confusion
- Incoherent speech
- Nocturnal hypoglycemic episodes
- Bizarre behavior
- Convulsions

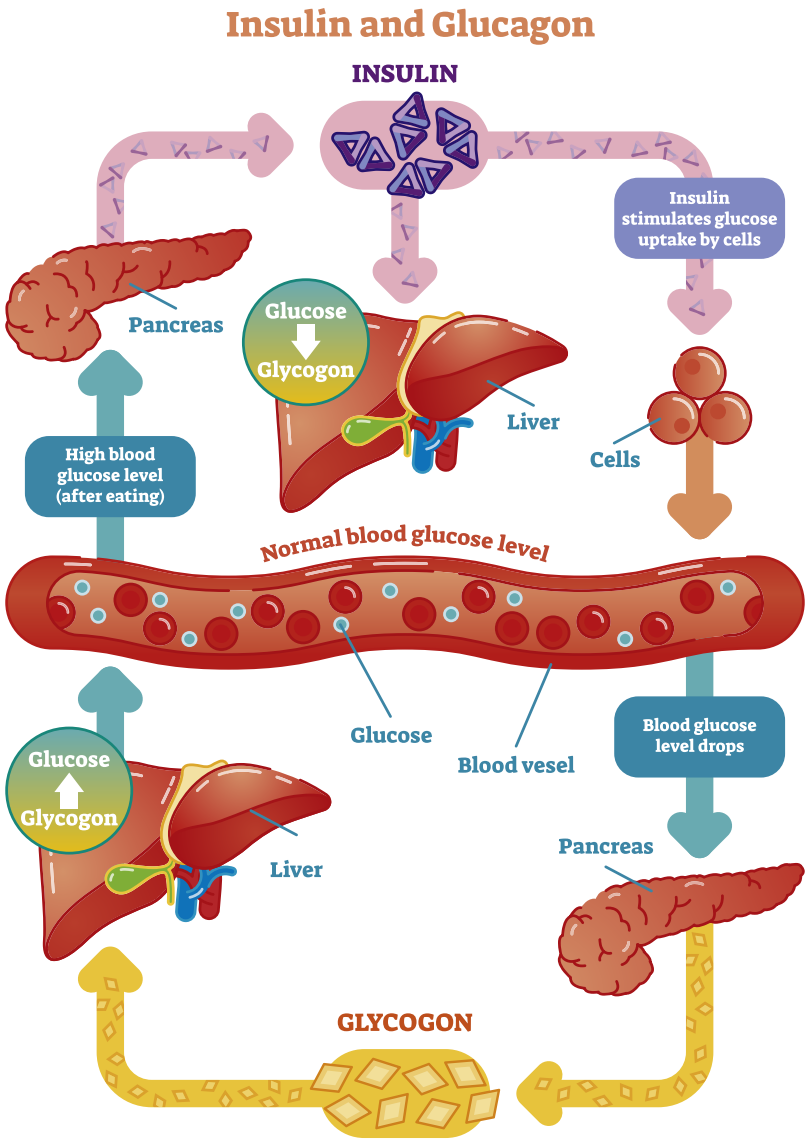

Fig. 181.1 The cycle of glucose control.

BOX 181.1 Oral Hypoglycemic Drugs

Alpha-glucosidase inhibitors
- Acarbose (Precose)
- Miglitol (Glyset)

Biguanide
- Metformin (Glucophage)

Meglitinides
- Repaglinide (Prandin)
- Nateglinide (Starlix)

Sulfonylureas
- Acetohexamide
- Chlorpropamide (Diabinese)
- Tolbutamide (Orinase)

Sulfonylureas (second generation)
- Glipizide (Glucotrol)
- Glibenclamide, Glyburide (DiaBeta, Micronase, Glynase)
- Glimepiride (Amaryl)

Thiazolidinediones
- Rosiglitazone (Avandia)
- Pioglitazone (Actos)

The heart is also dependent on glucose. In a study in Japan, oral glucose tolerance (OGTT) was assessed in 116 nondiabetic patients with coronary artery disease.[7] Reactive hypoglycemia was observed in 24% (28 individuals) of the patients. These patients exhibited significantly elevated insulin levels at 1 hour. Furthermore, a significant increase in the white blood cell count during OGTT was observed in the reactive hypoglycemia group compared with the nonreactive hypoglycemia group.

DIAGNOSTIC CONSIDERATIONS

Clinical hypoglycemia is identified by the modified Whipple's criteria, consisting of (1) central nervous system symptoms, including confusion, aberrant behavior, or coma; (2) a simultaneous blood glucose level equal to or less than 40 mg/dL; and (3) relief of these symptoms by the administration of glucose.[1] The normal fasting blood glucose level is between 65 and 100 mg/dL. A fasting plasma blood glucose measurement greater than 126 mg/dL on two separate occasions is diagnostic of diabetes.[8] Although the most specific criterion for the presence of hypoglycemia is a blood glucose level of 40 mg/dL or less, a blood glucose level below 50 mg/dL should arouse clinical suspicion.[1]

TABLE 181.1 Criteria of Response to the Glucose Tolerance Test

Diagnosis	Response
Normal	No elevation >200 mg <200 mg at the end of the first hour <140 mg at the end of the second hour Never <20 mg below fasting
Flat	No variation more than ± 20 mg from fasting value
Prediabetic	>140 mg at the end of the second hour
Diabetic	≥200 mg at the end of the second hour
Reactive hypoglycemia	A normal 2- or 3-hour response curve, followed by a decrease of ≥20 mg from the fasting level during the final hours
Probable reactive hypoglycemia	A normal 2- or 3-hour response curve, followed by a decrease of 10–20 mg from the fasting level during the final hours
Flat hypoglycemia	An elevation of >20 mg, followed by a decrease of ≥20 mg below the fasting level
Prediabetic hypoglycemia	A 2-hour response identical to the hypoglycemic prediabetic response but showing a hypoglycemic response during the final 3 hours
Hyperinsulinism	A marked hypoglycemic response with a value of <50 mg during the third, fourth, or fifth hour

A more functional test of blood sugar control is the OGTT. It is used in the diagnosis of both reactive hypoglycemia and diabetes, although it is rarely required for the latter. After fasting for at least 12 hours, a baseline blood glucose measurement is collected. The subject then consumes a glucose-containing drink. The amount consumed is based on body weight: 1.75 g/kg. Blood sugar levels are measured at 30 minutes, 1 hour, and then hourly for up to 6 hours. Blood sugar levels greater than 200 mg/dL indicate diabetes. Levels below 50 mg/dL indicate reactive hypoglycemia. Table 181.1 further explains in detail how to interpret the results of a GTT.

The Glucose–Insulin Tolerance Test

Relying on blood sugar levels alone is often not enough to diagnose hypoglycemia. It is now widely recognized that the signs and symptoms of hypoglycemia can occur in individuals having blood glucose levels well above 50 mg/dL, and there is a wide overlap between symptomatic patients and asymptomatic controls.[3] Many of the symptoms linked to hypoglycemia appear to be the result of increases in insulin or epinephrine. It has been recommended that insulin or epinephrine (adrenaline) be measured during a GTT because symptoms often correlate better with elevations in these hormones than with glucose levels.[9,10] Several studies have shown that the glucose–insulin tolerance test (G-ITT) leads to a greater sensitivity in the diagnosis of both hypoglycemia and diabetes than the standard GTT.[10,11]

The G-ITT uses a standard 6-hour GTT coupled with measurements of insulin levels. The G-ITT appears to be one of the best diagnostic indicators for faulty sugar metabolism.[11] As many as two thirds of subjects with suspected diabetes or hypoglycemia who have normal GTTs will demonstrate abnormal insulin tolerance tests. Table 181.2 lists the various patterns seen with the G-ITT.

24-Hour Continuous Glucose Monitoring

Continuous glucose monitors (CGMs) are electronic diagnostic systems that require the insertion of a sensing catheter under the skin of the patient's abdomen. The catheter contains a miniaturized electronic device that measures blood sugar and then sends this information every few seconds to a pager-sized computer module worn on the patient's belt for up to a week. The portable computer module translates and records blood sugar data, which can then be downloaded to a larger computer. A graph showing the average blood sugar reading every 5 minutes (288 blood sugar readings per day) can then be generated and studied in relation to food intake, appetite, food cravings, hypoglycemic symptoms, medication, and exercise. CGMs have been shown to be very useful tools in the diagnosis and monitoring of blood sugar control.[12,13]

TABLE 181.2 Criteria for the Glucose–Insulin Tolerance Test

Pattern	Response
Pattern 1	Normal fasting insulin 0–30 units. Peak insulin at 0.5–1 hour. The combined insulin value for the second and third hours is <60 units. This pattern is considered normal.
Pattern 2	Normal fasting insulin. Peak at 0.5–1 hour with a "delayed return to normal." Second- and third-hour levels between 60 and 100 units are usually associated with hypoglycemia and are considered borderline for diabetes; values >100 units considered definite diabetes.
Pattern 3	Normal fasting insulin. Definite diabetes.
Pattern 4	High fasting insulin. Definite diabetes.
Pattern 5	Low insulin response. All tested values for insulin <30. If this response is associated with elevated blood sugar levels, it probably indicates insulin-dependent diabetes ("juvenile pattern").

Using a CGM, Michael R. Lyon, MD, has discovered that most people with weight problems and insulin resistance go through their days with remarkably fluctuating blood sugar, or increased glycemic volatility. Rather than the absolute glucose level being the prime determinant of hypoglycemic symptoms, Lyon has found that feelings of hypoglycemia occur when the blood sugar drops rapidly, even when it is above the normal range (i.e., between 70 and 100 mg/dL) (Fig. 181.2). In such cases, symptoms of hypoglycemia can range from mild to severe and include such things as food cravings, headache, depression, anxiety, irritability, blurred vision, excessive sweating, and mental confusion.

Rather than referring to these patients as suffering from hypoglycemia, Lyon and Michael T. Murray, ND, propose that they suffer from a new clinical entity referred to as "elevated glycemic volatility."[14] These authors believe that such volatility is at the heart of most weight problems. Their data indicate that rapidly fluctuating blood sugar levels are generally related to some degree of insulin resistance and made worse by more-than-moderate consumption of foods with a high glycemic effect.

The Hypoglycemic Index

In borderline cases of hypoglycemia, the hypoglycemic index may aid in the diagnosis. This value is determined by calculating the fall in blood glucose levels during the 90-minute period before reaching the lowest point divided by the value of the lowest point. A hypoglycemic index greater than 0.8 usually indicates reactive hypoglycemia.

The Hypoglycemia Questionnaire

In many cases, when all is considered, the most useful measure in the diagnosis of hypoglycemia remains an assessment of symptoms. In general, when symptoms appear 3 to 4 hours after eating and disappear

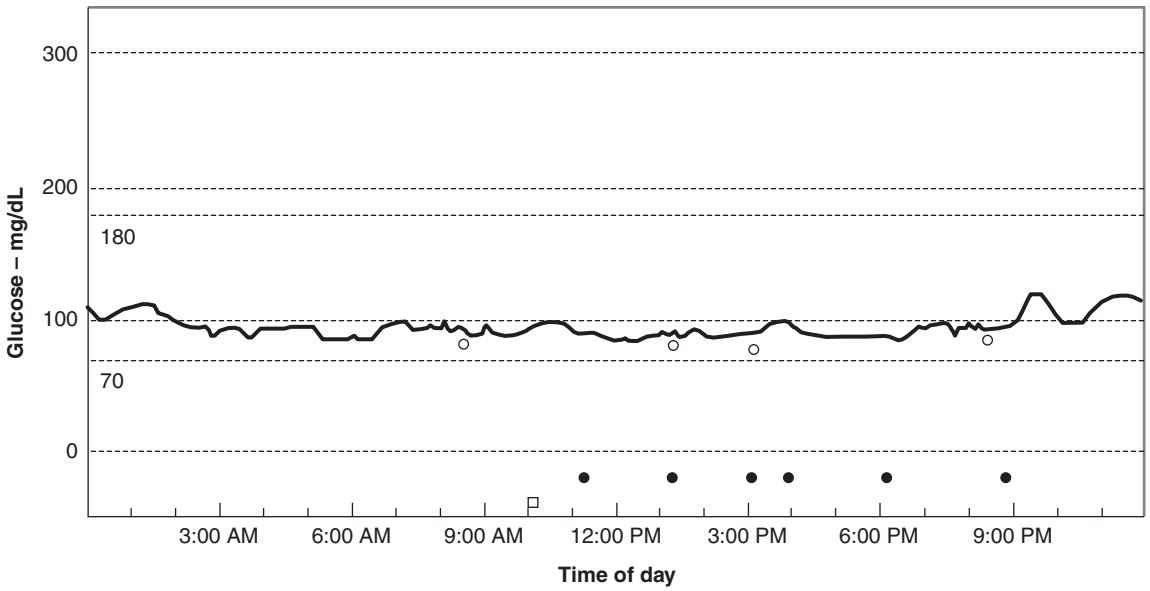

Fig. 181.2 Blood sugar stabilization from fiber supplementation (same patient as in Fig. 181.1). (Courtesy Dr. Michael Lyon.)

with the ingestion of food, hypoglycemia should be considered. The questionnaire shown in Table 181.3 is an excellent screening method for hypoglycemia.

GENERAL CONSIDERATIONS

In the 1970s, hypoglycemia was a popular "self-diagnosis" for a long list of symptoms; every symptom on the questionnaire in Table 181.3 was linked to hypoglycemia. Although all these symptoms may be due to hypoglycemia, many cases have other etiologies. The tremendous public interest in hypoglycemia and sugar intake was fueled by popular books like *Sugar Blues,* by William Duffy; *Hope for Hypoglycemia,* by Broda Barnes; and *Sweet and Dangerous,* by John Yudkin. The popularity of these books and the diagnosis of hypoglycemia were met with much skepticism from the medical community. Editorials in the *Journal of the American Medical Association* and the *New England Journal of Medicine* during the 1970s denounced this public interest in hypoglycemia and tried to invalidate the concept.[15,16]

Research has provided an ever-increasing amount of information concerning the roles that refined carbohydrates and the faulty control of blood sugar play in many disease processes. *Metabolic syndrome* or *syndrome X* describes a cluster of abnormalities that owe their existence largely to a high intake of refined carbohydrates, leading to the development of hypoglycemia, excessive insulin secretion, and glucose intolerance followed by diminished insulin sensitivity and leading to high blood pressure, elevated cholesterol levels, obesity, and ultimately, type 2 diabetes. Metabolic syndrome is discussed in greater detail later.

Hypoglycemia, or idiopathic postprandial syndrome, is without question a valid clinical entity. A substantial amount of information indicates that hypoglycemia is caused by an excessive intake of refined carbohydrates.[17,18] Although most medical and health organizations, as well as the U.S. government, have recommended that no more than 10% of the total caloric intake be derived from refined sugars added to foods, added sugar accounts for roughly 30% of the total calories consumed by most Americans.[19] The average American consumes more than 100 lb of sucrose and 40 lb of high-fructose corn syrup each year. This sugar addiction plays a major role in the high prevalence of ill health and chronic disease in the United States.

TABLE 181.3 Hypoglycemia Questionnaire

	None	Mild	Moderate	Severe
Crave sweets	0	1	2	3
Irritable if a meal is missed	0	1	2	3
Feel tired or weak if a meal is missed	0	1	2	3
Dizzy when standing suddenly	0	1	2	3
Frequent headaches	0	1	2	3
Poor memory (forgetful) or concentration	0	1	2	3
Feel tired an hour or so after eating	0	1	2	3
Heart palpitations	0	1	2	3
Feel shaky at times	0	1	2	3
Afternoon fatigue	0	1	2	3
Vision blurs on occasion	0	1	2	3
Depression or mood swings	0	1	2	3
Overweight	0	1	2	3
Frequently anxious or nervous	0	1	2	3

Total Scoring: <5, hypoglycemia not likely a factor; 6 to 15, hypoglycemia a likely factor; 15, hypoglycemia extremely likely.

Health Effects of Hypoglycemia

Hypoglycemia and the Brain

The brain depends on glucose as an energy source. During hypoglycemic events, brain dysfunction develops, resulting in dizziness, headache, clouding of vision, blunted mental acuity, emotional instability, confusion, and abnormal behavior.

The association between hypoglycemia and impaired mental function is well known. However, the role of hypoglycemia in various psychological disorders is often overlooked. For example, despite numerous studies of depressed individuals showing a high percentage of abnormal glucose or insulin tolerance tests, rarely is hypoglycemia considered, and rarely are depressed individuals offered dietary therapy.[20,21] There is no explanation for this oversight among so many

physicians, especially because dietary therapy (usually simply eliminating refined carbohydrates from the diet) is occasionally all that is necessary for effective therapy in patients who suffer from depression due to reactive hypoglycemia.

Aggressive and Criminal Behavior

A strong yet controversial link exists between hypoglycemia and aggressive or criminal behavior. Several controlled studies among psychiatric patients and habitually violent and impulsive criminals have shown that reactive hypoglycemia (as determined by an OGTT) is a common finding.[22,23] Furthermore, during the GTT, abnormal and sometimes emotionally explosive behavior is often observed. In one study, reactive hypoglycemia was shown to induce fire-setting behavior in arsonists.[24]

Several large studies involving more than 6000 inmates in 10 correctional institutions in three states have evaluated the effect of dietary intervention (i.e., the elimination of refined sugar) on antisocial or aggressive behavior.[25,26]

In the first study, 174 incarcerated juvenile delinquents were placed on a sugar-restricted diet, and another 102 offenders were placed on a control diet.[25] During the 2-year study, the incidence of antisocial behavior was reduced by 45% in the treatment group. The most significant changes were in the reduction of assaults (83%), theft (77%), "horseplay" (65%), and refusal to obey orders (55%). Antisocial behavior changed most in those charged with assault, robbery, rape, aggravated assault, auto theft, vandalism, child molestation, arson, and possession of a deadly weapon.

In the largest study, 3999 incarcerated juveniles were studied over a period of 2 years.[26] This study limited the dietary revisions to replacing sugary soft drinks with fruit juices and high-sugar snacks with nonrefined carbohydrate snacks (e.g., replacing a candy bar with popcorn). When the 1121 young men on the sugar-restricted diet were compared with the 884 on the control diet, there were significant differences: suicide attempts were reduced by 100%, the need for restraints to prevent self-injury was reduced by 75%, disruptive behavior was reduced by 42%, and assaults and fights were reduced by 25%. Interestingly, the dietary changes did not seem to affect the behavior of female subjects. This lack of effect seems to indicate that men and women may react to hypoglycemia differently. From an anthropological and evolutionary view, this makes sense. Low blood sugar levels were undoubtedly an internal signal for men to hunt for food.

The link between hypoglycemia and aggressive behavior also extends to men without a history of criminal activity. In one study, a GTT was given to a group of men who did not have a history of aggressive behavior or hypoglycemia.[18] In these subjects, a significant correlation was found between the tendency to become mildly hypoglycemic and scores on questionnaires used to measure aggression. The results indicate that aggressiveness often coincides with hypoglycemia.

Premenstrual Syndrome

The premenstrual syndrome (PMS) is a recurrent condition of women characterized by troublesome yet often ill-defined symptoms that usually appear 7 to 14 days before menstruation. The syndrome affects about one third of women between 30 and 40 years of age, about 10% of whom may have a significantly debilitating form.

An authority on PMS, Guy Abraham, MD, attempted to clarify the different forms by subdividing PMS into four distinct subgroups (A, C, D, and H).[27] Each subgroup is linked to specific symptoms, hormonal patterns, and metabolic abnormalities (see Chapter 212 for further information).

PMS-C is associated with increased appetite, craving for sweets, headache, fatigue, fainting spells, and heart palpitations. GTTs on patients with PMS-C during the 5 to 10 days before their menses typically displayed a flattening of the early part of the curve and reactive hypoglycemia, whereas during other parts of the menstrual cycle, the GTT was normal. A flat early portion of the GTT curve usually implies excessive secretion of insulin in response to sugar consumption. This appears to be hormonally regulated, but other factors may also be involved.[28] Sodium chloride ingestion enhances the insulin response to sugar ingestion, and decreased magnesium levels in the pancreas can result in the increased secretion of insulin in response to glucose. Regardless of the cause, women with PMS-C appear to be extremely sensitive to hypoglycemia.

Migraine Headaches

Migraine headaches are probably caused by excessive dilation (expansion) of a blood vessel in the head (see Chapter 198). Migraines are a surprisingly common disorder, affecting 15% to 20% of men and 25% to 30% of women at some time in their lives. More than one half of the patients have a family history of the illness. Since 1933, hypoglycemia has been shown to be a common precipitating factor in migraine headaches.[29]

Several studies have found that by eliminating refined sugar from the diets of migraine sufferers with confirmed hypoglycemia, significant improvement may be seen. In one study of 48 migraine sufferers with reactive hypoglycemia, 27 (56%) showed an improvement in symptoms of greater than 75%, 17 (35%) showed an improvement of greater than 50%, and 4 (8%) showed an improvement of greater than 25%.[30]

Atherosclerosis, Intermittent Claudication, and Angina

Substantial evidence indicates that reactive hypoglycemia or impaired glucose tolerance is a significant factor in the development of atherosclerosis. Although a high sugar intake leads to elevations in triglyceride and cholesterol levels, the real culprit may be the elevations of insulin.[31] Abnormal GTTs and elevations in insulin secretion are common findings in patients with heart disease.[32,33] High sugar consumption and reactive hypoglycemia can also be a cause of angina and intermittent claudication.[34,35]

Metabolic Syndrome

The term *metabolic syndrome* is used to describe a set of cardiovascular risk factors that includes glucose or insulin disturbances, high blood cholesterol and triglyceride levels, elevated blood pressure, and android obesity. Other terms to describe this syndrome include *syndrome X, Reaven's syndrome, insulin resistance syndrome,* and *atherothrombogenic syndrome.*[36,37]

The underlying common denominator in the metabolic syndrome is an elevated insulin level, along with insulin resistance. There is little doubt that an elevated intake of refined carbohydrates contributes to these elevations. An increased intake of simple sugar may first lead to hypoglycemia and potentially to diabetes. There exists considerable scientific evidence that the development of type 2 diabetes is preceded by elevations of serum insulin values and insulin insensitivity due to the prolonged consumption of refined sugars.[38] In most cases these defects presented themselves decades before the development of diabetes. Hypoglycemia, increased insulin secretion, metabolic syndrome, and type 2 diabetes can be viewed as a progression of the same illness—maladaptation to the Western diet.

THERAPEUTIC CONSIDERATIONS

Dietary Factors

Dietary carbohydrates play a central role in the cause, prevention, and treatment of hypoglycemia. Simple carbohydrates, or sugars, are

quickly absorbed by the body, resulting in a rapid elevation in blood sugar and stimulating a corresponding excessive elevation in serum insulin levels. It is thought by some that the assortment of natural, simple sugars in fruits and vegetables have an advantage over sucrose and other refined sugars in that they are balanced by a wide range of nutrients that aid in the utilization of the sugars. This is true. Perhaps more importantly, sugars found in whole, unprocessed foods are absorbed slower because they are contained within cells and are associated with fiber and other food elements.

Problems with carbohydrates begin during the refining process, which increases their rate of absorption and removes essential nutrients. Virtually all the vitamin and trace mineral content is removed from white sugar, white breads, pastries, and many breakfast cereals. When high-sugar foods are eaten alone, blood sugar levels rise quickly, producing a strain on blood sugar control. Eating foods high in simple sugars from any source (e.g., sucrose, honey, maple syrup) is harmful to blood sugar control. Large amounts of fruit juice, and even vegetable juice, may be problematic for individuals with hypoglycemia because the cell disruption characteristic of juicing increases the percentage of the sugars in the juices.

More than one half of the carbohydrates consumed in the United States are in the form of sugars added to processed foods as sweetening agents.[19] Patients should be instructed to read food labels carefully for clues to sugar content, noting that various words are used to describe refined simple carbohydrates. Any of the following might appear on the label as sugar: *sucrose, glucose, maltose, lactose, fructose, corn syrup, evaporated cane juice,* and *white grape juice concentrate.*

A Closer Look at Simple Carbohydrates

Glucose is not particularly sweet-tasting compared with fructose and sucrose. It is found in abundant amounts in fruits, honey, sweet corn, and most root vegetables. Glucose is also the primary repeating sugar unit of most complex carbohydrates.

Fructose, or fruit sugar, is the primary carbohydrate in many fruits, maple syrup, and honey. Fructose is very sweet, roughly 1.5 times sweeter than sucrose. Although fructose has the same chemical formula as glucose, its structure is quite different. To be used by the body, fructose must be converted to glucose within the liver.

Many physicians have recommended that individuals with diabetes or hypoglycemia avoid fruits and fructose. However, research challenges this. Fructose does not cause a rapid rise in blood sugar levels. Because fructose must be changed to glucose in the liver to be used by the body, blood glucose levels do not rise as rapidly with fructose consumption as they do with that of other simple sugars. For example, the ingestion of sucrose results in an immediate elevation in the blood sugar level. Although most individuals with diabetes or hypoglycemia cannot tolerate sucrose, most can tolerate moderate amounts of fruits and fructose without loss of blood sugar control. In fact, fructose and fruits are not only better tolerated than white bread and other refined carbohydrates, but they also produce more gradual elevations in blood sugar levels, compared with most sources of complex carbohydrates (starch).[39] In addition, fructose at concentrations found in most single servings of fruit (~10 g) has been shown to enhance sensitivity to insulin.[40]

Regular fruit consumption may help control sugar cravings and promote weight loss in overweight individuals. Although studies have shown aspartame (NutraSweet), glucose, and sucrose to increase the appetite, fructose has been shown in several double-blind studies to decrease the calories and fat consumed. Typically, subjects are given food or drink containing an equivalent caloric amount of fructose or other sweetener 30 minutes to 2.5 hours before consuming as much food as they want at a dinner buffet. Consistently, subjects receiving the fructose-sweetened food or drink consume substantially fewer calories and fat compared with the groups receiving aspartame, sucrose, or glucose.[41–43]

TABLE 181.4 Glycemic Index of Isocaloric Amounts of Some Common Foods

	Food	Glycemic Index
Sugars	Fructose	20
	Glucose	100
	Honey	75
	Maltose	105
	Sucrose	60
Fruits	Apples	39
	Bananas	62
	Orange juice	46
	Oranges	40
	Raisins	64
Vegetables	Beets	64
	Carrot, cooked	36
	Carrot, raw	31
	Potato, baked	98
	Potato (new), boiled	70
Grains	Bran cereal	51
	Bread, white	69
	Bread, whole grain	72
	Corn	59
	Corn flakes	80
	Oatmeal	49
	Pasta	45
	Rice	70
	Rice, puffed	95
	Wheat cereal	67
Legumes	Beans	31
	Lentils	29
	Peas	39
Other foods	Ice cream	36
	Milk	34
	Nuts	13

Modified from Truswell AS. Glycaemic index of foods. *Eur J Clin Nutr.* 1992;46(suppl 2):S91–S101.

The Glycemic Index and Glycemic Load

The glycemic index (GI) and the glycemic load (GL) are two helpful methods of categorizing foods based on the ability of the food to alter blood sugar.

The GI was developed in 1981 to express the rise of blood glucose after a particular food is eaten.[44] The standard value of 100 is based on the rise seen with the ingestion of glucose. The GI ranges from about 20 for fructose and whole barley to about 98 for a baked potato. The insulin response to carbohydrate-containing foods is similar to the rise in blood sugar.

The GI is used as a guideline for dietary recommendations for people with either diabetes or hypoglycemia (see Table 181.4). People with blood sugar problems are advised to avoid foods with high values and choose carbohydrate-containing foods with lower

values. However, the GI should not be the only dietary guideline. For example, high-fat foods like ice cream and sausage may have a low GI, but because a diet high in fat has been shown to impair glucose tolerance, these foods are not good choices for people with hypoglycemia or diabetes.

The GL uses the information the GI provides in a more comprehensive way to assess the effect of carbohydrate consumption.[45] Although the GI reveals how quickly a food's carbohydrate content can raise blood glucose levels, it still does not explain how much of the blood sugar–increasing carbohydrate is in a certain food.

The dietary GL is defined as the value of a food's GI divided by 100 and then multiplied by its available carbohydrate content. A GL of 20 or more is considered high, 11 to 19 is considered intermediate, and 10 or less is considered low. The GI of watermelon, for example, is 72, and a typical serving of 120 g has 6 g of available carbohydrate. Therefore the GL for watermelon is

$$(72/100) \times 6 = 4.32$$

Even though the GI for watermelon is fairly high, the GL is low, indicating that within reasonable serving amounts, it does not adversely stress blood sugar control. Appendix 6 provides a complete listing of foods and their GI, fiber content, and GL.

The GL reinforces the idea that foods containing natural soluble and insoluble fibers, as well as whole foods that are minimally processed, remain better choices in terms of glycemic influence and insulin response.[46]

Further research indicates that diets with a high GL are directly linked to conditions such as diabetes[38]; coronary heart disease[47]; and colon,[48] ovarian,[45] and pancreatic[49] cancers.

The Importance of Fiber

Population studies and clinical and experimental data show blood sugar disorders to be clearly related to inadequate dietary fiber intake.[19,50] These results indicate that although the intake of refined sugars should be curtailed, the intake of complex carbohydrate sources that are rich in fiber should be increased.

The term *dietary fiber* refers to the components of the plant cell wall as well as the indigestible residues from plant foods. Different types of fibers possess different actions. The water-soluble forms exert the most beneficial effects on blood sugar control and include hemicelluloses, mucilages, gums, and pectins. These types of fiber are capable of the following actions:

- Slowing down the digestion and absorption of carbohydrates, thereby preventing rapid rises in blood sugar
- Increasing cell sensitivity to insulin, thereby preventing the excessive secretion of insulin
- Improving uptake of glucose by the liver and other tissues, thereby preventing a sustained elevation of blood sugar (Fig. 181.3)

For a full discussion of the importance of fiber, see Chapter 132.

The majority of fiber in most plant cell walls is water soluble. Particularly good sources of water-soluble fiber are legumes, oat bran, nuts, seeds, psyllium seed husks, pears, apples, and most vegetables. Patients should be advised to consume a large amount of plant food to obtain adequate levels of dietary fiber. A daily intake of 50 g is a healthful goal.

PolyGlycoPlex

Based on their work with CGM, Drs. Lyon and Murray have uncovered many important findings on how to effectively reduce blood sugar volatility. For example, they confirmed earlier work that although a low-glycemic diet is very important in reducing blood sugar levels, it has little effect in eliminating blood sugar volatility.[51] The most effective way to reduce glycemic volatility is a low-glycemic diet along with the use of a novel matrix of soluble fibers known as PolyGlycoPlex (PGX). Several double-blind studies have shown a reduction of postprandial hypoglycemia by PGX in a dose-dependent manner, independent of food form.[52–54] The PGX matrix produces a higher level of viscosity, gel-forming properties, and expansion with water compared with any other known fiber. This translates to a significant reduction in the glycemic effect of any food or meal. The typical dosage is 1.5 to 5 g before meals.

Chromium

Chromium is vital to proper blood sugar control because it functions in the body as a key constituent of the "glucose tolerance factor." Without chromium, the action of insulin is blocked, and glucose levels are elevated. A chromium deficiency may be an underlying factor to the tremendous number of Americans who have hypoglycemia, have diabetes, or are obese.[55] Evidence exists that marginal chromium deficiency is quite common in the United States and may be responsible for many cases of reactive hypoglycemia.[56]

In one double-blind crossover study of eight female patients, 200 mcg of chromium (as chromium chloride) given twice daily for 3 months alleviated hypoglycemic symptoms and the glucose nadir at 2 to 4 hours after a glucose load.[56] In addition, insulin binding improved, and the number of insulin receptors increased.[57,58]

Lifestyle Factors

Alcohol

Alcohol consumption severely stresses blood sugar control and is often a contributing factor to hypoglycemia. Alcohol induces reactive hypoglycemia by interfering with normal glucose utilization as well as increasing the secretion of insulin. The resultant drop in blood sugar produces a craving for food, particularly foods that quickly elevate blood sugar, as well as a craving for more alcohol. In the presence of more alcohol, the increased sugar consumption aggravates the reactive hypoglycemia, again due to alcohol-induced impairment of normal glucose utilization and increased secretion of insulin.

Hypoglycemia is an important complication of acute and chronic alcohol abuse. Hypoglycemia aggravates the mental and emotional problems of the alcoholic and the withdrawing alcoholic with symptoms such as the following[59]:

- Sweating
- Tremor
- Rapid heartbeat
- Anxiety
- Hunger
- Dizziness
- Headache
- Visual disturbance
- Decreased mental function
- Confusion
- Depression

Although acute alcohol ingestion induces hypoglycemia, chronic alcohol use leads to hyperglycemia and diabetes. Eventually the body becomes insensitive to the augmented insulin release caused by the alcohol. In addition, alcohol itself can cause insulin resistance even in healthy individuals.[60] There is also evidence from large population studies that alcohol intake is strongly correlated with diabetes.[19,61] The greater the alcohol intake, the more likely it is that an individual will have or develop diabetes.

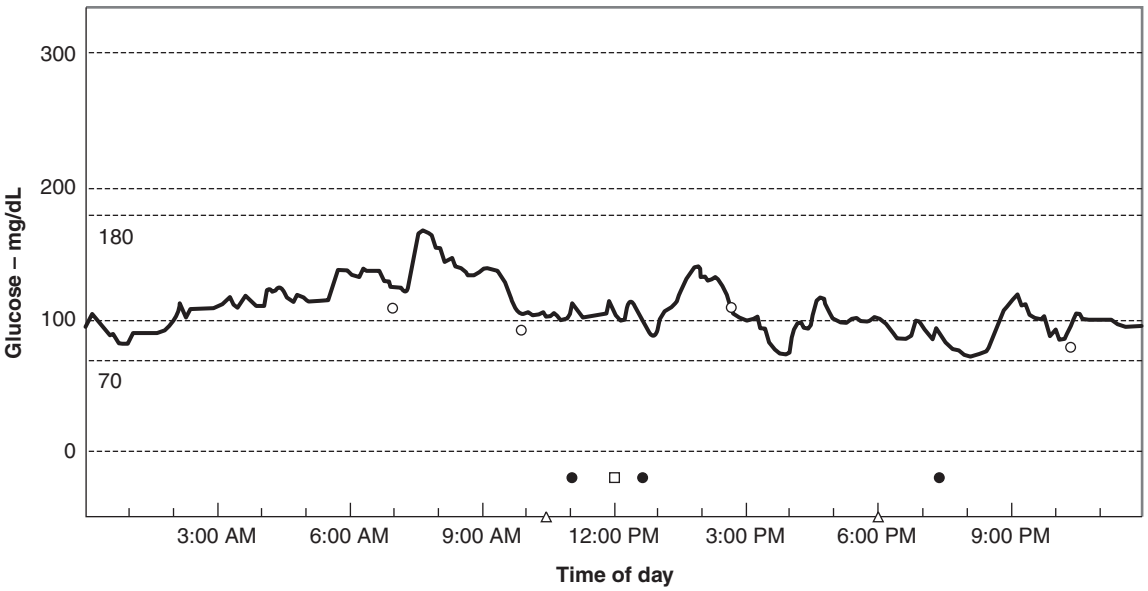

Fig. 181.3 Blood sugar fluctuation revealed by 24-hour monitoring. (Courtesy Dr. Michael Lyon.)

Exercise

Regular exercise has been well documented to prevent type 2 diabetes, and it improves many aspects of glucose metabolism, including enhancing insulin sensitivity and improving glucose tolerance in those who are already diabetic. Some effects of exercise on blood sugar control may stem from the fact that exercise increases tissue chromium concentrations.[62]

Toxin Exposure

A significant amount of research demonstrates the effects of toxins and toxicants on glycemic control. Although most results demonstrate hyperglycemic effects, others have the opposite effect. For example, vanadium potentiates the action of insulin and lowers blood glucose levels by inhibiting some tyrosine-protein phosphatases increasing phosphorylation levels of various insulin pathway intermediaries.[63] There have been reports of severe hypoglycemia that may threaten life in vanadium acute intoxication.[64] Hypoglycin-A (methylene cyclopropyl-alanine, MCPA), a compound found in ackee fruit, causes hypoglycemic encephalopathy in a dose-dependent manner and has been implicated in ackee-fruit poisoning in Africa and West Indies.[65]

THERAPEUTIC APPROACH

The primary treatment of hypoglycemia is the use of dietary therapy to stabilize blood sugar levels. Reactive hypoglycemia is not a disease; it is a complex set of symptoms caused by faulty carbohydrate metabolism induced by an inappropriate diet.

Diet

All simple, processed, and concentrated carbohydrates, as well as food choices with a high GL, must be avoided. Foods rich in soluble fiber, such as legumes and low-glycemic vegetables, should be consumed regularly. Frequent small meals may be more effective than larger meals further apart in stabilizing blood sugar levels. Alcohol must be avoided because it can cause hypoglycemia. Further dietary recommendations mirror those in Chapter 165.

Supplements

Many essential nutrients are critical for proper carbohydrate metabolism. Taking a multivitamin–multimineral formula providing at least the recommended dietary intake levels appears warranted.

Chromium: 200 to 400 mcg/day
PGX: 1500 to 5000 mg before meals

Exercise

Because the beneficial effects of exercise in improving insulin sensitivity decrease within 3 days after exercise and are no longer evident after 1 week, a sustained program is required.[66] A graded long-term exercise program should be developed that is appropriate to the individual's fitness level and interest; it should elevate the heart rate to at least 60% of its maximum for half an hour three times a week.

Hypothyroidism

Alan G. Christianson, NMD

OUTLINE

DIAGNOSTIC SUMMARY

- Depression
- Dry skin
- Headaches
- Lethargy or fatigue
- Memory problems
- Menstrual problems
- Hyperlipidemia
- Recurrent infections
- Sensitivity to cold
- Thinning of head hair
- Muscle pain
- Voice changes
- Weight gain

GENERAL CONSIDERATIONS

Thyroid gland hormones are required for mitochondrial metabolism in every cell of the body. As a result, a deficiency of thyroid hormones can affect virtually all bodily functions. The severity of symptoms in adults ranges from mild deficiency states that may not be apparent with standard blood tests (e.g., early-stage Hashimoto's) to severe deficiency states that can be life-threatening (e.g., myxedema).

The pathophysiology of hypothyroidism may result from the lack of stimulation by the pituitary gland, defective hormone synthesis, impaired cellular conversion of T4 to T3, or a decrease in the cellular uptake of active hormones. The pituitary gland regulates thyroid activity through the secretion of thyroid-stimulating hormone (TSH). The combination of low thyroid hormone and elevated TSH blood levels usually indicates defective thyroid hormone synthesis, which is defined as *primary hypothyroidism.* When TSH and thyroid hormone levels are both low, the pituitary gland is responsible, a situation termed *secondary hypothyroidism. Tertiary hypothyroidism* develops as a result of a deficiency of thyroid hormone-releasing hormone (THRH) from the hypothalamus. Normal thyroid hormone and TSH blood levels combined with low functional thyroid activity (as defined by a low basal metabolic rate) suggest cellular hypothyroidism.

Most estimates on the rate of hypothyroidism are based on an elevated TSH and a suppressed level of T4. Using these criteria, it is estimated that 5% to 10% of the adult population suffers from hypothyroidism.[1–4] The Colorado Thyroid Disease Prevalence Study suggests that no fewer than 10% of the adult population is affected, with the rate exceeding 20% among senior citizens.[5]

Thyroid disease of all types is more common among females. Reports suggest a 4:1 female-to-male ratio. Hypothyroidism is more prevalent among whites and Mexican Americans (5.7%) than among African Americans (1.7%).[6] The rate of hypothyroidism increases steadily with advancing age.

If symptoms and basal body temperature were used for diagnosis, it is likely that the true rate of hypothyroidism may be approximately 25% of the adult population and significantly higher among the elderly.

Symptoms of Hypothyroidism

Psychological

The human brain is sensitive to the slightest fluctuations of thyroid hormone. Depression, weakness, and fatigue are usually the first symptoms of hypothyroidism.[7] Later, the hypothyroid individual has difficulty concentrating and may experience memory lapses.

Metabolic

A deficiency of thyroid hormones can lead to substantial suppression of the basal metabolic rate. Moderate weight gain and sensitivity to cold (demonstrated by cold hands or feet) are common.

Cholesterol and triglyceride levels are increased even in mild forms of hypothyroidism. Before the current generation of thyroid tests, cholesterol was used as a marker of thyroid function. This may explain

the increased rate of heart disease due to atherosclerosis in individuals with hypothyroidism.[8]

In addition, hypothyroidism can cause increases in capillary permeability and slow lymphatic drainage, resulting in the swelling of tissue (edema) as well as fluid retention, commonly noticed in the lower extremities.

Endocrine

Various hormonal symptoms can exist in hypothyroidism. The most common are decreased libido in both genders and menstrual abnormalities in women. Women with mild hypothyroidism may have prolonged, heavy menstrual bleeding with a shorter menstrual cycle. Female infertility may also result. If a woman with untreated hypothyroidism becomes pregnant, there is an increased risk for miscarriage, premature delivery, and stillbirth. Hypotheses for the occurrence of these conditions include hyperprolactinemia from increased production of TRH leading to ovulatory dysfunction,[9] and hypothyroidism interferes with normal physiological pulsatile gonadotrophin-releasing hormone secretion, which is a prerequisite for normal follicular development and ovulation.[10]

Adrenal dysfunction is a common comorbidity with primary and secondary hypothyroidism. Patients with thyroid antibodies are more likely to possess adrenal cortex antibodies associated with Addison's disease. Furthermore, cortisol secretion may increase to compensate for low T3 levels because cortisol raises the cell membrane's permeability to T3.

Skin, Hair, and Nails

Most individuals with hypothyroidism have dry, rough skin covered with fine superficial scales along with coarse, dry, and brittle hair. Hair loss can be quite severe and is generally diffuse and uniform as opposed to patchy. The nails become thin and brittle and typically show transverse grooves.

Muscular and Skeletal

Muscle weakness and joint stiffness are predominant features of hypothyroidism. Some individuals with hypothyroidism may also experience muscle and joint pain as well as general tissue tenderness. Slow reflexes are common, and a slow Achilles reflex time can be diagnostic.

Cardiovascular

Overt and subclinical hypothyroidism predispose individuals to atherosclerosis as a result of increases in cholesterol and triglycerides, as well as elevated levels of homocysteine and C-reactive protein (CRP).[11] Hypothyroidism can also lead to hypertension, reduced cardiac function, and bradycardia.

Other Manifestations

Shortness of breath, constipation, and impaired kidney function are other common features of hypothyroidism.

Causes of Hypothyroidism

Iodine Deficiency

About 95% of all cases of clinical hypothyroidism are primary. The thyroid gland adds iodine to the amino acid tyrosine to create thyroid hormones. Iodine deficiency leads to hypothyroidism, the development of an enlarged thyroid gland (i.e., goiter), or both.

Goiters are estimated to affect more than 200 million people worldwide, and in more than 95% of cases, the cause is an iodine deficiency. Iodine deficiency is now quite rare in the United States and other industrialized countries due to the addition of iodine to table salt.

Few people in the United States are considered iodine-deficient, yet some still develop goiters. Prolonged thyrotropin (TSH) elevation can lead to thyrocyte hypertrophy, which can manifest as a goiter. Goiters generally regress as thyrotropin is suppressed but in rare cases may require surgical resection.

Nodules can also form within the gland during or independent of output dysfunction. Approximately 20% of adult patients have nodules on palpation, and random screening by ultrasound reveals nodules in up to 50% of the population. About 5% of nodules may be cancerous. Goiters or nodules in patients with adequate but marginal iodine intake may result from excessive ingestion of dietary or environmental goitrogens. See Nutritional Considerations for details on dietary goitrogens.

Environmental goitrogens include perchlorate, iodine more than 290 mcg/day, fluoride, and mercury. Medications that induce goiters and suppress thyroid function include amiodarone, carbamazepine, lithium, potassium iodide, phenobarbitone, phenytoin, and rifampin.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis is an autoimmune inflammatory disorder and is the most frequent cause of clinical hypothyroidism in the United States. The antibodies that bind to the thyroid (specifically against the thyroid peroxidase enzyme, thyroglobulin, and TSH receptors) are formed and prevent the manufacturing of sufficient levels of thyroid hormone. In addition to binding to thyroid tissue, these antibodies may also bind to the adrenal glands, pancreas, and acid-producing cells of the stomach (parietal cells). Autoimmune thyroid disease can exist in the absence of serum hypothyroidism, although those with autoimmune thyroid disease progress to hypothyroidism in almost all cases. The presence of Hashimoto's disease raises the risk of developing other autoimmune diseases. Hashimoto's thyroiditis is formally a histological diagnosis. However, the presence of serum antibodies against thyroid proteins such as thyroglobulin (TG) or thyroid peroxidase (TPO) is often sufficient for diagnosis; 10% to 15% of individuals may be antibody-negative.

If a histological assessment is done via biopsy, fine-needle aspiration, or postthyroidectomy, the typical finding is cellular infiltration of immune cells, especially lymphocytes.

Variables that predict Hashimoto's thyroiditis include a family history of thyroid disease of any type and exposure to environmental triggers. Environmental toxins generate free radicals, which activate immune responses and may sensitize immune cells to surrounding thyroid proteins.

Chemicals documented to correlate with Hashimoto's disease include the following:

- Iodine (in excess or when intake increases significantly)
- Perchlorate
- Fluoride
- Lithium
- Mercury
- Bisphenol A
- Teflon

Toxins

Many groups of chemicals have thyroid-disrupting potential. These chemicals have various mechanisms of action and, when combined, may have synergistic effects.[12] Many aspects of the many components of thyroid production and effects can be adversely affected, such as decreased TSH production, decreased T4 production, poor or inconsistent conversion of T4 to T3, reduced cellular response to T3, decreased absorption of iodine, and impaired mitochondrial response to T3 limiting adenosine triphosphate (ATP) production. In addition,

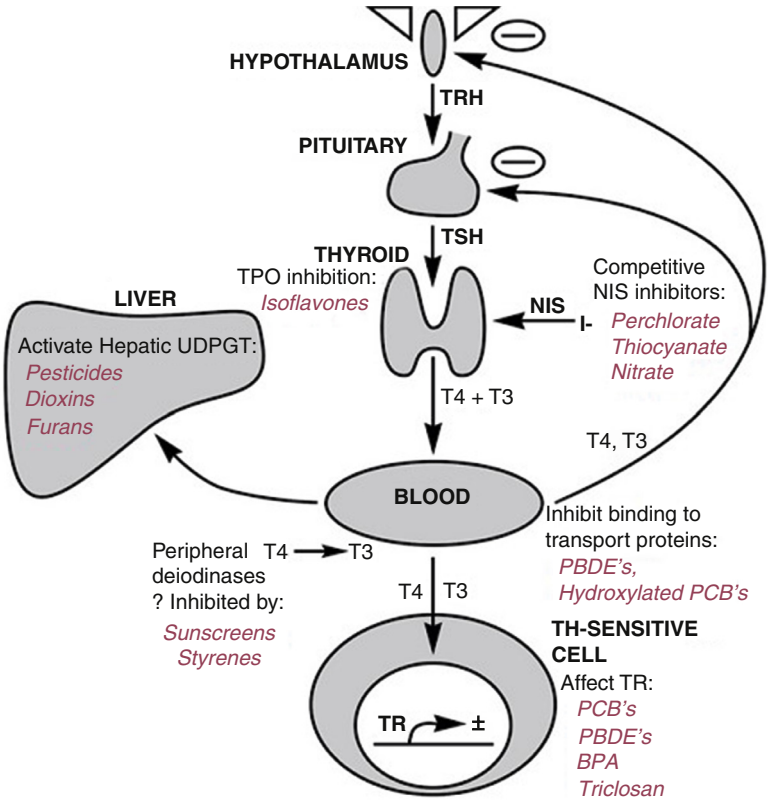

Fig. 182.1 Mechanisms of various thyroid disruptors. (From Pearce EN, Braverman LE. Environmental pollutants and the thyroid. *Best Pract Res Clin Endocrinol Metab.* 2009 Dec;23[6]:801–813. Review. PubMed PMID: 19942155.)

the function of the sodium iodide symporter (NIS) or TPO can be inhibited or stimulated by chemicals, and transthyretin (TTR), a transport protein, may be a source for competitive binding of environmental chemicals. Fig. 182.1 demonstrates the mechanisms of action of several toxicants.[13]

PCBs, Dioxins, and Furans

Polychlorinated biphenyls (PCBs) and thyroxine both consist of two connected benzene rings with halogens attached. PCBs have chlorine attached, and thyroxine has iodine. PCBs inhibit the production, activation, and utilization of thyroid hormones. There is a dose-dependent decrease in total T4 among U.S. adults with exposure to dioxin-like toxic equivalents (TEQs) at levels similar to those found in the general U.S. population.[14] Several animal studies confirm that exposure to PCBs or dioxin results in reduction of serum thyroid hormone levels, especially T4.[15,16] Dioxins and furans adversely affect the thyroid hormone–metabolizing enzymes uridine-diphosphate-glucuronyl transferase, iodothyronine deiodinase, and sulfotransferases found in the liver and brain. Hydroxylated PCBs also inhibit iodothyronine sulfotransferase activity, adversely affecting peripheral metabolism of thyroid hormones. German children showed a significant positive correlation between PCB serum levels and elevation of TSH, as well as a significant inverse correlation between serum PCB levels and FT4.[17] U.S. Air Force personnel participating in operation Ranch Hand (the spraying of broadleaf defoliants) during the Vietnam War were found to have high serum tetrachlorodibenzo-p-dioxin (TCDD) levels that were significantly associated with elevated levels of TSH.[18] Thus PCBs reduce peripheral thyroid hormone levels, inducing a compensatory increase in TSH.

PCBs, dioxins, and furans have demonstrated in vitro activity in binding transthyretin, blocking the transport of thyroxine.[19] Hydroxylated PCBs bind to TTR with a stronger binding affinity than their parent compounds.

Elevated antithyroid antibodies, both antiperoxidase and antithyroglobulin, were found in workers in a PCB manufacturing plant.[20] However, no difference was found in the levels of T4 and TSH in these TCDD workers than in the control group. Swedish women who consumed at least two meals of fish from the Baltic Sea each month showed a significant inverse correlation between serum PCB levels and TT3 and an insignificant inverse correlation with TT4.[21]

DDT was found to be higher in a group of hypothyroid Indian women than in euthyroid female controls, whereas Dieldrin was significantly associated with low T4 levels.[22] Canadian newborns had significantly lower T4 concentrations in their cord blood when pentachlorophenols (PCPs) were also present.[23]

Organophosphate Pesticides

Individuals with acute organophosphate pesticide (OP) poisoning have revealed a host of hormonal alterations, including elevations of ACTH, cortisol, and prolactin. Interestingly 31.8% of these individuals also experienced sick euthyroid syndrome with low FT3, FT4, or TSH. OP pesticide formulators had significantly low TT3 and nonsignificantly elevated TSH levels,[24] and persons using backpack sprayers with dithiocarbamates (also acetylcholinesterase inhibitors) had increased TSH levels.[25]

Mercury

Mercury accumulates in the thyroid and reduces the uptake of iodine by binding to the sodium/iodide transporting molecule. Mercury also inhibits deiodinase function in the peripheral tissues, preventing the production of triiodothyronine (T3) from thyroxine (T4).

Methylmercury, particularly when combined with a selenium deficiency, inhibits D1, the predominant deiodinase in the liver, kidney, and intestines.

Both adolescents and adults in the 2007 to 2008 National Health and Nutrition Examination Survey (NHANES) had a negative association between blood mercury levels and total T3 and T4.[26] Adolescents also showed a higher risk for both antithyroglobulin and anti-TPO antibodies. Women in the same NHANES cohort with blood mercury of greater than 1.8 ug/L (approximately the 80th percentile) were more likely to have antithyroglobulin antibodies, than those with blood mercury of less than 0.4 ug/L.[27]

Perchlorate

Newborn TSH levels in cities with 100% perchlorate-contaminated drinking water were significantly higher than those in newborns in cities with noncontaminated water.[28] Perchlorate is known to competitively inhibit iodide uptake at the sodium iodide symporter and has been used in the past in the diagnosis and treatment of thyrotoxicosis.

Cadmium

Increasing serum cadmium levels is associated with elevating TSH and lowering FT4 levels. Cadmium has been shown to reduce TSH levels,[29] although this effect is completely blunted in animals given zinc and selenium.[30] Cadmium accumulates primarily in the kidneys and at lower levels in the lungs, and liver and thyroid hyperplasia and hypertrophy are often seen with chronic cadmium toxicity.

Polybrominated Flame Retardants

Brominated flame retardants, such as polybrominated diphenyl ethers (PBDEs), pentabromophenol (PBP), and tetrabromobisphenol A (TBBPA), have a structural resemblance to thyroxine (T4) and are potent competitors for T4 binding to TTR. PBDEs suppress TH-regulated gene expression in humans and interfere with TH signaling.[31] Several animal studies indicate that PBDEs decrease the levels of circulating thyroid hormones,[32–34] and perinatal maternal exposure reduces thyroid hormones pre- and postnatally.[35,36]

Phthalates

Phthalates have various mechanisms of action on thyroid homeostasis, including interfering with the activity of the NIS,[37] inhibiting T3 uptake in cells,[38] and competitively binding to TTR.[39] Significant mild negative correlations were found between TT4 and FT4 and urinary phthalate monoesters in pregnant women exposed to di-n-butyl-phthalate (DBP).[40] In adult men, an inverse association exists between urinary concentration of mono(2-ethylhexyl) phthalate (MEHP) and serum levels of FT4 and TT3.[41]

Other Causes

Other causes of clinical hypothyroidism include thyroid surgery, ablation, and postpartum hypothyroidism, which is a transient form of hypothyroidism, affecting 5% to 10% of women in the United States. Annual follow-up should be offered to any woman who develops postpartum hypothyroidism because 25% of these women will develop overt hypothyroidism within the next 5 years.[42]

SUBCLINICAL HYPOTHYROIDISM AND HYPOTHYROIDISM SYNDROME

Subclinical hypothyroidism is defined as elevated TSH levels with normal serum thyroid levels. Using this criterion, subclinical hypothyroidism is a relatively common finding in primary care, affecting 2% to 7% of adults. Subclinical hypothyroidism has been shown to be linked to an increased risk for cardiovascular disease.[43]

Thyroid disease in the absence of overt laboratory findings is more accurately known as hypothyroid syndrome and can be defined by the following clinical findings:

- The presence of hypothyroid symptoms
- The absence of other explanatory diseases
- Possible functional thyroid abnormalities, as found on basal body temperature (BBT) and Achilles reflex testing

In addition, one or more of the following objective findings will help confirm the presence of thyroid disease:

- Suboptimal blood levels
- Abnormal antibody studies
- Abnormal findings on ultrasound
- Abnormal findings on fine-needle aspiration of the thyroid

DIAGNOSTIC CONSIDERATIONS

Before the use of blood measurements, it was common to diagnose hypothyroidism using basal body temperature (BBT; i.e., the temperature of the body at rest) and Achilles reflex time (reflexes are slowed in hypothyroidism). With the advent of sophisticated laboratory measurement of thyroid hormones in the blood, these "functional" tests were no longer used Normal BBT is 97.6°F to 98.2°F. Many consider BBT to be an indicator of thyroid status, yet it is affected by many other variables, including adrenal function, body composition, activity level, menstrual status, and immune function. Therefore it has little specificity for thyroid function. Furthermore, reliance on BBT as a factor superseding blood levels in determining optimal thyroid dosing can expose patients to dangerous supraphysiologic doses of thyroid hormones. BBT can, however, be used as a general indicator within the context of a complete clinical evaluation. Instructions for taking BBT are outlined in Appendix 10.

Clinical Assessment

A clinical score based on the Colorado Thyroid Disease Prevalence Study has been created to simplify the process of symptom evaluation in patients with suspected hypothyroidism. In this study of more than 25,000 people, it was shown that many patients with significant symptoms did not have clinical hypothyroidism. The symptoms listed in Table 182.1 serve as the best predictors of hypothyroidism.

Laboratory Evaluation

When clinically indicated, thyroid screening ideally includes a marker of thyroid regulation (e.g., TSH), markers of thyroid output (e.g., free T4, free T3), and markers of thyroid inflammation (e.g., thyroid microsomal antibody, thyroid peroxidase antibody, antithyroglobulin antibody). The American Thyroid Association recommends TSH screening every 5 years beginning at age 35.

The diagnosis of hypothyroidism by laboratory methods is primarily based on the results of total T4, free T4, free T3, and TSH levels (Table 182.2). TSH is a more sensitive test for both hyper- and hypothyroidism than free T4. The diagnosis is straightforward in overt cases (Table 182.3). In subclinical cases, the diagnosis is clear, but the benefit of treatment in the absence of symptoms is debated. An elevation in TSH with a normal T4 level is considered subclinical. The accepted normal TSH range is extremely broad, 0.35 to 5.50 mIU/mL. Some physicians do not recommend treatment unless the TSH is greater than 10 mIU/mL. Given the importance of adequate thyroid hormone to human health, the recommendation presented here is more aggressive.

Patients with a combination of subclinical hypothyroidism and objective signs of autoimmune thyroiditis can benefit from TSH reduction. This can be achieved through diet and lifestyle changes and possible thyroid replacement therapy.

TABLE 182.1 Accuracy of 12 Symptoms and Signs in the Diagnosis of Primary Hypothyroidism

	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)	Score IF Present
Symptoms					
Impairment of hearing	22	98	90	53	1
Diminished sweating	54	86	80	65	1
Constipation	48	85	76	62	1
Paraesthesia	52	83	75	63	1
Hoarseness	34	88	73	57	1
Weight increase	54	78	71	63	1

Data from Zulewski H, Müller B, Exer P, et al. Estimation of tissue hypothyroidism by a new clinical score: evaluation of patients with various grades of hypothyroidism and controls. *J Clin Endcrinol Metab.* 1997;82:771–776.

TABLE 182.2 Normal Value of Serum Thyroid Hormone

T4	4.8–13.2 mg/dL
Free T4	0.9–2 ng/dL
T3	80–220 ng/dL
Thyroid-stimulating hormone	0.35–5.50 mIU/mL

THERAPEUTIC CONSIDERATIONS

Fig. 182.2 provides an algorithm for managing patients with hypothyroidism; it combines clinical evaluation, BBT, and laboratory evaluation. Although the conventional diagnostic model may be restrictive, relying solely on symptoms or BBT to determine the need for thyroid treatment often leads to several attempts at proper dosing, side effects, and limited to no benefits. Furthermore, if such measures are used as the sole factors for determining dosing strategies, many will end up on dangerous supraphysiologic doses. Adult patients who have reached full physiological doses of thyroid and have TSH scores lower than 1.0 should be considered to have maximal improvement from thyroid treatment. Because supraphysiologic doses speed the rate of T4 degradation, further increases in dosage will not yield lasting benefit. Higher doses should also be discouraged because a chronically suppressed TSH raises the risk of dementia, atrial fibrillation, and osteoporosis.

Patients with "hypothyroid syndrome" may have a positive clinical response to thyroid treatment when they possess the following characteristics:

- Objective signs of early Hashimoto's disease. This would include positive serum antibodies or abnormalities on thyroid anatomy evidenced by examination or ultrasound.
- Pertinent hypothyroid symptoms. These include the highly sensitive symptoms gleaned from the Colorado study delineated earlier.
- Suboptimal thyroid blood levels. TSH scores greater than 2.5 increase the likelihood of Hashimoto's disease and hypothyroid symptoms.

Patients with less sensitive hypothyroid symptoms, such as overweight, depression, or poor libido, yet lacking the previously listed three criteria, may respond poorly to thyroid treatment even if they possess low BBTs or delayed Achilles tendon reflexes.

Diet/Iodine Status

Although the key role of iodine deficiency in hypothyroidism has been known for over a century, there are clearly problems with even modestly excessive levels. There is a correlation between iodine intake and autoimmune thyroid disease. In one Furans study, a group of 45 adults with hypothyroidism secondary to Hashimoto's thyroiditis were divided into two groups. One group was placed on a low-iodine diet of under 100 micrograms per day of iodine, whereas the other group did not modify their diets. Of those on the low-iodine diet, 78.3% returned to euthyroid status with no other treatment, as opposed to 45% in the control group.[44] The average TSH score changed from 14.28 IU/mL to 3.28 IU/mL in those who recovered.

Physiological/Hormonal Considerations

Thyroid-binding globulin (TBG) is a protein generated by the liver that transports thyroid hormones, including 75% of circulating T4. Certain factors may lead to increased TBG levels, including pregnancy, oral estrogen supplementation from birth control pills, and hormone replacement therapy. Tamoxifen therapy for breast cancer and liver diseases also increase TBG levels. High TBG levels can hinder the availability of free thyroid hormone for use in the peripheral tissues, thus contributing to hypothyroid symptoms. Depending on the clinical picture, it may be useful to moderate hormonal excesses by decreasing the intake of oral estrogens, changing to nonoral regimens that do not involve first-pass metabolism through the liver, or helping the liver efficiently metabolize estrogens.

Iodine and Tyrosine

Thyroid hormones are made from iodine and the amino acid tyrosine, which is found in a wide variety of animal- and plant-based protein foods.

TABLE 182.3 Laboratory Findings in Thyroid Disease

Disease	Primary Hypothyroidism	Secondary Hypothyroidism	Tertiary Hypothyroidism	Peripheral Hypothyroidism
THRH	High/normal	High	Low/normal	Normal/high
TSH	High	Normal/low	Low/normal	Normal/high
Free T4	Low	Low	Low	Normal
Free T3	Low/normal	Low/normal	Low/normal	Low
Reverse T3	Normal	Normal	Low/normal	Normal/high

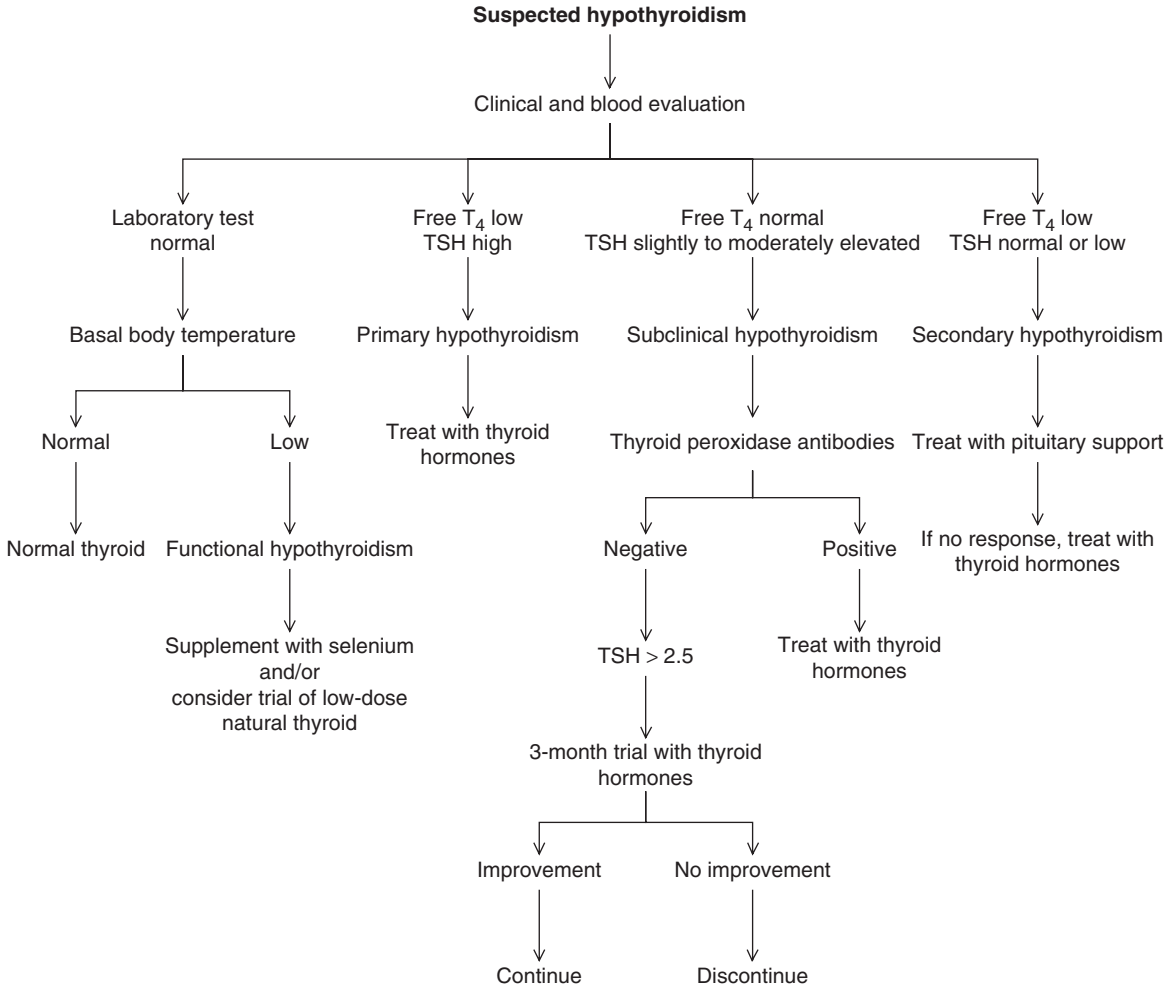

Fig. 182.2 Hypothyroidism diagnostic flowchart.

The recommended dietary allowance (RDA) for iodine in adults is 150 mcg. The average intake of iodine in the United States is estimated to be more than 600 mcg/day. However, intake has decreased substantially in the past several decades due to decreased use of iodized table salt (more people now eat prepared foods, which typically use salt that has no added iodine), dairies using antibiotics instead of iodine for cleaning udders, and bakers switching from iodine-based to bromine-based leavening agents. Too much iodine can inhibit thyroid gland synthesis. Because the only role of iodine in the body is to provide for thyroid hormone synthesis, it is recommended that dietary levels or supplementary iodine not exceed 600 mcg/day for any length of time. Individuals with an iodine intake under 300 mcg daily have the lowest rates of development of thyroid disease or thyroid disease progression.[45]

Vitamins and Minerals

Zinc, vitamin E, and vitamin A function together in the manufacturing of thyroid hormone. A deficiency of any of these nutrients results in lower levels of active thyroid hormone production. Low zinc levels, as well as hypothyroidism, are common in the elderly, indicating a possible correlation.[46] Riboflavin (B_2), niacin (B_3), pyridoxine (B_6), and vitamin C are also necessary for thyroid hormone manufacture.

The trace minerals zinc, copper, and selenium are required cofactors for iodothyronine deiodinase, the enzyme that converts T4 to the more active T3. This enzyme has several different forms, each requiring a different trace mineral. Supplementation with zinc has been shown to reestablish normal thyroid function in patients with hypothyroidism who were zinc-deficient even though they had normal serum T4 levels.

Individuals living in areas where selenium is deficient have a greater incidence of thyroid disease. Although a selenium deficiency does not decrease the conversion of T4 to T3 in the thyroid or the pituitary, it does result in a decrease in this conversion in other cells of the body.[47] People with a selenium deficiency have elevated levels of T4 and TSH, and supplementation with selenium results in a decrease in T4 and TSH and a normalization of thyroid activity.[48] Moreover, selenium is known to decrease thyroid antibody levels in autoimmune thyroid conditions.[49] Antioxidant supplementation has been shown to increase thyroid function in rats with methimazole-induced hypothyroidism. Statistically significant results were reported in rats given vitamin C, vitamin E, and *Curcuma longa* (turmeric) extract with decreased abnormal thyroid weight changes, less suppression of T4 and T3, and attenuated increases in cholesterol levels.[50] Furthermore, in one animal study, thyroid hormone abnormalities also correlated with decreased glutathione antioxidant status in testicular tissues.[51] Although there are no human studies to corroborate these findings, given the safety and beneficial profile of these supplements, it seems a reasonable approach to consider them in an anti-inflammatory and antioxidant treatment regimen.

Exercise

Exercise stimulates thyroid gland secretion and increases tissue sensitivity to thyroid hormone. Many of the health benefits of exercise may be a result of improved thyroid function. A consistent effect of dieting is a decrease in the metabolic rate as the body strives to conserve fuel. Exercise has been shown to prevent the decline in metabolic rate in response to dieting.

Thyroid Hormone Replacement

If nutritional and lifestyle interventions are inadequate to reestablish normal thyroid activity, the prescription of thyroid hormones is necessary. Several thyroid hormone preparations are available, each with advantages and disadvantages. Conventional treatment involves the administration of oral tetraiodothyronine/levothyroxine sodium (T4). Levothyroxine preparations are bioidentical to human tetraiodothyronine and readily absorbed orally. The half-life of tetraiodothyronine is roughly 7 to 10 days. Therefore once-daily dosing is adequate for steady blood levels. For maximum and consistent absorption, it is best to take thyroid hormones at least 1 hour before food and beverages other than water. Morning administration is preferred to mimic the circadian thyroid cycle.

Dosages are titrated to reduce TSH and to elevate T4 to normal ranges. The most common starting dose is 50 mcg (0.05 mg), and the most common ending doses range from 88 to 137 mcg for women and 100 to 150 mcg for men.

Some patients who remain clinically hypothyroid may poorly deiodinate levothyroxine (T4) into triiodothyronine (T3). In these cases, oral T3 is given. Like T4, T3 (Cytomel or liothyronine) is well absorbed orally and is easily bound by many nutrients. The half-life of T3 is approximately 2½ days, so once-daily dosing is recommended. Common doses are 5 to 10 mcg daily.

Many naturopathic physicians prefer the use of natural desiccated thyroid (NDT). NDT contains all thyroid hormones, not just thyroxine. Studies in rats whose thyroids were removed demonstrated that normal tissue levels of T4 and T3 were achieved only with an infusion of T4 and T3, and not by T4 alone.[52] The advantage of NDT is that it provides T4, T3, T2, and relevant amino acids and micronutrients (including 0.2% iodine per table). The main drawback often cited by those who prefer thyroxine is that NDT lacks consistency. However, according to the U.S. Pharmacopoeia (USP), these preparations must contain not less than 85% and not more than 115% of the labeled amount of T4 and not less than 90% and not more than 110% of T3. The labeled amount is 38 mcg of T4 and 9 mg T3 per grain (65 mcg). The equivalencies of the thyroid agents based on clinical response are as follows:

- 100 mcg of T4 (e.g., Synthroid)
- 20 to 25 mcg of T3 (e.g., Cytomel)
- 1 grain of desiccated thyroid
- 12.5 mcg of T3 + 50 mcg of T4 (e.g., Thyrolar)

THERAPEUTIC APPROACH

Natural treatment strategies for normalizing thyroid function vary depending on the diagnosis of an autoimmune hypothyroid condition, Wilson's syndrome, or subclinical or clinical hypothyroidism.

Treatments for Autoimmune Hypothyroidism (Hashimoto's Disease)

Thyroid Replacement

The use of thyroid replacement achieves two objectives in the patient with autoimmune hypothyroidism: the normalization of decreased thyroid hormone levels and the suppression of thyroid activity, thus decreasing autoimmune processes. Either desiccated or synthetic thyroid replacement may be used in sufficient doses to decrease TSH to 0.1 or 1.5, the levels found in healthy euthyroid populations. It should be noted that some reports say that TSH values equal to or less than 0.1 mIU/mL may carry a risk of numerous hyperthyroid side effects as well as atrial fibrillation. Desiccated thyroid may be beneficial in stimulating blocking antibodies to antithyroid antibodies and by acting as decoys for thyroid antibodies. Some patients recover from Hashimoto's thyroiditis after an extended treatment time with thyroid hormone and no longer need maintenance replacement. Some patients may not benefit from desiccated thyroid, leading to an adverse reaction to antigenic thyroid substances. These patients should promptly be placed on a combination of synthetic T4 and T3 thyroid instead. In either case, frequent TSH and antibody tests are essential to verify the suppression of thyroid activity and monitor autoimmune activity. Often in early Hashimoto's disease, a hyperthyroid picture is more prevalent. In this case thyroid replacement may be contraindicated.

Diet/Lifestyle

Food elimination, detoxification, and gut-healing options may be useful treatments aimed at ameliorating a possible root factor of antigenic autoimmune activity (see Chapter 14).

Other Recommendations

Dehydroepiandrosterone (DHEA) is a beneficial supplement in the treatment of several autoimmune conditions.[53] Although many clinical studies have employed high dosages (100–200 mg/day), much lower physiological doses ranging from 5 to 10 mg/day in women and 10 to 20 mg/day in men may be beneficial and safe. Laboratory work should be done to confirm physiological ranges with DHEA supplementation. DHEA should be used with caution, particularly in patients at risk for developing hormone-dependent cancers.[54]

Two hundred mg/day of selenium is recommended for Hashimoto's autoimmune thyroiditis, especially in patients who have high titers of antithyroid peroxidase (TPO) antibodies.

Treatments for Nonautoimmune Overt or Subclinical Hypothyroid Disorder

Diet

The diet should be sufficient in vitamins and trace minerals needed for thyroid hormone production and activation, including selenium, zinc, B vitamins, and vitamin D. Sources of zinc include seafood (especially oysters), beef, oatmeal, chicken, liver, spinach, nuts, and seeds. Copper

is found in liver and other organ meats, eggs, yeast, beans, nuts, and seeds. Sources of B vitamins include yeast, whole grains, and liver. A great source of selenium is unshelled Brazil nuts. Organically grown foods are recommended because of their higher levels of trace minerals and reduced levels of toxins.

Supplements

- Zinc: 20 to 30 mg/day
- Copper: 1 to 2.5 mg/day
- Selenium: 200 to 400 mcg/day
- Vitamin C: 1 to 3 g/day in divided doses
- Vitamin E (mixed tocopherols): 200 to 400 IU/day

Thyroid Hormones

Thyroid hormone replacement options include the following:

- Desiccated natural thyroid: ¼ grain initially; can be adjusted incrementally up or down as needed
- T4 (Levothyroxine): 25 to 200 mcg
- T4 and T3 Use 10:1 T4/T3 Ratio for isolated T4 and T3 medications such as Synthroid and Cytomel.

Compounded thyroid medication is not recommended due to variabilities in production.

Brand consistency is recommended for thyroid medication. Do not prescribe generic medications. Both of these practices can lead to fluctuating thyroid levels due to variables in inactive ingredients from one product to the next.

Reevaluation of TSH T4, T3, free T3, and free T4 levels 4 to 6 weeks after initiating therapy is recommended. The goal of treatment is to normalize serum hormone levels and improve patient symptoms. After stabilization of dosage, periodic evaluations are based on the individual patient's needs. Follow-up is recommended at least once a year.

Thyroid hormone replacement therapy is to be taken on an empty stomach to increase absorption. The patient should avoid taking thyroid hormones at the same time as other medications and supplements (especially those containing iron), which may affect absorption. Once-a-day dosage generally produces stable increases in thyroid hormone levels.

Thyroid hormone dosage during pregnancy will likely have to be adjusted because estrogens increase serum thyroid hormone–binding globulin, thereby reducing the level of free thyroxine. Careful monitoring is required during pregnancy. Dose requirements may increase by 30% to 50% during pregnancy and return to prepregnancy levels shortly after delivery.

Detoxification

All patients with hypothyroidism without apparent cause should have their toxic load measured and treated.

Infectious Diarrhea

Robert Kachko, ND, LAc, and *Peter B. Bongiorno, ND, MSAc, LAc*

OUTLINE

DIAGNOSTIC SUMMARY

- Increased bowel movement frequency (usually more than three bowel movements per day)
- Increased stool liquidity
- Abdominal pain
- A sense of fecal urgency
- Fecal incontinence
- Perianal discomfort
- Blood, mucus, or both possibly present in the stool

GENERAL CONSIDERATIONS

Diarrhea is not only an important clinical entity but has also played a central role in the course of human history. Since the ancient times of Herodotus, the "father of history," diarrhea has had a particularly significant effect on the course of military strategies and consequently on world events. Infectious diarrhea has modified the wartime outcomes of the Roman Empire and the Crusades as well as the relatively modern-day military campaigns of Henry V, the Civil War, World War I, and World War II.[1] Walt Whitman, who visited the sick and wounded Union soldiers in Washington, D.C., hospitals, wrote that war consisted of "about 999 parts diarrhea to 1 part glory."[1]

Although there is considerable variation in normal bowel habits, diarrhea is defined as the passage of loose or watery stools, typically at least three times in a 24-hour period.[2,94] Acute diarrhea occurs for 14 days or fewer, persistent diarrhea for more than 14 but fewer than 30 days, and chronic diarrhea is longer than 30 days' duration. Diarrheal disease can be classified into three major clinical syndromes: acute watery diarrhea, bloody diarrhea, and persistent diarrhea. For most patients, any increase in stool mass, stool frequency, or stool fluidity is perceived as diarrhea. For most adults, this consists of a daily stool production in excess of 250 g containing 70% to 95% water. More than 14 L of fluid may be lost daily in severe cases.[3] Low-volume, painful, bloody diarrhea is known as dysentery (or invasive diarrhea).

Even today diarrheal illness is a common cause of morbidity and mortality. Infectious agents cause more than 200 million cases of diarrhea in the United States yearly.[4] Although it is a major cause of mortality in developing nations, infectious diarrhea also has significant costs in developed nations in terms of hospitalization and lost time.[5] Intestinal infection is the most common cause of diarrhea worldwide and is responsible for the deaths of 3 to 4 million individuals annually, the majority of whom are preschool-age children.[6] According to the World Health Organization, nearly 2 million children die each year because of diarrheal illness.[1] Despite these alarming statistics, approximately 90% of cases of acute diarrhea are mild and self-limited and respond within 5 days to simple rehydration therapy or antidiarrheal agents.[7] The prognosis in research-rich settings is significantly better than in resource-poor settings.

INFECTIOUS AGENTS AND SYMPTOMS

An increasingly wide variety of viral and bacterial agents are being recognized as causes of serious diarrheal illness.[4] Overall, the causes of infectious diarrhea can be categorized as viral, bacterial, or parasitic. In general, these pathogens create a diarrheal effect by inhibiting intestinal absorption and increasing secretion; in causing inflammation, they promote secretory and exudative diarrheal symptoms. Most cases of acute diarrhea are likely viral; stool cultures are positive in only 1.5%

to 5.6% of samples in most studies. In severe cases, however, bacterial etiology is more common: in a study of 173 community-dwelling healthy adults with severe diarrhea, a bacterial etiology was discovered in 87% of cases.[8]

Viral Agents

Viruses are important causes of diarrhea. In healthy adults, the clinical manifestation of viral diarrhea is generally an acute, self-limited gastroenteritis. Although at least 25 different bacteria and protozoa can cause an identical clinical syndrome, greater than 75% of diarrhea-associated cases of gastroenteritis are caused by viruses. Viruses are suspected when vomiting is prominent, the incubation period is longer than 14 hours, and the entire illness is over in less than 4 days. Viral pathogens are likely when there are no warning signs of bacterial infection (e.g., high fever, bloody diarrhea, severe abdominal pain, more than 6 stools in 24 hours) and there are no epidemiological clues from the history (i.e., travel, sexual contact, antibiotic use) suggesting an alternative diagnosis.[9]

Rotavirus

Rotavirus is one of the most ubiquitous agents of diarrhea. It can contribute to an acute, dehydrating diarrhea in children and is estimated to cause more than 800,000 annual deaths of young children in developing countries.[10] Rotavirus-associated diarrheal disease is seasonal; in the United States it begins in the autumn in the Southwest and ends in the spring in the Northeast. Rotaviruses are spread via a fecal–oral route that includes person-to-person transmission. Although the precise mechanisms of disease have yet to be fully elucidated, rotaviruses are known to infect the villous enterocytes of the small intestine and cause a watery diarrhea. In addition to diarrhea, patients often have fever and vomiting.[11]

Parvovirus (Norwalk Virus)

Often categorized within the family of the Norwalk virus are the caliciviruses, also referred to as Norwalk-like viruses or small, round-structured viruses. The Centers for Disease Control and Prevention (CDC) estimates that 66% of 13.8 million cases of food-related illnesses are caused by these viruses each year in the United States. This family of viruses is often suspected when acute gastroenteritis sweeps through a semiclosed community (e.g., family, school, residential home, hospital, ship, dormitory).[9] These viruses are transmitted through contaminated food and water or from person to person. Sources of outbreaks have included well water, raspberries, lunch meat, and, in several instances, oysters.[11] Individuals infected by caliciviruses experience nausea/vomiting, diarrhea, abdominal cramping, and headache; low-grade fever, malaise, and myalgias also occur.[11]

Cytomegalovirus

Cytomegalovirus (CMV) is present in a latent state in most people, having been acquired either at birth or through sexual or parenteral exposure. CMV comes out of latency when there is strong allergenic or antigenic stimulation of the immune system. Often those with severe immunodeficiency also have activation and replication of CMV. When CMV becomes active in the bowel wall, gastrointestinal disease may occur. The disease is seen primarily in patients with severe immune deficiency such as acquired immunodeficiency syndrome (AIDS), transplantation, and cancer chemotherapy[9] and is a major cause of diarrhea in these conditions.

Epstein–Barr Virus

By the age of 20 years, almost all adults are infected with Epstein–Barr virus (EBV). This virus infects B cells and then persists for life because these cells proliferate indefinitely. Proliferation is usually controlled by virus-specific cytotoxic T lymphocytes. EBV causes diarrhea mainly in immunocompromised patients.

Bacterial Agents

Escherichia coli

At least four distinct varieties of diarrheogenic *Escherichia coli* exist: enterotoxigenic (ETEC), enterohemorrhagic (EHEC), enteroinvasive (EIEC), and enteroadherent. In North America, the most prominent diarrheogenic *E. coli* is the EHEC serotype, *E. coli* O157:H7.[11] Contaminated ground beef is the most common vehicle of transmission because contaminating bacteria are distributed throughout the meat during grinding and are not killed if hamburgers are undercooked. After an incubation period from 1 to 8 days, typical symptoms include abdominal cramping and diarrhea that can present as mild, moderate, or severe. Early in the disease course, bowel movements may be loose and watery; in time, however, they may contain gross blood. A subset of patients, often children, may develop the severe, life-threatening hemolytic-uremic syndrome, characterized by the clinical triad of hemolytic anemia, renal failure, and thrombocytopenia.[11]

Campylobacter jejuni

Campylobacter is part of the intestinal flora in many mammals. Contaminated and improperly cooked meat contributes significantly to the spread of disease. Unpasteurized dairy products, contaminated water, and other foods also may encourage transmission. Symptoms begin 1 to 7 days after ingestion of the bacteria and consist of fever, headache, and malaise. These may herald the onset of diarrhea and abdominal cramps by 1 to 2 days. The nature of the diarrhea varies from watery to bloody. *Campylobacter* enterocolitis is usually acute and self-limited over 7 to 10 days. Rarely, relapses, complications, severe disease, and death may occur.[11]

Clostridium difficile

C. difficile infection has become the most common cause of infectious diarrhea in hospitalized patients[12] and is most likely to affect the elderly. *Clostridium* can be catalyzed by the use of antibiotics.

Salmonella

The spread of resistant *Salmonella* strains continues to increase worldwide,[13] and there are more than 2200 currently known serotypes. Spread chiefly through contaminated food, *Salmonella enteritidis* accounts for 85% of all salmonella infections in the United States. Other prominent salmonella infections include *Salmonella typhi* and *Salmonella paratyphi,* which are responsible for typhoid fever. Nontyphoidal salmonellosis may present as fever, gastroenteritis-related diarrhea, and localized infections of the gastrointestinal tract, endothelial surfaces, pericardium, meninges, lungs, joints, bones, urinary tract, or soft tissues. Typhoidal symptoms include a gradual onset of fever, headache, arthralgias, pharyngitis, constipation, anorexia, and abdominal discomfort.

Shigella

Among the bacterial enteric pathogens, *Shigella* is unique in that ingestion of fewer than 200 organisms and possibly as few as 10 organisms may cause clinically apparent disease. *Shigella,* like other enteric pathogens, may be transmitted through contaminated food and water. However, person-to-person spread and transmission by flies may also occur because so few organisms are necessary to cause disease.[11] The incubation period is usually 1 to 4 days. Adults present with nonbloody diarrhea with or without fever and possible gripping abdominal pain, urgency, and relief with defecation. As the infection progresses,

episodes may increase, with the presence of mucus and blood in the stool. Infections often resolve spontaneously in 4 to 8 days for mild cases or 3 to 6 weeks in severe cases.

Yersinia enterocolitica

Yersinia enterocolitica, like *Salmonella* and *Shigella,* is a member of the *Enterobacteriaceae* family. *Yersinia* species are significantly less frequent causes of bacterial enterocolitis in North America than elsewhere. Pathogenic strains of *Y. enterocolitica* are usually transmitted through fecally contaminated food or water but infrequently are transmitted by contaminated blood products. A 4- to 7-day incubation period occurs, followed by watery to bloody diarrhea. This organism is invasive and demonstrates a propensity for lymphoid tissues, causing mesenteric lymphadenitis that may be clinically mistaken for acute appendicitis.[11] Disease usually resolves within 1 to 4 weeks, but occasionally complicating septicemia may develop, usually in patients with underlying disease.

Laribacter hong-kongensis[14]

Described and characterized in 2001, *Laribacter hong-kongensis* is a novel genus and species originally isolated from the blood and empyema pus cultures of a cirrhotic patient with bacteremic empyema thoracis. Since then, it has been described in six patients with diarrhea in Hong Kong and Switzerland. Although more extensive epidemiological studies are necessary, there is reason to consider its role in future studies of diarrheal outbreaks worldwide.

Parasitic Agents

Diarrheal diseases caused by parasites still constitute the greatest single worldwide cause of illness and death. The problem is more severe in underdeveloped countries with poor sanitation, but even in the United States, diarrheal diseases are a major cause of sickness and death. Furthermore, the ease and frequency of worldwide travel and increased migration to the United States are resulting in growing numbers of parasitic infections. In addition to normal inhabitants of the gastrointestinal system acting as parasites, there are also significant diarrheal diseases associated with protozoa and helminths.

Giardia lamblia is the most frequent cause of parasitic enteritis in the United States and should be suspected in cases where history suggests recent hiking and drinking out of streams. Waterborne infection is also important in the developed world, particularly as a result of contamination of domestic water supplies with the cysts of *Giardia intestinalis* and *Cryptosporidium parvum.*[6] Other diarrhea-associated parasites include *Entamoeba histolytica, Microsporidium, Isospora belli,* and *Strongyloides* species.

Although the most commonly reported symptoms of parasitic infection are abdominal pain and cramping with concomitant explosive diarrhea, these symptoms do not occur in all cases. In fact, a growing number of individuals are experiencing milder-than-usual gastrointestinal symptoms due to parasitic infections or symptoms not traditionally considered to be linked to parasitic infections. For example, in some cases of irritable bowel syndrome, indigestion, and poor digestion, parasites may be causing the symptoms. In addition, parasitic infections are often an unsuspected cause of chronic illness and fatigue.

DIAGNOSTIC CONSIDERATIONS

Patients presenting with bloody diarrhea, persistent fever, severe and unremitting abdominal pain, and/or symptoms of severe dehydration warrant in-office evaluation. Immune-compromised/immune-suppressed patients, those with the potential for cardiovascular compromise, or those with a history of inflammatory bowel disease may warrant hospitalization. The initial assessment should include careful history (including travel history and other sources of recent exposure from food or occupational hazard) and physical examination to assess for volume depletion. Diarrhea of small bowel origin is more typically of large volume, watery, and associated with abdominal bloating, cramping, and gas.[15] Fever and bloody stool are rare. In contrast, diarrhea of large bowel origin is typically lower volume and more frequent but is more likely to present with painful bowel movements, fever, and blood/mucus. Visibly bloody stool is most often caused by *E. coli* O157:H7, *Shigella, Salmonella,* or *Campylobacter.*[16] The timing of recent food intake may provide some nonspecific clues to etiology; early symptoms (<6 hours postingestion) suggest the presence of preformed toxin (likely from *Staphylococcus aureus* or *Bacillus cereus*). An onset of greater than 16 hours suggests viral or bacterial infection. An onset between 8 and 16 hours may indicate *Clostridium perfringens* infection. Recent antibiotic use or hospitalization greater than 72 hours should be considered (particularly if within the prior 3 months), especially to rule out a high likelihood of *C. difficile.*

The physical examination to assess for signs of dehydration or more serious illness should include an assessment of skin turgor, dryness of mucous membranes, hypotension, and altered mental state. An abdominal examination may show signs of generalized tenderness and pain with percussion, as well as general distension.

Laboratory Diagnosis

Numerous laboratory procedures exist for the assessment of patients with diarrhea. Stool diagnostic studies may be used if available in cases of dysentery, moderate to severe disease, and symptoms lasting more than 7 days. Other potentially concerning components of the history that may warrant stool testing include more than 6 loose stools within 24 hours, severe abdominal pain, or signs of frank blood in the stool. When visible blood was present in the stool, more than one third of cases were caused by Shiga toxin–producing *E. coli* (STEC) O157:H7 (making this the most common STEC in the United States).[4] Consideration in bloody diarrhea should also be made for the presence of amebiasis, especially in recent travelers.

Bacterial cultures using selective media, detection of pathogen-specific genes using polymerase chain reaction (PCR), electron microscopic examination and antigen detection for viruses, and direct examination with or without the use of special stains for protozoa are some of the plethora of diagnostic tests available. Despite this wide array, a microbiological cause is identified in only 50% of patients at best.[14] One hospital survey of more than 30,000 stool specimens sent for testing revealed a specific pathogen in only 5.6% of cases. In descending order, the most commonly identified pathogens were *Campylobacter jejuni, Salmonella, Shigella,* and *E. coli* O157:H7.[4]

Confounding this issue, it has been shown that substantial variation exists in the use of stool testing, which typically does not correlate with the clinical characteristics of affected patients.[4,17] One study has identified several important independent variables that may be predictive of positive stool culture in adult patients with a clinical picture of infectious diarrhea. These variables are month of presentation, fever, duration of abdominal pain at presentation, and requirement of intravenous fluid therapy. Surprisingly, this study demonstrated that neither a history of bloody diarrhea nor persistent diarrhea was associated with positive stool culture.[17]

Testing for ova and parasites is of low yield in most cases and should be run only when diarrheal illness persists for more than 7 days.[4] In the case of persistent diarrhea, parasites most likely to be discovered include *Giardia, Cryptosporidium,* and *E. histolytica,* and assessment should include ova and parasite inspection of three specimens separated by at least 24 hours.

THERAPEUTIC CONSIDERATIONS

Conventional Medicines

Although appropriate in certain cases, the antibiotics and opiates used to treat diarrhea are also well known to have their limitations because many of these drugs adversely affect gastrointestinal motility; furthermore, increasing numbers of pathogens are proving resistant to antimicrobial agents. Increasing numbers of isolates resistant to antimicrobial agents and the risk of worsened illness (e.g., hemolytic uremic syndrome with STEC O157:H7) further complicate antimicrobial and antimotility drug use.[4] Additionally, available antiperistaltic or antisecretory drugs to reduce the severity of diarrhea can cause serious side effects in children.[10]

Generally, selective antibiotic treatment is recommended for traveler's diarrhea, *Shigella,* and *Campylobacteria* infection. Bismuth salts (e.g., Pepto-Bismol) can be used for travel abroad to coat the intestinal lining and help prevent infection. The role of antibiotic therapy in salmonellosis and *E. coli* O157:H7 infection remains unclear, although in general, enterohemorrhagic *E. coli* should not be treated with empiric antibiotics. Avoidance of antimotility agents in bloody diarrhea is emphasized, especially when illness is caused by *E. coli* O157:H7, which could increase the risk of subsequent hemolytic-uremic syndrome. In select at-risk populations, wider use of vaccines, including the oral typhoid vaccine and the oral cholera vaccine (available only outside the United States), is recommended.[4]

Some newer therapeutic approaches include 5-HT_2 and 5-HT_3 receptor antagonists, calcium-calmodulin antagonists, and alpha-receptor agonists. These may be useful to avoid adverse effects on gastric motilility.[6]

Underlying and Predisposing Factors

Although a pathogenic agent is often responsible for infectious diarrhea, a number of host factors can predispose individuals to experience illness. Poor digestive function, which is often characterized by low stomach acid output or achlorhydria and inadequate pancreatic enzyme output, should be explored in patients who are susceptible to infectious diarrhea. In these cases, hydrochloric acid and pancreatic enzyme supplementation may be advisable. Immunoglobulin A (IgA) antibodies help discourage epithelial adherence of pathogenic organisms. Depressed levels of secretory IgA can leave the immune system of the gastrointestinal tract feeble and unable to deal with pathogenic infection. Decreased intestinal motility, which can be caused by chronic stress and high sugar intake, can also allow microbes to flourish in an intestinal environment. Recurrent infectious diarrhea may be encouraged by food allergy and sensitivities as well.

The clinician should also be aware that many drugs may actually increase susceptibility to infectious diarrheal illness. These include proton-pump inhibitors, antifolate drugs, and antibiotics. Hospitalized patients who receive proton-pump inhibitors are at increased risk of *C. difficile*–induced diarrhea.[18–20] As in the case of achlorhydria, it is likely that inhibition of upper gastrointestinal digestive acids by proton-pump inhibitors may allow pathogens and undigested food to reach the intestines without being properly broken down. Also, antibiotic-associated diarrhea is known to occur with broad-spectrum antibiotics.[21] Antibiotics can disrupt local bowel flora, allowing pathogenic organisms to flourish, and are well-known to leave patients susceptible to diarrhea (see "Probiotics" later in the chapter).

Hydration/Electrolyte Balance

It is of paramount importance to keep the patient with diarrhea well hydrated and to ensure electrolyte balance. This is most crucial in children. Of course, rehydration does not treat the diarrhea itself, which will persist until the infection resolves. Signs of dehydration may include decreased or absent urination, decreased skin turgor, and dry tongue. Rehydration using solutions of glucose, sodium, and potassium is appropriate. In cases of severe dehydration with weight loss of more than 10% or unconsciousness, intravenous rehydration is indicated.[22] Otherwise, oral rehydration solutions can be quite effective, given that glucose absorption via sodium–glucose cotransport remains intact during episodes of diarrhea.

Diet

Prevention of infectious diarrhea may be accomplished by avoiding undercooked meat or seafood, unpasteurized milk, or soft cheese.[4] Once the patient has symptoms, the use of the traditional "BRAT diet" can usually help decrease gastric motility. The components of this diet are foods that can slow peristalsis and tend to be more binding. These are bananas, white rice, apples, plain white toast or bread, and tea.

High-fat meals and dairy-based foods (due to secondary lactose malabsorption, which may last for several weeks to months after an infectious diarrheal event) should be avoided.

Evidence indicates that larger, less frequent meals are more taxing to the digestive and absorptive capacities of the gastrointestinal system. In one porcine study, 3-week-old piglets were assigned to one of four dietary regimens and were subsequently all infected with rotavirus, followed 24 hours later with enteropathogenic *E. coli.* The dietary regimen designed to tax the digestive and absorptive capacities of the piglets (a high nutrient intake with a three-times-a-day feeding) significantly produced the most prolonged diarrhea as well as the most advanced colonization of the gut by hemolytic enteropathogenic *E. coli* and persistent shedding of rotavirus. The same nutrient intake divided into 24 equal increments and administered hourly produced a less severe response. The least severe diarrhea was seen in piglets fed one-third the nutrient intake either hourly or three times a day.[23]

Traditional dietary preparations for diarrhea such as carrot soup and products based on rice can be useful because of their high absorbance capacity. They have been known to reduce stool output and the duration of diarrhea, although they may not necessarily diminish the intestinal loss of water and electrolytes.[22,24]

One study evaluated the effects of green banana and pectin on intestinal permeability in 57 boys with persistent diarrhea. Green banana and pectin contain nondigestible dietary sources of colonic short-chain fatty acids. The patients were given a week's treatment with a rice-based diet containing either cooked green banana, pectin, or a rice diet alone. Intestinal permeability was assessed before and after treatment by giving a lactulose-mannitol (LM) drink and measuring urinary recovery after 5 hours. Treatment with banana significantly reduced lactulose recovery, increased mannitol recovery, and decreased the LM ratio, indicating an improvement of permeability. Pectin produced similar results. Permeability changes were associated with a 50% reduction in stool weights, which correlated strongly with the LM ratio.[25] In a study of 154 male infants aged between 1 and 30 months, commonly allergenic soy- and casein-based diets were not helpful in alleviating persistent diarrhea, whereas yogurt and broken-down amino acid formulas were helpful in encouraging a significant reduction in stool output and in the duration of diarrhea.[26] Other studies also suggest, as an adjunctive measure for patients who experience vomiting, the administration of a small amount of glucose.[22]

Supplements

Vitamin A

The administration of vitamin A to children can reduce the incidence of severe diarrhea. One double-blind controlled trial examined 900 children from ages 1 to 5 with acute diarrhea. These young subjects

were assigned to receive either 60 mg of vitamin A or a placebo. They were followed up at home on alternate days until they recovered from the diarrheal episode. In all study children, those treated with vitamin A had a significantly lower risk of persistent diarrhea. However, there was no change in the duration or average stool frequency. Interestingly, the group who was not breastfed had a shorter average duration of diarrhea. In these children, the mean number of stools passed after the intervention, the proportion of episodes lasting greater than 14 days, and the percentage of children who passed watery stools on any study day were also significantly lower in those treated with vitamin A.[27]

Folic Acid and Vitamin B_{12}

Studies are beginning to emerge correlating low levels of folic acid and vitamin B_{12} with increased susceptibility to diarrhea. Folic acid deficiency is known to promote malabsorption due to the altered structure of the intestinal mucosal cells.[28] Thirteen patients diagnosed with megaloblastic anemia suffering from chronic diarrhea showed significant histological changes of the ileal mucosa, including inflammation, atrophy, erosion and flattening of the villi, lymphatic ectasia, and focal fibrosis. When given folate and cyanocobalamin supplementation, these patients quickly demonstrated decreased diarrheal episodes as well as intestinal restoration.[29]

Antifolate chemotherapeutic drugs such as methotrexate can contribute to folic acid and vitamin B_{12} deficiencies and can cause or contribute to diarrheal symptomatology. Cancer patients treated with this class of drugs who had lowered folic acid and vitamin B_{12} were found to be more susceptible to subsequent development of serious drug-related toxicities such as myelosuppression, diarrhea, mucosal toxicity, and infection. This suggests that toxicity is related to relative folate deficiency in some cancer patients.[30] In this study, nutritional supplementation led to a marked reduction in toxicity and the abolition of treatment-related deaths without affecting the efficacy of the antineoplastic drugs.

Tangential to the conversation of infectious diarrhea and folic acid, there is a concern for neural tube defects (NTDs) with folic acid and vitamin B_{12} deficiency. It has been suggested that gastrointestinal disturbances such as those caused by diarrhea might negatively affect the availability of these vitamins to the pregnant mother and fetus, thereby increasing the risk of birth defects. In one study evaluating the risk of neural tube defects with periconceptional diarrhea, it was observed that one or more episodes of periconceptional diarrhea were associated with an increased risk of NTD-affected pregnancies compared with no episodes of diarrhea. This association was independent of fever, obesity, maternal age, maternal birthplace, income, prior unproductive pregnancy, and dietary plus multivitamin folate intake.[31] Whether the cause of diarrhea is infectious or of any other origin, it is prudent to ensure proper folic acid and vitamin B_{12} nutrition in women who are trying to conceive as well as in newly pregnant women.

Folic acid supplementation appears to be without side effects, even at high doses (e.g., 15 mg/day). Patients with certain genetic polymorphisms, including COMT and/or MAO, may experience aggravations from high doses of methyl-donors secondary to impaired ability to metabolize increased neurotransmitter availability (a concept known as methyl-trapping). It has been reported that 8 of 14 healthy human subjects who consumed 15 mg/day of folic acid for 1 month developed abdominal distention, flatulence, nausea, anorexia, sleep disturbances with vivid dreams, malaise, and irritability.[32] This, however, has not been confirmed in a double-blind clinical study[33] and other investigations.[34,35] Vitamin B_{12} is not carcinogenic, teratogenic, or mutagenic. It is considered safe even at 1000 times the recommended daily allowance. However, during such treatment, care should be given to not take large amounts of folic acid because this may mask the nerve damage associated with vitamin B_{12} deficiency.

Zinc

In recent years, the nutritional importance of zinc has been established, and zinc deficiency and its symptoms have been well recognized. Diarrhea has been found to be one of the clinical manifestations of zinc deficiency. Zinc has demonstrated an antimicrobial effect on enteric pathogens such as *S. typhi, Salmonella, E. coli, Enterobacter, Shigella, Staphylococcus albus, Streptococcus pyogenes,* and *Vibrio cholerae*[36,37] and may contribute to the treatment of diarrhea. Zinc absorption occurs throughout the small intestine, not only in the duodenum, jejunum, and ileum. Many illnesses distinguished by chronic diarrhea entail insufficient absorption of zinc. In fact, in some cases of chronic enteropathies in infants, like celiac disease and cystic fibrosis, a deficiency of zinc has been isolated.[38]

Good dietary sources of zinc are meat, fish, and to a lesser extent, human milk. *Acrodermatitis enteropathica* is a rare but severe disease in which skin lesions, chronic diarrhea, and recurring infections are the main symptoms. The disease is related to the malfunctioning of intestinal absorption of zinc and can be treated by administering pharmacological doses of zinc orally. The amount of zinc absorbed in the small intestine is influenced by other nutrients: some compounds such as dietary fiber and phytates (which are found in foods including soy, wheat bran, peas, carob, and brown rice) may inhibit this process, whereas picolinic and citric acid facilitate it. Citric acid is thought to be the ligand that accounts for the high level of bioavailability of zinc in human milk.[38]

As a cautionary note, it is theoretically possible that some of the dietary treatments used by practitioners of natural medicine for persistent postenteritis diarrhea—such as elimination of cow's milk and increased fiber and carob powder as well as use of soy formula in infants—can contribute to a scarce supply of zinc and therefore promote the persistence of diarrhea itself.[38] Although these therapeutic approaches are being used, zinc supplementation may be warranted, especially if the patient tends to have diarrheal symptoms.

Glutamine

Glutamine is the most abundant amino acid in the blood. As one of the principal fuels used by the intestinal lining cells, it accounts for 35% of their energy production. Although glutamine is readily available in the diet and synthesized in the body, supplementation improves the energy metabolism of the gastrointestinal mucosa, thus stimulating regeneration.[39] Glutamine prevents intestinal mucosal damage and has been shown to decrease bacterial leakage across the intestines after they are damaged, presumably by stimulating repair.[40] Clearly, glutamine holds promise for enhancing the repair of mucosal injury by a wide range of infections or toxic agents and thus has great potential as a new oral rehydration and nutritional therapeutic for patients with enteric infection, malnutrition, or chemotherapy-induced or radiation-induced enteritis.[40]

Animal models have definitely shown the usefulness of this amino acid in diarrhea. Glutamine has been shown to enhance sodium and water absorption in a rabbit model of cholera and *Cryptosporidium*-infected piglet intestine and has proven effective in a bovine model of *Cryptosporidium* as well. One rat model of cholera toxin–induced diarrhea also showed that alanyl-glutamine (a more stable derivative of glutamine) enhanced water and electrolyte intestinal absorption even better than the traditional glucose solutions.[41]

In one double-blind clinical study of 128 healthy children ages 6 to 24 months old with acute diarrhea, 63 received 0.3 g/kg/day of glutamine, and 65 controls received a placebo for 7 days. The

average duration of diarrhea in the glutamine-treated group was significantly shorter than that in the placebo group (3.4 days vs. 4.57 days, respectively).[42]

Glutamine, even at high doses, is without side effects and is well tolerated.[41] A typical dosage of glutamine is 100 mg three times a day (see Chapter 84 for a more comprehensive discussion of glutamine).

Probiotics

Lactobacillus and *Saccharomyces*

Probiotics, translated as "for life," are bacteria residing in the intestine that are considered beneficial to health. The most important healthful bacteria are *Lactobacillus acidophilus* and *Bifidobacterium bifidum.* Other bacteria (including such beneficial strains as *Lactobacillus casea, Lactobacillus fermentum, Lactobacillus salivores,* and *Lactobacillus brevis*) also become established in the gut (see Chapter 105 for an extensive discussion of these useful clinical agents).

A substantially growing body of scientific evidence has now demonstrated that lactobacilli, *Saccharomyces,* and fermented foods play a significant role in human health. Probiotics are thought to have a protective effect against acute diarrheal disease and have been shown to be successful in the treatment or prevention of various types of infectious diarrhea, including that due to rotavirus, *C. difficile,* and traveler's diarrhea.[5,43,44] A review of the literature suggests that *Lactobacillus rhamnosus* GG (LGG) and *Saccharomyces boulardii* had the most compelling evidence of efficacy; they reduced the duration of disease by 24 hours in acute gastroenteritis and were both likely to improve outcomes in antibiotic-associated diarrhea.[95] Corroborating earlier reviews,[45,46] a Cochrane meta-analysis supports the use of probiotics to shorten the duration (reduced risk of diarrhea lasting 4 or more days by 59%) and reduce stool frequency in acute infectious diarrhea.[47]

Studies show that probiotic supplementation may also prevent future nosocomial rotaviral gastroenteritis, thus demonstrating an immune-modulating effect of probiotics,[5,48] possibly by significantly increasing the number of cells secreting IgA. *Lactobacillus* sp. have also shown remarkable ability to inhibit *E. coli* O157:H7, but not *Salmonella,* in refrigerated storage.[49] *Lactobacillus* may be considered as a future addition to stored foods used for low immune status and high susceptibility to *E. coli* O157:H7.

Children are especially susceptible to infectious diarrhea and its sequelae. In a recent Cochrane review of children with antibiotic-associated diarrhea, *L. rhamnosus* or *S. boulardii* at 5 to 40 billion colony-forming units/day was shown to be effective at improving symptoms, with a reasonable number needed to treat (NNT).[50] In one double-blind, placebo-controlled study, a standard infant formula was supplemented with the probiotics *Bifidobacteria bifidum* and *Streptococcus thermophilus.* Subjects in the probiotic group developed diarrhea at a statistically lower rate than those in the control group (7% vs. 31%). Additionally, rotavirus shedding was decreased statistically in the probiotic group (10% vs. 39%).[44] A second randomized placebo-controlled trial evaluated probiotics in a different but also high-risk population. In this case, 204 undernourished Peruvian children received LGG or placebo. Although a difference in rates of diarrhea was observed, where the treated group had statistically fewer episodes of diarrhea, the reduction was minor (from 6 episodes per child per year to 5.2 episodes per child per year). Interestingly, children who were breastfed did not seem to benefit at all, raising the possibility that probiotics provide a similar action as breast milk in the prevention of infection.[51] In a third double-blind study, 81 children aged 1 to 36 months were enrolled in a trial and randomly assigned at admission to receive 6×10^9 CFUs of LGG or placebo twice daily orally for the duration of their hospital stay. The *Lactobacillus*-treated children enjoyed a dramatically reduced risk of nosocomial diarrhea of 6.7%, versus 33.3% in those who were not given the probiotic. Once again, the use of LGG significantly reduced the risk of rotavirus gastroenteritis (2.2% vs. 16.7%).[52]

S. boulardii, also known as *Saccromyces cerevisiae,* is a nonpathogenic probiotic yeast that may be most helpful in diarrhea caused by *C. difficile,* a pathogen most likely to affect the elderly. Although in the conventional medical world vancomycin is the preferred treatment of severe cases, *S. boulardii* alone or in combination with vancomycin has been reported to be an effective therapeutic alternative for recurrent infection.[12] Although it is generally safe, a few case reports have demonstrated that fungemia and sepsis are rare complications of the administration of *S. boulardii* in immunocompromised patients,[53] in whom it may be contraindicated. The daily adult dose is usually 1 g/day in divided doses (500 mg twice a day) for at least 4 weeks.

L. acidophilus has been shown to correct the increase of gram-negative bacteria observed after the administration of broad-spectrum antibiotics, as occurs with any acute or chronic diarrhea.[54–59] Similarly, a mixture of *B. bifidum* and *L. acidophilus* inhibited the lowering of fecal flora induced by ampicillin and maintained the equilibrium of the intestinal ecosystem.[57]

Although it is commonly believed that acidophilus supplements are not effective if taken during antibiotic therapy, the research actually supports the use of *L. acidophilus* during antibiotic administration.[57,58] Reductions of friendly bacteria or superinfection with antibiotic-resistant flora, or both, may be prevented by administering *L. acidophilus* products during antibiotic therapy. A dose of at least 15 to 20 billion organisms is required. Probiotic supplements should, however, be taken as temporally far away from the antibiotic as possible.

Evidence indicates that the conventional medical world is beginning to take notice of the benefits of giving *Lactobacillus* with antibiotic therapy. In one double-blind, controlled study, the antibiotic containing ampicillin (250 mg) and cloxacillin (250 mg) with or without protected lactobacilli was evaluated in 740 patients undergoing cataract surgery. The incidence of diarrhea in patients receiving antibiotic alone was 13.3%, compared with 0% in patients receiving antibiotic with protected lactobacilli.[21] Although antibiotics should be used judiciously and only in cases where the benefits outweigh the risks, adjunctive therapy may decrease the untoward effects of antibiotic therapy on the gastrointestinal system.

Although many excellent companies provide high-quality probiotic products, it is difficult to sort through all of the manufacturers' claims of superiority, and some products have been shown to contain no active *L. acidophilus.*[60] Only high-quality, laboratory-tested probiotics should be used.

Botanical Medicines

Berberine-Containing Plants

Berberine-containing plants include goldenseal *(Hydrastis canadensis),* barberry *(Berberis vulgaris),* Oregon grape *(Berberis aquifolium),* and goldthread *(Coptis chinensis).* Berberine, an alkaloid, has been extensively studied in both experimental and clinical settings for its antibiotic activity. Berberine exhibits a broad spectrum of antibiotic activity, having shown antimicrobial activity against bacteria, protozoa, and fungi, including *Candida albicans.*[61–67]

Berberine's antibiotic action against some of these pathogens is actually stronger than that of the antibiotics commonly used for the disease these pathogens cause. Berberine-containing plants should be considered in infectious processes involving the previously mentioned organisms. Berberine's action in inhibiting *Candida,* as well as pathogenic bacteria, prevents the overgrowth of yeast, which is a common side effect of antibiotic use.

Diarrhea is a common symptom in patients with chronic candidiasis. Berberine has shown remarkable antidiarrheal activity in even

the most severe cases. Positive clinical results have been shown with berberine in relieving diarrhea in cases of cholera, amebiasis, giardiasis, and other causes of acute gastrointestinal infection (e.g., due to *E. coli, Shigella, Salmonella,* and *Klebsiella*) and may also relieve the diarrhea seen in patients with chronic candidiasis.[68–74]

The dosage of any berberine-containing plant should be based on berberine content. Because there is a wide range of quality in goldenseal preparations, standardized extracts are preferred. Three-times-a-day dosages are as follows:

- Dried root or as infusion (tea), 2 to 4 g
- Tincture (1:5), 6 to 12 mL (1.5–3 tsp)
- Fluid extract (1:1), 2 to 4 mL (0.5–1 tsp)
- Solid (powdered dry) extract (4:1 or 8%–12% alkaloid content), 250 to 500 mg

Note that the dosage recommendations for berberine would be 25 to 50 mg three times a day or a daily dosage of up to 150 mg. This dosage is consistent with the dosage range in the positive clinical studies in patients with gastrointestinal infections. For children, a dosage based on body weight is appropriate. The daily dosage would be the equivalent of 5 to 10 mg of berberine/kg (2.2 lb) body weight.

Berberine and berberine-containing plants are generally nontoxic at the recommended dosages; however, berberine-containing plants are not recommended for use during pregnancy, and higher dosages may interfere with B vitamin metabolism.

Potentilla tormentilla (Tormentil Root)

Tormentil root contains more than 15% tannic acid, giving this plant high astringent capacity[75]; it may be useful in treating infectious diarrhea, shortening the duration of rotavirus diarrhea, and decreasing the requirement for rehydration solutions.[10] A randomized double-blind placebo-controlled trial was conducted at a children's hospital in St. Petersburg, Russia. In this study, 40 children ranging in age from 3 months to 7 years with rotavirus diarrhea were divided into two groups: a treatment group consisting of 20 children given 3 drops of tormentil root extract per year of life three times a day until discontinuation of diarrhea or a maximum of 5 days and a control group of 20 children who received a placebo.

The duration of diarrhea in the group treated with tormentil root extract was 60% less than that in the placebo group (3 days, compared with 5 days in the control group). In the treatment group, 8 of 20 (40%) children were diarrhea-free 48 hours after admission to the hospital, compared with 1 of 20 (5%) in the control group. Children in the treatment group also received smaller volumes of parenteral fluids than subjects in the control group.[10] For adults, a reasonable dose is 60 drops of tincture twice daily. Some clinicians find the powdered herb to be more effective in adults at a dosage of 1/4 tsp twice daily.[75]

Allium sativum (Garlic)

Garlic appears to affect DNA and RNA synthesis and is being investigated as an effective antibiotic. In vitro antimicrobial sensitivity tests on *E. coli, Shigella* sp., *Salmonella* sp., and *Proteus mirabilis* found significant effects of garlic along with ciprofloxacin and ampicillin. The gram-negative diarrheagenic pathogens from the stool samples were highly sensitive to garlic, whereas ciprofloxacin was most effective against *E. coli.* The differences were inferred to result from genetic differences among the organisms and differences in the modes of action of the antibiotics. Most interestingly, no pathogens were resistant to garlic, which led the authors to conclude it was a promising antimicrobial agent.[76]

Other Antidiarrheal Botanicals

A recent review of the available evidence indicates the use of herbal compounds in children or adolescents suffering from acute diarrhea. An herbal preparation containing *Matricaria chamomilla* (German chamomile) was shown to significantly reduce the duration of diarrhea and frequency of bowel movements compared with placebo.

Carob bean juice was shown to be superior to placebo in reducing the required intake of a standard rehydration solution, total stool output, and the overall duration of diarrhea. The more commonly available carob powder, at a dosage of 15 g daily (in divided doses), has been used successfully in children.[77]

Other Antiparasitic Botanicals

A wide variety of botanicals have been used alone or in combination with anti-inflammatory and demulcent herbs to specifically stop parasitic infections and heal the digestive tract. Curcumin has been shown to protect against castor oil– and carrageenan-induced diarrhea in rat models.[78] The Brazilian *Ocimum selloi* essential oil produced a significant reduction in the severity and frequency of diarrhea produced by castor oil while also reducing transit time in mice.[79] A Thai herbal formula called Pikutbenjakul—which contains *Piper longum, Piper sarmentosum, Piper interruptum, Plumbago indica,* and *Zingiber officinale*—has shown promise in in vitro work against some *Vibrio* species, *Salmonella, Shigella, E. coli,* and *S. aureus.*[80] Unfortunately, human clinical trials are lacking to corroborate the safety and efficacy of their use. Future studies should evaluate the potential benefits and toxicities of the following antiparasitic herbs: *Artemisia absinthium* (wormwood), *Chenopodium abrosioides* (wormseed), *Curcuma longa* (turmeric), *Phytolacca decandra* (pokeweed, pokeroot), *Juglans* species (black and white walnut), and *Tanacetum vulgare* (tansy).

Homeopathy

A meta-analysis of three double-blind clinical trials of diarrhea found that individualized homeopathic treatment decreases the duration of acute childhood diarrhea. In this review, 242 children ages 6 months to 5 years were analyzed as one group. Children were randomized to receive either an individualized homeopathic medicine or placebo to be taken as a single dose after each unformed stool for 5 days. Parents recorded daily stools on diary cards, and health workers made home visits daily to monitor the children. The duration of diarrhea was defined as the time until there were fewer than three unformed stools per day for 2 consecutive days. A meta-analysis of the effect–size difference of the three studies was also conducted. Combined analysis showed a statistically significant duration of diarrhea of 3.3 days in the homeopathy group versus 4.1 in the placebo group.

Homeopathics commonly included as possible remedies for diarrhea include podophyllum (which is well known for its almost universal application for traveler's diarrhea[81]), aloe, china, mercurius, phosphorus, nux vomica, sulfur, aconite, veratrum album, and arsenicum. Although these results must still be evaluated further with larger-scale studies, given the safety and historical effectiveness of homeopathy, it should be thoroughly considered as part of the natural medicine practitioner's therapeutic choices.

Acupuncture

From a traditional Chinese medicine perspective, diarrhea is generally due to an imbalance of large intestinal regulation as well as deficiency of the spleen and stomach. Although there are variations depending on a particular patient's presentation, the four basic diagnoses are diarrhea due to Cold-Damp, Damp-Heat, Spleen-Yang Depletion, and Kidney Yang deficiency. Typically, diarrhea caused by infectious pathogens falls into the category of Damp-Heat and may present with pain, mucus, and blood in the stool.

A few studies have shown the effect that acupuncture[82–84] and Chinese herbal preparations have on intestinal movement.[2,85] One

study demonstrated that intestinal peristalsis was accelerated significantly by acupuncture at the abdomen but suppressed by moxibustion, which is the warming of certain acupuncture points with nearby burning of *Artemisia argyi*.[83] Depending on the desired result, the acupuncture practitioner may want to focus on moxa therapy for some cases where slower peristalsis is desired. Two studies measured the influence of electrical stimulation of acupuncture points including ST-36 (Zusanli) and SP-6 (Sanyinjiao) on the myoelectrical activity of the small intestine; as a result, a clear ability of acupuncture to alter intestinal motility was recorded. One of these trials employed 3 Hz of electroacupuncture on the ST-36 (Zusanli) point and demonstrated increased regularity of the gastric myoelectrical system.[84] However, another evaluation did not find acupuncture plus electrostimulation to be effective enough to normalize gastric dysrhythmia after pretreatment with atropine.[86]

Animal research has supported the historical use of acupuncture for infectious diarrhea. The effect of acupuncture was evaluated in the treatment of 32 young pigs with induced enteropathogenic *E. coli* diarrhea. The animals were all inoculated with *E. coli* and then divided into three groups. One group, the controls, remained untreated; a second group was treated with the antibiotic enrofloxacin; and the third group was treated with traditional acupuncture using GV-1 (Jiaochao). Using histopathological evaluation by hematoxylin-and-eosin stain, severe infiltration of inflammatory cells in the lamina propria was observed in the ascending and descending colon and in the fundic stomach of the untreated control group. Destruction of the fundic gland's architecture and necrotic lesions were also observed. However, in these same anatomic locations, the animals treated with acupuncture or antibiotics maintained mucosa of the colon and stomach that were relatively similar to those of the normal group.[87] Another corroborating similar study of 34 animals employed Du-20 (Bai-hui), BL-20 (Pishu), CV-12 (ZongWan), and ST-25 (TianShu). This study found no extra benefit from using electrical stimulation.[88]

Many Chinese practitioners find benefit in using acupuncture and Chinese herbs together to decrease the side effects associated with Western medicine.[89] One study of Keishi-ka-shakuyaku-to (Gui-Zhi-Jia-Shao-Yao-Tang) on diarrhea induced by pilocarpine, barium chloride, or castor oil found a significant reduction when the herbal combination was dosed at 1000 mg/kg. This herb may mechanistically act to inhibit excessively accelerated small intestinal movement. Another trial comprised 162 children suffering from chronic protracted diarrhea; it involved randomly dividing them into two groups and observing them clinically. In the Chinese herbal medicine group, Xiang Cheng San was externally applied to the umbilicus of each patient; in a second group, Western drugs were routinely given. The results showed that the therapeutic effects were markedly better in the herbal medicine group.[90] Although no control was used in this experiment, the results are encouraging. A wider variety of patent, granular, and loose herb combinations are used to treat various Chinese diagnoses for infectious diarrhea. Future clinical research will help elucidate their use.

Finally, complex chronic immune deficiency conditions leave patients quite susceptible to pathogenic infection and are difficult to treat. Diarrhea affects more than 60% of persons living with human immunodeficiency virus (HIV)/AIDS. AIDS patients already on a polypharmaceutical regimen have shown good responses to acupuncture and moxibustion used to alleviate symptoms of diarrhea.[91,92] In one pilot study, 15 HIV-positive men with chronic diarrhea received the same acupuncture/moxibustion treatment for six sessions over a 3-week period. In all subjects, stool frequency was reduced by approximately one episode per day. Stool consistency also improved from baseline to week 3 and week 4 by more than 1 point on Hansen's stool consistency scale. Once again, more studies are necessary, but preliminary results are promising for antidiarrheal therapy that does not require additional pharmaceuticals.

Overall, Chinese medicine modalities have proved to be quite safe. In one 6-year Japanese study, the results of 84 therapists and 65,482 treatments were evaluated. Participants were required to report all adverse events. In total, only 94 (0.14%) adverse events were recorded, and none was serious (serious events included conditions like pneumothorax, infection, and spinal cord injury). The authors concluded that serious or severe adverse events are rare in standard practice. Although more research is clearly necessary to elucidate the benefits of acupuncture, given the little risk and long history of positive anecdotal evidence, it is certainly worth using.[93] More research on Chinese herbs is also necessary to elucidate the toxicity in those preparations that appear therapeutically beneficial.

THERAPEUTIC APPROACH

Overall, natural treatments can adequately manage most cases of non–life-threatening diarrhea. Importantly, diarrhea itself is an eliminative function used by the body to clear toxins and should not be completely suppressed. Of course, chronic diarrhea and diarrhea that causes extreme or rapid electrolyte and water loss may require conventional interventions. It is imperative to maintain hydration and electrolyte balance. Nowhere is this need more immediate than in children younger than 5 years of age.

Underlying Factors

Addressing underlying factors such as low stomach and pancreatic output and depressed levels of IgA helps decrease the chances of pathogenic infection. When possible, eliminating iatrogenic causes such as proton-pump inhibitors and antibiotics also helps prevent recurrences. Diets low in refined sugar and cow's milk dairy are encouraged. Food allergies and intolerances should be assessed in those with recurrent infections. Methods to relieve stress also help encourage proper digestive function.

Proper treatment with either an antibiotic or a natural alternative requires close monitoring by standard laboratory methods (e.g., repeating multiple stool samples 2 weeks after initiation of therapy).

Diet

The BRAT diet may be useful to discourage large volume loss in infectious diarrhea. Green banana and pectin fiber may be a useful part of the BRAT diet. Small, frequent meals (hourly, if possible) may be best, with glucose administration in the case of vomiting. Avoidance of soy, casein, and other known allergenic foods may be beneficial.

Nutritional Supplements

Dosages are for adults unless otherwise indicated.

- Vitamin A: 60 mg/day in children and up to 50,000 IU/day for 1 to 2 days for adults with infections. Caution against high doses (above 10,000 IU/day in pregnant women).
- Folate: 1 mg/day
- Vitamin B_{12} (methylcobalamin): 600 to 1000 mcg/day
- Zinc picolinate: 30 mg/day
- Glutamine: 100 mg twice a day
- *Lactobacillus* sp. and *Bifidobacteria sp.* 6 to 10 billion CFU of LGG or other high-quality probiotic twice a day orally. For prevention of antibiotic-induced diarrhea, a dosage of at least 15 to 20 billion organisms is required. Probiotic supplements should be taken as far away from the antibiotic as possible (2–4 hours is ideal). In children younger than age 6 experiencing antibiotic-induced diarrhea,

the probiotic should be taken every day of the antibiotic dose and continued for 1 week after discontinuing the antibiotic.
- *S. boulardii:* Specifically to treat *C. difficile,* a daily adult dose of 1 g/day in divided doses (500 mg twice a day) for at least 4 weeks. Can be used adjunctively with vancomycin.

Botanicals

- Berberine: Dosage recommendations for berberine would be 25 to 50 mg three times a day or a daily dosage of up to 150 mg. For children, a dosage based on body weight is appropriate. The daily dosage would be the equivalent of 5 to 10 mg of berberine/kg (2.2 lb) body weight. See earlier discussion for more details.
- Tormentil: 60 drops of tincture twice a day or powdered herb at 1/4 tsp twice a day. In children, 3 drops of tormentil root extract per year of life three times a day until discontinuation of diarrhea or a maximum of 5 days.
- Carob powder: 15g daily (in divided dose), mixed into applesauce or similar mixture

Homeopathy

- Typical remedies for diarrhea include podophyllum, aloe, china, mercurius, phosphorus, nux vomica, sulfur, aconite, veratrum album, and arsenicum. The specific choice of remedy should be based on the individual patient and his or her presentation.

Acupuncture

- Acupuncture points may include ST-36 (Zusanli) and SP-6 (Sanyinjiao), DU-20 (Bai-hui), BL-20 (Pishu), CV-12 (ZongWan), and ST-25 (TianShu).
- Acupuncture is appropriate for stress relief as well as in the direct treatment of intestinal issues and is excellent for treating HIV/AIDS-related diarrhea.

Infertility, Female

Leah Hechtman, MSci (RHHG), BHSc (Nat), ND

OUTLINE

DIAGNOSTIC SUMMARY

- Inability to conceive a child after 12 months of regular unprotected intercourse (at least twice weekly) with the same male partner and in the absence of male causes

GENERAL CONSIDERATIONS

Females are believed to contribute to 50% of infertility cases as the primary (30%) and combined (20%) factor. Recent Centers for Disease Control and Prevention (CDC) infertility statistics include the following[1]:

- Percentage of women aged 15 to 44 with impaired fecundity: 12.1%
- Percentage of married women aged 15 to 44 who are infertile: 6.7%
- Number of women aged 15 to 44 who have ever used infertility services: 7.3 million
- Percentage of women aged 15 to 44 who have ever used infertility services: 12.0%

Infertility statistics suggest that one in seven couples in the United States experiences this condition. It is defined by a lack of conception after 12 months of regular unprotected intercourse (at least twice weekly) with the same male partner and in the absence of male causes. After 12 months, intervention and treatment are recommended. It is advisable to initiate earlier intervention and treatment for women over 35 years of age. After this time, the recommendations are that women should receive a comprehensive review and discussion surrounding natural or assisted conception owing to age-related concerns.

A person's fertility is a reflection of his or her general health and well-being. Because we are genetically constructed to pass on the best information for the next generation, the optimal ages for reproduction are believed to be between 18 and 35 years for a female and 16 and 40 years for a male.

Delaying the decision to have children contributes to the proportion of couples who are involuntarily childless. Demographic[2] and clinical studies[3] have shown that women experience optimal fertility before the age of 30 to 31 years. After the age of 31, the probability of conception declines rapidly, but this can be partly compensated for by continued insemination for additional cycles. In addition, the probability of an adverse pregnancy outcome starts to increase at about the same age.[3]

Thereafter, fertility gradually decreases, with acceleration toward the age of 40 years. In women, fertility remains relatively stable until 30 years of age, generally producing more than 400 pregnancies per 1000 exposed women per year; it then begins to decrease substantially.[4] By 45 years of age, the fertility rate is only 100 pregnancies per 1000 exposed women.[5] Already at the age of 40 to 41 years, half of women will have completely lost their capacity for reproduction. It is generally accepted that reproductive aging is in fact ovarian aging and is related to the decreasing quantity and quality of the pool of follicles preserved in the ovaries.[6]

To achieve a normal conception, the following are needed[4]:

- Production of viable sperm with respect to motility, morphology, count, and DNA integrity
- Transport of sperm through the male genital tract and deposition in the female genital tract, usually near the cervix of the uterus during sexual intercourse
- Normal oocyte production (ovulation) by the ovaries
- Transport of sperm and the oocyte within the female genital tract to the site of fertilization in one fallopian tube
- Penetration of sperm into the oocyte, fertilization, development of a preembryo, and its transport to and implantation in the uterus

The reader is directed to Chapter 180, Infertility, Male, for specific information for the male partner. Additionally, Chapter 185 covers the definitions of infertility—primary, secondary, and unexplained.

Fecundity is defined as the couple's chance of conception in a single menstrual cycle. The normal monthly success rate for couples trying to conceive naturally at age 25 is 25%. This figure decreases with increasing age, particularly after 35 years of age for women. It was once believed that a woman's age was the only major contributing factor; however, it is now known that male fertility declines with age concurrent with abnormalities evident in semen parameters.

TABLE 184.1 Causes of Female Infertility

Ovulation disorders (40%)	Aging
	Diminished ovarian reserve
	Endocrine disorder (e.g., hypothalamic amenorrhea, hyperprolactinemia, thyroid disease, adrenal disease)
	Polycystic ovary syndrome
	Premature ovarian failure
	Tobacco use
Tubal factors (30%)	Obstruction (e.g., history of pelvic inflammatory disease, tubal surgery)
Endometriosis (15%)	
Other (approximately 10%)	
Uterine/cervical factors (>3%)	Congenital uterine anomaly
	Fibroids
	Endometrial polyps
	Poor-quality/quantity cervical mucus (caused by smoking, infection); mucous hostility (sperm antibodies)
	Uterine synechiae or adhesions (Asherman's syndrome)

Data from Jose-Miller, A., Boyden, JW, Frey, KA. Infertility. *Am Fam Physician.* 2007;75(6):849–856.

The probability of a couple's fecundity is calculated to determine the monthly chance a couple has of conceiving a child. It factors in a number of variables and considerations for both the male and female partners. In diagnosing the cause of infertility, it is important to consider all variables as pieces of a couple's reproductive and fertility health. The clinical presentation may suggest either blatant fertility impediments (e.g., genetic abnormality) or each partner may have minor health concerns that, when combined, constitute major impediments to a successful fertility outcome (Table 184.1).

Assisted Reproductive Technologies and Natural Medicine

The statistics suggest that 4.6% of U.S. infants born in 2005 (95% uncertainty range: 2.8%–7.1%) resulted from ovulation treatments not involving assisted reproductive technologies (ARTs). National ART Surveillance System data indicate that ART treatments currently account for 1.2% of total U.S. live births, 16% of U.S. twins, and 38% of U.S. triplets or higher-order (quadruplets or more) live-born infants.[7] Therefore the prudent clinician must be aware of potential interactions and consider each treatment protocol accordingly. It is advisable for clinicians to recommend the following approach to their patients for safe, integrated treatment:

- Before an in vitro fertilization (IVF) cycle, a 3- to 4-month preconception program for both partners should be encouraged to ensure appropriate nutritional status and detoxification to optimize successful outcome.
- Any causative or contributing factors that may hinder the success of an IVF cycle should be investigated and eliminated thoroughly.
- Any preexisting health conditions during the preconception window of 3 to 4 months must be addressed and treated.
- During an IVF cycle, it is crucial to enable optimal communication between the naturopath and fertility specialist to prevent any interactions. Dietary and lifestyle recommendations should be encouraged; however, nutritional and/or herbal medicine prescriptions must consider potential negative interactions with IVF medications. As such, all prescriptions must be individualized.
- Once IVF has concluded and a successful outcome has been attained, treatment can be modified to support the pregnancy, focusing on miscarriage prevention in the first trimester and then adjusting as the pregnancy continues.

Optimizing Natural Fertility

Natural conception is clearly the ideal scenario for any couple. It is therefore necessary to assess a few key variables, including ovulation detection and the timing and frequency of intercourse. Before infertility is diagnosed, the current recommendations are to encourage couples to attempt conception for a minimum of 12 months of unprotected, appropriately timed intercourse. The time period is reduced in couples where the female is older than 35 years. In these couples, a diagnosis of infertility is achieved after 6 months.

A couple's fertility is generally highest in the first few months of unprotected sex and declines gradually thereafter. If no conception occurs within the first 3 months, monthly fecundity decreases substantially among those who continue their efforts to conceive.[8] Therefore couples who are likely to conceive naturally are likely to do so in a few short cycles. In cases where conception takes longer, other impediments may be present. These may be physical or genetic factors, which may require assistance from ART. However, the cause may simply be a compounding health variable such as a blatant nutritional deficiency. Appropriate investigations, as discussed later on in this chapter, will elucidate the approach required.

Couples should be encouraged to attempt conception during the fertile window. A recently ovulated egg will survive for only a few hours (maximum of 24 hours); however, sperm can survive for up to 5 to 6 days in the presence of fertile-quality cervical fluid. The fertile window is best defined as the 6-day interval ending on the day of ovulation.[9] As estrogen increases in the female in the lead-up to ovulation, she produces fertile-quality cervical fluid, which protects the sperm from the acidic pH of the vagina, provides a medium in which it can travel, and provides nutritional sustenance for it to survive on its journey.

A widely held misconception is that frequent ejaculations decrease male fertility. A retrospective study analyzed 9489 men with normal semen quality, sperm concentrations, and motility and found that profiles remained normal even with daily ejaculation.[10] Of more importance is the finding that males with abnormalities such as oligozoospermia, lowered sperm count, and poor motility concerns may be improved with more frequent (daily) ejaculation.[10]

In supporting patients with natural conception, ovulation detection is a key component. Box 184.1 includes the main methods available and highlights their most appropriate application.

DIAGNOSTIC CONSIDERATIONS

Female Reproductive Assessment

A thorough assessment of the female patient is crucial to accurately determine her general and fertility health. Some of these assessments may require referral to a fertility specialist, gynecologist, or endocrinologist; however, thorough questioning should be conducted by the naturopath to elucidate a full history and assess causative or contributing factors (Table 184.2). All fertility patients should be screened with the queries in Table 184.3, and stage 1 investigations should be conducted with all fertility patients (Table 184.4).

Miscarriage

The comprehensive coverage of the topic of miscarriage is beyond the scope of this chapter. Because the incidence is as high as one in four pregnancies,[11] the prudent clinician should be informed about the background, useful assessments, and treatment approaches to miscarriage as part of the holistic approach to female fertility.

BOX 184.1 Ovulation Detection

Fertility charting incorporates consideration of basal body temperature (waking temperature) and changes in both cervical fluid and cervical positions.

Waking temperature is a hindsight measurement that confirms ovulation occurrence. It is only able to assist in *predicting* ovulation once a woman is aware of her cyclic changes. It is used to confirm the luteal shift to progesterone and is beneficial for assessing the lengths of the follicular and luteal phases. It is also used to assess progesterone stability in the luteal phase to support implantation and pregnancy; it can also confirm anovulatory cycles. Progesterone causes the endometrium to support the implantation of a fertilized ovum. It also causes temperature to rise perceptibly, typically 0.4°F/0.2°C. Temperature is best taken immediately on waking after a minimum of 6 hours of unbroken sleep via oral assessment.

Fertile-quality cervical fluid is produced 3 to 5 days before ovulation in response to increasing estrogen levels before the luteinizing hormone (LH) surge. Sperm can theoretically survive for 5 to 6 days in the presence of fertile-quality cervical fluid. The role of cervical fluid is multifaceted; it buffers the pH of the vagina to provide a hospitable environment for sperm survival; provides a medium for sperm to swim in on their journey through the female's reproductive system; provides nutritional supplementation for sperm survival; and acts as a lubricant to increase sexual pleasure and increase frequency of intercourse, thus providing more opportunities for conception. Assessment should be conducted from the vagina (inserting a finger into the vaginal opening and extracting fluid for assessment) rather than relying on toilet paper or underwear changes.

Cervical position assessment is the most controversial of self-assessments, with reproductive specialists often discrediting its value. This is because the position of the cervix is affected by numerous variables, including the timing of bowel movements. The cervical tissue is responsive to fluctuations in estrogen and produces physical and tangible changes when ovulation is approaching. Signs of fertility include a softening, opening of the cervical os, increased wetness from cervical fluid, and a lengthening of the vaginal canal as the cervix shortens away from the vaginal opening. Signs of infertility include a closed os, hardening, shortening, and dryness.

Urine-based ovulation testing detects the LH surge that occurs before ovulation, typically occurring 24 to 36 hours before ovulation. Testing can produce false positives and is inadvisable in women with polycystic ovary syndrome (PCOS) or other, similar conditions due to LH increases in these populations. Additionally, because sperm require an optimal 2 days' travel time, detection of the LH surge can often be too late to optimize conception. It is therefore advisable to make sure that all variables are synchronistic rather than isolated. Additionally, there are some women whose LH surge is shorter (12 hours or less). This can occur in those with hyperprolactinemia and other conditions that interfere with follicle-stimulating hormone (FSH)/LH secretion from the anterior pituitary. In these individuals it is advisable to encourage LH testing twice a day (i.e., morning and night), as they can often "miss" the surge.

Saliva assessment testing and tools base their justification on the premise that with increasing estrogen fluctuations, changes in cervical fluid are synchronistic with other fluid media, including saliva. Fertility potential is detected by the presence of a "ferning" pattern in the saliva (viewed by microscopy) suggestive of a synchronicity in cervical fluid changes that enable sperm travel. This method is inappropriate for older patients owing to natural estrogen reductions and is also not optimal for hypothyroid patients because of the relationship between estrogen and thyroid function. Additionally, caution with patients experiencing estrogen displacement, such as those with fibroids and/or endometriosis, is advisable.

TABLE 184.2 Fertility Enquiry

Assessment	Elaboration and Explanation
Age	What are the ages of the couple?
Fertility history	How long have they been trying to conceive, and have they ever conceived previously (together/separately)? Do they have any idea why they have not been able to conceive?
Sexual history	Potential sexually transmitted disease exposure, symptoms of genital inflammation (e.g., vaginal discharge, dysuria, abdominal pain, fever)
Medical history	Genetic disorders, endocrine disorders, history of pelvic inflammatory disease
Medication history	Hormone therapy, contraceptive pills, psychotropics, nonsteroidal anti-inflammatory drugs (NSAIDs)
Surgical history	Such as previous reproductive or genitourinary surgery
Contraception	When it was ceased and the likely speed of its reversibility
Fertile times	Whether the couple engage in regular intercourse during fertile times
Lifestyle factors	Diet, exercise, alcohol, smoking cessation, recreational drug use, caffeine, environmental toxin screen
Prior paternity	Previous fertility
Psychosexual issues	Interference with conception
Pubertal development	Poor progression can suggest underlying reproductive issue; initial query regarding age of menarche and secondary sexual characteristics to eliminate Turner's syndrome and the like
Physical examination	Breast formation Galactorrhea Genitalia (e.g., patency, development, masses, tenderness, discharge) Signs of hyperandrogenism (e.g., hirsutism, acne, clitoromegaly) Body mass index and waist:hip ratio to assess weight effect

Modified from Hechtman, L, 2018, Clinical naturopathic medicine. Sydney, Australia: Elsevier; 2011.

TABLE 184.3 Stage 1 Investigations

Assessment	Timing in Cycle	Justification
Follicle-stimulating hormone (FSH)	Day 2–3	Stimulates follicle development. High levels can indicate menopause or declining fertility; query primary ovarian failure. Useful to assess ratio comparative to luteinizing hormone to ensure that hormone status is optimal. Eliminates primary ovarian failure.
Luteinizing hormone (LH)	Day 2–3 or preovulation (day 13)	Triggers ovulation when surges; excessive levels may indicate polycystic ovary syndrome (PCOS). Useful to assess ratio comparative with FSH to ensure hormone status is optimal.
Progesterone (P4)	Day 21 (7 days postovulation)	Evaluates adequacy of progesterone; confirms ovulation. Eliminates luteal-phase defect.
17-OH-progesterone (17 hydroxy progesterone)	Follicular phase of cycle—preferably day 2–3	Ensures adrenal involvement is eliminated from affecting ovulation and progesterone insufficiency.
Prolactin (PRL)	Any day	Inhibits ovarian production of estrogen, inhibitory role with progesterone if high, stimulates production of breast milk. Ensure women sit relaxed for 20 min before blood draw for accuracy of result.
Estradiol (E2)	Day 2–3	Stimulates egg maturation and endometrial maturation for implantation; responsible for fertile-quality cervical fluid
Testosterone (TT), free androgen index (FAI), androstenedione	Any day	Eliminate PCOS or testosterone dominance
Specific hormone-binding globulin (SHBG)	Any day	Evaluates if concentration of SHBG is affecting the amount of testosterone available to body tissues
Transvaginal ultrasound	Day 7–11	Evaluates follicle maturation, ovulation, endometrial thickness, and character. General assessment of pelvic organs for diagnosing abnormalities of the uterus and ovaries. Assesses thickness and appearance of endometrium to be followed. Enables antral follicle count.
β-hCG	Any day	Eliminate pregnancy or tumor.
Anti-Müllerian hormone (AMH)	Day 2–3	Assesses ovarian reserve (best when combined with antral follicle count through ultrasound)
General Health Screen		
CBC, UEC, LFT, iron studies, TSH and urinary iodine (24-hour or morning spot); plasma zinc and serum copper (including ratio); ceruloplasmin, red blood cell folate, active B_{12}, homocysteine, 25[OH] D, Fasting glucose, cholesterol profile, celiac screen, celiac HLA, Pap smear	NA	General health assessments to eliminate other abnormalities
General Prepregnancy Screen		
Blood group and agglutinins, infectious disease screening, rubella immunity	NA	General prepregnancy assessments
High Cervical Swab and Urinalysis		
Bacterial culture, screen for sexually transmitted infections	NA	Assess for infective pathogen compromising fertility. General urinalysis to eliminate underlying infection or abnormality. Urogenital infections have been found to play a part in the genesis of miscarriage[297] and infertility[298]; however, patients may be unaware of their presence owing to the asymptomatic nature of many infections. Screening for a range of genitourinary infections is necessary in preconception care to detect possible infection and thus barriers to conception. The most common and essential infections that require screening include the following: Primary genitourinary tract infections: *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma genitalium/hominis, Neisseria gonorrhea* Secondary genitourinary tract infections: *Gardnerella vaginalis,* Group B *Streptococcus,* beta-hemolytic *Streptococcus, Staphylococcus aureus, Staphylococcus millerii*

Continued

TABLE 184.3 Stage 1 Investigations—cont'd

Assessment	Timing in Cycle	Justification
Other Fertility Assessments		
Waking temperature, cervical fluid assessment cervical position assessment, ovulation testing (urine), ovulation testing (saliva)	Various	Assessment and interpretation of self-directed assessments (if used). See Box 179.1 for further discussion.
Other Considerations		
Salivary hormone screen, including reproductive and adrenal	NA	Salivary screen provides an advantage over blood levels in yielding significantly greater accuracy for interpretation of findings. The adrenal hormone profile determines adrenal function and may help determine the presence or extent of acute and/or chronic mental and/or physical stress. Prolonged stress has been shown to have suppressive effects on the fertility of both the male and female. Of importance, it is likely to have a profound effect on gonadotropin release (FSH, LH).
Nutrient and toxic element screening	NA	Assessment of toxic elements, including aluminium, arsenic, cadmium, lead, and mercury is crucial so that these can be eliminated as causative or contributing factors. It is widely accepted that excessive exposure to heavy metals has detrimental effects on fertility[299] and must therefore be assessed and remedied during the preconception period. Pre- and postchelation challenge testing should be considered for some patients.
Environmental screen	NA	Other environmental assessments including those that check for porphyrins, PCBs, chlorinated pesticides, volatile solvents, phthalates, parabens, and other toxins. These should additionally be considered owing to their deranging effects on reproductive function, endocrinology, gamete development, and thus embryological potential.

CBC, Complete blood count; *HLA,* human leukocyte antigen; *LFT,* liver function test; *PCB,* polychlorinated biphenyl; *TSH,* thyroid-stimulating hormone; *UEC,* urea, electrolytes, creatinine.
Modified from Hechtman, L. *Clinical Naturopathic Medicine*. Sydney, Australia: Elsevier; 2011.

TABLE 184.4 Stage 2 Investigations

Assessment	Timing in Cycle	Justification
Thyroid antibodies and reverse T3	NA	Indicated if thyroid function appears compromised, ovulation potential is reduced, or patient appears to have implantation issues
Sperm antibodies (serum)	NA	Determines whether antibodies are present against the partner's sperm. If blood results are positive, cervical mucus sperm antibodies may be required.
Laparoscopy, hysteroscopy, and salpingoscopy	Before ovulation	Inspection of uterotubal junctions. Diagnosis and treatment of pelvic diseases (endometriosis) or adhesions. Hysteroscopy complements hysterosalpingography (HSG) in revealing pathology that disturbs the shape of the endometrial cavity, especially intrauterine adhesions, submucosal fibroids, and endometrial polyps. These can be diagnosed with HSG, but hysteroscopy is required to locate the pathology accurately and treat it accordingly.
HSG ± selective salpingogram (if indicated)	Day 7	Vaginal examination and injection of radiographic fluid into the uterus and fallopian tubes on x-ray. Determines whether fallopian tubes are clear and uterine cavity is normal.
Clomid challenge test	Day 2–3, FSH and estradiol Day 10, FSH	Determines ovarian reserve and if pregnancy can occur before assisted reproductive techniques are implemented.
Curettage or endometrial biopsy	Day 26 (just before menses are expected)	Reveals the tissue structure of the endometrium. Estimates normal ovulation owing to timing. Not advised regularly because of risk of scarring.
Methylation genetics and profile	NA	Methylation testing to assess SAM:SAH ratio and levels as well as folate cycle intermediates to determine methylation function. Addition of methylation genetics to assess competence of pathways due to contribution of effect to impede optimal fertility.
Other	NA	If all results show no abnormality or if the patient is older than 38 years, the clinician is advised to consider a number of miscarriage assessments to improve outcomes because a number of these assessments are associated with implantation failure as well as miscarriage (see Table 184.5)

FSH, Follicle-stimulating hormone; SAH, S-adenosylhomocysteine; SAM, S-adenosylmethionine.
Modified from Hechtman, L. *Clinical Naturopathic Medicine*. Sydney, Australia: Elsevier; 2011.

TABLE 184.5 Miscarriage Screen

Key

General medical or naturopathic referral

Reproductive endocrinology and infertility subspecialist

Research interest in recurrent miscarriage

Assessment	Justification	Interpretation
On presentation: at any time in the ovarian (menstrual) cycle		
General health screen, including CBC, LFT, UEC, fasting glucose, blood group, and agglutinins	General medical checkup	Various; assess for compounding factors.
Red blood cell folate, active B_{12}	Unsuspected folate deficiency; if low, test fasting serum homocysteine.	Folate supplementation in vitamin B_{12} deficiency masks pernicious anemia and the risk of subacute spinal cord degeneration. RBC and serum are not definitive assessment tools for these nutrients. Additional assessments may be warranted.
Fasting homocysteine	Elevations can correlate with vitamins B_9 and B_{12} findings, presence (or absence) of MTHFR polymorphism and coagulation or vascular abnormalities	Treat as indicated with high doses of vitamins B_6, B_9, and B_{12}. Correlate findings with vitamins B_9 and B_{12} and MTHFR status.
Thyroid function tests (TFTs)	Although mild hypothyroidism is strongly associated with anovulation, even mild hyperthyroidism is strongly associated with miscarriage	It is important to keep all aspects of a TFT well within normal limits: avoid even slightly excessive thyroid replacement in cases of hypothyroidism.
Antithyroglobulin Abs (TG Abs), thyroid peroxidase Abs (TPO Abs), TSH receptor Abs	The presence of thyroid antibodies can occur with a normal TFT (especially TPO Abs) and is strongly correlated with a first-trimester miscarriage	Miscarriage is increased in the presence of any of the thyroid Abs directly correlating with immune modulation requirements of gestation (i.e., implantation and throughout the first trimester at individual increments).
Fasting plasma glucose	Assess for preclinical diabetes, If raised, assess insulin and HbA_{1c} (± GTT) and assess for PCOS factors	Miscarriage is increased in overt diabetes and PCOS.
Serum testosterone, free androgen index, SHBG, ± androstenedione	Screen for PCOS. If results are positive, confirm with day 7 ultrasound.	Miscarriage is more likely to occur due to disordered follicular development and oocyte function.
Serum gliadin antibodies (IgG, IgA), serum IgA levels, and antibodies to tissue transglutaminase or endomysial antibodies. If the patient is already on a low-gluten or gluten-free diet, referral for celiac gene screen is advisable. Note that it is only 95% accurate, and a negative reading is not conclusive.	Asymptomatic celiac disease an occasional (though not unequivocal) cause of unexplained infertility or repeated miscarriage. Underdiagnosed in young adult women (population prevalence 1:250 and satisfies WHO criteria for population screening[300]).	Confirmation is via small bowel biopsy needed for diagnosis; however, this will require consumption of gluten for 3 months. Objective clinical opinion is required to warrant this necessity in the fertility context. Note that missing celiac disease in a woman with otherwise unexplained reproductive dysfunction might prove embarrassing when, later, it manifests more classically. Classic presentation may include marked anemia and/or general nutritional deficiencies
Pregnancy infection screen (rubella, Hep B, Hep C+, HIV, toxoplasmosis, CMV, EBV)	Each infection can correlate with miscarriage eventualities (dependent on each infection and timing in pregnancy)	As indicated with each assessment
Serum copper, plasma zinc, and ceruloplasmin	Wilson's disease, a rare copper storage disorder, can present in young women with repeated miscarriage before other symptoms and signs develop (liver disease, Kayser–Fleischer rings, cerebral dysfunction).[301] Screen for high copper and ceruloplasmin levels; confirm with elevated 24-hour urinary copper excretion (and then liver biopsy). In assessing zinc status, a 1:1 zinc:copper ratio should be observed. Zinc supplementation can then be calculated on an as-required basis.	Population prevalence is ~1:30,000 (in any ethnic group); ATP7B mutant gene carrier frequency is ~1:90; more than 100 mutations are known and affected people are usually compound heterozygotes. Possible mechanism: raised copper levels in uterine secretions compromising mitochondrial function in the conceptus. Additionally, raised copper levels are antagonistic to zinc absorption and will warrant supplementation. Depending on copper reading, treatment with copper-binding agents may be required and has been shown to reverse pregnancy losses.
Prolactin and βhCG	Assess effect of these hormonal levels on pregnancy sustenance and achievement.	Address as indicated; typically, hormonal modulation is required to ensure that hormone levels are optimal for each stage of pregnancy (and preconceptually).

TABLE 184.5 Miscarriage Screen—cont'd

Assessment	Justification	Interpretation
Karyotype, peripheral blood (both partners)	Assess for balanced chromosomal translocation in either partner. If an imbalance is detected, couples are prone not only to conceive embryos with unbalanced translocations; their unstable meiotic spindles also make otherwise unremarkable aneuploidies more common.	Referral for genetic counseling to estimate unbalanced chromosomal segregation patterns and initiate PGD if required.
Hysterosalpingogram	To assess tubal patency and fallopian tube structure	Address as relevant
Antinuclear antibody, anticardiolipin antibody (IgM, IgG), lupus inhibitor/anticoagulant, IgA	Screening for the antiphospholipid syndrome, either secondary to SLE or, more commonly but often less aggressively, primary	Laboratory testing for anticardiolipin antibody is not well standardized, and interpretations of isolated elevations are difficult. SLE requires referral to immunologist or rheumatologist. Treatment of definite cases is treated through allopathic means with low-molecular-weight heparin, vaginal progesterone (immunosuppressive locally), corticosteroids, and occasionally plasmapheresis. Naturopathic means include immune modulation, blood coagulation normalization, and dietary modification to support appropriate immune and hematologic systems.
CA-125	Presence does not automatically confirm cancer; however, it can correlate with cancerous conditions, endometriosis, or proliferative disorders	In instances of endometriosis can indicate increased development, poor management, or contributing factors to miscarriage
Anti-TjA antibody (anti-PP1Pk hemolysin)	Rare but well described[302]	Plasmapheresis and immunoglobulin replacement during pregnancy can enable term delivery[303]
Thrombophilia screen	Protein S, protein C, activated protein C (APC) resistance, antithrombin III	Protein S deficiency: second-trimester miscarriage increase × 7.4. Protein C deficiency: less convincing APC resistance: first trimester × 2.1, second trimester × 3.317
Thrombophilia PCR testing (DNA assessments)	Test for factor V Leiden, prothrombin G20210A, MTHFR C677T, and A1298C	Meta-analysis[304] reports the following increased risks of miscarriage with homozygosity: Factor V Leiden: first trimester × 2.1, second trimester × 3.3. Prothrombin G20210: first trimester × 2.3, second trimester × 2.3. MTHFR alleles (increase miscarriage risk with elevated homocysteine): × 4.3 (if controlled with adequate folate may actually protect against miscarriage and intrauterine growth retardation). The naturopathic model also acknowledges the effect of MTHFR on folate metabolism and its subsequent effects on ensuring that DNA replication within each cell (including the cells of the fetus) is consistent. Additionally, folate is responsible for a number of other roles in the body. Therefore an MTHFR abnormality can correlate with a number of other health concerns regardless of homocysteine status.
Day 2–3 of the menstrual cycle		
Serum FSH, LH, estradiol (E2) Note: ovulation tracking over 2 cycles is advisable (E2, LH, and P4)	Reduced oocyte numbers: serum FSH > 11 U/L PCOS: suspected when LH:FSH (U/L) > 2:1. In either case, E2 > 200 pmol/L = more severe. Correlate any findings with a day 7 ultrasound.	Low oocyte numbers: risk of early menopause; IVF may be indicated if also infertile. PCOS: requires additional treatment changes, incidence correlates highly with increased miscarriage risk.
Anti-Müllerian hormone (AMH)	Reduced levels may indicate failing ovarian reserve. Increased levels can indicate PCOS.	Interpretation is controversial; however, in instances of reduced AMH, refer to fertility specialist and possibly concurrent ART.
Day 7 of the menstrual cycle (or estimated 1 week before ovulation) Transvaginal ultrasound		
Uterine assessment	Normal endometrium is >5 mm thick and echolucent (thick echogenic endometrium means hyperplasia or polyp; if it is thin, consider endometritis). Assess for fibroid or diagnose other uterine abnormalities.	Treat specific to finding (i.e., thin endometrium will require progesterone support; thick endometrium will respond to uterine tonics, such as herbal medicines) and antioxidant regulation. For fibroid-specific treatment, see Chapter 223.

Continued

TABLE 184.5 Miscarriage Screen—cont'd

Assessment	Justification	Interpretation
Ovarian assessment	Follicles present in the ovary indicate the typical number of eggs achievable: many peripheral follicles indicate PCOS; few follicles can indicate premenopause (or oopause).	If PCOS, low follicle numbers or endometriotic cyst, specialist management is indicated, possibly including IVF.
Vaginal and cervical swabs and culture (cervical swabs are often indicated for the most accurate interpretation)	Vaginosis, either *Gardneralla vaginalis* or other organismal overgrowth, with loss of *Lactobacillus*. Primary genitourinary infections: *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma genitalium or hominis, Neisseria gonorrhoeae* Secondary genitourinary infections: *Gardnerella vaginalis,* group B *Streptococcus,* beta-hemolytic *Streptococcus, Staphylococcus aureus, Staphylococcus millerii*	Urogenital infections have been found to play a part in the genesis of miscarriage[14,305] and infertility[298]; however, patients may be unaware of their presence due to the asymptomatic nature of many infections. Midtrimester (and later) pregnancy losses can occur after internal cervical os becomes covered by growing sac, at 13 weeks. Vaginal flora modulation is required. Herbal douches, probiotic supplementation, and in some instances, antibiotic treatment.
7 days postovulation (typically days 21–28)		
Serum progesterone (P4)	Screen for ovulation confirmation	If <35 nmol/L, consider further investigation confirming ovulation. Support progesterone cascades as required.
12 days postovulation (premenstrual phase)		
Premenstrual endometrial biopsy for dating	Check integrated action of almost 2 weeks of progesterone on decidualizing the endometrium; confirm progesterone falling to low level and negative βhCG day before test. Extremely time-critical investigation: usefulness lost if performed in midluteal phase.	Often deficient stromal decidualization in disorders of ovulation (adjust treatment as indicated if present). A deficiency can also indicate endometrial atrophy (which can be untreatable) or, rarely, a molecular defect: in these two cases, gestational surrogacy may be the only treatment option. Best screen for rare molecular bases for decidualization failure causing implantation failure.
Premenstrual endometrial biopsy for lymphocyte (T-cell) subsets on immunocytochemistry [with adjunct T-cell subsets in blood]	Specialist labs can look for relative abundance of peripheral NK cells (CD57+) versus normal uterine (CD56+) NK cells in relation to T-cell numbers[306]	If unfavorable, consider vaginal progesterone during early pregnancy. Relevance of findings is conflictual. Naturopathic treatment measures adapt to module the immune response in relevant instances.

ART, Assisted reproductive technology; *βhCG,* beta-human chorionic gonadotropin; *CBC,* complete blood count; *CMV,* cytomegalovirus; *EBV,* Epstein–Barr virus; *FSH,* follicle-stimulating hormone; *GTT,* glucose tolerance test; *IgA,* immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *IVF,* in vitro fertilization; *LFT,* liver function test; *LH,* luteinizing hormone; *MTHFR,* methylene-tetra-hydro folate reductase; *NK,* natural killer; *PCOS,* polycystic ovary syndrome; *PCR,* polymerase chain reaction; *PGD,* pregenetic diagnosis; *RBC,* red blood cell; *RM,* recurrent miscarriage; *SHBG,* sex hormone–binding globulin; *SLE,* systemic lupus erythematosus; *TPO,* thyroid peroxidase antibodies; *TSH,* thyroid-stimulating hormone; *UEC,* urea, electrolytes, creatinine; *WHO,* World Health Organization.
Data from Jansen R., Gee A. Testing for miscarriage. *O&G Magazine*. 2008:10(2):48–52.

Implantation of the developing embryo into the receptive endometrium is a critical and key event in the establishment of early pregnancy. The unique process of cell adhesion of the trophoblast to the endometrium at the time of implantation and its subsequent invasion into the maternal tissue is dynamically balanced through the expression of specific cell adhesion molecules and endocrine, paracrine, and autocrine signals. The process can be viewed as a series of distinct events, many of which are similar to those of an inflammatory reaction and are greatly influenced by the factors present in the uterine microenvironment, including hormones, growth factors, and inflammatory and proinflammatory cytokines.[12] The secretion of a number of factors achieves modulation of the immunological response of the trophoblast. Cytokines produced at the fetal-maternal interface play a key role in regulating maternal tolerance to the fetus and successful pregnancy.

Although approximately 25% of all recognized pregnancies result in miscarriage, less than 5% of women will experience two consecutive miscarriages, and only 1% experience three or more.[11] Recurrent pregnancy loss is a disease distinct from infertility, defined by two or more failed pregnancies.[13] When the cause is unknown, each pregnancy loss merits careful review to determine whether specific evaluation may be appropriate. Although the general consensus is to evaluate after three or more losses, it is more in keeping with the naturopathic paradigm to review all patients even after the first and more comprehensively after the second or subsequent miscarriage.

The risk of miscarriage is highest immediately after implantation. It is thought that around 50% of all fertilized eggs do not survive, coming away with a normal (or slightly late) period. This is often referred to as an "unnoticed miscarriage" because it is usually not formally acknowledged by the woman, who is never aware of her pregnancy.

In summarizing the possible clinical scenarios, it is useful to group them into three distinct categories:

1. For a healthy, viable pregnancy to initiate and continue successfully, a number of biochemical, anatomical, and molecular events must occur in a systematic and timely manner. Any deviation can disrupt the process and abort the pregnancy.
2. The overlapping clinical continuum of presentation can conflict with or complicate the fertility presentation. Each clinical presentation

has the potential to present as infertility (occult implantation failure), subclinical or clinical miscarriage in the first trimester, a fetal loss in the midtrimester before viability, a premature birth, or as a birth defect presenting at or after term. Each presentation is unique and must be considered holistically and individually.

3. The number of similarities between previous miscarriages (if any) can enable the clinician to ascertain the most definitive scenario and develop and adjust treatment accordingly.
4. As seen in Table 184.5, various conditions can be associated causally or coincidentally with miscarriage.

Classic Causes of Miscarriage

- Genetic/chromosomal: 60% or more of early miscarriages are due to chromosomal abnormalities.
- Age: after age 40, one third of pregnancies end in miscarriage.
- Hormonal abnormalities: luteal-phase deficiencies (low progesterone) are the most common cause. This can relate to hyperprolactinemia.
- Metabolic abnormalities: poorly controlled blood sugar levels or diabetes mellitus and polycystic ovary syndrome increase miscarriage risk.
- Uterine abnormalities: distortion of the uterine cavity can account for 15% to 20% of miscarriages.
- Antiphospholipid syndrome: this can account for 3% to 15% of pregnancy losses.
- Thrombophilias: this creates an increased risk of thrombosis and consequent increased risk of pregnancy loss, especially in the second half of pregnancy.
- Male factors: abnormal sperm DNA can result in pregnancy loss (see Chapter 185 for a full discussion).
- Unexplained: no explanation is found in 50% to 75% of couples.

Unexplained Causes of Miscarriage

When the causes of miscarriage are unexplained, the naturopath can provide the most beneficial support and care. A miscarriage, especially a first-trimester loss, can occur for any number of natural biological reasons. A marked deficiency in any nutrient (macro or micro) can theoretically cause a miscarriage. A full discussion of macro- and micronutrients and their relation to pregnancy loss is offered later in this chapter. Additionally, the naturopath's consideration of the patient's general health and comprehensive review of all other factors is invaluable.

THERAPEUTIC CONSIDERATIONS

Supporting Female Fertility

On being asked to consider a patient with infertility, it is crucial for the practitioner to assess several factors initially to determine the best approach to treatment. As in the case of male fertility, naturopathic treatment cannot address all variables, such as genetic factors or overt physical impediments; however, it can attenuate various presentations. In the clinician's initial assessment, the prime objective is to assess the patient fairly and holistically. Therefore consideration should be given to the patient's previous pregnancy, duration of infertility, age of partner, severity of present pathology, and other factors. For example, in the case of a 41-year-old female who has had no prior pregnancies, has been infertile for 2 years, and suffers from endometriosis, it is crucial to initiate integrative care with a reproductive endocrinology and infertility (REI)/fertility specialist because ART is likely to be required. If this patient had sought consultation 4 years earlier, time constraints would not be as severe, and the naturopathic paradigm would possibly be of help. Unfortunately, age is one of the variables that cannot be modified. Similarly, if the couple incorporates donor gametes, the clinician must acknowledge the potential limitations to treatment.

A useful summary to delineate the possible approaches is as follows:

- Treatable conditions: Some patients present with blatant deficiencies or disease processes that require interventions to improve their natural fertility. Most people respond positively to a preconception program focusing on detoxification, which enables conception more readily at the conclusion.
- Untreatable subfertility: After naturopathic intervention, some infertility factors may not be possible to address, or alternatively, referral for ART/IVF may be required.
- Untreatable female sterility: This can occur in instances of mature patients, genetic disorders, or previous conditions that compromise fertility. Adoption or donor oocytes are the only possibilities for couples in this group who wish to have a family. Donor oocytes may not be an option for all patients.

Naturopathic Preconception Treatment

As in the case of male infertility, during naturopathic preconception treatment, the most optimal approach for females is to encourage a program that correlates with the final stages of gamete development (oocytes). Although women are born with all of their oocytes at birth, there are limited treatment options to remedy the primordial stage of development (unless we can modify potential epigenetic factors). Because the primary follicle development from the primordial follicle takes up to 120 days, preconception care is best prescribed within this time period. Following this treatment approach, we can successfully influence additional stages of oocyte development (secondary → antral → Graafian). By influencing the oocyte's environment during development and the correlating general health of the patient, practitioners are able to positively influence the development of oocytes and address and attenuate related health concerns.

The principles of the preconception approach are to attenuate preexisting conditions; optimize nutritional repletion; detoxify the body from dietary, lifestyle, and environmental perspectives; and encourage a healthy approach to parenting on all levels. It is imperative to acknowledge that nutritional repletion is required throughout the preconception period and that prescriptions may require higher quantities than typical to optimize the patient's status. Fertility occurs when a person's individual health is optimal. The notion of a healthy body being a fertile one cannot be ignored. As discussed in Chapter 185, the body is primed to pass genetic material only when the environment and conditions are at their best. If survival from an evolutionary perspective is compromised, fertility will be hindered. Everything a person eats, drinks, experiences, or is exposed to can and will influence his or her fertility. True naturopathic fertility supports, acknowledges, and considers absolutely all variables for holistic health. Couples should be encouraged to participate in treatment for 3 to 4 months to properly address all genetic and epigenetic variables.

The concept of preconception care was pioneered by Foresight, the Association for the Promotion of Preconceptual Care. It was established in the United Kingdom in 1978 and is a preconception program that incorporates dietary and lifestyle advice to enhance fertility, thereby increasing the chances of a healthy conception. Readers may wish to review this research in more detail for additional information. However, published studies lack sufficient evidence owing to poor study design and delivery (one was provided as a letter to an editor and is referred to as a study); nevertheless, the evidence of successful outcomes cannot be refuted. It is hoped that further investigation into this highly effective approach will be conducted in the future.

If the practitioner is incorporating ART, it is beneficial to inform patients that cotreatment is likely to produce the best outcome. In

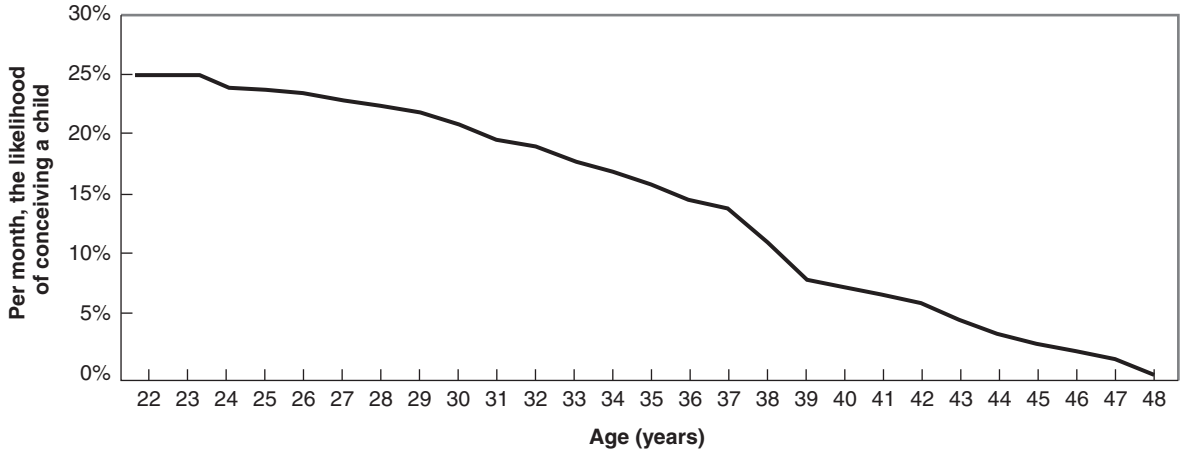

Fig. 184.1 Effect of Age on Fertility.

one study, 65% of couples who had previously undergone multiple IVF cycles were able to conceive within 2 years of a preconception program.[14]

It is important to acknowledge that most fertility patients are incorporating several treatment options concurrently.[15] It is therefore prudent to point out the scope of all treatments and to discuss individual treatment protocols openly so as to foster a collaborative approach and reduce the risk of negative interactions.

Fertility-Damaging Factors

Age. The biggest preventable cause of infertility is undoubtedly a woman's age. Approximately 20% of women wait until after age 35 to begin their families. Several factors have contributed to this trend, including contraception choices, career pathways, marrying at older ages, high divorce rates, financial security, or—most concerning—the fact that many women simply do not realize that their fertility begins to decline in their late 20s, with a rapid decrease from age 35 onward. After 35 years of age, a women's fertility declines rapidly in conjunction with the deteriorating quality of her oocytes (Fig. 184.1). She may enter oopause in her 30s, depending on her genetic makeup, thus further reducing the chances of a successful fertility outcome. Regardless of a woman's health, age-related changes cannot be prevented or modified. The age of a woman's oocytes is fixed, and as she ages further, fertility potential undergoes a statistical decline. Although over 95% of healthy couples will conceive within 3 years of trying when the woman is 35 years of age, that figure drops to 77% when she reaches age 38. By the age of 41, less than half of the healthy couples will conceive after 3 years of trying.

A number of considerations regarding the effects of age on fertility should be considered. These include the following[4]:

- Ovarian function: As women age, fertility declines owing to normal age-related changes in the ovaries. Women are born with all the oocytes they will ever have, with approximately 300,000 follicles remaining at menarche. They will then lose between 20 to 30 follicles each cycle. Of the oocytes remaining at puberty, it is believed that approximately 360 to 400 of these follicles will mature over 30 years and be released by the body, with the remainder being lost in each cycle. The rest will undergo atresia, a degenerative process that occurs regardless of whether a woman is pregnant, has normal menstrual cycles, uses birth control, or is undergoing infertility treatment. Smoking appears to accelerate atresia and is linked to earlier menopause.
- Ovarian reserve: Ovarian reserve declines with each cycle. Diminished ovarian reserve is usually age related and occurs because of the natural loss of eggs and decrease in the average quality of the eggs that remain. The remaining eggs become "poor responders" to follicle-stimulating hormone (FSH) and luteinizing hormone (LH), thus shortening the menstrual cycles. Young women may also have reduced ovarian reserve because of smoking, a family history of premature menopause, prior ovarian surgery, or even if they have no known risk factors.
- Genetic abnormalities: Aging affects oocyte quality and increases the risk of neonatal genetic abnormalities. As a female ages, her risk for having a child with Down syndrome and total chromosomal abnormalities increases dramatically. At 20 years of age, her risk for producing a child with Down syndrome is 1 in 1667 (1 in 526 total risk for any chromosomal abnormalities); at 35 years of age, that risk increases to 1 in 378 (1 in 192). At 45 years of age, the risk increases again to 1 in 30 (1 in 21).[16]
- Miscarriage risk: Older oocytes increase the risk of miscarriage. The risk of miscarriage remains at 10% between 15 and 29 years of age; it then increases to 12% at 30 to 34 years of age and to 18% at 35 to 39 years of age. Thereafter, it escalates significantly to 34% at 40 to 44 years of age and to 53% after the age of 45.[16]

Weight balance. For optimal conception, women must ensure that their body fat percentage is between 20% and 25% to support fertility and the subsequent health of their child. A body fat percentage below 17% can result in anovulation, with some research suggesting that it can take as long as 2 years before regular conception occurs even after body fat percentage has been corrected.[17] Women with a body mass index (BMI) below 19 who have irregular or absent menses should be advised to gain weight to improve their chance of conception. Malnutrition can be a relatively simple solution for conception difficulties (provided mental health issues are addressed).

Although anorexia or underweight is a concern, obesity poses a similar and significant risk for infertility. The effect of obesity is much more comprehensive than that of underweight, and the necessary treatment is easier to prescribe.

Obesity affects female reproduction by disturbing the general body metabolism, hormone metabolism, and the follicular environment. Obesity is associated with the following:

- Suboptimal oocyte quality and development, oocyte fertilization, and embryo development and implantation[18,19]
- Adverse effect on ovarian reserve[20,21]
- LH surge and corpus luteum dysfunction[22–24]

The risk of infertility in obese women is three times that of normal-weight women.[25] A systematic review of the literature concluded that weight-loss interventions were likely to result in ovulation improvements and pregnancies. Miscarriage rates were not affected by weight-loss interventions.[26] In a retrospective cohort study, meaningful weight

loss (10% of their maximum weight) was found to increase conception rates (88% vs. 54%) and live birth rates (71% vs. 37%) in patients with infertility compared with women who did not lose weight.[27]

The effect of obesity on reproductive function is as follows[28]:

- Ovulation potential: Ovulation returns with a relatively modest degree of weight loss from diet and exercise. Approximately 90% of obese women will resume ovulation if they lose more than 5% of their pretreatment weight, and 30% will conceive. In very obese women, these statistics are higher for pregnancy rates than can be expected from a single IVF cycle. This recommendation is crucial and encouraging for obese women wishing to have children.
- IVF outcome: The success rate of ART is significantly reduced in obese women. IVF success rates may be reduced by as much as 25% in obese patients and 50% in very obese patients. A retrospective cohort study of 4609 women with obesity found a 68% reduction in live births from an ART cycle compared with women of normal weight.[29] It has been proposed that altered endometrial gene expression in obese patients may contribute to the lower implantation rates and increased miscarriage rates seen in obese infertile patients.[30] Obesity also promotes inflammatory markers that are negatively correlated with pregnancy rates in women undergoing IVF treatment.[31] In women undergoing ART, obesity has a greater effect on fertility in women under 35 years of age. After age 35, age becomes a more important factor in regard to the chance of conception than obesity.[18,32] IVF centers are very reluctant to perform fertility treatment on women with a BMI greater than 35 and generally recommend a target BMI of 30 before starting treatment.[33]
- Miscarriage: The risk of miscarriage in the first trimester increases from 12% to 15% in normal-weight women under 37 years of age; for women with a BMI above age 35, it increases to 31%. The rate of recurrent miscarriage increases fourfold in obese women.
- Birth defects: Maternal obesity has a detrimental effect on fetal development (e.g., three times the risk of neural tube defects and structural heart defects). Folic acid supplementation is less effective in preventing neural tube defects, so high-dose supplementation is required for obese women (it is always beneficial to calculate nutrient requirements based on the patient's presenting weight, using Clark's rule).
- Pregnancy complications: Pregnancy complications are more common in obese women (gestational diabetes is six times more common), and pregnancy-induced hypertensive diseases are more common (specifically, gestational hypertension and preeclampsia). Complications increase the risk of premature delivery and/or the need for cesarean section. Babies born to obese women have heavier birth weights (fetal macrosomia), which increases the risk of traumatic vaginal delivery. Additionally, there is a higher complication rate for cesarean and vaginal deliveries in obese women (e.g., excessive blood loss, thromboembolic disease, and postoperative infection).
- Pregnancy outcomes: Increasing BMI increases the risk of stillbirth (twice the risk vs. normal-weight women).
- The newborn: Maternal obesity carries long-term risks for the newborn infant (e.g., increased risk of being overweight as an adult and the likelihood that these children will have weight-related diseases in adulthood).

A recent prospective cohort study of 501 couples found that the body composition both partners needs to be taken into account. In couples where both partners are obese, a longer time to pregnancy was observed than in leaner couples.[34] A recent Cochrane review was unable to suggest any evidence-based recommendations on the best interventions for improving pregnancy outcomes for women who are overweight or obese[35]; however, an individualized weight-loss program involving dietary, lifestyle, and exercise changes should be implemented.

Immunological considerations. Although this topic is beyond the scope of this chapter, the immunological considerations associated with successful conception and a healthy birth are worthy of review. Because optimal production of gametes requires a healthy immune response, any deviation from "normal" can significantly affect the outcome. In females, any immunological aspect that can affect general health, conception, implantation, and the maintenance of pregnancy can cause problems. A number of miscarriage factors (including implantation factors) relate to autoimmune diseases. Therefore stabilizing and modulating the immune response is a key objective of treatment. The immune system must "switch itself off" at conception, implantation, and a number of key stages in the first trimester. Therefore consideration of these variables is crucial.

Environmental factors. Increased industrialization and the use of agricultural chemicals has contributed to an increased exposure to thousands of chemicals now associated with a negative effect on male and female fertility. Exposure to environmental toxins such as radiation (including mobile phone use),[36] heavy metals, and chemicals can cause oxidative stress and damage to DNA, leading to a negative effect on female fertility.[37]

A comprehensive discussion of the environmental effects on fertility is provided in Chapter 185. The reader is specifically directed to the discussion regarding estrogen exposure and general environmental pollutants. Specific considerations for women should acknowledge the effect of substances more commonly associated with females, including makeup, fragrances, hair dyes, nail polishes, and other beauty products. All of these can have a negative effect on reproductive function and hormone cascades. It is therefore prudent to reduce such exposures as much as possible, specifically within the preconception window and during the first trimester, when embryogenesis and placentogenesis are paramount.

Of greater concern is the fact that gestational exposure to carcinogens, endocrine disruptors, and other toxins has been shown to affect more than one generation in some cases. Most studies unfortunately have not investigated effects beyond the third (F2) generation. Further studies are required in this intriguing area of genetics, especially because the F2 generation may have experienced the exposure directly. Chemicals known to induce phenotypic effects in unexposed generations include alloxan,[38] cyclophosphamide,[39] orthoaminoasotoluol,[40] benzpyrene,[41] diethylstilbestrol,[42] and vinclozolin.[43] The underlying mechanisms are not known, and in most cases, inherited genetic lesions cannot be ruled out, especially in cases of mutagens (e.g., cyclophosphamide). As time progresses, it is likely that these chemicals will induce greater damage to subsequent generations due to their cumulative effects and earlier generational effect.

A full discussion on potential environmental effects is provided in Chapter 35.

Sleep irregularities. Shift work is associated with negative effects on the regularity of the menstrual cycle and reproductive function and also increases the risk of an adverse pregnancy outcome. In one study, the effect of shift work on nurses (all less than 40 years of age) was reviewed; the investigators evaluated sleep, menstrual function, pregnancy outcome, and reproductive function. It was found that 53% of the women studied noted menstrual changes owing to shift work, changes that clearly could affect fertility.[44] It is therefore essential that women wishing to achieve pregnancy normalize their cycles and find a way to optimize and regulate their sleep patterns.

Lifestyle

Smoking. Both active and passive cigarette smoking are known to have a significant effect on both pregnancy rates and long-term ovarian function. Additionally, smokers are more likely to have a premature menopause, thus making smoking one of the most readily

avoidable causes of infertility. Smoking appears to reduce fertility by having a direct effect on the uterus, oocytes, and embryos by increasing the thickness of the zona pellucida.[45] It becomes difficult for the sperm to penetrate the increased thickness of the zona pellucida. Overall, research indicates that smoking can age oocytes prematurely by as much as 10 years. Considering that the average age for conception is 30 years and the average age at which fertility begins to decline steeply is 38 years, it appears prudent to recommend immediate smoking cessation coupled with systematic antioxidant therapy.

On review of the research, smoking has been shown to decrease ovarian vascularization and reduce oocyte maturation.[46] It is linked with premature ovarian aging (premature menopause) and an increased risk of miscarriage.[47] It is important to note that smoking, either current or historical, is strongly correlated with negative effects on the health of the oocytes. A trial comprising 14,779 women between the ages of 18 and 23 years showed that current smokers and ex-smokers had an increased risk of menstrual symptoms and miscarriage compared with women who had never smoked.[48] Of more importance, it was found that women who smoked 20 or more cigarettes a day and for the longest periods were most at risk. Additionally, those who started smoking at a younger age had the worst outcome.

A 2010 Cochrane review found that active and passive smoking reduced fertility and decreased the chance of a healthy live birth in both fertile and infertile populations.[49] Additionally, a number of meta-analyses have proved that smokers perform poorly in IVF/ART procedures compared with their nonsmoking counterparts.[50,51] Smoking has been associated with delayed conception and a significant decrease in the odds for pregnancy and live delivery per IVF/ART cycle. There is also a marked increase in the odds for spontaneous miscarriage and ectopic pregnancy.[52] Cigarette smoke is composed of many toxic chemicals and pro-oxidants that increase reactive oxygen species (ROS). Each stage of reproductive function—folliculogenesis, steroidogenesis, embryo transport, endometrial receptivity, endometrial angiogenesis, uterine blood flow, and uterine myometrium—is a target for cigarette smoke components.[52,53]

Caffeine. Patients should be encouraged to avoid caffeine during the preconception period and during pregnancy. Caffeine has been shown to increase time to conception[54–56] and has also been linked with endometriosis and an increased risk of spontaneous abortion.[57] Caffeine has been shown to increase dopamine production, which in turn stimulates progesterone secretion, thus inhibiting the production of prolactin (owing to the antagonistic and regulatory interrelationship between progesterone and prolactin). Any prolactin abnormality, either excess or deficiency, can affect a woman's fertility negatively. According to several studies, as little as one caffeinated beverage a day can lead to a temporary reduction in conception.[58,59] Owing to its prolactin-modulating effects, caffeine appears to increase early follicular estrogen levels.[60] Caffeine is also likely to interfere with adrenal function and associated cortisol secretion. In addition, caffeine's diuretic effects increase the loss of nutrients that are beneficial to fertility. It is important to note that the quantity of coffee has a direct correlation with pregnancy rates. Women who drink less than one cup of coffee a day are twice as likely to conceive compared with moderate coffee drinkers.[55]

Caffeine has been shown to reach the follicular fluid. Increased serum caffeine levels are associated with a decrease in the number of harvested eggs in IVF treatment.[61] Some studies have found that coffee intake is unrelated to fertility. In women undergoing ART, coffee intake was unrelated to treatment outcomes, but consumption of caffeinated herbal tea had lower odds of achieving pregnancy during treatment.[62] In a prospective cohort study of fertile women, it was found that caffeine in general does not have negative effect on time to pregnancy.[63] Similarly, a recent prospective cohort study of 2135 women found that there was no significant association between coffee intake and fecundity. Once again, caffeinated tea was associated with slight reductions in female fecundability.[64]

Alcohol. A review of the literature regarding alcohol intake and female fertility indicates that there are many factors that can affect each woman uniquely. There are strong associations with alcohol intake and miscarriage[65]; excessive alcohol consumption is associated with hyperprolactinemia,[66] adverse effects on oocyte retrieval, and a lower chance of subsequent pregnancy in IVF[67]; and a minimum of 50% reduction in conception can be seen with intake as low as one drink per week during a menstrual cycle.[68] Additionally, research suggests that alcohol produces negative effects on blastocyst development and implantation and increases estrogen levels, causing a subsequent reduction in FSH secretion and suppressing folliculogenesis, thus leading to anovulation and infertility.[69] Acute alcohol consumption can cause increases in estradiol, testosterone, and LH levels.[70] Regular alcohol use leads to overproduction of ROS, which is associated with delayed conception. A Danish study demonstrated that alcohol might exacerbate age-related infertility. Women over the age of 30 who consumed more than seven alcohol servings per week had an increased risk of infertility.[71] Clinical studies to date have been inconclusive in their findings; however, a recent systematic review and meta-analysis of the literature concluded that female alcohol consumption is associated with reduced fertility and that the association is dose dependent.[72] It is advisable to recommend the cessation of alcohol intake during the preconception period. Conclusive evidence exists regarding fetal abnormalities and associated alcohol intake during pregnancy. This evidence can often be sufficient to motivate patients. Because detoxification is encouraged during the preconception period, the avoidance of alcohol is recommended.

Marijuana. As discussed in Chapter 61, marijuana contains cannabinoids, which have been shown to impair signaling pathways, alter hormonal regulation, and interfere with the timing of implantation.[73] Additionally, it is believed to cause ovulatory abnormalities and to disrupt ovarian function,[74] and regular marijuana use results in an elevated risk of primary infertility compared with nonusers.[52] Furthermore, marijuana has been shown to have harmful effects on the developing fetus.[75] Therefore avoidance is strongly recommended.

NUTRITIONAL CONSIDERATIONS

The Fertility Diet

There are countless papers documenting dietary modifications to support and improve a woman's fertility. Specifically, research suggests that dietary modulation improves ovulation, conception, and the birth of a healthy child.

The strongest evidence in favor of dietary modification to support fertility can be seen in the prospective study developed from the information ascertained from the Nurses' Health Study II (NHS-II).[76] Of importance, the information acquired was from 2 years before the report of infertility in this study, thus enabling a preconception interpretation. Information included dietary and lifestyle characteristics (body weight, physical activity) and medical health factors. In this intriguing study, the participants were followed for 8 years.

The "high-fertility diet" thus characterized includes the following:

- Lower intakes of trans fatty acids and greater intake of monounsaturated fats[77]
- Lower intake of animal protein and greater intake of vegetable protein[78]
- Higher intake of high-fiber, low-glycemic carbohydrates

- Higher dietary sources of dairy foods (Note: This is controversial because there are conflicting studies on this.[79,80])
- Higher dietary sources of nonheme iron
- Higher frequency of multivitamin use
- More likely to consume coffee, tea, and alcohol
- More likely to be physically active (vigorous activity for 30 minutes or more daily)
- Less likely to smoke
- Less likely to have long menstrual cycles
- More likely to be a recent user of the oral contraceptive pill
- Weight balance: BMI between 20 and 25

Researchers concluded that these components of a fertility diet are conducive to the most successful outcome. When these approaches are combined with the control of body weight and increased physical activity, the majority of infertility problems involving ovulation may be prevented.

In another trial, researchers noted that the Mediterranean diet increased the chance of a successful pregnancy in those undergoing IVF/intracytoplasmic sperm injection (ICSI). It was found that the high content of B vitamins (especially vitamin B_6) combined with the high intake of vegetable oils may be the mechanism responsible for this positive outcome.[81] These findings are supported by a case-control study of 485 Spanish women that showed improved fertility in women who adhered to a Mediterranean diet compared with those who followed a Western dietary pattern.[82] Adequate folate intake is associated with female fertility, and a study found that a higher adherence to a Mediterranean diet was significantly related to a greater folate intake.[83]

In another cohort study, adherence to the Dutch dietary recommendations (characterized by high intake of whole grains, monounsaturated or polyunsaturated oils, vegetables, fruit, meat or meat replacers, and fish) before IVF treatment was associated with an increased probability of pregnancy.[84]

Another aspect of diet that needs to be considered is fat intake. High-fat diets have been associated with changes in reproductive function, including altered menstrual cycle length, as well as changes in reproductive hormone levels and embryo quality in ART settings. These effects on reproductive function are present in normal-weight women, and the effect is worsened in obesity.[85] Trans fatty acid intake is associated with reduced fecundability.[86] A recent prospective cohort study of 60 women undergoing IVF treatment found a negative correlation between the trans fatty acid index and IVF outcomes.[87]

Advanced glycation end products (AGEs) have been shown to have a negative effect on ART outcomes and appear to be related to diminishing ovarian reserve or abnormally functioning folliculogenesis.[88] Dietary AGEs are formed during the cooking process (grilled, burned, or barbequed foods), especially in animal-derived foods that are high in fat and protein.[89]

The evidence is mounting that a healthy diet can reduce the risk of infertility. With regard to pregnancy loss, results from the NHS-II cohort found no relationship between preconception adherence to any one specific dietary pattern and risk of pregnancy loss.[90]

L-Arginine

Arginine is a precursor of nitric oxide synthesis and is required for angiogenesis, embryogenesis, fertility generally, and hormone secretion.[91] Additionally, it is required for the replication of cells, making it essential for oocyte development and embryo formation.

One study[92] produced notable results. The specific population was "poor responders"—women who had failed to achieve an adequate number of mature follicles and/or adequate serum estradiol levels after gonadotrophin stimulation. This trial indicated that arginine supplementation (oral at 16 g/day) improved ovarian response, endometrial receptivity, and pregnancy rates. The women were divided into two groups: (1) flareup gonadotrophin-releasing hormone analog (GnRHa) plus elevated pure follicle-stimulating hormone (pFSH) (n = 17) or (2) flareup GnRHa plus elevated pFSH plus oral L-arginine (n = 17). Results indicated that group 2 (the arginine group) demonstrated a lower cancellation rate, increased number of oocytes on collection, and increased embryo quality and transfer compared with the control group. Additionally, 3 of 17 women in the arginine group conceived, whereas none in the control group did so.

The literature regarding arginine and fertility outcome is impressive; however, although the trial showed very promising results, it assessed only a small sample of women, too small to allow definitive conclusions. Further research into the potential of this promising adjunct during ART procedures is recommended.

L-Carnitine

Similar to its role in male reproductive function, L-carnitine plays a vital role in fatty acid metabolism. It is derived from the amino acids lysine and/or methionine and works synergistically with coenzyme Q_{10}. It is essential in the transport of fatty acids into the mitochondria; a deficiency results in a decrease in fatty acid concentrations in the mitochondria and reduced energy production. Prescriptions must use the L form and not the DL form to ensure effectiveness and safety. The mitochondria are crucial components of oocyte development, acceptance of the spermatozoa, and subsequent embryogenesis. It is the mRNA within the oocyte that requires the power of the mitochondria to allow conception to occur. Therefore the prescription of carnitine is specifically indicated in women who are experiencing implantation issues and/or presenting with aging oocytes. In addition to mitochondrial energy production, L-carnitine improves female fertility by reducing cellular stress and maintaining hormonal balance.[93]

In mouse studies, carnitine has been found to exert a protective effect on mouse oocytes, reducing damage to the oocyte's cytoskeleton and also mitigating embryo apoptosis induced by incubation in the peritoneal fluid of patients with endometriosis.[94] Although peritoneal fluid has a strong effect on endometriosis, it helps regulate endometrial lining production and implantation factors. A small in vitro study of follicular fluid from 22 infertile women with mild endometriosis undergoing IVF treatment found that L-carnitine with N-acetylcysteine prevented oocyte damage.[95] As such, although human studies are lacking, the prescription of carnitine for patients experiencing endometriosis and/or implantation failure due to endometrial factors is recommended.

A trial in 170 women with clomiphene-resistant polycystic ovary syndrome (PCOS) found that administering L-carnitine (3 g/day) in conjunction with clomiphene citrate (250 mg/day) from day 3 until day 7 of the cycle significantly improved both the ovulation and pregnancy rates. The lipid profile and BMI of the women were also improved.[96]

A small prospective study (n = 24) of acetyl-L-carnitine supplementation (1 g/day) over 16 weeks in women with stress-induced hypothalamic amenorrhea found a significant increase in LH levels in hypo-LH women, via modulation of the hypothalamic–pituitary–gonad (HPG) axis. LH response to naloxone was restored in the treatment group.[97] These results were supported in a follow-up study of 27 women with functional hypothalamic amenorrhea who were administered L-carnitine (500 mg/day) with acetyl-L-carnitine (250 mg/day) over 12 weeks. LH plasma levels increased (in hypo-LH women), whereas cortisol and amylase levels decreased significantly.[98]

Antioxidants

Compared with male fertility, there is little evidence supporting the use of specific antioxidants. However, the consensus remains that the

use of antioxidants combined with a good diet improves fertility in women.[15] One Cochrane review assessed the use of vitamin supplementation in the prevention of miscarriage. It concluded that patients given multivitamins plus iron and folic acid, compared with controls, had reduced risk for stillbirth, but there was no effect on miscarriage risk.[99] The same review concluded that there is a lack of evidence to support antioxidant supplementation for reducing the risk of miscarriage. Therefore it is highly likely that any vitamin prescription, provided that it is prescribed holistically and effectively, will have a positive effect on female fertility.

Transgenerational epigenetic effects include both the physiological and behavioral (intellectual) transfer of information across generations. Although in most cases the underlying molecular mechanisms are not understood, modification of the chromosomes that pass to the next generation through gametes is sometimes involved; this is called transgenerational epigenetic inheritance.

The oocyte, a highly sensitive structure, is highly vulnerable to its external environment and external influences. Every female is born with all of her oocytes. As such, they are thus exposed to everything she experiences throughout her entire life. Additionally, from an epigenetic perspective, a woman's oocytes are also exposed to everything to which her mother and even her maternal grandmother were exposed.

Oxidative stress has a detrimental effect on female fertility by increasing time to conception, decreasing fertilization rates, decreasing oocyte penetration function and viability, decreasing implantation, and increasing loss of implantation.[100]

The oocyte requires a regular antioxidant supply to continue to reduce oxidative damage both from current circumstances and historical (or transgenerational) exposure. Glutathione is the major nonenzymatic antioxidant found in oocytes and embryos.[52] During conception, the mRNA is responsible for using antioxidant reserves to address any DNA fragmentation or oxidation from both the sperm and the oocyte. The very act of conception and the subsequent travel of the embryo through the fallopian tubes before implantation generate free-radical damage. Because oxidative stress has been shown to hinder optimal fertility,[101,102] it is imperative to provide sufficient support for the oocyte so that conception and implantation can occur.

It is important to note that physiological levels of ROS are required for healthy oocyte development and better IVF outcomes. It is a prerequisite for the first meiotic phase (meiosis I) and is also required for folliculogenesis; however, if levels are abnormally high, they are negatively associated with oocyte and embryonic development and pregnancy outcomes. Antioxidant intake is important to suppress ROS buildup and maintain physiological levels of free radicals for homeostasis and proper cell functioning.[103] Excessive ROS production (through lifestyle factors such as advanced age, obesity, smoking, alcohol intake, recreational drug use, and exposure to environmental pollutants) can overpower the body's natural antioxidant defense system, creating an environment unsuitable for normal female physiological reactions, leading to unexplained infertility.[52,103–105]

Women with idiopathic infertility have lower total antioxidant status in the peritoneal fluid, and it has been suggested that peritoneal fluids with increased ROS and decreased antioxidant status diffuse into the fallopian tubes and can damage the sperm, which is highly sensitive to oxidative stress.[105] Oocyte quality is also affected by oxidative stress, limiting successful ovulation and fertilization. Follicular fluid contains high levels of antioxidants that protect oocytes from ROS damage, and a small pilot study has shown that higher levels of melatonin (a powerful antioxidant) in the follicular fluid are associated with both the quantity and quality of oocytes and can predict IVF outcomes.[106] Selenium and glutathione peroxidase levels have been found to be lowest in follicular fluid in patients with unexplained infertility, and antioxidant capacity levels were found to be higher in follicles of patients whose oocytes fertilized successfully.[107]

Oxidative stress causes alterations in certain protein pathways, the abnormal expression of which could possibly lead to the pathophysiology of infertility.[103]

In women undergoing IVF treatment, it was found that increased intakes of β-carotene, vitamin C, and vitamin E were associated with time to pregnancy, but the effect of individual antioxidants varies by age and BMI.[104] Although is it clear that antioxidant status plays a role in reproduction and infertility, the success of antioxidant supplementation in female subfertility is not so clear. A 2013 Cochrane review found that the quality of the evidence in the studies was low and that antioxidant supplementation was not associated with an increased live birth rate or clinical pregnancy rate.[108] This conclusion was supported by a later trial of women with unexplained subfertility undergoing IVF treatment, which showed that daily oral antioxidant supplementation (multivitamins and minerals) did not improve oocyte quality and pregnancy rates.[109]

R-Alpha Lipoic Acid

In both its lipid- and water-soluble forms, alpha-lipoic acid is a powerful antioxidant found in virtually all cells of the human body, scavenging the free radicals implicated in oxidative stress. It assists in the chelation of heavy metals, thus minimizing the risk of cellular damage and regenerating other antioxidants, including vitamins C and E, coenzyme Q_{10}, and glutathione.[110]

Vitamin A

Vitamin A is a powerful antioxidant that assists in cellular growth and differentiation, both crucial for embryogenesis and placentogenesis.[111] It is required for gene expression and cellular differentiation in organogenesis and embryonic development[112] as well as for immunity, regulatory functions, the integrity of epithelial tissue, and the health of the cilia in the fallopian tubes. It has a direct relationship with zinc, and the deficiency of zinc has been linked with infertility, miscarriage, and the development of cleft palate. It is a cofactor of 3-β-dehydrogenase in steroidogenesis (specifically for estrogen production), and deficiencies may result in impaired enzyme activity.[113] Additionally, low concentrations of vitamin A are associated with anovulation,[114] and plasma levels have been observed to be decreased in women suffering from habitual miscarriage.[115] A Cochrane review has found no evidence, however, to support the use of vitamin A supplementation to reduce the risk of miscarriage.[99]

Supplementation during pregnancy is inadvisable due to the potential for malformation and congenital abnormalities. However, supplementation in the preconception period is strongly advised. Owing to its lipid solubility and the liver's high storage capacity, it is advisable to keep prescriptions below 10,000 IU/day. It is also important to note that cross-placental transfer occurs primarily with lipid-soluble nutrients. Therefore cessation of vitamin A supplementation is advisable as a cautionary measure immediately before conception attempts.

An alternative is to prescribe carotenoids (β-carotene), owing to their lower toxic potential. An additional benefit is that they have a role in ovarian oocyte and follicular maturation and function.[116] However, 15% to 25% of whites are unable to convert β-carotene to vitamin A, so it is not a substitute for vitamin A (see also Chapters 57 and 125).

Coenzyme Q_{10}

Coenzyme Q_{10}, also known as ubiquinone (ubidecarenone) or ubiquinol, is an endogenous enzyme involved in intracellular adenosine triphosphate (ATP) production; it serves as a cofactor in oxidative stress respiration for the citric acid cycle and the electron transport chain.[117] It

is a fat-soluble antioxidant and free-radical scavenger found in every cell in the body and plays a vital role in all energy-dependent processes. It is required in the maintenance of cell membrane integrity and cell functioning and is therefore specifically important for all new cells in the body and the development of cells in their maturation process. The presence of coenzyme Q_{10} in human follicular fluid indicates its potential role in reproductive outcomes. Higher coenzyme Q_{10} levels were seen in the follicular fluid of mature oocytes and good-grade embryos compared with immature eggs and poor-grade embryos, respectively.[118,119] It is endogenously produced from tyrosine in a 17-step process that requires riboflavin (B_2), niacinamide (B_3), pantothenic acid (B_5), pyridoxine (B_6), cobalamin (B_{12}), folic acid (B_9), vitamin C, tetrahydrobiopterin, and trace elements as cofactors. Therefore an ample supply of these key nutrients is essential for the production of this enzyme. Additionally, it can be expected that patients with thyroid irregularities (both hyper- and hypothyroid) would require additional coenzyme Q_{10} owing to its reliance on tyrosine as an initial building block.

In women with clomiphene-resistant PCOS, it was found that supplementing with coenzyme Q_{10} (180 mg/day) in conjunction with clomiphene citrate resulted in significantly improved ovarian response, luteinization (midluteal progesterone), endometrial thickness, ovulation, and most importantly, pregnancy rate compared with treatment with clomiphene citrate alone.[120] The use of coenzyme Q_{10} supplementation (600 mg/day) in women undergoing IVF procedures resulted in reduced aneuploidy and increased pregnancy rates compared with placebo.[121] Clinical trials are very limited; however, there are countless papers supporting its inclusion in culture media used in an IVF setting, and it is considered a crucial component to mimic various reproductive fluids incorporated in natural conception. In the clinical setting, its role can be extrapolated fairly conclusively; therefore, its use should certainly be considered because its clinical and therapeutic effectiveness are irrefutable. Because dietary sources are poor choices for optimal effect, supplementation is essential. In choosing supplements, it is essential to select the ubiquinol form because it is the active antioxidant.

Specifically in the context of female fertility, coenzyme Q_{10} can be seen to support mitochondrial function and to have positive applications for maturing oocytes, which are at greater risk of oxidative damage. Oxidative damage is typically seen in the zona pellucida of the oocyte, thus preventing the acrosome reaction with sperm (fertilization). Receptivity of the zona pellucida is strongly correlated with the antioxidant status of the oocyte, and coenzyme Q_{10} is believed to be the most specific antioxidant for this application. Understandably, requirements for coenzyme Q_{10} will be greater for more mature oocytes (women above 35 years of age) or women undergoing ART procedures owing to the increased oxidative effect on the oocyte of such procedures.

Vitamin C

Vitamin C is the body's primary water-soluble antioxidant. It is protective against free radicals, protects folic acid and vitamin E from oxidation, and has been shown to improve fertility outcomes in women with luteal-phase defects.[122] The ovary is considered the primary site of ascorbic acid accumulation because the midcycle change of retention and excretion of ascorbic acid is one of the main markers of ovulation. In the literature, vitamin C is seen to be crucial for collagen biosynthesis and its positive effect on the growth and repair of the ovarian follicle and the development of the corpus luteum[123]; it may also facilitate luteal steroidogenesis. It is necessary for the maturation of the preovulatory follicle and reduces the risk of preeclampsia when prescribed concurrently with vitamin E. Deficiency increases the risk of miscarriage, spontaneous rupture of membranes, and brain tumors in the offspring.

Vitamin C is best coprescribed with bioflavonoids, which provide the additional benefits of strengthening capillaries, preventing miscarriage, and preventing breakthrough bleeding during the pregnancy. Evidence levels are still low, and according to a Cochrane review, there is insufficient evidence to support the use of vitamin C supplementation alone, or in combination with other supplements, to help prevent stillbirth, poor fetal growth, preterm birth, or preeclampsia.[124]

Vitamin E

Vitamin E is a powerful lipid-soluble antioxidant that is essential for fertility and reproduction. It is a plant-derived fat-soluble vitamin that exists in eight different isomers. Alpha-tocopherol is the most biologically active form for conception and is the focus in nutrition research. It has been shown to maintain the health of the ovaries[125]; help premenstrual syndrome (PMS) sufferers, including relief of affective and physical symptoms[126]; relieve benign breast disease[127]; and ameliorate menstrual migraine,[128] indicating effects in the regulation of hormonal activity. The literature suggests that it may be of benefit in infertile women by reducing scar formation (especially keloid scarring when applied topically).[129] This may make it particularly useful to those suffering from endometriosis and/or complicated reproductive conditions such as Asherman's syndrome. Additionally, one study found that women suffering from infertility and endometriosis had lower levels of vitamin E and increased lipid peroxidation.[130] This was confirmed by another study indicating that levels of vitamin E were low in infertile patients compared with controls. This research suggests that the antioxidant capacity was compromised in infertile women and may cause subsequent risk of oxidative damage.[131]

A recent study found that higher levels (10–15ml/dL) of serum vitamin E were associated with higher-quality embryos in women undergoing IVF treatment.[132]

As far as intervention trials go, one trial assessing outcomes in women with unexplained infertility undergoing ART showed that vitamin E (400 IU/day) combined with clomiphene citrate resulted in increased endometrial thickness. However, no statistical difference was found in implantation or ongoing pregnancy rates compared with clomiphene citrate treatment without vitamin E.[133] A double-blind, randomized controlled trial (RCT) of 105 infertile women with PCOS undergoing IVF treatment showed that clinical pregnancy and implantation rates were significantly higher in the treatment group compared with placebo. Treatment consisted of supplementation with vitamin E (400 mg/day) and vitamin D_3 (50,000 IU/once every 2 weeks) over an 8-week period. Oxidative stress was not reduced, and antioxidant status was not increased, in the treatment group in this study, and it was concluded that the positive results were due to the increase in vitamin D_3 levels of the participants.[134] Further high-quality trials are needed in this area. A 2015 Cochrane review found no evidence to support vitamin E supplementation in pregnancy to prevent stillbirth, baby death, preterm birth, preeclampsia, or low-birthweight babies.[135]

Selenium

Selenium is a powerful antioxidant with marked immune-modulating properties. Deficiency has been linked to female infertility, miscarriage, preeclampsia, gestational diabetes, fetal growth restriction, preterm labor, and obstetrical cholestasis.[136] Supplementation appears to reduce the risk of miscarriage, especially in association with thyroid autoantibodies.[137]

Supplementation has been suggested as a powerful supportive nutrient to regulate and control thyroid autoimmunity, specifically thyroid peroxidase (TPO) antibodies.[137] Selenium is essential in thyroid hormone synthesis because several of the enzymes involved are selenoproteins.[138] Selenium also plays a role in the immune system and the coagulation system.[139,140]

In a double-blind, randomized clinical trial, selenium substitution decreased TPO antibody levels in euthyroid subjects and increased quality of life.[140] In another trial, it also decreased TPO antibody levels in hypothyroid patients treated with T4 substitution.[141] Specifically in this specialized population, lowered selenium levels have been observed in the hair of women with recurrent miscarriage compared with controls who have had successful pregnancies[139]; decreased serum selenium has also been observed in women who suffered from miscarriage in the first trimester as well as recurrent miscarriage.[142]

Serum and follicular fluid levels of selenium appear to be reduced in women undergoing IVF, and this has been associated with nonfertilization of the harvested oocytes.[143] Multivitamin/mineral supplementation has been shown to normalize selenium in serum and follicular fluid in women undergoing IVF.[144] It has been shown that selenium levels in hair correlate positively with follicle number and oocyte yield after ovarian stimulation, suggesting that selenium has a positive effect on ovarian response to gonadotrophin therapy for IVF.[145]

In pregnancy, selenium supplementation (100 mcg/day) reduces prelabor membrane rupture and preeclampsia.[146,147] In a preliminary study of healthy women, dietary selenium was significantly associated with lower odds of luteal phase deficiency. A 10-mcg increase in average daily selenium consumption decreased the odds of luteal-phase deficiency by 20%. Luteal-phase deficiency refers to inadequate progesterone secretion by the corpus luteum, which may render the endometrium less receptive to implantation and result in infertility or early pregnancy loss.[148]

Zinc

More than 200 enzymes require zinc for their activity; these include the enzymes required for the production of the nucleic acids in DNA and RNA.[149] Zinc has specific antioxidant properties required for the reproductive system and protects the oocytes from free radicals and reactive oxygen species.[150] It enables reproduction, ovulation, fertilization, and the development of the oocyte.[151,152] Deficiency may result in altered synthesis/secretion of follicle-stimulating hormone or luteinizing hormone[153] because it has been reported to have a role in the synthesis, transport, and peripheral action of hormones. Low zinc status is associated with low circulating concentrations of several hormones.[154]

Deficiency may produce symptoms such as abnormal ovarian development, increased risk of miscarriage, or increased risk of teratogenicity.[155] It is considered to be the single most important nutrient for preconception and pregnancy and is frequently disrupted with the use of an oral contraceptive pill or a copper intrauterine device. In animal trials, low zinc levels were associated with impaired ovulation and a larger number of deteriorated oocytes[151]; in such circumstances, supplementation may be beneficial. Caution is advised because an excessive intake of zinc can be detrimental[156]; doses should be calculated on the basis of assessments and clinical findings.

In the preconception period, zinc supplementation used to enhance fertility will further support a healthy pregnancy and subsequent healthy birth. Poor maternal zinc status is associated with a number of adverse pregnancy outcomes, including low birth weight, premature delivery, complications of labor and delivery, and congenital anomalies in the offspring.[157] Intrafollicular zinc levels in women with endometriosis have been observed to be higher in those women who successfully achieved pregnancy after IVF than in those who did not become pregnant.[158] Additionally, requirements increase during pregnancy because marginal zinc deficiency has been shown to be prevalent during this time.[159] Monitoring is crucial because suboptimal levels are associated with growth retardation in the fetus.[159] In one study, supplementation of 25 mg from at least 19 weeks' gestation resulted in significantly greater birth weight.[160] Additionally, a meta-analysis of supplementation trials indicates that zinc supplementation produced a 14% reduction in premature deliveries.[161] However, a Cochrane review found that although zinc supplementation in pregnancy leads to a slight reduction in preterm births, it does not prevent other problems such as low birth weight or preeclampsia.[162]

B-Complex Vitamins

It is imperative to take the B-group vitamins in a stable, combined formulation owing to their interrelation and interdependence in a number of key reactions in the body. Their synergy of effect can be seen in countless scenarios; however, some patients may require additional key B vitamins such as folate for methylenetetrahydrofolate reductase (MTHFR), polymorphisms, or vitamin B_6 in instances of luteal-phase defects or progesterone insufficiency.

Deficiencies of this group of vitamins have been associated with a number of fertility problems, including fetal abnormalities such as neural tube defects,[163] neonatal or perinatal death, low birth weight, and miscarriage.[164,165] It is important to consider that alcohol, carbohydrate-rich diets, and the oral contraceptive pill increase the body's requirements for B vitamins. Therefore any couple wanting to optimize their fertility may require additional B vitamins to prepare themselves for conception. Acknowledging that stress also increases requirements for B vitamins and that stress has been identified as playing a major role in couples who are having difficulty conceiving, the importance of adequate B-vitamin intake is further emphasized.

Vitamin B_1 (Thiamine)

In animal models, vitamin B_1 has been shown to stabilize the membranes of newly generated neuronal cells during embryogenesis concurrent with slowing cell death. Additionally, it has been shown to be involved in the plasma membrane transformation of uterine epithelial cells during pregnancy.[166] It plays a key role in reproductive function, with deficiency associated with altered cellular differentiation and proliferation and interference with hormonal processes, thus increasing the risk of miscarriage.[167] Additionally, when taken preconceptually in combination with vitamins B_3 and B_6, it has been shown to contribute to the prevention of oral-facial clefts.[168]

Vitamin B_2 (Riboflavin)

Vitamin B_2 is crucial for energy production, antioxidant defense, and numerous enzyme systems that rely on the presence of B vitamins. Insufficient levels can lead to altered estrogen and progesterone levels, often causing irregular menstruation. Supplementation often addresses irregularities such as general menstrual difficulties, irregular menses, PMS, and infertility.[169]

Vitamin B_2 is essential for the development of the fetus; according to animal studies, deficiency appears to affect embryonic growth and cardiac development. Therefore supplementation has been encouraged to prevent these complications.[170] Low dietary intake has also been associated with low birth weight[171] and has been shown in one study to increase the risk of congenital heart defects in the offspring of mothers who did not take vitamin supplements in the periconceptual period or consume sufficient dietary saturated fatty acids.[172]

Vitamin B_6 (Pyridoxine)

Vitamin B_6 is required for the metabolism of amino acids, lipids, pathways of gluconeogenesis, and synthesis of neurotransmitters during the periconception period.[111] It is required for the synthesis of prostaglandins; it also plays a key role in conjunction with vitamins B_9 and B_{12} in their regulation of homocysteine, which, when elevated, has been linked to infertility and recurrent spontaneous miscarriage.[173,174] Additionally, elevated homocysteine concentrations in follicular fluid

are also associated with poor oocyte and embryo qualities in patients with PCOS who are undergoing assisted reproduction,[175] thus further supporting the B-vitamin combination.

In addition, vitamin B_6 helps reduce elevated prolactin levels; support luteal-phase defects by increasing progesterone secretion; increase the influx of magnesium into the myometrium; improve the absorption of zinc; and prevent preeclampsia, toxemia, and infarction of the placenta. Serum levels are often low in hyperemesis gravidarum, and a deficiency may be associated with a higher incidence of gestational diabetes.

A study examining a Mediterranean diet in couples undergoing IVF demonstrated an increase in plasma vitamin B_6 levels and, in those with high adherence to the diet, a 40% increase in the probability of pregnancy.[81]

Vitamin B_9 (Folate, Folinic Acid or L-5MTHF)

Folic acid is required for healthy DNA and RNA synthesis, optimal protein synthesis, and the regulation of gene expression.[176] Impaired folate metabolism disturbs endometrial maturation and results in poor oocyte quality. The most important variation in folate metabolism in terms of effect is the MTHFR polymorphism, which could be one reason for unexplained infertility.[177]

Deficiency can be corrected with supplementation, which is recommended for at least 3 months for any woman planning pregnancy.[178] The primary justification for its preconceptual prescription is to prevent neural tube defects and spina bifida, as confirmed by a 2015 Cochrane review[179]; however, it must be supplemented for the first 28 days of gestation to achieve this goal.[180] Therefore a preconceptual prescription for 3 months before conception is the safest option because most women are unaware of their pregnancy status until it is confirmed after a minimum of 14 days.

Supplementation of folic acid is associated with a decreased incidence of ovulatory infertility[76,181] and has been identified as being important for oocyte quality and maturation.[152] A 2016 Cochrane review found no evidence to support the use of folic acid supplementation for reducing the risk of early or late miscarriage or stillbirth.[99]

Folate and vitamin B_{12} levels have been found to be largely inadequate among women undergoing IVF treatment.[182] Inadequate folate results in elevated homocysteine and alters DNA methylation negatively, influencing oocyte and early embryo quality.[183] Inadequate B-vitamin status and raised concentrations of homocysteine are also associated with the early loss of pregnancy, as evidenced by a systematic review, which found that folate-deficiency–induced hyperhomocysteinemia posed a risk for placenta-mediated diseases such as preeclampsia, spontaneous abortion, and placental abruption.[184]

In a prospective cohort study of women undergoing IVF (n = 232), live birth rates were 20% higher among women with the highest amount of supplemental folate intake (>800 mcg/day) compared with women taking the lowest amount (<400 mcg/day). This study also suggested that folate supplementation was superior to dietary folate.[185] Similarly, in a study of 100 women, higher serum concentrations of folate and vitamin B_{12} before ART treatment were associated with higher live birth rates.[186] Contrary to these positive findings, a 2014 study found that neither folic acid supplementation nor folate status increased the chance of achieving a pregnancy after ART in women with unexplained infertility.[187]

Folate intake has been related to a lower frequency of sporadic anovulation in young healthy women,[188] and folic acid supplement use was also associated with a shorter time to pregnancy among a large cohort of 3895 women.[189] In women undergoing IVF treatment, higher urinary bisphenol A (BPA) concentrations were associated with a 66% lower probability of implantation. This effect was ameliorated by higher levels of dietary folate intake (more than 400 mcg/day).[190]

Preconception folic acid intake may increase fertility and increase a woman's chance of becoming pregnant. Doses higher than recommended for the prevention of neural tube defects may offer the greatest benefit, as might the additional intake of vitamin B_{12}.

Vitamin B_{12} (Hydroxo-, Adenosyl- or Methyl-Cobalamin)

It is common for women to take folate in isolation and not acknowledge its copartner in all metabolic reactions, vitamin B_{12}. Vitamins B_9 and B_{12} work together to ensure that the replication of DNA and RNA in all cells is uniform and regulated. In one longitudinal study, it was noted that although folate levels decreased slightly during pregnancy and remained decreased for up to 6 weeks postdelivery, vitamin B_{12} progressively declined during pregnancy and reached marginal or deficient levels in some individuals.[191] Clinicians are reminded that supplementation of either vitamin B_9 or B_{12} in isolation can cause a rebound anemia of the other nutrient and that pernicious anemia can be masked with supplementation of one vitamin in isolation, as evident on the basis of red blood cell indices. Furthermore, low maternal levels of vitamin B_{12} have been associated with a threefold risk of neural tube defects,[192] again confirming its combined role with folate.

Vitamin B_{12} deficiency has been linked to infertility and recurrent spontaneous miscarriage.[193] Moreover, pregnancy has been shown to occur after correction of this deficiency.[193] In addition, it is prudent to acknowledge the collaborative role of vitamin B_{12} in cases of elevated homocysteine levels.

Vitamin D

The Third National Health and Nutrition Examination Survey (NHANES III) reported a prevalence of vitamin D deficiency of between 25% and 57% among adults.[194] It is important to note that the accepted levels of this vitamin in this analysis are below what naturopaths would consider a safe, therapeutic level for optimal health. Therefore it can be hypothesized that the deficiency percentage is actually much higher. Each week a new paper emerges highlighting an additional application for this crucial vitamin. Its main functions include calcium homeostasis; modeling and remodeling of bone (supporting the skeletal health of both mother and child); immune activation; cell differentiation, proliferation, and growth; and many others.

In the context of female fertility, the active form of vitamin D, 1-25-dihydroxyvitamin D3, has been shown to regulate the transcription and function of genes associated with placental invasion, normal implantation, and angiogenesis.[195] Vitamin D is a powerful immune modulator and therefore an effective prescription for those who experience autoimmune conditions that affect fertilization, implantation, and an increased risk of miscarriage. This is because of the vitamin D receptors found in cells involved in the immune response. Specifically, in fertilization, it is believed to have receptors on the zona pellucida of the oocyte as well as in the head of the sperm. Researchers have theorized that the acrosome reaction with the zona pellucida is enabled by an adequate vitamin D status. Vitamin D receptors are also found in the ovaries, uterus, placenta, and endometrium.[196] Additionally, this vitamin appears to be involved in the acceptance of the sperm by the oocyte, whereby the vitamin D receptors act as gatekeepers to enable immune regulation and thus prevent rejection. Although the effect of vitamin D deficiency is unclear, no association with ovarian reserve or risk of spontaneous abortion has been observed[197,198]; however, a positive association of vitamin D levels with endometrial thickness has been observed.[199] Maternal vitamin D deficiency has also been suggested to be an independent risk factor for preeclampsia, and a number of animal studies highlight the fact that vitamin D deficiency is associated with infertility.[200]

There has been an increased level of interest in the effect of vitamin D on fertility, as evidenced by a search on the literature, and although some studies have yielded positive findings, similar numbers of studies have found no association.

Studies of women undergoing IVF treatment found that higher serum and follicular fluid levels of 25(OH)D had increased pregnancy rates. Each ng/mL increase in follicular fluid 25(OH)D increased the chance of becoming pregnant by 6%.[201–203] Similar results were found in women undergoing single blastocyst transfer—vitamin D deficiency was found to impair pregnancy.[204] These findings were not supported in other studies.[205–208] One study even found that that higher follicular fluid levels of 25(OH)D negatively affected embryo quality and led to poorer IVF outcome.[209]

Other studies have failed to find a significant association between serum and follicular fluid 25(OH)D levels and IVF outcome.[210,211] In women undergoing euploid embryo transfer, vitamin D status was unrelated to pregnancy outcomes.[212]

A case-control study compared early pregnancy levels of vitamin D between women who took 12 to 24 months to get pregnant with age-matched women conceiving in less than 1 year and found no association.[213] A recent study of 70 infertile women found that 64% of the women were vitamin D deficient, but this did not correlate with anti-Müllerian hormone levels.[214]

A retrospective cohort study found that the relationship between vitamin D status and pregnancy rates differed by race. In non-Hispanic white women, pregnancy rates declined with lower levels of vitamin D, whereas in Asian women, the reverse association was seen.[215] A study in donor–recipient IVF cycles showed that insufficient vitamin D levels of the recipients (rather than the donors) was associated with lower pregnancy rates, suggesting that the effects of vitamin D may be mediated through the endometrium rather than through the follicle or oocyte.[216] Once again, however, these results were not supported by another study, which found no difference in pregnancy rates in recipients who had differing vitamin D levels (normal, insufficient, or deficient).[217]

Given the heterogeneity of findings, little can be conclusively stated from the results on vitamin D and fertility. Vitamin D deficiency might be detrimental to fertility, but it is not clear whether higher levels of vitamin D confer additional benefit once sufficiency has been achieved.

A Cochrane review concluded that supplementing with vitamin D during pregnancy may reduce the risk of preeclampsia, low birth weight, and preterm birth. However, vitamin D and calcium supplementation combined increases the risk of preterm birth.[218] At this stage, the clinician is advised to use serum levels to ascertain the best clinical approach and be mindful of not overprescribing.

Calcium

Calcium is an important nutrient for conception, embryogenesis, and gestation. It is required for oocyte maturation, fertilization,[219] and bone formation of both mother and child. It has also been shown to exhibit a protective effect against preeclampsia. A Cochrane review emphasized that calcium supplementation appeared to almost halve the risk of preeclampsia,[220] which supports the prescription of calcium for all preconceptual women whose dietary intake is inadequate.[221]

Iodine

Iodine deficiency has increased in the past two decades because of changes in the dairy industry. The primary supplementation for most people consisted of their dairy intake owing to the iodine solutions used to clean the dairy equipment.[222] This practice has been modified, and today, chloride and bromide solutions are used instead. More than 30% of nonpregnant women of childbearing age have suboptimal urinary iodine concentrations.[223,224]

Adequate dietary intake of iodine preconceptually is imperative because it can minimize the risk of thyroid-related disorders and/or mental retardation in the infant, defects that are commonly seen in the offspring of deficient mothers. Additionally, low iodine has been shown to negatively affect the development of the central nervous system in the fetus and can hinder conception owing to its role as a nutrient donator for the T3 and T4 hormones that regulate thyroid function and thus ovulation.

Maturing oocytes are highly dependent on healthy thyroid hormone levels for optimal reproductive function[225]; deficiency may result in a spectrum of disorders, including miscarriage, stillbirth, mental retardation, and cretinism (deaf-mutism and spasticity).[226,227] Additionally, thyroid autoimmunity is significantly higher among infertile women than among fertile women and increases the rate of miscarriage.[228] Therefore iodine can help supply building blocks for thyroid hormones that are compromised by the autoimmune process.

Subclinical hypothyroidism may be associated with ovulatory dysfunction and adverse pregnancy outcomes; it is therefore crucial to assess thyroid (and iodine) status for both infertile males and females because correction of this condition can reverse or prevent infertility.[229] In one study, 4980 women (462 of whom were pregnant) were tested for iodine status. Repeated miscarriage and stillbirth were associated with higher levels of deficiency, which increased the risk of reproductive failure.[230] A recent population-based prospective cohort study of 501 women found that moderate to severe iodine deficiency is associated with a 46% decrease in fecundability.[231] A 2017 Cochrane review found no conclusive evidence for the benefits or harms of iodine supplementation in women before, during, or after pregnancy. Iodine supplementation appears to decrease the likelihood of postpartum hyperthyroidism and increases the likelihood of digestive intolerance in pregnancy.[232]

As early as 1939, Kemp[233] acknowledged a link between a deficiency of iodine and stillbirth of unknown origin. In the late 1970s, Potter et al.[234] discussed the decline in stillbirth rates after iodine supplementation, highlighting the positive relationship that ensued between iodine (when taken at the correct dose) and a reduced incidence of stillbirth. Current research[235] indicates that 2000 babies continue to be stillborn every year. In spite of advances in technology, the cause of one third of these deaths is unknown.

It is recognized that a diagnosis of hypothyroidism based on thyroid-stimulating hormone (TSH) values in isolation may not suffice to diagnose mild to moderate iodine deficiency in the pregnant woman.[236] It is therefore prudent to assess the urinary iodine status of each patient either as a morning spot urine test, 24-hour urinary excretion test, or iodine:creatinine ratio, as recommended by the World Health Organization.[237,238]

Iron

Iron is required for the formation of red blood cells, subsequent transport of oxygen to the tissues via hemoglobin, and nucleic acid metabolism, as well as being involved in numerous enzyme systems within the body.[111] Because there may be a risk of hemochromatosis, it is imperative that all patients be assessed thoroughly before prescription to ensure that their health is prioritized. If supplementation is needed, patients should address this deficiency in the preconceptual period to help prevent iron deficiency during the pregnancy.[221] Results from the NHS-II suggest that women who consume iron supplements have a significantly lower risk of ovulatory infertility than women who do not.[107,239]

In one article, iron supplements up to 40 mg or more were shown to reduce the risk of ovulatory infertility by up to 60% and to improve the chances of conception compared with women who did not take iron supplements.[239] The link between iron deficiency and infertility has been confirmed by a number of other articles.[240] Therefore practitioners should study the patient's iron profile and ensure that all components are within the normal range, aiming to achieve serum ferritin stores of 80 ng/mL before conception and saturation of greater than 30%. It is imperative to assess a full iron study profile because ferritin can be elevated due to inflammatory processes in the body and give a false sense of iron repletion. This is especially important because some women are unable to take iron supplements during the first trimester owing to their tendency to aggravate nausea.

Magnesium

Magnesium is involved in numerous reactions in the body relevant to fertility, including cell signaling and energy production. Women experiencing spontaneous abortion have been observed to have lower plasma magnesium levels than healthy controls,[241] and those experiencing associated stress regarding their fertility will benefit from both magnesium and B vitamin supplementation. Stress is associated with impaired fertility, including miscarriage and failed pregnancy outcomes.[242]

Essential Fatty Acids

Women undergoing preconception care are encouraged to consume a diet rich in essential fatty acids (EFAs)[221] because omega-3 fatty acids are required to maintain the lipid bilayer in all cell membranes and to serve as precursors for prostaglandin synthesis. Specifically, in the prevention of miscarriage, omega-3 fatty acids (4 g/day providing 795 mg of docosahexaenoic acid [DHA] and 1190 mg of eicosapentaenoic acid [EPA]) have been found to improve the velocity of blood flow in the uterine arteries in women with recurrent miscarriage due to impaired uterine perfusion.[243]

Supplementation with omega-3 fatty acids has been shown to improve endometrial function. In vitro studies of decidualized cells have identified a decrease in prostaglandin production by up to 80%, indicating that prescription is beneficial for all women but most importantly, those suffering from endometriosis or endometrial insufficiency.[244] Additionally, supplementation is believed to assist in reducing spontaneous preterm births associated with intrauterine inflammation.[245] In a North America cohort, women with the lowest intake of omega-3 fatty acids had lower fecundability than women with higher intakes.[86] DHA has been associated with a reduced risk of anovulation in a cohort of healthy, regularly menstruating women.[246]

The role of EFAs in IVF treatment has received a little more attention. A study of women undergoing IVF treatment found that omega-3 fatty acid intake has a beneficial effect on fertility. Women with a higher alpha-linolenic acid (ALA) intake had higher baseline estradiol levels, and ALA and DHA intake was associated with improved embryo morphology.[247] A study investigating the associations between serum levels of polyunsaturated fatty acids (PUFAs) and embryo implantation in women undergoing IVF found that an increased ratio of omega-6 to omega-3 was more important than individual levels of PUFAs in increasing implantation and pregnancy rates.[248] In overweight and obese women undergoing IVF in Australia, intake of PUFAs, specifically omega-6 PUFAs and linoleic acid and possibly omega-3, was associated with improved pregnancy rates; however, there was no association with live birth rates.[249] A cohort study among 105 women undergoing IVF treatment in Iran found that serum levels of EPA were significantly higher in women who achieved pregnancy compared with those who did not.[250]

Probiotics

Alterations in the microflora of the vagina and subsequent genital and intrauterine infections[251] have been linked to reproductive failure and adverse pregnancy outcomes such as preterm labor, miscarriage, and spontaneous preterm birth.[251–253] In one study, during the first half of pregnancy, women with altered vaginal flora of bacterial origin were four times more likely to have a spontaneous preterm birth compared with the overall preterm birth rate.[254]

Bacterial vaginosis is associated with ascending infections, which may lead to tubal factor infertility. Selected *Lactobacillus* strains are typically used for treating bacterial vaginosis because the human vaginal microbiota is a predominantly *Lactobacillus* community.[255]

Botanical Medicines

Actaea racemosa (Black Cohosh)

Actaea racemosa has historically been described by the eclectics as a uteroovarian tonic for "pains of a dull aching character; dragging pains in the womb, with sense of soreness; the dull tensive pains incident to reproductive disorders of the female, as well as the annoying pains accompanying pregnancy; false pains; after pains."[256] Its modern clinical application focuses heavily on mitigating menopausal complaints and regulating the estrogen cascade specifically in this life stage; however, its potential benefits are far broader, and it shows promise in assisting fertility. In one trial, women with unexplained fertility who were not responding to clomiphene citrate were divided randomly into two groups, both of which received clomiphene. However, one group was also given 120 mg of *A. racemosa* on days 1 to 12 of the cycle. Results showed that pregnancy rates were higher in the *A. racemosa* plus clomiphene group compared with the group that received clomiphene is isolation. The A. *racemosa* group had increased LH, progesterone, and estradiol, in addition to increased endometrial thickness.[257]

A subsequent trial of women with unexplained infertility who were undergoing clomiphene induction compared clomiphene citrate cycles with follicular-phase supplementation with *A. racemosa* (120 mg/day on days 1–12 of the cycle) or ethinyl estradiol. Results showed that *A. racemosa* supplementation improved endometrial thickness, follicular maturation, and estradiol levels. There was no statistically significant difference in clinical pregnancy rates between the two treatment groups.[258] Similar results were seen in a study of women with PCOS and infertility. Treatment with clomiphene citrate alone or clomiphene citrate combined with *A. racemosa* (120 mg/day) found that the *A. racemose* group had improved cycle outcomes and pregnancy rates.[259]

Alchemilla vulgaris (Lady's Mantle)

Unfortunately, there is little research on this valuable herb. *Alchemilla vulgaris* has a strong clinical and traditional use as a therapeutic astringent, which makes it an effective prescription for patients experiencing menorrhagia or frequent early miscarriage. Its tannin content supports the antihemorrhagic property, and *A. vulgaris* has traditionally been prescribed to halt bleeding and heal wounds (internal or external).[260] *A. vulgaris* is used to treat female reproductive problems, including menstrual disorders; to prevent miscarriage; and as an aid to conception.[261]

Angelica sinensis (Dang Gui)

Angelica sinensis is a traditional Chinese herbal medicine with a gentle warming action. It is believed to nourish the blood, restore the body's natural balance, and serve as a female tonic for a number of gynecological conditions, including amenorrhea. It appears to contain components that can increase uterine tone and relax the uterine musculature. The two active constituents most associated with this function include ligustilide[262] (an essential oil component) and ferulic acid.[263] Like many other herbal medicines, it is supported by a long history of use

and clinical efficacy. In the absence of human studies, animal experiments have demonstrated that compounds in *A. sinensis* also regulate prostaglandin synthesis and can regulate experimentally induced inflammatory responses due to prostaglandin release.[264] Additionally, thromboxane A2, which increases blood viscosity and promotes blood clotting, appears to be regulated by this herb.[265] These mechanisms may explain its strong reputation as a blood tonic. *A. sinensis* is specifically prescribed for women with compromised fertility who also have blood disorders, menorrhagia, and reproductive inflammatory responses such as those present in endometriosis. It is important to remember that the very process of fertilization and implantation is a marked inflammatory event, which may explain the efficacy of *A. sinensis* as an antimiscarriage herbal medicine serving to promote and sustain conception.

A. sinensis is known to have spasmolytic effects on the uterus, specifically in the treatment of dysmenorrhea. It appears to normalize uterine activity and ease pelvic blood flow, which relieves pelvic congestion and pain. Traditionally it has been combined with *Paeonia lactiflora*[266] and *Ligusticum wallichii*[263] for menstrual pain that is aggravated by the cold. Modern herbalists extrapolate that usage to suggest that *A. sinensis* is a relaxing blood mover that can improve circulation to the uterus and thus assist in normalizing the endometrial lining and supporting implantation.

Asparagus racemosus (Shatavari)

A. racemosus is an Ayurvedic botanical renowned for its effects on the female reproductive system; it has been used for this purpose since the 16th century. *A. racemosus* is believed to function as an aphrodisiac, promoting strength and enhancing sexual appetite while preventing miscarriage and supporting healthy fertility. The roots were traditionally boiled in milk and consumed with sugar owing to their ability to promote libido and to increase *ojas* (which can be likened to the naturopathic version of "vital force"). In Western herbal medicine, Shatavari is primarily prescribed as a female reproductive herb; in animal studies, it has been observed to exert estrogenic effects.[267] Unfortunately, few well-blinded human clinical studies are to be found in the literature; however, in Ayurveda, this herb has been used safely over long periods of time, even during pregnancy and lactation.[268]

Chamaelirium luteum (False Unicorn Root)

An important herbal medicine for reproductive disorders, *C. luteum* is a restricted herb owing to its threatened status from excessive wild crafting. Therefore practitioners are encouraged to prescribe other herbal medicines containing similar steroidal saponins, such as *Dioscorea villosa* (wild yam) and to prescribe *Chamaelirium luteum* if the clinical objective is not achieved. Additionally, the combination of *A. racemosus* (Shatavari) and *D. villosa* (wild yam) may be an even better choice owing to the synergistic action of these herbs.

C. luteum has a strong traditional application as an antimiscarriage herbal medicine. It is undoubtedly one of the most effective herbal medicines for this purpose. The rhizomes appear to function as a uterine tonic and, since the time of the eclectics, have been prescribed to remedy any imbalance or symptom in the female reproductive tract. King's dispensatory documents the use of *C. luteum* for treating repeated and successive miscarriages, and Ellingwood[269] highlights its use for uterine displacement, particularly where there is threatened abortion, saying that it should be combined with *Viburnum prunifolium* to optimize this effect. It has a strong traditional application in the regulation of ovarian function and is particularly indicated to assist in the regulation of menstrual issues experienced in the first half of the cycle.[270] Additionally, it is described as an ovarian amphoteric because of its ability to regulate and normalize ovarian function.[270] Unfortunately, its precise mechanism of action is unknown; however, researchers have determined that it contains steroidal saponins, which are converted through digestion into the sapogenin diosgenin. This constituent has been shown to produce effects on ovarian function via its action on the hypothalamic–pituitary axis.

Paeonia lactiflora (White Peony)

Paeonia lactiflora has long been used in traditional Chinese medicine for its effects on the female reproductive system. In Chinese medicine, *P. lactiflora* is used in a formulation known as Dang-Gui-Shao-Yao-San, a combination of medicinal herbs used for the treatment of ovulatory disorders and thus to promote a good fertility outcome. Another formulation, Unkei-to (a traditional Japanese herbal medicine consisting of Shakuyaku [*Paeonia radix, Paeonia lactiflora Pallas*] and Keihi [*Cinnamomi cortex, Cinnamomum cassia Blume*]) demonstrates stimulatory effects on the ovulatory process and human granulosa cells in vitro.[271] This formulation has been found to promote steroidogenesis, cytokine secretion, 17 beta-estradiol secretion, and progesterone secretion in highly luteinized granulosa cells obtained from IVF patients.

Tribulus terrestris (Tribulus)

Tribulus terrestris is generally thought of as a male tonic; however, it is used extensively in Western herbal medicine for the treatment of female reproductive disorders, including infertility.

A common clinical use of *Tribulus* involves its FSH-stimulating properties at the start of the menstrual cycle in initiating ovulation and improving conception rates. Most of the evidence for this claim, although clinically relevant, lacks research substantiation.

In a clinical context, one can expect to see a marked increase in cervical fluid within a few days of taking the prescription. This increase precedes ovulation and supports conception outcome markedly. It is especially beneficial for patients who have delayed or absent ovulation because it regulates the ratio of follicle-stimulating hormone to luteinizing hormone. Patients are generally more aware of their increased fertility, libido, and release of cervical fluid. This has a positive effect on their mood and confidence in their fertility.

Most articles and documentation refer back to a poorly designed study by Tabakova et al.,[272] who conducted a nonrandomized trial in 51 women with endocrine sterility to assess the effect of Tribestan (standardized *Tribulus* extract) on infertility. Although the results of this study were encouraging, larger studies of better design are needed to evaluate the effectiveness of Tribestan in treating female infertility. Subjects took Tribestan, 1 to 2 tablets (250 mg per tablet) by mouth three times daily, either on days 5 to 14 of the cycle (schedule I) or on days 1 to 12 of the cycle (schedule II) for the first 3 months. After a washout period, the patients were treated with Tribestan, 1 to 2 tablets by mouth three times daily days 1 to 12 of the cycle, plus either Stimovul, 1 to 2 tablets daily on days 5 to 14 of the cycle, or clomiphene citrate 1 to 2 tablets daily on days 5 to 9 of the cycle. The authors found that 67% of the patients treated with Tribestan had normalized ovulation with or without pregnancy. Compared with other drugs, Tribestan was inferior to Stimovul alone. Of 36 patients, 20 went on to receive combination treatment.

Vitex agnus castus (Chaste Tree)

Vitex agnus castus, one of the best-known adjuncts to fertility treatment, is beneficial for anovulatory cycles, hyperprolactinemia, hypothalamic dysfunction, hypothalamic–pituitary–ovarian (HPO) axis modulation, and promoting a regular and normal menstrual cycle. It is well known for its beneficial effects in PMS, and numerous trials have been undertaken in multiple countries to evaluate its effectiveness. It

has been proved to alleviate symptoms associated with latent hyperprolactinemia, whereby it is characterized by lower-than-normal progesterone secretion and normal to mildly elevated prolactin levels. These characteristics are believed to cause a number of menstrual disorders, including typical PMS symptoms, altered menstrual cycle lengths, and amenorrhea. Causative factors appear to relate to an alteration in the hypothalamic–pituitary axis. *V. agnus castus* has been shown to correct menstrual irregularities,[273] including amenorrhea,[274] specifically when caused by latent hyperprolactinemia, owing to its ability to inhibit prolactin secretion.[275] This is achieved by competitively binding to dopamine D2 and opioid receptors, suggesting a dopaminergic effect.[276]

An uncontrolled study using a blend of *V. agnus castus* combined with green tea extract and nutrients (L-arginine; vitamins E, B_6, and B_{12}; folate; as well as iron, magnesium, zinc, and selenium) administered to 30 women who had been unsuccessful in their attempt to conceive despite trying for 6 to 36 months also observed beneficial results.[277] After 5 months of treatment, 5 women out of 15 in the treatment group were pregnant (33% vs. 0%, $P < 0.01$). Four of the five women had healthy live births.

A randomized, double-blind, controlled trial of *V. agnus castus* compared with placebo was shown to improve hormone levels, facilitate the recurrence of menstruation in women with amenorrhea, and ameliorate pregnancy outcome in women with fertility problems.[278] Women were given a registered product called Mastodynon, and the results were impressive. In those with amenorrhea or luteal-phase insufficiency, pregnancy occurred in the active group more than twice as often as in the placebo group, with minimal side effects.

Another study used a preparation containing *V. agnus castus* as well as other botanicals.[279] Ninety-six women with secondary amenorrhea, luteal insufficiency, or idiopathic infertility received either the *Vitex* combination or placebo over three menstrual cycles. Of these women, 15 went on to conceive (7 with amenorrhea, 4 with idiopathic infertility, and 4 with luteal insufficiency).

THERAPEUTIC APPROACH

General Measures

- Avoid exposure to free radicals.
- Identify and eliminate exposure to environmental hazards, including pesticides, solvents, heavy metals, and other toxins
- Use effective stress-reduction techniques and employ psychological counseling if needed.[280,281]
- Avoid cigarette smoking, alcohol, and recreational drugs
- Avoid douches, vaginal sprays, scented tampons, or other feminine products that change the pH of the vagina and disturb vaginal microecology.
- Ensure that weight is within a healthy body mass index (20%–25%).
- Avoid medications that affect the quality of cervical fluid, including antihistamines, some cough mixtures, dicyclomine, progesterone (taken before or at ovulation), propantheline, tamoxifen, and others.
- Avoid all personal lubricants (unless sperm-friendly types are chosen) because several studies show that some common lubricants kill sperm as effectively as contraceptive jellies do.[282–294]

Diet

- Encourage the principles of the fertility diet.
- Avoid dietary sources of free radicals, saturated fats, hydrogenated oils, trans fatty acids, and cottonseed oil.
- Increase consumption of good dietary sources of antioxidant vitamins, carotenes, and flavonoids (dark vegetables and fruits) as well as essential fatty acids (nuts and seeds).
- Follow the recommendation of daily consumption of 8 to 12 servings of vegetables and 1 to 2 servings of fresh fruits.
- Optimize protein intake from both vegetarian and organic animal sources.
- Ensure that hydration requirements are met using a 30-mL/2.2-lb (1-kg) formula to calculate requirements individually and optimize hydration and renal function.
- Eliminate caffeine, alcohol, sugar, and artificial substances (preservatives, colorings, additives). Artificial sweeteners have been found to be associated with unfavorable embryo development.[295] Sugared beverages, independent of their caffeine content, are associated with lower oocyte and embryo quality in women undergoing IVF treatment.[296]
- Encourage sufficient essential fatty acid intake in the form of half a cup of raw nuts or seeds, cold-pressed oils, and sustainably farmed fish (from organic sources).

Nutritional Supplements

Supplementation is best achieved by incorporating the repletion model (as previously discussed). A comprehensive summary of all nutrients is listed in Table 184.6; however, an individualized prescription based on a thorough assessment is advisable to accurately determine the most essential supplements required.

Botanical Medicines

Actaea racemosa (Black Cohosh)

- Fluid extract (1:2): 2 to 4 mL (0.5–1 tsp) three times daily
- Extracts equivalent to dry herbal medicine: 42.25 mg/day

Alchemilla vulgaris (Lady's Mantle)

Supplementation is best achieved by incorporating the repletion model (as previously discussed). A comprehensive summary of all nutrients is listed in Table 184.6; however, an individualized prescription based on a thorough assessment is advisable to accurately determine the most essential supplements required.

- Fluid extract (1:1): 6 to 12 mL/day

Angelica sinensis (Dang Gui)

- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp) three times a day

Asparagus racemosus (Shatavari)

- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp) three times a day

Paeonia lactiflora (White Peony)

- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp) three times a day

Tribulus terrestris (Tribulus)

- Standardized extract, equivalent to dried herb (aerial parts of leaf), standardized to contain furostanol saponins as protodioscin 12.22 mg/1 g, 9 to 36 g per day.

Vitex agnus castus (Chaste Berry)

- The usual dosage of chaste berry extract (often standardized to contain 0.5% agnuside) in tablet or capsule form is 175 to 225 mg per day. If using the liquid extract, the typical dosage is 2 to 4 mL (1/2–1 tsp) per day.

TABLE 184.6 Summary of Nutrient Considerations to Promote Fertility

Vitamin A[a]	3000–10000 IU/day
Vitamin B_1 (thiamine)	50–100 mg/day
Vitamin B_2 (riboflavin)	50 mg/day
Vitamin B_3 (niacin)	50–200 mg/day
Vitamin B_5 (pantothenic acid)	50–200 mg/day
Vitamin B_6 (pyridoxine)	50–250 mg/day
Vitamin B_9 (folate/folinic acid/L-5MTHF)	800–5000 mcg (dependent on methylation status and homocysteine levels)
Vitamin B_{12} (hydroxo-, adenosyl- or methyl-cobalamin)	800–5000 mcg (reflecting vitamin B_9 with a 1:1 ratio where possible, choice of form of B_{12} dependent on methylation status)
Vitamin C	1000–4000 mg/day in divided doses
Vitamin D3[b]	1000–10,000 IU/day pending blood levels (decrease to 1000 IU/d in summer and 2000 IU/d in winter when repleted)
Vitamin E (mixed tocopherols and tocotrienols)	500–1000 IU/day
Vitamin K[c]	2–75 mg/day
Beta carotene	10–30 mg/day
Coenzyme Q_{10}	100–800 mg/day in divided doses
Calcium	1000–1500 mg/day
Chromium[d]	100–1000 mcg/day
Copper[e]	2–4 mg/day
Iodine[f]	200–400 mcg/day (decrease to 200 mcg/day when repleted)
Iron[g]	10–100 mg/day
Magnesium	400–800 mg/day
Selenium	150–300 mcg/day
Zinc	40–80 mg/day (decrease to 25 mg/day when repleted)
Total omega-3 essential fatty acids	1000–5000 mg/day
Docosahexaenoic acid (DHA)	400–700 mg/day
Eicosapentaenoic acid (EPA)	800–1000 mg/day
Total omega-6 essential fatty acids	1000–2000 mg/day
Evening primrose oil	1000–1500 mg/day
L-Arginine	3000–10,000 mg/day
L-Carnitine	1000–4000 mg/day
Probiotics (mixed strains)	$25–50 \times 10^9$/day

[a]Retinol equivalents (REs) are now used: 1 mcg RE = 1 mcg retinol = 6 mcg beta-carotene = 12 mcg other carotenoids. Avoid during pregnancy. Ensure that prescription is based on need due to fat solubility and potential for placental transfer in second trimester. Monitor dose carefully. Alternatively, beta-carotene may be a more appropriate prescription.
[b]Prescribe based on pathology results.
[c]Consider prescription in instances of coagulation disorders. Monitor closely to ensure no drug interaction is present.
[d]Dose dependent on blood sugar level control and weight requirements. Calculate based on patient's weight.
[e]Avoid in instances of Wilson's disease (assess before prescription) and ensure that prescription is recommended only when zinc:copper ratio is considered.
[f]Assessment before prescription is essential to determine dose. Should only be conducted when thyroid function values can be reviewed.
[g]Prescription must have pathology interpretation before recommendation to determine required dosage.

Infertility, Male

Leah Hechtman, MSci (RHHG), BHSc (Nat), ND

OUTLINE

DIAGNOSTIC SUMMARY

- Inability to conceive a child after 12 months of regular unprotected intercourse (at least twice weekly) with the same female partner and in the absence of female causes
- Sperm abnormalities confirmed by two properly performed semen analyses of sperm count, morphology, motility, or other aspects

GENERAL CONSIDERATIONS

Infertility affects about 6.7 million women and their partners in the United States, which equates to approximately 11% of the reproductive-age population.[1] One out of seven couples will experience difficulty conceiving. Infertility affects men and women equally, with approximately one third of cases being due to male factors, one third to female factors, and the remaining one third to joint issues. In the United States, it is estimated that about 6% of men between the ages of 15 and 50 years are infertile.[2]

Throughout the world, there has been a recent and dramatic decline in fertility.[3] It is estimated that 48.5 million couples are affected globally, with male-factor infertility counting for about 20% to 30% of these cases. It has been calculated that least 30 million men worldwide are infertile, with the highest rates in Africa and Eastern Europe.[4] A recent review identified an overall 57% decline in mean sperm concentration over the past 35 years, with a significant decline noted in North America, Europe, Asia, and Africa.[5]

Globally there has been a decline in childbirth that appears to be unrelated to the socioeconomic status of any given country; however, deferred childbearing and improved contraception are undoubtedly major factors. Population growth is below the replacement rate in several countries—such as Sri Lanka, Denmark, and Spain—where there have been no obvious increases in abortion rates or contraceptive use. This loss of fertility has affected Denmark to the point where approximately 7% of all newborn babies are now being conceived by assisted methods.[6] In the United States, some patients will require assisted reproductive technologies (ARTs) to conceive. Statistics indicate that in vitro fertilization (IVF) and similar treatments account for less than 3% of infertility services and approximately 0.07% of U.S. health care costs.

As a general rule, it is considered that 3 out of 5 couples conceive within 6 months of trying; 1 in 4 takes between 6 months and a year. For the rest, conception takes more than a year, indicating that there may be a problem. Therefore we can define primary infertility as existing when pregnancy has never occurred despite regular unprotected intercourse for a year or more. Secondary infertility is defined as existing if, despite having achieved a pregnancy in the past (which may or may not have resulted in the birth of a child), a couple is unable to conceive again after a year or more of regular unprotected intercourse.

Unexplained infertility occurs in approximately 5% to 10% of couples trying to conceive. Generally, assessments reveal limited information and find no apparent cause for infertility. The effort to determine whether unexplained infertility is a true diagnosis is often complicated by poor investigation or the lack of current assessment strategies. The naturopath can often elucidate answers in these situations by taking a holistic view in assessing the patients and thus producing positive outcomes.

Most causes of male infertility reflect abnormal sperm counts, morphology, or motility. Although it takes only one sperm to fertilize an egg, a male ejects nearly 200 million sperm in an average ejaculate. Because of the natural barriers in the female reproductive tract, only about 40 sperm ever reach the vicinity of an egg. There is a strong correlation between the number of sperm in an ejaculate and fertility.

Fertility is a reflection of general health and well-being and can also indicate latent or undiagnosed genetic abnormalities or other etiological considerations. These considerations are many and varied; thus a comprehensive, holistic review is essential. An overview of the causes of male infertility is given in Table 185.1.

TABLE 185.1 Semen Terminology[272]

Aspermia	An absence of semen despite male orgasm
Azoospermia	A complete absence of sperm (spermatozoa) in the semen
Oligozoospermia	Reduced number of normal motile sperm cells (spermatozoa) in the ejaculate (compared with *azoospermia,* which means no sperm in the ejaculate). It includes laborious terms such as *asthenozoospermia, teratozoospermia,* and *oligoasthenoteratozoospermia*
Teratozoospermia	Sperm with abnormal morphology
Necrospermia	Death of sperm
Oligoasthenoteratozoospermia	An unnecessarily long name that indicates low count, weak motility, and abnormal morphology

- A smooth, oval head that is 5 to 6 μm long and 2.5 to 3.5 μm around (smaller than the point of a needle)
- A well-defined cap (acrosome) that covers 40% to 70% of the sperm head
- No visible defect of neck, midpiece, or tail
- No fluid droplets in the sperm head that are bigger than half of the sperm head's size[7]

If a sperm deviates from normal, it is defined by the terminology given in Table 185.1.

SPERMATOGENESIS

In healthy young men, sperm are produced by repeated divisions of cells in small, coiled tubules within the testes at an average rate of approximately 100 million per day. Each spermatogenic cycle consists of six stages, and approximately five cycles are required to produce one mature sperm. From the beginning of the division of the stem cell to the appearance of mature sperm in the semen takes between 72 and 76 days. Therefore anything that the male experiences during spermatogenesis can affect mature sperm regardless of his health at the time of examination. Factors to consider would include illness, toxicity, trauma, nutritional status, and others.

The sperm spend 2 to 10 days passing through the epididymis, during which time they mature and become capable of swimming and penetrating oocytes. At the beginning of ejaculation, sperm are transported from the tail of the epididymis via the vas deferens to the urethra. The seminal vesicles, prostate gland, and Cowper's glands secrete most of the volume of semen; these secretions help deliver the sperm during ejaculation. The volume of liquid coming from the two epididymides is less than 5% of the total semen volume. Approximately 60% of the semen volume comes from the seminal vesicles and 30% from the prostate gland. The average semen volume for healthy men ejaculating every 2 days is 3 mL; the average sperm concentration is 85 million/mL (more specifics are given later). During ejaculation, the sperm and prostatic fluid are usually ejected first, and the seminal vesicle fluid follows. The seminal vesicle fluid coagulates, giving the semen a lumpy, gel-like appearance. Liquefaction occurs after 20 minutes or so, when the gel disappears.

DIAGNOSTIC CONSIDERATIONS

Semen Analysis

In a fertility context, the semen analysis forms the primary basis of assessment. It provides the clinician with a snapshot of the male's fertility and reflects his general health in the preceding 72 to 76 days.

An individual's semen quality can vary considerably between samples, even in males with normal semen parameters. In interpreting the assessment, it is imperative that the clinician acknowledge the important fact that a diagnosis is not achieved until an abnormality is confirmed by two separate investigations. As a result, at least two and occasionally three semen analyses are needed, each several weeks apart, to gain an accurate picture of an individual's *average* semen quality. It is well recognized that sperm count can be adversely affected by illness, especially fevers, which may temporarily suppress sperm count in normal males for several months. In this case the semen analysis should, of course, be delayed. Additionally, general recommendations such as in-clinic collection (vs. at-home collection), careful consideration of laboratory guidelines (abstinence timing, lubricant usage), and the standard of the andrology laboratory facility must be considered in reviewing the results. Table 185.2 outlines the World Health Organization's (WHO's) guidelines for assessing a semen analysis.

In 2010 the WHO released updated guidelines for semen analysis. The fourth edition (released in 1999, with a review in 2003) had presented a more positive picture of male fertility. The 2010 guidelines suggest that, overall, male fertility is declining. (Note that all andrology laboratories have adopted the new guidelines. The greatest difference can be noted by reviewing morphology, owing to differing criteria and percentage scales.)

A semen analysis can be conducted by a number of assessments, including the following:

- General semen analysis (SA): To assess motility, morphology, concentration, volume, appearance, and so forth
- Sperm chromatin integrity test: To determine the level of DNA damage to sperm
- Immunobead test: To assess for antibodies against sperm
- Semen culture: To assess for infection
- Retrograde ejaculatory testing: To assess for retrograde semen flow or obstruction if semen analysis yields an extremely low count
- Trial wash: To assess sperm factors and determine whether IVF or intracytoplasmic sperm injection (ICSI) is more appropriate, conducted before IVF and/or ICSI procedures
- MESA/TESE/PESE (microsurgical epididymal sperm aspiration/testicular sperm extraction/percutaneous epididymal sperm aspiration): To extract sperm from the testicles by a specialized procedure when sperm count is low/absent or if ejaculation is not possible

Male Reproductive Assessment

A thorough assessment of the male patient is crucial to accurately determine his general and fertility health. Some of these assessments may require referral to a fertility specialist, urologist, or endocrinologist; however, thorough questioning should be conducted by the naturopath to elucidate a full history and assess causative or contributing factors. Tables 185.3 through 185.6 highlight the most relevant assessments required in a fertility workup.

THERAPEUTIC CONSIDERATIONS

When the clinician is presented with a male patient complaining of infertility, the first step is to determine whether he has been given a thorough, comprehensive assessment. Assessment results can help determine whether the issue can be effectively treated because genetic factors or overt physical impediments will require additional interventions.

- *Treatable conditions:* One in eight infertile men has a treatable condition that can be overcome so that natural conception may become possible.

TABLE 185.2 Interpretation of Semen Analysis

Semen Parameter	Lowest Reference (Reference Range)	Interpretation and Treatment Objective
Standard Components of a Semen Analysis		
Abstinence	Parameters are defined based on abstinence of 3 days.	It is essential to ensure that males ejaculate and then count the required 3 days' abstinence.
Collection method	*Optimal collection is via masturbation; however, specialized condoms can be provided for males with religious restrictions. Additionally, standard lubricants can interfere with the accuracy of the reading and must be avoided. Andrology laboratories are able to supply alternatives.*	
Specimen	Semen sample must be complete.	Incomplete samples are frequent and will distort readings. Assessment can be determined only by reviewing a full sample owing to variations in prostatic secretion vs. epididymal involvement.
Analysis time	*Sample must be analyzed within 60 min and is best collected in the clinic environment to prevent complications.*	
Appearance	Nil debris, nil clumping, or viscosity changes, liquefaction complete.	Debris, clumping, viscosity, or liquefaction issues can suggest systemic congestion, poor hydration, poor elimination, or immune reactions (clumping especially). It can also indicate poor ejaculation frequency.
pH	>7.2 (7.2–7.8)	pH control is essential for sperm survival. An abnormally high or low semen pH can kill sperm or affect their ability to move or to penetrate an egg. The pH of the sample will be affected if there was a delay between sample collection and analysis. If the pH is <7.0 and the sample is azoospermic, there may be an obstruction of the ejaculatory ducts or congenital bilateral absence of the vas deferens (CBAVD). pH irregularities can relate to dietary intake and hydration level. Very acidic samples can indicate obstruction and require referral.
Volume	>1.5 mL (1.4–1.7 mL)	Volume can be affected by the period of abstinence (3 days are recommended), incomplete ejaculation, and retrograde ejaculation. It generally indicates dehydration; treatment should consist of hydration calculation based on weight and energy expenditure.
Concentration		
Sperm concentration Total sperm count	> 15 million/mL (12–16 million/mL) >39 million per ejaculate (33–46 million per ejaculate)	Concentration can be affected by a number of factors, including: • Incomplete collection of the sample • Health status of the individual • Obstruction • Genetic condition The finding of no sperm in the ejaculate suggests either an absence of sperm production or obstruction to sperm outflow. It is most important that an azoospermic semen sample be spun down to carefully examine whether the ejaculate contains even a few sperm. The naturopathic approach considers defects in internal processes and hormonal pathways as potential hindrances to an optimal count. Nutritional deficiencies are essential, and interferences with pathways for spermatogenesis require exploration.
Motility		
Total motility	40% (38%–42%) (>25% rapid, >40% progressive, >50% motile)	Sperm must be able to move forward (or "swim") through cervical mucus to reach an egg. A high percentage of sperm that cannot swim properly may impair a man's ability to father a child.
Progressive rating	>3	There are other important conditions that predominantly affect sperm motility, such as sperm autoimmunity, a condition that accounts for about 6% of male infertility. No movement (immotile sperm) may be due to structural problems in the sperm's tail or to death of sperm.
Progressive motility	>32% (31%–34%) with forward movement	
Vitality	>58% (55%–63%) live	The percentage of sperm that are alive (sperm vitality) is noted because this declines in association with genital tract infections and disorders of sperm transport through the genital tract. The proportion of live sperm is assessed if total motility is <50%. Low motility and high vitality could indicate a disturbance of the motility apparatus. If >75% of sperm are dead, immobilizing antisperm antibodies might be present, and testing is encouraged. Poor motility can often indicate autoimmune processes; infection; lack of mitochondrial energy to propel the sperm; or medication, alcohol or other toxins that affect semen quality.

Continued

TABLE 185.2 Interpretation of Semen Analysis—cont'd

Morphology		
Sperm morphology	4% (3%–4%) normal forms (Tygerberg criteria) Note: A trial wash can provide specificities of morphological abnormalities (i.e., head, neck, tail).	Sperm shape is an important predictive indicator of the sperm's fertilizing ability. Morphology is performed on Pap-stained sperm using the Strict Tygerburg criteria of assessment. These criteria have a strong correlation with the presence of abnormalities and clinical pregnancies and accept only sperm that are normal in every way. Morphology is often a direct reflection of generalized toxicity because semen is a by-product of the body and is a major eliminatory channel. Detoxification, avoidance of environmental toxins, and immaculate dietary practices are essential. Key nutrients in sperm structure must be considered, including protein, essential fatty acids (DHA), all antioxidants including coenzyme Q_{10}, zinc, vitamins C and E, and selenium.
Teratozoospermia index (TZI)	<1.64 TZI	
Specialized Additions to a Semen Analysis		
Immune Factors		
Peroxidase-positive leukocytes	<1.0 million/mL	The presence of white blood cells or bacteria indicates the presence of a genitourinary infection.
Semen culture	Negative	Ascertaining the type of infection is the primary objective, with subsequent targeted treatment to eradicate it. It is essential to assess the female partner to prevent cross-infection.
Mixed antiglobulin reaction (MAR) test (motile sperm with bound particles)	<50%	Antibodies attach to the surface of the sperm and reduce their life span, impairing their motility and ability to penetrate the partner's cervical mucus. Antibodies located on the sperm head may prevent the sperm from fertilizing the egg.
Immunobead test (motile spermatozoa with bound beads)	<50% sperm with adherent particles	Abstinence or a barrier method until the immune system is regulated is essential, along with concurrent autoimmune treatment with herbal medicines, dietary modifications, lifestyle modifications, and nutritional supplementation.
GAM or isotype	>20% positive >50% pathologically significant (except tail tip binding)	
Sperm DNA Damage		
SCIT (sperm chromatin integrity test)	DNA Fragmentation Index (DFI): Excellent DNA integrity (<15%) Good DNA integrity (15%–24%) Fair DNA integrity (25%–29%) Poor DNA integrity (>29%) High green stain (HG): Normal (<15%) Abnormal (15%–100%)	Various methods have been developed to measure strand breaks in sperm DNA in situ. Currently, there are four major tests of sperm DNA fragmentation, including the Comet, Tunel, SCIT, and the acridine orange test (AOT). DNA fragmentation can be attributed to various pathological conditions including cryptorchidism, cancer, varicocele, fever, age, infection, leukocytospermia, and others. Many environmental conditions can also affect DNA fragmentation, such as chemotherapy, radiation, prescribed medicines, air pollution, smoking, pesticides, chemicals, heat, and assisted reproductive technology (ART preparation protocols. Research indicates that sperm with high levels of DNA fragmentation have a lower probability of producing a successful pregnancy. Samples with a DNA fragmentation level greater than 29% are likely to have significantly reduced fertility potential, including a significant reduction in term pregnancies and an increased miscarriage rate. Sperm that appears to be normal by traditional semen analysis parameters may have extensive DNA fragmentation. It is normal for up to 1:5 sperm (20%) to have some DNA fragmentation. Mature sperm are protected from damage because 85% of the chromosomes are bound by protamines into a condensed, compact structure. If more than 20% of sperm have DNA damage, there is an increased risk of infertility, poor oocyte fertilization, defective/impaired embryo development, increased probability of implantation failure, miscarriage, and recurrent miscarriage (up to 3–4 times higher) and disease or childhood cancer in the next generation. Reasons for testing include unexplained infertility, low fertility rates, poor embryo quality, implantation failure after in vitro fertilization (IVF), recurrent miscarriage, exposure to environmental toxins, abnormal semen analysis, and in males above 45 years of age.

TABLE 185.2 Interpretation of Semen Analysis—cont'd

		Once male germ cells have completed meiosis, they lose their capacity for DNA repair, discard their cytoplasm (containing the defensive enzymes that protect most cell types from oxidative stress), and eventually become separated from the Sertoli cells that have nursed and protected them throughout their differentiation into spermatozoa. In this isolated state, spermatozoa must spend a week or so journeying through the male reproductive tract and, uniquely in our species, a further period (up to 3 or 4 days) in the female tract waiting for an egg. During this period of isolation, sperm DNA is vulnerable to damage by both xenobiotics and electromagnetic radiation. Such DNA damage is associated with male infertility; its aberrant repair in the fertilized egg may result in mutations in the embryo with the potential to either induce abortion or impair the health and fertility of the offspring. Treatment consists of environmental review and modification as well as exceptionally high doses of antioxidant prescription.
Other		
Seminal zinc	>2.4 mol per ejaculate	Low levels suggest that supplementation is required.
Seminal fructose	>13 mol per ejaculate	Normal levels are 300 mg/100 mL ejaculate. Absence may indicate that the man was born without seminal vesicles or may have a blockage of seminal vesicles. Referral is essential for further investigation.
Seminal neutral glucosidase	>20 mU per ejaculate	Alpha-glucosidase is a normal constituent of human semen produced mainly in the epididymis. It is significantly correlated with sperm count. Its activity is low in cases of epididymal obstruction.

Data from World Health Organization. *WHO Laboratory Manual for the Examination and Processing of Human Semen,* 5th ed. Geneva, Switzerland: WHO; 2010, cited in Hechtman L. *Clinical Naturopathic Medicine*. Chatswood, Australia: Elsevier Australia, 2018.

- *Untreatable subfertility:* Three quarters of infertile men have sperm present in the semen, but in lower numbers than normal. In these cases, the problem cannot be solved without intervention. These men are often defined as subfertile because pregnancies may occur but at lower rates than usual. On average, more months of trying are needed to achieve conception, or conception may simply not occur. After naturopathic intervention, it may be possible to address infertility factors or, alternatively, offer a referral for ARTs/IVF.
- *Untreatable male sterility:* About one in nine infertile men has no sperm in his semen or testes and cannot be treated. Sperm-producing cells in the testes either have not developed or have been irreversibly destroyed. Adoption or donor insemination are the only possibilities for couples in this group who wish to have families.

In treating males for infertility, the optimal approach is to adopt a preconception program for both prospective parents. Preconception treatment adheres to the philosophy that the final stages of gamete production can be modified and influenced. The final stages of spermatogenesis last between 72 and 76 days. By influencing the environment to which sperm are exposed and optimizing the general well-being of the host, practitioners may be able to influence sperm development positively and to address and deal with related health concerns.

Of importance, acknowledging and addressing nutritional status throughout this developmental stage can significantly influence the prospective outcome. The concept of nutrient repletion is highly applicable within a fertility context. Optimal fertility is best achieved when prime health is realized. The repletion model indicates that prescriptions are required for a minimum of 3 months to properly address any deficiencies present and to ensure that all nutrients are used within each required pathway in the body. For example, zinc is involved in hundreds of pathways, including those that affect reproductive health and function. To rectify all possible deficiencies, sufficient zinc supplementation at a repletion dose (typically higher than in general prescriptions) for an extended time (at least 3 months) can enable optimal correction. At lower doses or doses of insufficient duration, zinc treatment may address only those health concerns that have the highest priority (i.e., immune function vs. sperm production).

Within the naturopathic framework, it is crucial to naturally support and attenuate all coexisting health conditions. Therefore treatment should be structured to acknowledge all health concerns; that is, to optimize the general health of the male patient as an underlying position.

Finally, it is always important to acknowledge that the most favorable fertility occurs when the individual's health is optimal. The body is primed to pass on genetic material only when the environment and other conditions are at their best. If survival from an evolutionary perspective is compromised, fertility will be hindered. Everything a person eats, drinks, experiences, or is exposed to can and will influence fertility. True naturopathic supports of fertility acknowledge and consider absolutely all variables of holistic health. Couples should be encouraged to participate in treatment for 3 to 4 months to properly address all genetic and epigenetic variables affecting the gamete.

Improving Sperm-Controlling and Sperm-Damaging Factors

The first step in improving sperm counts, morphology, and function is controlling factors that can damage or impair sperm formation. These include the following:

- Scrotal temperature
- Estrogen and xenoestrogen exposure
- Heavy metals
- Radiation
- Cigarettes, alcohol, and illicit drugs
- Obesity
- Infection
- Diabetes

TABLE 185.3 Fertility Inquiry

Assessment	Elaboration and Explanation
Age	What ages are the couple?
Fertility history	How long have they been trying to conceive, and have they ever conceived previously (together/separately)? Do they have any idea why they have not been able to conceive?
Sexual history	Sexually transmitted infection (STI) screen: Potential sexually transmitted disease exposure, symptoms of genital inflammation (e.g., urethral discharge, dysuria)
Medication history	Such as sulfasalazine (Azulfidine), methotrexate, colchicine, cimetidine (Tagamet), spironolactone (Aldactone), proton-pump inhibitors
Surgical history	Such as previous genitourinary surgery
Contraception	When it was ceased and the likely speed of its reversibility
Fertile times	Whether the couple engage in regular intercourse during fertile times
Lifestyle factors	Diet, exercise, alcohol, smoking cessation, recreational drug use, environmental toxin screen
Prior paternity	Previous fertility
Psychosexual issues (erectile, ejaculatory)	Interference with conception
Pubertal development	Poor progression suggests underlying reproductive issue
A history of undescended testes	Risk factor for infertility and testicular cancer
Previous genital infection (STI) or trauma	Risk of testis damage or obstructive azoospermia
Symptoms of androgen deficiency	Indicative of hypogonadism
Previous inguinal, genital, or pelvic surgery	Testicular vascular impairments, damage to vasa, ejaculatory ducts, ejaculation mechanisms
Medications, drug use	Transient or permanent damage to spermatogenesis
General health (diet, exercise, smoking)	General health screen

Modified from Hechtman L. *Clinical Naturopathic Medicine*. Chatswood, Australia: Elsevier Australia; 2018.

Scrotal Temperature

The scrotal sac normally keeps the testes at a temperature of between 94°F and 96°F. At temperatures above 96°F, sperm production is greatly inhibited or stopped completely. Heat stress modifies gene expression in the testes, causing impaired spermatogenesis. Sperm cells, being extremely vulnerable, respond by apoptosis and DNA damage.[8] Typically, the mean scrotal temperature of infertile men is significantly higher than that of fertile men. A reduction in the scrotal temperature in infertile men is often enough to make them fertile. This is best achieved by having them avoid tight-fitting underwear, tight jeans, and hot tubs.

In addition, the following exercise or exercise equipment can raise scrotal temperature, especially if a man is wearing synthetic fabrics, exceptionally tight shorts, or tight bikini underwear: rowing machines, simulated cross-country ski machines, treadmills, and jogging. After exercising, a man should allow his testicles to hang free to allow them to recover from heat buildup.

TABLE 185.4 Physical Examination

Assessment	Elaboration and Explanation
General examination	Acute/chronic illness, nutritional status
Genital examination	Assess for varicocele, testicular size, and other genital factors Testes: Small testes suggest spermatogenic failure Presence of vas deferens: may be congenitally absent Epididymides: thickening or cysts may suggest previous infection and resultant obstructive problems Varicoceles: detected when standing, coughing, or performing Valsalva maneuver Penis: assessed for abnormalities (e.g., Peyronie's disease) that may interfere with intercourse
Degree of virilization assessment	Assess for signs of virility Signs of androgen deficiency (e.g., increased body fat, decreased muscle mass, decreased facial and body hair, small testes, Tanner stage <5)
Prostate examination	Assess if history suggests prostatitis or a sexually transmitted infection

Modified from Hechtman L. *Clinical Naturopathic Medicine*. Chatswood, Australia: Elsevier Australia; 2018.

TABLE 185.5 Endocrinological Assessments

Assessment	Justification for Assessment
Follicle-stimulating hormone (FSH)	Assessment to ensure that hormonal status is optimal to eliminate hormonal abnormalities
Progesterone (P4)	Testosterone
Prolactin (PRL)	Testosterone is often normal (8–27 nmol/L) even in men with significant spermatogenic defects. Some men with severe testicular problems display a fall in testosterone levels and a rise in serum LH. These men should undergo evaluation for androgen deficiency. The finding of low serum testosterone and low LH suggests a hypothalamic–pituitary problem (e.g., prolactinoma; serum prolactin levels required).
Luteinizing hormone (LH)	FSH Elevated levels are seen when spermatogenesis is poor (primary in testicular failure); in normal men, the upper reference value is approximately 8 IU/L. In azoospermic men, 14 IU/L strongly suggests spermatogenic failure, 5 IU/L suggests obstructive azoospermia; a testis biopsy may be required to confirm that diagnosis.
Total testosterone, free testosterone	
Sex hormone–binding globulin (SHBG)	Evaluates if concentration of SHBG is affecting the amount of testosterone available to body tissues.
Dehydroepiandrosterone sulfate (DHEA-S), cortisol	Additional hormone levels should be reviewed on an individual basis, including a full adrenal profile if the effect of stress is considered relevant.

Modified from Hechtman L. *Clinical Naturopathic Medicine*. Chatswood, Australia: Elsevier Australia; 2018.

TABLE 185.6 Other Assessments

Assessment	Justification
General Health Assessments	
FBC, blood type	General health assessments to eliminate other abnormalities
Standard blood chemistries	
25[OH]D3	
Fasting glucose	
Cholesterol profile	
General sexually transmitted infection (STI) screen	
TSH and urinary iodine (24-hour or morning spot)	Query thyroid function and iodine status
Urinalysis/swab	
Infection screen	General urinalysis to eliminate underlying infection or abnormality. Urogenital infections have been found to play a part in the genesis of miscarriage and infertility. Most patients are unaware of their presence owing to the asymptomatic nature of these infections. The most common infections that require screening include *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, and Neisseria gonorrhoeae.*
Advanced Fertility Assessments	
Karyotyping and subsequent genetic testing	Advanced fertility assessments if previous results show no abnormality or if infertility remains unexplained. WHO guidelines suggest that peripheral blood karyotyping analysis can be diagnostically helpful. Abnormal genotype may be present in up to 12% of azoospermic men and 4% of oligospermic men. Cystic fibrosis screening is recommended for azoospermia if due to CBAVD. Optional screening for Y-chromosome microdeletion if sperm count is <5 million/mL.
Scrotal (testicular) ultrasonography	History of undescended testes or concern regarding testicular cancer.
Transrectal ultrasonography	If ejaculatory duct obstruction suspected.
MTHFR C677T/*MTHFR* 1298C	Indicated in instances of miscarriage, unexplained infertility, marked sperm abnormalities, or implantation issues.
Prothrombin G20210A	
Factor V Leiden	
Selenium assay	
Fasting homocysteine	
Other Considerations	
Nutrient and toxic element screening	Assessments of toxic elements, including aluminum, arsenic, cadmium, lead, and mercury, are crucial so as to eliminate them as causative or contributing factors. It is widely accepted that excessive exposure to heavy metals has a detrimental effect on fertility and must therefore be assessed and remedied during the preconception period. Pre- and post-chelation challenge testing is advisable for more definitive assessment.
Environmental effect	Other environmental assessments, including those that assess porphyrins, PCBs, chlorinated pesticides, volatile solvents, phthalates, parabens, and other toxins. These should additionally be considered due to their deranging effects on reproductive function, endocrinology, gamete development, and thus embryological potential.
Methylation profile and methylation genetics	Methylation defects are strongly associated with changes to sperm parameters.

CBAVD, Congenital bilateral absence of the vas deferens; *FBC,* full blood count; *PCB,* polychlorinated biphenyl; *TSH,* thyroid-stimulating hormone; *WHO,* World Health Organization.
Modified from Hechtman L. *Clinical Naturopathic Medicine.* Chatswood, Australia: Elsevier Australia; 2018.

Infertile men should wear boxer-type underwear and periodically apply a cold shower or ice to the scrotum. They can also choose to use a device called a testicular hypothermia device or "testicle cooler" to reduce scrotal temperatures. The testicle cooler looks like a jockstrap from which long, thin tubes have been extended. The tubes are attached to a small fluid reservoir filled with cold water that attaches to a belt around the waist. The fluid reservoir is also a pump that causes the water to circulate. When the water reaches the surface of the scrotum, it evaporates and keeps the scrotum cool. Because of evaporation, the reservoir must be filled every 6 hours or so. It is recommended that the testicle cooler be worn daily during waking hours. Most users claim that it is fairly comfortable and easy to conceal.[9]

Increased scrotal temperature can be due to the presence of a varicocele. A large varicocele can lead to scrotal temperatures high enough to inhibit sperm production and motility. Surgical repair may be necessary, but scrotal cooling should be tried first.

Estrogen and Xenoestrogen Exposure

According to experts on the effect of the environment and diet on fetal development, we now live in an environment that can be viewed as "a virtual sea of estrogens."[10,11] Increased exposure to environmental

BOX 185.1 Compounds That Exert Estrogenic Activity

- Alkylphenols (intermediate chemicals used in the manufacture of other chemicals)
- Atrazine (weed killer)
- 4-Methylbenzylidene camphor (4-MBC; sunscreen lotions)
- Butylated hydroxyanisole (BHA; food preservative)
- Bisphenol A (monomer for polycarbonate plastic and epoxy resin; antioxidant in plasticizers)
- Dichlorodiphenyldichloroethylene (one of the breakdown products of DDT)
- Dieldrin (banned insecticide)
- DDT (banned insecticide)
- Endosulfan (widely banned insecticide)
- Erythrosine, FD&C Red No. 3
- Ethinylestradiol (released into the environment as a xenoestrogen)
- Heptachlor (restricted insecticide)
- Lindane, hexachlorocyclohexane (restricted insecticide)
- Metalloestrogens (a class of inorganic xenoestrogens)
- Methoxychlor (banned insecticide)
- Nonylphenol and derivatives (industrial surfactants; emulsifiers for emulsion polymerization; laboratory detergents; pesticides)
- Pentachlorophenol (restricted general biocide and wood preservative)
- Polychlorinated biphenyls (PCBs; banned; formerly used in electrical oils, lubricants, adhesives, paints)
- Parabens (lotions)
- Phenosulfothiazine (a red dye)
- Phthalates (plasticizers)
- DEHP (plasticizer for polyvinyl chloride [PVC])
- Propyl gallate (used to protect oils and fats in products from oxidation)

estrogens and other environmental pollutants during fetal development as well as during the reproductive years is suggested to be a major cause of the tremendous rise in the incidence of disorders of development and function of the male sexual system[12] (Box 185.1).

One can best view the relationship between estrogens and male sexual development by examining the effects of the synthetic estrogen diethylstilbestrol (DES). Between 1945 and 1971, several million women were treated with DES. By 1970, the side effects of DES became better known. DES is now recognized to have led to substantial increases in the number of men suffering from developmental problems of the reproductive tract as well as decreased semen volume and sperm count.[10] Apart from having been used in humans, DES and other synthetic estrogens were used for 20 to 30 years in the livestock industry to fatten the animals and make them grow faster.

Although most synthetic estrogens like DES are now outlawed, many animals, both livestock and poultry, are still hormonally manipulated, especially dairy cows. Cow's milk contains substantial amounts of estrogen because of modern farming techniques. The rise in dairy consumption since the 1940s inversely parallels the drop in sperm counts. Avoidance of hormone-fed animal products, including milk products, is important for male sexual vitality, especially in men with low sperm counts or low testosterone levels.

There are reports that estrogens have been detected in drinking water.[11,13] Presumably they are recycled from excreted synthetic estrogens (birth control pills) at water treatment plants. These estrogens may be harmful to male sexual vitality because they are more potent—they do not bind to sex hormone–binding globulin (SHBG). Purified or spring water may be a suitable option to prevent exposure. It is also important to ensure that bottled water is avoided owing to the bisphenol A content of plastic bottles.

Other sources of estrogen in the environment (food, water, and air) can weaken male sexual vitality. For example, many of the chemicals with which we have contaminated our environment in the past 50 years are weakly estrogenic. Most of these chemicals, like polychlorinated biphenyls (PCBs), dioxin, and dichlorodiphenyltrichloroethane (DDT), are resistant to biodegradation and are recycled in our environment until they find a safe haven in our bodies. For example, even though DDT has been banned for nearly 30 years, it is still often found in the soil and in root vegetables such as carrots and potatoes. These toxic chemicals are known to interfere with spermatogenesis, but their effects during sexual development may be even more important.

All of the estrogenic factors previously discussed are thought to have their greatest effect during fetal development. On the basis of animal studies, these estrogens inhibit the multiplication of the Sertoli cells. The number of Sertoli cells is directly proportional to the number of sperm that can be produced because each Sertoli cell can support only a fixed number of germ cells that will develop into sperm. Sertoli cell multiplication occurs primarily during fetal life and before puberty and is controlled by follicle-stimulating hormone (FSH). In animal studies, estrogens administered early in life have been found to inhibit FSH secretion, resulting in a reduced number of Sertoli cells and, in adult life, diminished sperm counts.

One example of the impairment of male sexual development by environmental estrogens is the ability of vinclozolin, a fungicide used in the wine industry, to disrupt the fertility of male rats.[14] Alarmingly, just one exposure of a pregnant female rat to this fungicide was found to disrupt spermatogenesis in more than 90% of the male offspring for at least four generations via an effect exclusively transmitted through the male germline.

Environmental toxins are also linked to increasing testicular cancer rates, testicular dysgenesis syndrome (TDS), cryptorchidism, and hypospadias.[6,15] Whether the outcome is impaired spermatogenesis, TDS, testicular cancer, or any other disturbance may depend on the timing and nature of the xenobiotic attack and the genetic background on which these factors are acting. As such, a determination of the outcome will have to take into account the patient's polymorphism profile for proteins involved in detoxification, such as the cytochrome P450s and glutathione-*S*-transferases. The bottom line is that the environmental effect on spermatogenesis cannot be underestimated. Industrial growth since the end of World War II has introduced many complex chemicals into the environment that are novel to biological detoxification systems. Some of these molecules are reproductive toxicants, capable of impairing fertility and inducing developmental abnormalities in the embryo, including errors in normal sexual differentiation.

The power of reproductive toxicants that target the germline lies in their capacity to generate damage that can be passed down the generations via genetic or epigenetic means. A prime example is the effect of paternal smoking. Men who smoke heavily generate spermatozoa that may have high levels of DNA damage, largely as a result of oxidative stress. One of the consequences of this DNA damage is that the children of such men exhibit an increased incidence of childhood cancer.[16] Although we have traditionally focused on the ability of cigarette smoke to induce lung cancer, a far more sinister effect is its ability to induce DNA damage in the germline and thereby influence the health and well-being of future generations.

It is therefore advisable to discourage exposure to cigarette smoke in all male fertility patients and, in those with suspected heavy exposure, to initiate further investigations and specialized treatments to chelate and support detoxification.

Exposure Route

Environmental toxins may exert their genetic or epigenetic effects on the germline via several potential routes of exposure:

1. Women may be exposed to xenobiotics during pregnancy, thereby disrupting the normal differentiation of the germline in the fetus.
2. Women exposed to toxicants may transmit xenobiotics to their offspring via breast milk.
3. Because of acquired toxicity, men may contribute adverse effects on the integrity of DNA in the male germline. Toxicological studies in animal models reporting infertility, abortion, and birth defects as a result of male exposure to xenobiotics demonstrate that such associations are possible.[17] Epidemiological studies suggest that they are clinically significant.[6,15]

For a full discussion of potential environmental effects, see Chapter 35, Environmental Medicine.

Assessment

It is advisable to thoroughly assess all presenting patients for exposure to environmental toxins and, depending on the results, to offer appropriate treatment. Specific areas to consider include the following:

1. Full occupational exposure review
2. Nonoccupational exposure
   - The area in which the couple lives
   - Age of the couple's home
   - Ages of carpet, floor coverings, floorboards
   - Renovations—when, what, and how
   - Type of heating/air conditioning
   - Use of indoor or outdoor pesticides
   - Attached garage
   - Blinds, curtains
   - Cleaning products
   - Pool/spa/sauna
   - Pets—type, medicines, foods
   - Food sources
   - Water source
   - Prescription drugs
   - Others

It is best to recommend the avoidance of other exposures, such as those from renovation materials, cleaning products, personal toiletries, new furniture, new carpet or cabinets, plastics, gas, chemical gases, and many others. Organic, environmentally sound, sustainable practices are generally the safest.

For men who work in occupations that may affect fertility, it is important to wear protective clothing and follow all occupational health and safety guidelines.

Persistent organic pollutants, phthalates, and PCB serum levels in males have been associated with reductions of up to 30% in fecundity in couples trying to conceive.[18] An unexpected source of exposure to phthalates is via prescription medications, where phthalates and polymers are used as excipients to enable the timed release of active ingredients. A recent Danish case-control study included more than 18,500 males with poor semen quality, and more than 31,000 controls, from the Danish IVF Register over a 10-year period. Exposure to medicinal products containing ortho-phthalates and/or polymers within 90 days of testing was associated with a 30% and 71% increased risk of poor semen quality, respectively. The highest association was found in exposure to polymers from bisacodyl and sulfasalazine, alimentary tract and metabolism drugs.[19]

Heavy Metals

Sperm are also particularly susceptible to the damaging effects of heavy metals such as lead, cadmium, arsenic, and mercury.[12,20,21] The results of a recent meta-analysis of 20 case-control studies indicate that men with low fertility have higher semen levels of lead and cadmium and lower semen zinc levels. Lead and cadmium have a direct toxic effect on the testis and also inhibit the formation of sperm and induce sperm morphology changes, leading to a decline in the quality and quantity of semen.[22] A hair mineral analysis for heavy metals should be performed on all men with reduced sperm counts to rule out heavy metals as a cause.

Radiation

Cell phones operate at 400- and 2000-MHz frequency bands and emit radiofrequency electromagnetic waves (EMWs).[23] Cordless phones must be considered in this context as well; these use the 900-MHz, 1.9-GHz, 2.4-GHz, and 5.8-GHz bands. Reports of potential adverse effects of radiofrequency EMWs on the brain, heart, endocrine system, and DNA in humans and animals are commonly found in the literature. Specifically, from a fertility context, they have also been implicated in DNA strand breaks.[24] The relationship between cell phone use and male infertility remains unclear. Harmful EMWs emitted from cell phones may interfere with normal spermatogenesis and result in a significant decrease in sperm quality. Specific findings pertaining to sperm motility in humans have also been noted.[25,26]

In one observational study,[27] the use of cell phones decreased semen quality by decreasing the sperm count as well as the sperms' motility, viability, and normal morphology. This decrease in sperm parameters was dependent on the duration of daily exposure to cell phones and independent of initial semen quality. Of greatest importance was that sperm count, viability, and morphology declined as cell phone use increased. Specifically, the use of a cell phone for more than 4 hours a day caused a 25% drop in the number of sperm produced, and only 20% of these looked normal. These results were not supported in a longitudinal cohort study of 153 men attending a fertility clinic. Results were inconsistent between different patterns of cell-phone usage, and overall, no evidence was found for a relationship between cell phone use and semen quality.[28]

By comparison, a retrospective analysis of 468 men at a fertility clinic found that cell-phone storage in trouser pockets had an effect on sperm morphology and luteinizing hormone (LH) levels. Cell-phone storage in pockets was also significantly associated with increased varicocele, which in turn have an effect on sperm concentration and testosterone levels.[29] A 2014 meta-analysis reported a statistically significant decrease in sperm motility with mobile phone use, but no relationship with sperm concentration.[30] A second meta-analysis reported that mobile-phone use in epidemiological studies was not related to semen volume, motility, sperm concentration, or normal morphology. However, mobile-phone EMW was related to significant decreases in sperm motility in in vitro studies as well as decreases in motility and concentration in animal studies.[31] The authors of both of these meta-analyses, despite inconsistent results from a small of number studies, concluded that mobile-phone use may negatively affect semen quality. Studies have also shown a negative correlation between wireless Internet usage duration and the total sperm count. Wi-Fi was shown to have a more destructive effect than cell-phone use.[32] A recent in vitro study found that the effects of EMWs emitted from 3G+ Wi-Fi modems cause a significant decrease in sperm motility and velocity.[33]

It is therefore prudent to encourage limiting Wi-Fi use and exposure and discourage cell-phone use. It is recommended that male patients refrain as much as possible from storing cell phones in their pockets, owing to increased genital exposure to the frequency bands.

Cigarettes, Alcohol, Caffeine, and Illicit Drugs

Lifestyle exposures, including cigarette smoke, alcohol, and caffeine, have all been studied in relation to male reproductive health. Over the years, the focus has primarily been on semen quality and/or fertility.

More recently, the literature evaluating direct adverse effects of lifestyle exposures on sperm, chromosomes, and chromatin has grown because of concern that induced damage could be transmitted to offspring, causing transgenerational health effects.

Cigarette smoking. A common source of oxidants is cigarette smoking, which is associated with decreased sperm counts and sperm motility as well as a higher frequency of abnormal sperm.[34] Cigarette smoking, as well as the increase in environmental pollution, is thought to be a major contributor to the diminution in sperm counts seen in many industrialized nations over the past few decades.

Although passive and active smoking are known to lead to a number of health concerns, male patients are often complacent about its effect. However, heavy smokers have been shown to produce more than 20% less sperm. Tobacco smoke contains high levels of reactive oxygen species (ROS), which cause DNA damage. The cadmium, lead, and nicotine in cigarettes also cause DNA strand breaks.[35] Cigarette smoking accelerates DNA damage of the sperm, and smoking cessation is the quickest treatment strategy to reverse such damage and thus affect sperm morphology parameters positively. Stopping smoking for 3 months allows sperm quality to improve.[36]

When the sperm enters the oocyte during conception, the mRNA within the oocyte attempts to defragment the DNA and provide antioxidant support so as to improve sperm quality. It is important to note that the improvements to sperm occur before any oocyte maintenance. It is only once the sperm has been positively addressed that the mRNA and any antioxidant potential within the oocyte can address any oocyte deficiency, oxidative process, or DNA (or chromosomal) abnormality. When the male partner is a heavy smoker, it often means that there are simply insufficient reserves to repair the damage for both gametes; as a result, the oocyte fails, causing either fertilization deficits, a lack of implantation, or abnormalities in the embryo, thus initiating an early miscarriage or negative effects on the long-term health and fertility of the subsequent child.[37] The female's surveillance does not typically allow the compromised embryo to grow beyond early miscarriage because the chance of a healthy birth is then unlikely. Therefore this highly pertinent clinical discussion can motivate most male patients to take responsibility for their oxidative processes and commit to smoking cessation.

A systematic Cochrane review found that in *both* fertile and infertile populations, active and passive smoking are associated with reduced fertility and a decreased chance of producing a healthy, live infant. In males, cigarette smoking has been observed to impair sperm respiration, thus affecting the sperms' mitochondrial function[38] as well as causing a reduction in sperm motility and semen quality.[39] Reproductive hormone system disorders, dysfunction of spermatogenesis and the sperm maturation process, and impaired spermatozoa function have been observed in smokers. Tobacco smoking leads to reduced semen quality, including semen volume, sperm density, motility, viability, DNA fragmentation, seminal zinc levels, and normal morphology. The effects are directly correlated with cigarette quantity and duration of smoking.[40,41] A systematic review and meta-analysis (n = 5865 men) on the effects of cigarette smoking suggested an overall negative effect on semen parameters. An association was seen with reduced sperm count and motility, and the effect is greater in moderate and heavy smokers.[42]

It is therefore strongly recommended that all males cease both passive and active smoking for at least the preconception period and ideally beyond it.

Alcohol intake. Excessive alcohol consumption in men is strongly associated with diminished sperm function; however, there is a scarcity of comprehensive research in this area. The limited available data suggest that moderate or occasional alcohol intake does not affect semen quality as do regular high levels of consumption.[43–45]

A review of the literature in 2013 suggests that alcohol consumption alters sperm parameters (most commonly morphologically abnormal spermatozoa) and testicular pathology. It is noted that genetic factors, as well as nutritional deficiencies, may modulate the effect of alcohol on spermatogenesis.[43]

More recently, a cross-sectional study of 8344 healthy men in Europe and the United States found that moderate alcohol intake was not associated with a reduction in semen quality. However, this study only looked at alcohol consumed the week before the semen testing, which does not account for the long-term effects of alcohol consumption.[44] Another study of 347 men investigating the effect of the last 5 days' worth of alcohol intake found that alcohol intake was associated with impairment of most semen characteristics. There was a tendency toward lower semen parameters with higher intake of alcohol, but no statistically significant dose-response association was found.[45] Without further rigorous studies, the best available evidence suggests that alcohol intake and fertility are linked only with high levels of consumption (more than 8 drinks per week, or more than 40 g alcohol per day, depending on the study).[46]

A recent review of 15 cross-sectional studies has shown a detrimental effect of alcohol consumption on semen volume and morphology, mainly in daily, not occasional, consumers. This suggests that moderate consumption of alcohol should not adversely affect semen quality parameter.[47] As with smoking, abstaining from alcohol reverses semen parameter damage. A case report of a 6-year follow-up of a male patient showed that stopping alcohol consumption led to a rapid, dramatic improvement in semen characteristics. Normal semen parameters were observed after 3 months.[48]

From a naturopathic viewpoint, however, it is important to encourage avoidance for a number of reasons, including effects on the liver and detoxification as well as on endocrinology (especially estrogen pathways), calorie consumption, hyperglycemic effects, and others. It is prudent to recommend alcohol avoidance in the preconception period so as to ensure optimal functioning of the male body and subsequent positive effects on sperm parameters. It is of prime importance to recommend abstinence from binge drinking and regular heavy drinking.

Caffeine. High dosages of caffeine have been shown in vitro to increase protein oxidative damage in Sertoli cells, but moderate caffeine intake appears to be safe in male reproductive health. Although caffeine intake boosts semen volume, it also lowers the concentration.[49,50] Caffeine intake of less than 800 mg/day does not appear to affect motility, morphology, or DNA fragmentation.[51]

A recent systematic review of the relationship between caffeine and parameters of male fertility found that caffeine intake may negatively affect male reproductive function; however, the data to date are inconsistent and inconclusive.[52] An observational study on the effects of caffeine and alcohol on men at a fertility clinic found no association between caffeine or alcohol intake on semen parameters; however, pretreatment caffeine and alcohol intake did affect live birth outcome after infertility treatment with ART. Caffeine intake was associated with a lower probability of achieving live birth; however, alcohol intake was related to a higher probability of live birth. Alcohol intake was assessed on reported drinking habits over 1 year; therefore the effect of acute alcohol intake preceding ART was not assessed.[53]

Marijuana and other recreational drugs. The effects of marijuana and other recreational drugs are difficult to determine because their use is illegal; however, the illicit drugs that have been found to adversely affect male fertility are marijuana, opioid narcotics, methamphetamines, cocaine, and anabolic-androgenic steroids.[54,55] The use of such drugs generally should be discouraged, particularly because they have well-documented harmful effects on the developing fetus.[56]

A known fertility toxicant, marijuana contains constituents known as cannabinoids, which have been shown to impair signaling pathways, alter hormonal regulation, and complicate timing issues during embryo implantation.[57] In males, cannabinoids have been found to inhibit the mitochondrial respiration of sperm,[58] reduce testosterone production,[57] decrease sperm motility, compromise sperm morphology, and decrease sperm function, specifically capacitation and acrosome reactions.[59]

In vivo and in vitro studies have shown that cannabis may disrupt the hypothalamus–pituitary–gonadal axis, spermatogenesis, and sperm function (motility, capacitation, acrosome reaction).[60]

Consuming cannabis several times per week for 5 years results in a reduction in the volume and number of spermatozoa and changes sperm morphology and motility, reducing their fertilization capacity.[61]

Obesity, Weight Loss, and Exercise

Obese men are known to have lower sperm counts (up to 50%), reduced sperm motility, reduced spermatogenesis, increased DNA fragmentation in sperm, and increased levels of erectile dysfunction.[62] A meta-analysis of 21 studies demonstrated an increased risk of DNA fragmentation and azoospermia or oligozoospermia in overweight or obese males.[63]

Obesity can alter the physical and molecular structure of germ cells in the testes and ultimately affect the mature sperm.[64,65] Obesity induces a state of inflammation, and proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6) are increased in the serum, testicular tissue, and seminal plasma of obese males. In the testes, proinflammatory cytokines can directly impair the seminiferous epithelium. A proinflammatory state can also damage epididymal epithelium function, impeding sperm maturation and fertilization ability.[66]

Obesity also causes oxidative stress due to the excess of ROS, which causes damage to DNA and plasma membrane integrity in sperm.[67] Additionally, extra-abdominal weight can increase scrotal temperature. Hormonal changes are primarily responsible for such changes in obese men. The levels of total and free testosterone are reduced in obese men in proportion to the level of obesity. Estrogen is increased owing to the peripheral aromatization of androgens in adipose tissue. The estrogens produced have a negative-feedback effect on gonadotropin production, thereby reducing FSH. This reduction in FSH further reduces testosterone production and spermatogenesis. Additionally, increased body fat and a sedentary lifestyle are associated with raised testicular temperature, which further adversely affects spermatogenesis.[62] Obesity has been shown to affect semen parameters, including decreased sperm concentration, decreased sperm motility and vitality, and increased abnormal morphology.[67–70] Similarly, it was found that being underweight also had a negative effect on sperm quality. Maintaining an adequate or normal body weight is an important factor for male fertility,[71] and weight loss in obese men can increase sperm count and normal sperm morphology.[72]

Regular physical activity has beneficial effects on sperm parameters, as demonstrated in a cross-sectional study of 32 men that found a significant enhancement in semen volume, viability, motility, and morphology in the physically active men compared with sedentary men.[73]

A study of 419 sedentary men attending a fertility clinic found that moderate aerobic exercise training for 24 weeks favorably improved seminal markers of inflammation and oxidative stress and enhanced antioxidant defense system. This correlated with improvements in semen parameters, sperm DNA integrity, and pregnancy rate. Improvements were seen after 12 weeks of the trial.[74] These results are supported by additional studies showing that in healthy men, moderate-intensity aerobic exercise training can induce significant improvements in semen parameters and sperm DNA integrity, mainly through adaptations in the seminal antioxidant defense system and attenuating seminal markers of inflammation.[75–78] It should be noted that prolonged intensive exercise and training may lead to alterations in reproductive hormone levels; atrophy of the testicular germinal epithelium and adverse effects on spermatogenesis; and changes in semen parameters, including abnormal sperm morphology and reduced sperm motility.[77]

Sedentary Lifestyle

A study of 189 young men found that sperm concentration and total sperm count were directly related to physical activity. Measurement of physical and leisure time activities was not related to sperm motility and morphology in this study; however, TV watching has been inversely associated with sperm concentration and sperm count.[79] In another small study (n = 31) of healthy males, it was found that physically active men have a more anabolic hormonal environment and healthier semen production compared with their sedentary counterparts.[80] Physical activity also helps maintain a healthy weight: body mass index (BMI) and waist circumference are associated with a decrease in total sperm count and ejaculate volume.[81]

Infections and Infertility

Infections in the male genitourinary tract—including infections of the epididymis, seminal vesicles, prostate, bladder, and urethra—are thought to play a major role in many cases of infertility.[82] The exact extent of this role is largely unknown because of the lack of suitable diagnostic criteria coupled with the asymptomatic nature of many infections. The presence of antisperm antibodies or high levels of debris in the semen sample is considered to be a good indicator of chronic infection in the absence of other clinical findings.

A wide number of bacteria, viruses, and other organisms can infect the male genitourinary system. Table 185.6 offers a list of the more common potential causative agents.

DIETARY CONSIDERATIONS

A single sperm comprises the key nutritional ingredients (Fig. 185.1).

The dietary guidelines in Chapter 44 provide sound guidance for improving fertility. In particular, it is important to eat the right types of fats. Surrounding the entire sperm is a "shield" of essential fatty acids protecting its structure, enabling continuity of movement, and safeguarding the integrity of the precious genetic material within. The male's dietary intake must be assessed so as to ensure that all trans, rancid, and oxidized fats and excessive saturated fats are avoided. High intakes of saturated fats are negatively associated with sperm count and sperm concentration.[83–85] It is recommended to prescribe sufficient essential fatty acids from both supplemental and dietary sources. The presence of essential fatty acids ensures that sperm are kept fluid and flexible, which regulates the acrosome reaction, sperm-oocyte fusion, and sperm-oocyte fertilization.[86]

Because of the effects of fats and oils on agglutination and cell-membrane dynamics, certain fats are best avoided in infertile men, and consumption of others should be increased. Hydrogenated oils, trans fatty acids, and cotton oils should be avoided. Trans fats are unable to be endogenously synthesized, and excessive consumption contributes to fat accumulation in the testicular environment,[87] and trans-fat intake has been shown to be inversely related to sperm count and testicular volume.[88,89] Cottonseed is especially problematic because it may contain toxic residues as a result of the heavy spraying of cotton and its high levels of gossypol, a substance known to inhibit sperm function. In fact, gossypol is being investigated for possible use in a "male birth control pill." Its potential as an antifertility agent became known after

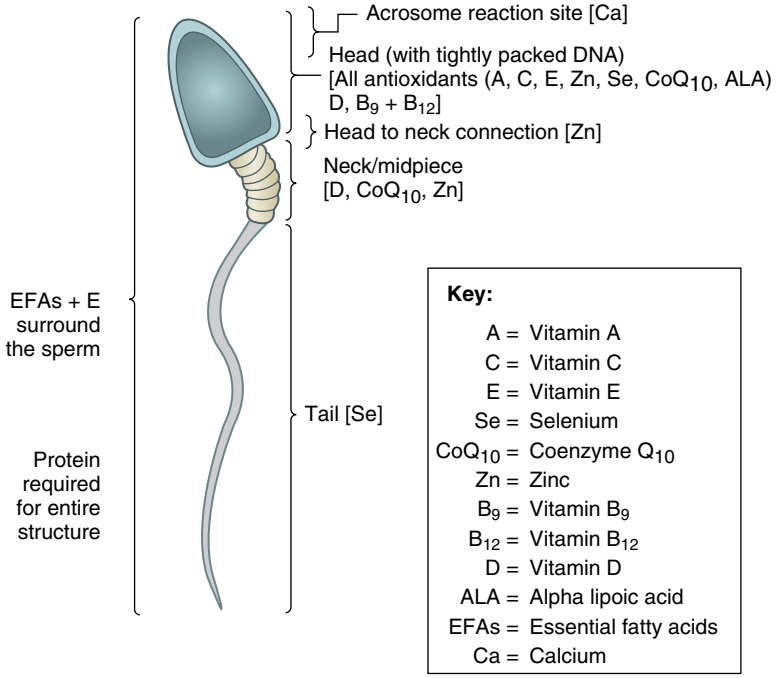

Fig. 185.1 Sperm morphology and composition.

studies demonstrated that men who had used crude cottonseed oil for cooking had low sperm counts followed by total testicular failure.[90] Excessive consumption of long-chain saturated fats from meat should also be avoided; these, combined with an inadequate intake of essential fatty acids, can change the fatty acid composition of the sperm membranes, thus reducing fluidity and interfering with sperm motility. The patient must be taught to read food labels carefully and avoid all sources of cottonseed oil and other damaging oils.

To promote proper sperm membrane function, it is important to supplement with the long-chain omega-3 fatty acids from fish oil because studies have shown that sperm motility and morphology strongly correlate with levels of omega-3 fatty acids, in particular, docosahexaenoic acid (DHA), in the sperm membrane.[83,91] One paper noted that excessive omega-6 compared with omega-3 fatty acids in seminal fluid decreased sperm concentration, sperm motility, and sperm morphology among patients with idiopathic oligoasthenoteratozoospermia.[92] It is therefore advisable to encourage omega-3 sources as a preference and to restrict the use of popular omega-6 cooking oils, such as soy, corn, and safflower. Supplemental goals should be to prescribe an optimal dose of 1000 to 2000 mg of eicosapentaenoic acid (EPA)+DHA daily, with additional dietary recommendations such as raw nuts and seeds; cold-pressed monounsaturated oils like olive, canola, and macadamia nut oils; avocados; and wild and sustainably farmed fish containing high essential fatty acids (EFAs).

In a double-blind, placebo-controlled, randomized controlled trial (RCT) of men with idiopathic oligoasthenoteratospermia (n = 238), it was shown that 1.84 g/day of omega-3 fatty acids (DHA and EPA) over 32 weeks resulted in a significant improvement of sperm cell total count and sperm cell concentration in the omega-3 groups compared with placebo.[93] An RCT of 57 men found that supplementation with DHA-enriched oil (990 mg of DHA and 135 mg of EPA per day) over a 10-week period resulted in a significant decrease in sperm DNA fragmentation compared with placebo. No significant effect was found on semen parameters.[94] Walnuts contain EFAs and are also a good source of antioxidants in the diet, and a study has shown that 75 g of walnuts per day for 3 months improved sperm vitality, motility, and morphology in a group of healthy men consuming a Western-style diet.[95]

Adequate dietary protein is also an important consideration. The entire sperm is dependent on the protein status of the male. Insufficient protein in the diet undermines the quality of the sperm, reflected primarily in their morphology but undoubtedly also in their inability to move adequately and in the right direction (motility). Similar to the rest of the body, if protein needs are not met, deterioration of bodily processes and structures can eventuate. It is crucial to thoroughly assess the protein levels of all male patients both in laboratory assessments (total protein status) and through dietary calculation. The standard calculation of 0.8 to 1.2 g protein per 2.2 lb (1 kg) body weight is a positive general rule; 0.8 g protein is best for more sedentary patients, and 1.2 g protein is more appropriate for more active types. For example, an active patient weighing 176 lb (80 kg) should be prescribed 96 g pure protein per day, ideally from a variety of sources. The quality of the protein is also important. A high intake of processed meats is associated with fewer morphologically normal sperm compared with a low intake. It's also associated with a higher risk of asthenozoospermia. Fish intake is related to higher sperm count and morphologically normal sperm.[96,97]

Hydration must also be optimized. Sperm are manufactured and spend time within semen. On reviewing the nutritional components of semen, it becomes clear that it is a by-product of the body, as is urine or feces. Therefore, if a male is dehydrated, it is understandable that the resultant coagulation of semen will increase, and exposure to toxin and by-products from eliminatory channels will occur. Thus optimal hydration can dilute semen, reduce sperm exposure, and improve motility considerably. Calculating a male's hydration requirements is best achieved using a 30-mL/2.2-lb (1-kg) rule; that is, for a 176-lb (80-kg) patient, minimal hydration requirements would be 2.4 L per day, with additional intake required for dehydration, exercise, and alcohol or caffeine intake.

A recent review of observational studies concluded that adherence to a healthy diet (e.g., the Mediterranean diet pattern and diets characterized by higher intakes of seafood, poultry, whole grains, fruits, and vegetables in non-Mediterranean countries) has been consistently associated with better semen parameters in a wide range of studies in North America, Europe, the Middle East, and East Asia.[98–100] It has been shown that following a diet characterized by higher intakes of

legumes, vegetables, cereals, fruits, and olive oil and low intakes of dairy, mayonnaise, margarines, sauces, snacks, and sweets was associated with semen quality—particularly sperm concentration and progressive motility—among men from couples planning pregnancy.[101] A study in men with asthenozoospermia showed an association between following a dietary nutrient intake pattern comprising mainly antioxidants, vitamin D, fiber, and polyunsaturated fatty acids with a significantly lower risk of asthenozoospermia.[102]

NUTRITIONAL SUPPLEMENTS

Antioxidants

A 2014 Cochrane review[103] assessed the effect of antioxidants on male subfertility by reviewing 48 trials and 4179 subfertile men. Of importance, the authors concluded that there is sufficient evidence to prove that antioxidant supplementation in subfertile males improves the outcomes of live births and pregnancy rates for subfertile couples undergoing ART cycles.

Other reviews found an improvement in sperm quality (predominantly motility, but including concentration and morphology), along with increased pregnancy rates, after antioxidant supplementation. Significant reductions in measures of sperm oxidative stress and DNA damage were found in 95% of the studies after oral antioxidant treatment.[104–106]

A study found that combined antioxidant therapy consisting of vitamin C (80 mg/day), vitamin E (40 mg/day) and coenzyme Q_{10} CoQ_{10} (120 mg/day) administered over a period 6 months in men with oligoasthenozoospermia (n = 169) resulted in significant improvements in sperm concentration and motility.[107] Similarly, combination therapy with L-carnitine (440 mg), CoQ_{10} (ubiquinol 30 mg), vitamin E (75IU), and vitamin C (12 mg), two or three times per day, for 3 to 6 months improved sperm concentration in infertile men.[108] A study of 120 men with idiopathic infertility showed that supplementation with NAC (600 mg/day) for 3 months resulted in improvements in semen volume, motility, and viscosity. Serum antioxidant capacity was increased, and the total peroxide and oxidative stress index were lower.[109] A clinical trial on the effects of curcumin in infertile men found that supplementation with curcumin (80 mg/day) over 10 weeks resulted in statistically significant improvements in semen parameters and total antioxidant capacity, compared with placebo.[110]

In greater detail, important points in these reports include the following:

- Antioxidant use was associated with a statistically significant increased pregnancy rate compared with control (pooled odds ratio [OR] 4.18, 95%; confidence interval [CI] 2.65–6.59; $P < 0.00001$).
- No studies reported evidence of harmful side effects of the antioxidant therapy used.
- One man in 20 will be affected by subfertility, and 3% to 80% of male-factor subfertility is believed to be due to oxidative stress.[111]
- Subfertile men are confirmed to have lower levels of antioxidants in their semen than fertile men.[111,112]
- Levels of ROS are significantly higher in infertile sperm samples compared with others from healthy controls; 25% to 80% of infertile men present with elevated ROS in the semen.[113]
- ROS cause fertility problems by
  a. Damaging the sperm membrane, which contains high levels of unsaturated fatty acids, which are susceptible to oxidation, thus affecting sperm motility and the ability of spermatozoa to break down the oocyte membrane (zona pellucida). Damage to the sperm membrane leads to loss of membrane integrity, increased permeability, and structural DNA damage.[112,113]
  b. Altering sperm DNA: the integrity of sperm DNA is one of the major determinants of normal fertilization and embryo growth in natural and assisted conception.

All antioxidants are concentrated in the head of the sperm to varying degrees. The general recommendation is to encourage the prescription of combination products to ensure that the greatest antioxidant potential is achieved. Antioxidants are responsible for protecting the DNA within the head of the sperm and reducing the workload of the mRNA in the eventual oocyte. By optimizing oxidant status, the survival and longevity of the sperm are also promoted, and the sperm is enabled to detect signals from the recently ovulated oocyte. A reduction in antioxidants is likely to present specifically as high DNA damage or poor morphology. However, individual antioxidants such as zinc are responsible for regulating hormone status and thus sperm count; therefore all must be considered in a holistic infertility treatment protocol.

Free-radical or oxidative damage to sperm is thought to be responsible for many cases of male infertility, high levels of free radicals having been found in the semen of approximately 40% of infertile men.[114–116] The following three factors combine to render sperm particularly susceptible to damage by free radicals:

- A high membrane concentration of polyunsaturated fatty acids (PFAs)
- Active generation of free radicals
- A lack of defensive enzymes

All of these factors combine to make the health of the sperm critically dependent on antioxidants. Although most free radicals are produced during normal metabolic processes, the environment contributes greatly to the free-radical load. Men exposed to higher levels of free radicals are much more likely to have abnormal sperm and sperm counts.[114–116] Antioxidants are required to protect sperm against oxidative damage (which may alter DNA) as well as to instigate cellular repair of damage caused by environmental factors or aging. In the healthy male, the seminal plasma is naturally rich in antioxidants because sperm are highly susceptible to the effects of ROS.

Sperm are extremely sensitive to free radicals because they depend so much on the integrity and fluidity of their cell membranes for proper function. Without proper membrane fluidity, enzymes are activated, possibly leading to impaired motility, abnormal structure, loss of viability, and ultimately death of the sperm.

The major determinant of membrane fluidity is the concentration of PFAs, particularly omega-3 fatty acids like DHA, which are highly susceptible to free-radical damage. The sperm have a relative lack of superoxide dismutase and catalase, which can prevent or repair oxidative damage. Adding to this more susceptible state is the fact that sperm generate large quantities of free radicals to help break down barriers to fertilization.

Vitamin C

Vitamin C improves all semen parameters. A marginal deficiency causes oxidative damage to sperm, resulting in reduced sperm motility and viability. Supplementation leads to improvement in both viability and motility, reduced numbers of abnormal sperm, and reduced sperm agglutination.[117,118]

The generation of ROS and associated links with infertility have been established and extensively studied. In particular, the effects of increased ROS in the serum, semen, and testicular tissues have been considered. Alterations in the testicular microenvironment and hemodynamics can increase the production of ROS and/or decrease local antioxidant capacity, resulting in the generation of excessive oxygen species.

Vitamin C (ascorbic acid), a major antioxidant present in extracellular fluid, is present at a high concentration in seminal fluid compared with blood plasma (364 vs. 40 mM) and is present in detectable amounts in sperm,[119] where it prevents sperm agglutination and oxidative damage. In infertile men, vitamin C has been found in reduced quantity in the seminal plasma.[120,121] Males with inadequate seminal vitamin C have also been observed to suffer from sperm DNA damage,[120] suggesting that a defect or inadequate intake of vitamin C may prompt ROS to cause breakage and oxidation of sperm DNA.

When dietary vitamin C was reduced from 250 to 5 mg/day in healthy human subjects, the ascorbic acid content in seminal fluid decreased by 50%, and the number of sperm with damage to their DNA rose by 91%.[122] These results indicate that dietary vitamin C plays a critical role in protecting against sperm damage and that low dietary vitamin C levels were likely to lead to infertility. A study examining vitamin C as an adjunct therapy for men after undergoing varicocelectomy (n = 115) showed that 3 months of daily vitamin C supplementation (500 mg/day) resulted in a significant improvement in sperm motility and morphology in the treatment group compared with placebo.[123] Another study has shown that supplementation with 1000 mg vitamin C per day for 6 months resulted in improvements in sperm concentration and motility in fertile but obese men. There was no change in semen volume or percentage of normal sperm morphology in the study.[124]

It is now well documented that cigarette smoking greatly reduces vitamin C levels throughout the body, and it is proved that smokers require at least twice as much vitamin C as nonsmokers. In one study, men who smoked one pack of cigarettes a day received either 0, 200, or 1000 mg of vitamin C. After 1 month, sperm quality improved in proportion to the level of vitamin C supplementation.[125] Nonsmokers appear to benefit from vitamin C as much as do smokers. In one study, 30 infertile but otherwise healthy men received either 200 or 1000 mg of vitamin C or placebo daily.[126] Sperm count, viability, motility, agglutination, abnormalities, and immaturity were measured weekly. After 1 week, the 1000-mg group demonstrated a 140% increase in sperm count, the 200-mg group a 112% increase, and the placebo group no change. After 3 weeks, both vitamin C groups continued to improve, with the 200-mg group catching up to the improvement of the 1000-mg group. One of the key improvements was observed in the number of agglutinated sperm. Sperm become agglutinated when antibodies produced by the immune system bind to them. Antibodies to sperm are often associated with chronic genitourinary tract or prostatic infection. When more than 25% of the sperm are agglutinated, fertility is very unlikely. At the beginning of the study, all three groups had more than 25% agglutinated sperm. After 3 weeks, the proportion of agglutinated sperm in the vitamin C groups dropped to 11%. Although this result is significant, the most impressive result of the study was that at the end of 60 days, several men in both of the vitamin C groups had impregnated their wives, compared with none in the placebo group. Therefore vitamin C supplementation can be very effective in treating male infertility, particularly if it is due to antibodies against sperm.

Vitamin E

Vitamin E supplementation appears to be especially warranted because this vitamin is the main antioxidant in various cell membranes, including those surrounding sperm. Free radicals, if left alone, lead to the peroxidation of phospholipids in the mitochondria of the sperm, making the sperm immotile. Vitamin E has been shown to play an essential role in inhibiting free-radical damage to the unsaturated fatty acids of the sperm membrane[127] and in enhancing the ability of sperm to fertilize an egg in an IVF setting. Additionally, it has been shown to protect DNA within the sperm from damage.[128] Infertile men have significantly lower serum and seminal vitamin E concentrations than fertile men.[129]

In one study, supplementation with vitamin E was found to decrease malondialdehyde concentration in sperm pellet suspensions and to improve sperm motility. Even more important, however, 11 of 52 (21%) treated infertile men impregnated their spouses, whereas none in the placebo group did so. After completion of the study, 26 of the placebo patients were switched to vitamin E; soon thereafter, 4 were able to successfully impregnate their spouses.[130] In another study, vitamin E (400 IU) and selenium (225 mcg) significantly improved sperm quality.[131] This was supported by a study in which a combined therapy of vitamin E (400 IU/day) and selenium (200 mcg/day) was administered for 6 months, resulting in a significant increase in sperm motility and a reduced percentage of defective spermatozoa.[132] A prospective randomized study compared the effectiveness of vitamin E alone, clomiphene citrate alone, or a combination of both treatments on semen parameters of 90 patients with idiopathic oligoasthenozoospermia (OAT). After 6 months, there was a significant improvement in sperm concentration and sperm motility in the combined-treatment group.[133]

Supplementation with vitamin E may also be useful for couples undergoing IVF. Vitamin E (200 mg/day for at least 3 months) was found to improve the in vitro fertilization rate of fertile normospermic males with low fertilization rates after 1 month of treatment, possibly by reducing the lipid peroxidation potential.[134] Beneficial results have also been observed in patients undergoing ICSI, where vitamin E helps prevent DNA fragmentation, thus improving ICSI outcomes.[135]

Vitamin A, Beta-Carotene, and Lycopene

Vitamin A is an antioxidant required for cellular growth and differentiation, gene expression and cellular differentiation, immunity, regulatory functions, and epithelial tissue integrity. It is necessary for the health of the testes and for sperm production. Low concentrations of vitamin A are associated with abnormal semen parameters in men,[136] and deprivation of vitamin A in animals has been shown to lead to a loss of spermatogenesis due to degeneration of the germ cells, which is restored once vitamin A is reintroduced.[137] Studies are lacking on the effects of vitamin A supplementation in men; however, studies of vitamin A in combination with other nutrients show improved effects on sperm motility and sperm count.[138] Beta-carotene levels are significantly reduced in immune-infertile men. Intake is associated positively with a higher sperm concentration as well as higher quantities of motile sperm.[139] In one study of 189 young, healthy men, higher β-carotene and lutein intake from food sources was associated with better sperm motility, whereas a moderate intake of β-carotene and vitamin C was associated with higher sperm concentration and sperm count.[140] The same study found that higher lycopene intake was associated with better sperm morphology, and lycopene may be even more useful than β-carotene. Lycopene is found in high concentrations in the testes and seminal plasma, and reduced levels have been demonstrated in men with infertility.[141] In one clinical trial, 30 men with idiopathic nonobstructive oligo-/astheno-/teratozoospermia were administered 2 mg of lycopene twice a day for 3 months. Twenty patients (66%) showed an improvement in sperm concentration, 16 (53%) had improved motility, and 14 (46%) showed improvement in sperm morphology. In patients showing an improvement, the median changes were 22 million/mL in concentration, 25% in motility, and 10% in morphology.[131] Lycopene levels in semen can be significantly increased with dietary intake of natural sources of lycopene.[142] A randomized controlled study found that regular consumption of tomato juice significantly increased seminal plasma lycopene levels and increased sperm motility. In this study, 44 infertile men consumed one can of tomato juice per day (30 mg lycopene) for 12 weeks. Improved results were seen after 6 weeks of the trial.[143]

Vitamin D

Vitamin D is a lipid-soluble vitamin that is required structurally and functionally. It enhances male and female fertility and facilitates the absorption of calcium. The vitamin D receptor and enzymes that metabolize vitamin D are found in the sperm head and midpiece of human sperm and in the testes and male reproductive tract of rats. It has been suggested to play an important role in the production and transport of sperm,[144] and the expression levels of vitamin D receptor in CYP24A1 in spermatozoa are positive markers for semen quality.[145] Studies show that men who are vitamin D deficient have a lower percentage of motile spermatozoa compared with those who have sufficient vitamin D[146,147]; however, both low and high vitamin D levels are associated with a decline in semen parameters.[148] This trend is supported by a further study investigating the association between vitamin D status and semen quality in 307 young, healthy men. High vitamin D levels were associated with lower total sperm count and percentage of normal morphology sperm.[149]

Vitamin D supplementation has been shown to increase testosterone levels in a small study ($n = 54$). All men in the study were vitamin D deficient at the start of the study and had testosterone levels at the lower end of the reference range.[150] This result was not confirmed in other studies. Other studies found that vitamin D supplementation did not affect testosterone levels.[147,151] A cross-sectional study of 1362 men did find that plasma 25(OH)D levels were positively associated with total and free testosterone levels.[152] Given the level of available evidence, supplementation with vitamin D might improve semen quality in at least some of the idiopathic cases of male infertility in a safe and noninvasive manner. Data from small intervention studies and association studies indicate that vitamin D supplementation may only be beneficial for men with vitamin D deficiency,[153] and this finding is supported by a recent prospective study of more than 1000 infertile men.[154] Vitamin D supplementation (5000 IU/day for 2 months) was found to improve sperm motility in idiopathic infertility patients who had low vitamin D levels.[155] Similarly, in a prospective pilot study of infertile men, the incidence of low vitamin D was 76.9% (mean serum vitamin D level 23.6 ng/mL). After treatment with vitamin D supplements, the rate of low sperm motility (<40%) improved.[156]

Selenium

Selenium is a critical antioxidant that is essential for male fertility because of its role in testosterone synthesis, normal sperm maturation, and motility[157]; moreover, clinical trials reveal that selenium has the ability to increase sperm motility and assist in the production of healthy spermatozoa.[158] Selenium is also required structurally because the sperm's capsular selenoprotein is involved in the stability and motility of the mature sperm and also forms part of the glutathione peroxidase antioxidant system, which is vital for spermatogenesis and protects the sperm against the effects of ROS.[159] Lack of selenium leads to atrophy of the seminiferous epithelium, testis volume reduction, and disorders of spermatogenesis and maturation of spermatozoa in the epididymis. Selenium in seminal plasma correlates with good spermatozoa concentrations, motility, and morphology.[160]

In animal studies, depletion of mitochondrial glutathione peroxidase has been found to cause impaired sperm quality and severe structural abnormalities in the midpiece of spermatozoa, leading to infertility.[161] The tail of the sperm relies on adequate selenium status to maintain its "whip-like" action. Without sufficient selenium, sperm are unable to swim in the right direction or may display marked immotility, thus preventing oocyte location and fusion. A supply of selenium for the selenoproteins in the testis is critical to spermatogenesis, and deficiency or an excess of dietary selenium may impair spermatogenesis, resulting in poor semen characteristics and quality and infertility.[162]

The effects of selenium on sperm motility are highlighted in a study involving a subgroup of individuals with poorly motile sperm and subsequent subfertility.[163] Over a 3-month period, the administration of selenium (either on it its own or as a combination of antioxidants, including vitamins A, C, and E) to males led to increased sperm motility compared with placebo. Five men (11%) achieved paternity in the treatment group, in contrast to none in the placebo group. This small study highlights the efficacy of selenium supplementation in subfertile men and suggests that improved selenium status can, in turn, improve sperm motility and the possibility of successful conception. Although this number may be seen as small, it was highly meaningful to those who were successful in conceiving—and all the more significant in terms of the cost and convenience of supplementation compared with IVF or ICSI.

Selenium (200 mcg/day) in combination with the antioxidant N-acetyl-cysteine (600 mg/day) was found to improve semen parameters in idiopathic oligo-asthenoterato-spermiaplasma males in a double-blind, placebo-controlled, randomized study undertaken over 6.5 months.[164] Improvements in sperm count, motility, and morphology were all observed; however, once supplementation stopped, the parameters reverted back to their readings at baseline in two spermatogenesis cycles. This study did not include pregnancy rate.

Zinc

Zinc is perhaps the most important trace mineral for male sexual function and is found in high concentrations within the prostate and testes; particularly high amounts are also found in the semen (approximately 2.5 mg of zinc is lost per ejaculate). It is involved in virtually every aspect of male reproduction, including hormone metabolism, spermatogenesis, and sperm motility.[165]

Zinc plays an important role in all human living cells; it is involved in the transcription of RNA, the replication of DNA, and the synthesis of protein, all of which are crucial for reproduction and fertility. Additionally, it protects against free-radical damage and ROS, which can impair sperm.[166] Deficiency of zinc in males can lead to gonadal dysfunction[165] and has been observed to be associated with idiopathic male infertility[166] and impotence.

Zinc levels are typically much lower in infertile men with low sperm counts, indicating that a low zinc status may be the contributing factor to infertility.[167,168] It has also been shown that zinc status directly correlates with an increase in sperm count as well as improvements in morphology and motility.[160,169] In considering sperm structure, zinc has been shown to influence motility and the head–neck connection of the sperm[170]; it is also important in the stabilization of cell membranes and sperm chromatin.[171] Zinc has been shown in vitro to improve seminal antioxidant states in infertile men, but it does not prevent sperm lipid peroxidation.[172] Finally, it has been shown to exert an antimicrobial effect on the seminal plasma, which is helpful if sperm antibodies or underlying genitourinary infection is present.[173]

Several studies have evaluated the effect of zinc supplementation on sperm counts and motility.[174–177] The results of all of the studies support the use of zinc supplementation in the treatment of oligospermia, especially in the presence of low testosterone levels. The effectiveness of zinc is best illustrated by a study in 37 men with infertility of greater than 5 years' duration whose sperm counts were less than 25 million/mL.[27] Blood testosterone levels were also measured. The men received a supplement of zinc sulfate (60 mg elemental zinc daily) for 45 to 50 days. In the 22 patients with initially low testosterone levels, the mean sperm count rose significantly from 8 to 20 million/mL. Testosterone levels also increased, and 9 of the 22 wives became pregnant during the study. This result is quite impressive, given the long-term nature of the infertility and the rapidity of the results. In contrast, in the 15 men

who had normal testosterone levels before the study, sperm counts increased slightly, but there was no change in testosterone levels, and no pregnancies occurred.

In a 3-month study of 45 asthenozoospermic men, it was found that supplementing with zinc sulfate (200 mg twice daily) alone, in combination with vitamin E, or in combination with both vitamin E and vitamin C was associated with improved sperm parameters, less oxidative stress, sperm apoptosis, and sperm DNA fragmentation compared with placebo. No difference in effect between the three treatment groups was found.[178] Two other studies have shown that supplementation with zinc sulfate (24 mg for 45–50 days, and 89 mg for 4 months) significantly increases testosterone, seminal zinc levels, and sperm count.[179] An additional study of zinc sulfate supplementation (220 mg/day for 3 months) in 110 men found that it resulted in increased semen volume, increased sperm motility, and normal sperm count. Antioxidant status was improved in spermatozoa and seminal plasma.[180] Oral zinc supplementation (440 mg zinc sulfate per day) successfully restored seminal catalase-like activity and improved sperm concentration and progressive motility in a group of asthenozoospermic men.[181] A recent systematic review and meta-analysis of the literature examined 22 studies including 2600 cases and 867 controls. The review concluded that seminal plasma zinc concentrations in infertile males were significantly lower than those of fertile males, and zinc supplementation could significantly increase the sperm quality of infertile males.[182]

Optimal zinc levels must be attained if optimal male sexual vitality is desired. Zinc deficiency is increasing throughout the world and is dependent on the country's soil content and on environmental legislation that prevents harmful farming practices. Additionally, owing to the negative effects of excess copper, it is advisable to check serum zinc and copper status. Where a deficiency state is diagnosed, it is important to ensure that a 1:1 ratio (or better) is achieved.

B Vitamins (Especially Folate and Vitamin B_{12})

Folate and vitamin B_{12} are concentrated within the head of the sperm and provide vital nutritional potential in sperm generation and survival. Folate and B_{12} are required for healthy DNA and RNA synthesis, normal protein synthesis, and the regulation of gene expression.[176] These nutrients are required to ensure that the DNA within the head of the sperm is structured appropriately and that each sperm (and the DNA within it) replicates identically.

Both folate and B_{12} facilitate spermatogenesis,[183] which is reliant on DNA synthesis[176] for germ cell growth and the rapid division of cells. Multiple studies have found that low levels of folic acid in seminal plasma are associated with increased sperm DNA damage,[184] whereas B_{12} deficiency is strongly associated with reduced sperm motility and count.[185] Because the human body has a high turnover of B_{12} and requires a continuous supply on a daily basis, supplementation is advisable for all men experiencing infertility regardless of proved deficiency state and especially for men who have sperm counts below 20 million/mL or a motility rate of less than 50%. In one study, 27% of men with sperm counts less than 20 million/mL who were given 1000 mcg/day of B_{12} were able to achieve a total sperm count in excess of 100 million/mL.[177] In another study, 57% of men with low sperm counts who took 6000 mcg/day demonstrated improvements.[186] A recent small study showed that infertile men with varicocele administered a multivitamin including vitamin B_{12} at 1 mcg/day, for 3 months, had lower sperm DNA fragmentation by about 22.1%.[187] Similarly, a study found that vitamin B_{12} (1 mcg/day for 3 months) as part of an oral antioxidant treatment improved sperm vitality, motility, and DNA integrity.[188]

Infertile men have lower concentrations of serum folic acid than fertile men; however, serum folate concentration was not found to correlate with any semen parameters.[189] In another study, seminal plasma folate concentration was found to be lower in infertile men than fertile men and was significantly correlated with low sperm concentration.[190] Folic acid supplementation (5 mg/day) in conjunction with zinc sulfate (220 mg/day) did not improve sperm quality in 83 subfertile men in a 16-week trial.[191] However, another study found that coadministration of folic acid (5 mg/day) and zinc sulfate (66 mg/day) over a 6-month period significantly improved sperm parameters after surgical repair of varicocele.[192]

It is important to remember that it is advisable to refrain from prescribing one nutrient without the other owing to the possibility of inducing a rebound anemia. Where this occurs, disorders of homocysteine metabolism such as methylenetetrahydrofolate reductase (MTHFR) polymorphisms may present with count or morphological issues. In men with the *MTHFR* gene polymorphisms, vitamin B_9 and vitamin B_{12} dietary intake was associated with a decrease in homocysteine and improvement of sperm concentration, motility, and morphology. The greatest benefits were seen in men with the T allele of *MTHFR* C677T polymorphism.[193]

A recent study investigating high-dose folic acid supplementation (5 mg/day) over 6 months found that methylation of promoter regions in several genes involved in cancer and neurobehavioral disorders was altered. Care must be taken in folic acid supplementation to avoid overdosage problems, particularly in patients who are homozygous for the *MTHFR* C677T polymorphism.[194]

Carnitine

Carnitine is derived from the amino acids lysine and/or methionine and plays a vital role in fatty acid metabolism. It works synergistically with CoQ_{10}, highlighting the importance of coprescription for optimal benefit. It is essential in the transport of fatty acids into the mitochondria, and deficiency results in a decrease in fatty acid concentrations in the mitochondria and reduced energy production. It is believed to have protective antioxidant effects and provides energy to the testicles and spermatozoa specifically. Several studies comparing fertile with infertile men found that fertile men had a statistically significant larger amount of carnitine in their seminal sample than the infertile men and that low levels of L-carnitine in the seminal plasma may be a potent marker for infertility.[195]

Carnitine concentrations are extremely high in the epididymis and sperm, suggesting a role in male reproductive function. The epididymis derives the majority of its energy requirements from fatty acids, as do the sperm, during transport through the epididymis. After ejaculation, the motility of sperm correlates directly with carnitine content; the higher the carnitine content, the more motile the sperm. Conversely, when carnitine levels are low, sperm development, function, and motility are drastically reduced.[114]

Several clinical studies have shown that carnitine supplementation can produce dramatic improvements in sperm counts and sperm motility. In the Italian Study Group on Carnitine and Male Infertility, 100 subjects were given 3000 mg of L-carnitine daily for 4 months.[196] Carnitine was able to increase sperm counts and sperm motility in both a qualitative and a quantitative manner, as follows:

- The number of ejaculated sperm per milliliter increased from 142 billion to 163 billion.
- The percentage of motile sperm increased from 26.9% to 37.7%.
- The percentage of sperm with rapid linear progression increased from 10.8% to 18%.
- The mean sperm velocity increased from 28.4% to 32.5%.

These results are even more impressive if results for only the patients with the poorest sperm motility are examined. This subgroup saw even more significant gains on all parameters. For example, the

percentage of motile sperm increased from 19.3% to 40.9%, and the percentage of sperm with rapid linear progression increased from 3.1% to 20.3%. These results have been confirmed in several double-blind studies.[197–201] Carnitine, administered in conjunction with other nutrients, has been shown to improve sperm motility in infertile men with idiopathic asthenozoospermia or asthenoteratozoospermia. Carnitine (1500 mg/day) was given in combination with vitamin C, CoQ_{10}, selenium, zinc, B_{12}, folic acid and vitamin E.[188,202] These results are supported by another randomized interventional study in which L-carnitine (2 g/day) was administered in conjunction with a multivitamin for 3 months. Improvements were seen in sperm concentration, sperm count, and sperm motility in men with idiopathic oligo- and/or asthenozoospermia. The results were more significant in L-carnitine combined with multivitamin than in either of those interventions alone, compared with control.[203] Similarly, in a 3-month study of 199 subfertile men, supplementation with a combination of L-carnitine (440 mg), L-arginine (250 mg), zinc (40 mg), vitamin E (120 mg), glutathione (80 mg), selenium (60 mcg), CoQ_{10} (15 mg), and folic acid (800 mcg) once per day resulted in a significantly better improvement in sperm density and motility compared with supplementation with L-carnitine (500 mg) twice per day.[204] In ART, where sperm is cryopreserved, L-carnitine had an enhancing effect on sperm motility and viability after cryopreservation.[205]

R-Alpha-Lipoic Acid

Alpha-lipoic acid is a powerful antioxidant indicated for its lipid and water solubility and because it assists in the chelation of heavy metals regardless of their storage site in the body. It is especially useful owing to its ability to regenerate other antioxidants, including vitamins C and E, CoQ_{10}, and glutathione.[206]

Alpha lipoic acid exhibits marked antioxidant activity to sperm in animal studies.[207–209] On review of the research, it appears to act as a shield for the sperm, forming a protective barrier around the midpiece (aqueous layer) and within the structure itself (lipid layer). This protection is crucial because it has been identified as one of the first places at which free radicals attack.[209] It is therefore useful to consider in patients with high DNA fragmentation levels. Additionally, animal studies reveal that alpha-lipoic acid improves sperm motility and viability, minimizes DNA damage,[209] and protects against bacterial lipopolysaccharides, which can induce acute inflammation[210]; it and may also assist with energy supply to the sperm.[209] In a randomized, triple-blind, placebo-controlled clinical trial of infertile men (n = 44), alpha-lipoic acid supplementation (600 mg/day) for 12 weeks improved sperm count, concentration, and motility and seminal levels of total antioxidant capacity.[211]

Coenzyme Q_{10}

CoQ_{10} is concentrated in the head and midpiece (neck) of the sperm. It is considered to be the most crucial and powerful antioxidant in sperm structure because of its role in mitochondrial energy release. It is believed to promote motility, foster sperm survival, and provide optimal energy to assist the sperm's travel on its journey to the oocyte.

As a fat-soluble antioxidant and free-radical scavenger, CoQ_{10} is required for the maintenance of cell membrane integrity and cell functioning. It is also specific for the health of all new cells, especially spermatozoa. CoQ_{10} in the seminal fluid and sperm[212] helps maintain optimal sperm motility.[213,214] Decreased levels have been found in the seminal plasma and spermatozoa of males with idiopathic and varicocele-associated asthenospermia.[215]

There have been a number of trials of CoQ_{10} supplementation in infertile men with idiopathic oligoasthenoteratospermia (OAT). A 26-week RCT of 212 infertile men with idiopathic OAT showed that daily supplementation with CoQ_{10} (300 mg) resulted in a statistically significant improvement in sperm count, sperm motility, and sperm morphology.[216] These results were confirmed in a 3-month study of supplementation with CoQ_{10} (200 mg/day), resulting in a significant improvement in sperm morphology in men with idiopathic OAT. The supplementation also resulted in higher catalase and superoxide dismutase (SOD) activity, indicating improved oxidative stress in seminal plasma.[217] A longer, 12-month study of 187 infertile men with idiopathic OAT found that treatment with CoQ_{10} (300 mg/day) resulted in significant improvements in sperm motility and sperm morphology. There was also a beneficial effect on pregnancy rate in the group.[218] In men with varicocele, supplementation with CoQ_{10} (100 mg/day) for 3 months resulted in a 40% increase in seminal plasma antioxidant status and a small improvement in semen parameters.[219] Administration of 200 mg/day of ubiquinol (reduced form of CoQ_{10}) over 26 weeks in a group of 228 men with unexplained infertility resulted in significant improvements in sperm density, motility, and morphology.[220] These results were supported in a 6-month trial of 60 men where 150 mg ubiquinol daily was found to increase sperm count and motility.[221] Although CoQ_{10} supplementation has been shown to be of benefit in improving various parameters of male infertility, CoQ_{10} intake from food was not found to be related to semen parameters (sperm concentration, total and progressive motility, and morphology) among subfertile men. A study of 211 participants showed that these men had a mean dietary CoQ_{10} intake of 19.2 mg/day (ranging from 2 to 247 mg/day). Intake estimates varied greatly and were based on a validated food frequency questionnaire.[222]

L-Arginine

The amino acid arginine is required for the replication of cells, making it essential in sperm formation. Nitric oxide synthase (NOS) uses L-arginine to synthesize nitric oxide, which can protect spermatozoa from lipid peroxidase damage. Via its role as a precursor to nitric oxide synthesis, arginine is required for angiogenesis, spermatogenesis, and hormone secretion.[223]

Some studies have shown that L-arginine can improve sperm count and motility.[185,224] Stress, in particular, has been found to decrease the levels of arginine in sperm-production pathways. Arginine supplementation is often but not always an effective treatment for male infertility. The critical determinant appears to be the level of oligospermia. If sperm counts are less than 20 million/mL, arginine supplementation is less likely to be of benefit. To be effective, the dose of L-arginine must be at least 4 g/day for 3 months. In perhaps the most favorable study, 74% of 178 men with low sperm counts had significant improvements in sperm counts and motility after arginine therapy.[225]

One double-blind, randomized, placebo-controlled crossover clinical trial examined the effects of Prelox, a combination of 80 mg/day of Pycnogenol and 3 g/day of L-arginine aspartate.[226] The results showed an improvement in semen parameters in 50 males with idiopathic infertility over a treatment period of 4 weeks. Also observed were significant increases in ejaculate volume, concentration, and number of spermatozoa as well as the percentage of vital spermatozoa compared with placebo. The percentage of spermatozoa with good progressing motility also increased significantly, whereas the percentage of immotile spermatozoa decreased. These results appear to be due to a combination of the antioxidant activity of Pycnogenol and/or the activity of L-arginine in stimulating the activity of endothelial NOS, leading to enhanced motility of spermatozoa. In a small pilot study, Pycnogenol (200 mg daily for 90 days) alone was shown to improve sperm morphology by 38% and the mannose receptor binding assay scores by 19%.[227]

Probiotics

Two small preliminary studies into the use of probiotics for improving male fertility have been carried out recently, opening new avenues for treatment of male infertility.

In one study, nine men with asthenozoospermic were administered two different antioxidant probiotic strains (*Lactobacillus rhamnosus* CECT8361 and *Bifidobacterium longum* CECT7347) for 6 weeks. Each capsule contained an equal combination of both strains corresponding to 10^9 cfu/day. Results showed a significant improvement in sperm motility and a decrease in DNA fragmentation and intracellular ROS. Cell viability was not affected by the treatment. The authors concluded that the results were due to the antioxidant activity of the probiotic strains.[228]

The second randomized trial of 41 men with idiopathic oligoasthenoteratospermia found that treatment with a proprietary probiotic/prebiotic therapy (Flortec) over 6 months improved the quality and quantity of spermatozoa to a larger extent than placebo. Flortec is made up of *Lactobacillus paracasei* B21060 5×10^9 cells, arabinogalctan 1243 mg, oligo-fructosaccharides 700 mg, and L-glutamine 500 mg. The probiotic/prebiotic treatment improved the volume of the ejaculate, sperm concentration, number of ejaculated spermatozoa, motility, and the percentage of typical forms. The men's FSH, LH, and testosterone levels also improved. The improvements may be mediated by normalization of subtle alterations in hypothalamic–pituitary function, an antioxidant effect, and possibly even improvements in the prostatic microenvironment.[229] However, an alternative theory relating to the improvements seen in this study has been proposed.[230] Improvement in gut bacteria leads to improvement in intestinal mucosa barrier function, thereby resolving "leaky gut" and endotoxin-containing gut bacteria migrating into the systemic circulation. Endotoxin is a powerful immune stimulant, with recent data linking endotoxin activation of the immune system with impaired Leydig and Sertoli cell function via systemic inflammation and hypogonadism. Earlier reports have shown that *Lactobacillus* probiotics exert a beneficial effect on testicular function in mice via modulation of the immune system.[230]

Botanical Medicines

Panax ginseng (Korean Ginseng)

Current scientific investigation suggests that *Panax ginseng* (Chinese or Korean ginseng) may be supportive in the treatment of male infertility. Both botanicals have a long history of use as male "tonics." In studies with animals, *Panax* ginseng has been shown to improve the growth of the testes, raise sperm formation and testosterone levels, and increase sexual activity and mating behavior. It is classed as an energy tonic, indicated when there is lowered vitality and therefore impaired physical performance and sexual function. The active constituents (ginsenosides) have been shown to enhance nitric oxide production, which is useful in regulating the capacitating process of spermatozoa and the acrosome reaction, thus improving fertilization sperm motility.[231,232] Additionally, ginsenosides have been shown to affect different levels of the hypothalamic–pituitary–testicular axis,[233] which can assist in modulating stress-induced infertility or lowered testosterone from insufficient dehydroepiandrosterone (DHEA) synthesis. In clinical trials, *Panax* ginseng has been shown to increase testosterone levels as well as sperm counts and motility in patients with oligospermia, some of whom had varicocele,[233] and to improve erection and libido.[234,235]

An RCT of infertile male patients with varicocele ($n = 80$) found that supplementation with Korean red ginseng root powder (500 mg three times a day) resulted in significant improvements in sperm concentration, viability, motility, and morphology. The study participants were divided into four groups: nonvaricocelectomy with placebo or treatment; varicocelectomy with placebo or treatment. All groups except for the nonvaricocelectomy with placebo group showed similar improved sperm parameter results at the end of the trial.[236]

For additional information and references, see Chapter 99.

Pygeum africanum (Pygeum)

Pygeum africanum may be effective in improving fertility in cases where diminished prostatic secretion plays a significant role. *Pygeum* has been shown to increase prostatic secretions and improve the composition of the seminal fluid.[237–239] Specifically, *Pygeum* administration to men with decreased prostatic secretion has led to increased levels of total seminal fluid plus increases in alkaline phosphatase and protein content.

Pygeum appears to be most effective in men in whom alkaline phosphatase activity is reduced (i.e., <400 IU/cm^3) and there is no evidence of inflammation or infection (i.e., absence of white blood cells and immunoglobulin A[IgA]). The lack of IgA in the semen is a good indicator of clinical success. In one study, the patients with no IgA in their semen demonstrated an increase in alkaline phosphatase from 265 to 485 IU/cm^3.[239] In contrast, those with IgA showed only a modest increase, from 213 to 281 IU/cm^3.

Pygeum extract has also shown an ability, in a double-blind clinical trial, to improve the capacity of patients with benign prostatic hypertrophy (BPH) or prostatitis to achieve an erection, as determined by nocturnal penile tumescence.[240] BPH and prostatitis are often associated with erectile dysfunction and other sexual disturbances. Presumably by alleviating the underlying condition, *Pygeum* can improve sexual function.

Tribulus terrestris

Tribulus terrestris has been used traditionally in Ayurvedic medicine as a tonic and aphrodisiac and in European folk medicine to increase sexual potency. Protodioscin, one of the steroidal saponins, is considered the chief constituent responsible for the herb's effects on libido and sexual functioning. Of prime importance is correct sourcing of *Tribulus* to ensure its effectiveness. All of the data and clinical outcomes have been based on a leaf extract from Bulgaria, which has been shown to be highest in protodioscin. Therefore, if a *Tribulus* product is made from the root or fruit of the plant or is obtained from anywhere other than Eastern Europe, it will probably contain low levels of protodioscin and therefore not be effective.

In animal studies, *Tribulus* has been shown to increase the levels of certain sex hormones, including testosterone, and also to improve nitric oxide synthesis[241]; however, these same results have not been observed in some human studies.[242] One possible explanation is that there were differences in the extract and plant parts of the *Tribulus* used as well as the fact that many of the studies have comprised healthy males with normal testosterone levels rather than males with testosterone deficiency.

Tribulus appears to enhance male fertility through its ability to increase sperm count, viability, and libido; however, the published material is unclear, reporting older studies that were poorly designed and results that are not sufficiently definitive. A number of older papers supporting the extract product Tribestan highlight significant efficacy; however, owing to poor study design and lack of reliability, it is difficult to rely on these findings, which include increased ejaculate volume, sperm concentration, and motile sperm[243] and improved conception rates.[244] More recent studies have also produced conflicting results. In a recent prospective, randomized, double-blind, placebo-controlled trial, Tribestan (500 mg three times per day for 12 weeks) was found to successfully improve sexual function in men with mild to moderate erectile dysfunction ($n = 180$).[245] These results are in conflict with a previous study in which 400 mg of *Tribulus* treatment

(400 mg twice per day for 30 days) was found to be no better than placebo at improving erectile dysfunction, possibly due to suboptimal dosing and/or too short a study period.[246]

A recent in vitro study found that the addition of *Tribulus* to human sperm enhanced sperm motility, number of progressive motile spermatozoa, and curvilinear velocity. Sperm viability was also significantly enhanced.[247] *Tribulus* had an enhancing effect on sperm motility and viability after cryopreservation.[248] A human randomized trial of 30 male patients with idiopathic infertility found no significant improvement in levels of testosterone or semen parameters after 3 months of treatment with *Tribulus* (750 mg/day).[249] However, a trial of 65 men with abnormal semen evaluation found that administering Androsten (250 mg dried extract per capsule, including 37.5 mg protodioscin) three times per day over 12 weeks resulted in a significant enhancement of sperm count and motility but not morphology.[250] In conclusion, the exact role of *Tribulus* in male infertility is still inconclusive and controversial, and there may be a need to determine different mechanisms of action other than the current hypothesis that its desirable effects are due to androgen-enhancing properties.[251] Further large, robust studies are needed to reconcile the conflicting results to date.

Astragalus membranaceus

In experimental studies, *Astragalus membranaceus* has been observed to increase the motility of sperm in semen.[252] Studies show that *Astragalus* increases the motility of sperm in semen, but it also increases the motility of washed sperm, which is of special relevance to those seeking ART treatment.[253] Additionally, it has been shown to increase sperm motility and progression.[254]

Turnera diffusa (Damiana)

The traditional application of damiana was for "its positive aphrodisiac effects, acting energetically on the genito urinary organs of both genders where it was highly indicated for sexual weakness and debility,"[255] and "its ability to act as a stimulant tonic of the sexual apparatus especially if there is enfeeblement of the central nervous system."[256] Modern clinicians continue to prescribe damiana in this context and find it is especially beneficial when there is sexual debility, erectile difficulty, and depression. Human studies are lacking; however, a number of animal studies show promising supportive research. *Turnera diffusa* has been shown to facilitate the sexual behavior of male rats with sexual dysfunction, to reduce ejaculation latency,[257] to produce a restorative effect in sexually exhausted male rats, and to hasten their recovery.[258] It has also been observed to suppress aromatase activity, leading to the hypothesis that it may increase levels of testosterone.[259]

Mucuna pruriens (Velvet Bean)

Velvet bean has been used in Ayurvedic medicine for endurance against stress, general resistance against infection, retardation of the aging process, and eventual improvement of male sexual function; it has been known to alleviate disorders, including psychogenic impotence and unexplained infertility.[260] One paper showed that *M. pruriens* seed powder produced dramatic improvements in 70% of study participants and helped fight stress-mediated poor semen quality; it has also acted as a restorative and invigorating tonic/aphrodisiac in infertile subjects.[261] The same researchers reporting these positive effects determined that they were achieved through the regulation of steroidogenesis and resulting improvements in semen quality.[262] Specifically, this herbal treatment significantly improved testosterone, LH, dopamine, adrenaline, and noradrenaline levels in infertile men and reduced levels of FSH and prolactin. Sperm count and motility were also significantly improved in infertile men. In a follow-up study, it was found that treatment with *Mucuna pruriens* regulated steroidogenesis and improved semen quality and significantly improved testosterone, LH, dopamine, adrenaline, and noradrenaline levels in infertile men. Levels of FSH and prolactin were reduced. Sperm count and motility were also significantly recovered in infertile males after treatment.[263]

A 3-month study of *M. pruriens* seed powder administered to infertile men ($n = 180$) found a significant improvement in seminal plasma metabolic profile. Improvements were seen in alanine, citrate, glycerophosphocholine, histidine, and phenylalanine concentrations in seminal plasma.[264]

Withania somnifera (Withania)

Withania has shown considerable antistress and adaptogenic effects. To investigate the effects of *Withania* on male fertility, 75 normal healthy fertile men (control subjects) and 75 men undergoing infertility screening participated in a 3-month clinical trial. The men in the *Withania* group received 5 g of the powdered root daily. Before and after the treatment, semen analysis, antioxidant vitamins, and serum sex hormone levels were determined. Results showed that *Withania* inhibited lipid peroxidation and improved sperm count and motility. Treatment also significantly increased serum testosterone and LH and reduced the levels of FSH and prolactin (PRL), all beneficial effects in infertile men.[265]

A pilot study of 46 men with oligospermia found that supplementation with *Withania somnifera* (675 mg/d of high concentration, full-spectrum root extract) over 90 days resulted in a 167% increase in sperm count, 53% in semen volume, and 57% increase in sperm motility compared with placebo. Improvement and regulation of serum testosterone and LH levels were also observed in the treatment group.[266] The molecular mechanism of *W. somnifera* on semen quality was demonstrated to act via repairing disturbed concentrates of lactate, alanine, citrate, glycerophosphocholine, histidine, and phenylalanine in seminal plasma, thereby normalizing seminal plasma metabolites. *W. somnifera* actions include regulating reproductive hormones, fatty acid metabolism, and enzymatic activity of the TCA cycle.[267] A 3-month study into the effect of *W. somnifera* on stress-related male fertility found that treatment with *W. somnifera* powder (5 g/day dried root powder) resulted in a decrease in stress; improved antioxidant levels; and improvement in sperm concentration, motility, and liquefaction time. Treatment also resulted in increased serum testosterone and LH levels. Cortisol levels in the treatment groups were significantly decreased after treatment.[268] A 3-month treatment of normozoospermic, oligozoospermic, and asthenozoospermic men ($n = 75$) with *W. somnifera* (5 g/day root powder) showed that semen quality was improved by restoring the altered levels of intracellular ROS in spermatozoa and cell death and improving essential metal ion (Cu^{2+}, Zn^{2+}, Fe^{2+}, and Au^{2+}) concentrations.[269]

Nigella sativa (Black Cumin)

Nigella sativa is an herb displaying antioxidant properties. The main antioxidant components are thymoquinone and unsaturated fatty acids (linoleic and oleic acid). A study of infertile men with abnormal semen parameters ($n = 68$) found that treatment with *N. sativa* seed oil (2.5 mL twice daily) over 2 months improved sperm count, motility, morphology, and semen volume compared with placebo.[270] This study is supported by prior animal studies showing that *N. sativa* improves sperm parameters, semen Leydig cells, reproductive organs, and reproductive hormones.[271]

THERAPEUTIC APPROACH

Male infertility is a multifactorial condition, making a holistic treatment plan essential. Referral to a urologist or fertility specialist for a complete

evaluation is often necessary. It is advisable to encourage a detoxification program at the start of treatment so as to optimize spermatogenesis and the subsequent cohort of spermatozoa. Additionally, nutritional status should be optimized, environmental pollutants identified and eliminated, lifestyle practices modified, and fertility-enhancing botanicals consumed. It is also crucial to avoid all xenobiotics, pollutants, and toxicants owing to their disruptive endocrinological effects.

General Measures

Maintain scrotal temperature between 94°F and 96.8°F.

- Avoid exposure to free radicals.
- Identify and eliminate environmental pollutants.
- Stop or reduce all drugs, especially antihypertensives, antineoplastics such as cyclophosphamide, and anti-inflammatory drugs such as sulfasalazine.
- Use effective stress-reduction techniques and employ psychological counseling if needed.
- Avoid cigarette smoking and the use of recreational drugs.

Diet

- Avoid dietary sources of free radicals, saturated fats, hydrogenated oils, trans fatty acids, and cottonseed oil.
- Increase consumption of legumes, especially soy (high in phytoestrogens and phytosterols); good dietary sources of antioxidant vitamins, carotenes, and flavonoids (dark vegetables and fruits); and EFAs and zinc (nuts and seeds).
- Consume 8 to 12 servings of vegetables and 1 to 2 servings of fresh fruits daily.
- Optimize protein intake from both vegetarian and organic animal sources.
- Ensure that hydration requirements are met, using a 30-mL/2.2-lb (1-kg) rule.
- Eliminate caffeine, alcohol, sugar, and artificial substances (preservatives, colorings, additives).
- Ensure sufficient EFA intake several times a week in the form of a half a cup of raw nuts or seeds, cold-pressed oils (from organic sources), and sustainably farmed fish.

Nutritional Supplements

- High-potency multivitamin/mineral supplement
- Fish oils: 1000 to 2000 mg EPA+DHA
- Vitamin C: 500 to 1000 mg three times a day
- Vitamin E: 200 to 400 IU/day
- Beta-carotene: 15,000 to 30,000 IU/day (preferably as mixed carotenoids)
- Vitamin B_9 (folinic acid or L5MTHF): 1000 mcg/day
- Vitamin B12 (cyano- or methyl- cobalamin): 1000 mcg/day
- Zinc: 30 to 60 mg/day
- Selenium: 200 to 400 mcg/day
- Lycopene: 2 mg/day
- CoQ_{10}: 200 to 400 mg/day
- L-Carnitine: 2000 to 3000 mg/day
- L-Arginine: 2000 to 4000 mg/day

Botanical Medicines

Choose one or more of the following botanical medicines.

***Panax ginseng* (Korean Ginseng)**

- High-quality crude ginseng root: 1.5 to 2 g/day
- Standardized extract: Containing a minimum of 10.5 mg/mL ginsenosides with Rg1:Rb1 greater than or equal to 0.5 by high-performance liquid chromatography (HPLC), 1 to 6 mL/day

***Pygeum africanum* (Pygeum)**

- Standardized extract: 100 to 200 mg/day standardized to a 14% content of sterols in divided doses

***Tribulus terrestris* (Tribulus)**

- Standardized extract, equivalent to dried herb (aerial parts of leaf), standardized to contain furostanol saponins as protodioscin 12.22 mg/L g, 9 to 36 g/day
- Fluid extract (2:1): 7 to 21 mL/day

***Astragalus membranaceous* (Astragalus)**

- Dosages to be administered one to three times a day are as follows:
- Dried root (or as decoction or as a powder in capsules or tablets): 1 to 2 g
- Tincture (1:5): 2 to 4 mL
- Fluid extract (1:1): 1 to 2 mL solid (dry powdered) extract (standardized to contain 0.5% 4-hydroxy-3-methoxy isoflavone): 100 to 150 mg

***Turnera diffusa* (Damiana)**

- Dried leaves or as tea: 2 to 4 g/day
- Fluid extract (1:2): 3.0 to 6.0 mL/day
- Dry powdered extract (4:1): 500 to 1000 mg/day

***Mucuna pruriens* (Velvet bean)**

- Dosage equivalent to 5 g/day of the powdered dried seed

***Withania somnifera* (Withania)**

- Dosage equivalent to 5 g/day of the powdered root
- Dried powdered extract (root and leaves) 125 to 250 mg/day (standardized to contain 8% withanolide glycoside conjugates and 32% oligosaccharides)
- Fluid extract (2:1): containing a minimum of 4.0 mg/mL of withanosides, 2.5 to 5.0 mL/day

Nigella sativa

- Seed oil: 5 ml
- Fluid extract (1:2): 4 to 12 mL/day

Inflammatory Bowel Disease (Crohn's Disease and Ulcerative Colitis)

Gerard E. Mullin, MD

OUTLINE

DIAGNOSTIC SUMMARY

Crohn's disease:
- Abdominal pain the most common symptom—can be localized anywhere in the abdomen
- Complicated by intestinal obstruction, abscesses, fistulas, strictures, perianal disease
- Intermittent bouts of diarrhea or constipation, low-grade fever, and weight loss
- Frequently misdiagnosed as irritable bowel syndrome; time to diagnosis from onset is estimated to be approximately 8 years
- Ileocolonoscopy and capsule endoscopy are key diagnostic modalities
- Radiographic evidence of abnormality of the terminal ileum is characteristic
- Stools can be high in calprotectin—noninvasive inflammatory markers
- Genetic predisposition, environmental trigger (gut dysbiosis, medications, etc.), chronic full-thickness patchy intestinal inflammation
- Risk of digestive tract cancer higher than in the general population

Ulcerative colitis:
- Bloody diarrhea with cramps in the lower abdomen
- Mild abdominal tenderness, weight loss, and fever
- Involves only the colon; distinguishing point from Crohn's disease, which can involve any portion of the alimentary tract
- Inflammation is superficial and continuous, whereas Crohn's is full-thickness and tends to be patchy
- Diagnosis is confirmed by radiography and sigmoidoscopy
- Risk of colon cancer increased after 10 years of disease, universal distribution throughout colon and poorly controlled disease activity
- Genetic predisposition, triggers similar to those of Crohn's disease

GENERAL CONSIDERATIONS

Definition

Inflammatory bowel disease (IBD) is a general term for a group of chronic inflammatory disorders of the bowel. IBD is divided into two major categories: Crohn's disease and ulcerative colitis. Clinically, IBD is characterized by recurrent inflammatory involvement of specific intestinal segments, resulting in diverse clinical manifestations.

Crohn's Disease

Crohn's disease is characterized by a granulomatous inflammatory reaction comprising the entire thickness of the bowel wall. In approximately 50% of cases, however, the granulomas are either poorly developed or totally absent. The original description in 1932 by Crohn and colleagues localized the disease to segments of the ileum. However, the same granulomatous process may involve the buccal mucosa, esophagus, stomach, duodenum, jejunum, and colon. Rectal biopsies are routinely recommended during flexible sigmoidoscopy or colonoscopy because granulomas are most commonly found at this site. Crohn's disease of the small intestine is also known as regional enteritis. Involvement of the colon is known as Crohn's disease of the colon or granulomatous colitis; the latter designation is less accurate because granulomatous lesions develop in only some of these patients.

Ulcerative Colitis

In ulcerative colitis a nonspecific inflammatory response is limited largely to the colonic mucosa and submucosa. Well-developed granulomas are exceedingly rare. Crohn's disease and ulcerative colitis do have many features in common, however, and the diseases are discussed together when appropriate. Otherwise they are considered as separate entities. Bear in mind that 1% to 15% of IBD is characterized

as "indeterminate" when the disease has features of both Crohn's disease and ulcerative colitis. Over time, the disease may morph into one predominant disease pattern or remain indeterminate.

Common Features of Crohn's Disease and Ulcerative Colitis

- The colon is frequently involved in Crohn's disease and is invariably involved in ulcerative colitis.
- Although rarely, patients with ulcerative colitis who have total colon involvement may experience a so-called backwash ileitis. Thus both conditions may cause chronic inflammatory changes in the distal small intestine.
- Patients with Crohn's disease often have close relatives with ulcerative colitis, and vice versa.
- When there is no granulomatous reaction in Crohn's disease of the colon, the two lesions may resemble each other clinically as well as pathologically.
- There are many epidemiological similarities between the two diseases, including age, race, gender, and geographic distribution.
- The two conditions are associated with similar extraintestinal manifestations.
- There appear to be etiological parallels between the two conditions.
- Both conditions are associated with a higher frequency of colonic carcinoma and extraintestinal cancers.

Etiology

The epidemiological and etiological data on ulcerative colitis (UC) and Crohn's disease (CD) are quite similar.[1] The incidence and prevalence of the two diseases differ slightly, with most studies showing UC to be more common. Overall, the incidence of CD is rapidly rising in Western cultures.[2] The annual incidence of CD in North America is reported to be 3.1 to 20.2 per 100,000 with a prevalence of 201 per 100,000 population.[2] The current estimate of the incidence of UC in Western Europe and the United States is approximately 6 to 8 cases per 100,000; the estimated prevalence is approximately 286 cases per 100,000.[3] The incidence of CD is rising in Western cultures.[2] Overall, between 1 and 1.6 million Americans have IBD, with an overall prevalence of 504 per 100,000 in the population.[4] The incidence of IBD has been rising in newly industrialized countries in Africa, Asia, and South America, including Brazil and Taiwan.

IBD may occur at any age, but it most often occurs between the ages of 15 and 35 years. Females are affected slightly more frequently than males. White people have the disease two to five times more often than African or Asian Americans, and Jews have a threefold to sixfold higher incidence than non-Jews.[3]

Theories about the etiology of IBD can be divided into several groups, as follows (Fig. 186.1):

- Genetic predisposition
- Gut dysbiosis
- Immunological abnormality
- Dietary factors
- An assortment of miscellaneous concepts implicating psychosomatic, vascular, traumatic, and other mechanisms

Genetic Predisposition

Although the search for a specific genetic marker for IBD has been futile, several factors suggest a genetic predisposition. As already mentioned, IBD is two to five times more common among white than nonwhite people and three to six times more common among Jews than non-Jews. In addition, multiple members of the same family have CD or UC in 15% to 40% of cases.[5]

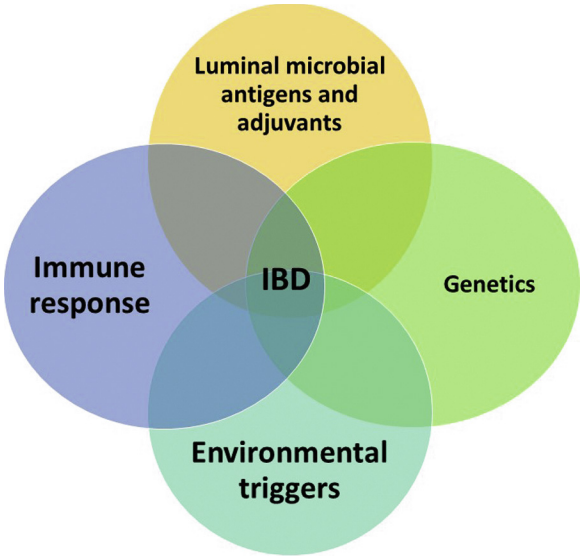

Fig. 186.1 Pathogenesis of Inflammatory Bowel Disease (IBD). The pathogenesis of IBD involves the interaction of four principal factors: genetics, gut microbiome, immune response, and environmental triggers.

Gut Dysbiosis

Many microorganisms have been hailed as putative causes of IBD; however, in spite of numerous attempts to confirm a bacterial, mycobacterial, fungal, or viral etiology, the idea that a transmissible agent is responsible for IBD is still a hotly debated subject. Viruses—rotavirus, Epstein–Barr virus, cytomegalovirus, measles virus, and an uncharacterized RNA intestinal cytopathic virus—and mycobacteria continue to be favored candidates. Gastrointestinal infections with *Aeromonas* bacteria (*Aeromonas sobria* and *Aeromonas hydrophila*) and the yeast *Candida albicans* can trigger a flare of disease, and all patients with IBD should be tested for these infections at the start and during the course of their illness.[6] Overall, a state of gut dysbiosis has been well characterized for both forms of IBD whereby bacteria and fungi have alterations in composition and biodiversity.[6]

Antibiotic Exposure

Before the 1950s, CD was found in select groups with a strong genetic component. Since that time there has been a rapid climb in developed countries, particularly the United States, and in countries that previously had virtually no reported cases. In fact, CD has spread like an epidemic since 1950. Are antibiotics to blame? Penicillin and tetracycline have been available in oral form since 1953. The annual increase in prescriptions of antibiotics parallels the rise in the annual incidence of CD. Comparative statistics have shown that wherever antibiotics have been used early and in large quantities, the incidence of CD is now quite high.

Over the years, researchers have sought to identify CD as an infectious process. The problem may be that the infectious agent is a component of the normal intestinal flora that suddenly produces immunostimulatory toxins or becomes invasive as a direct result of sublethal doses of antibiotics. Administration of sublethal amounts of antibiotics has been shown to induce a capacity for toxin production in intestinal organisms. When microbes are not given a full lethal dose, their usual response is to adapt and become even stronger in virulence and numbers. Other medications that have been implicated as etiopathogenic include nonsteroidal anti-inflammatory agents and, most recently, isotretinoin (Accutane). Antibiotic exposure is now being

TABLE 186.1 Dietary Components Can Favor the Risk of Inflammatory Bowel Disease

Dietary Component	Effect on IBD Risk	Reference
Animal protein	Increased	137
Heme iron, sulfur	Increased	138
Refined sugars	Increased	139
High fat (trans)	Increased	140
High *n*-6 PUFA/*n*-3	Increased	140
High trans fat	Increased	140
Fiber	Decreased	138
Fruit	Decreased	141
Vegetables	Decreased	141
High omega-3 fatty acids	Decreased	142

IBD, Inflammatory bowel disease; *PUFA,* polyunsaturated fatty acid.

linked more to CD than UC. A total of 15 observational studies (8748 IBD patients) were systematically evaluated and confirmed that antibiotic exposure was linked with CD but not with UC.[7] The antibiotics that were most strongly linked to CD onset included the penicillins, cephalosporins, metronidazole, and fluoroquinolones, whereas the effect of the tetracycline-family antibiotics was unclear.

Immune Mechanisms

An overwhelming amount of evidence points to immunological derangements in IBD, but whether they are causal or secondary phenomena remains unclear. Theories relating humoral mechanisms, immunological regulatory defects, and cell-mediated reactions to the etiology of IBD have all been proposed, but the current evidence seems to indicate that these derangements are probably secondary to the disease process.[8]

Dietary Factors

Despite the fact that a dietary etiology of CD is barely considered (if mentioned at all) in most standard medical and gastroenterology texts, several lines of evidence strongly support dietary factors as being the most important etiologically, as recently reviewed by Limketkai et al.[9]

The incidence of CD is increasing in cultures consuming the Western diet, but it is virtually nonexistent in cultures consuming a more primitive diet.[10–15] Food is the major factor in determining the intestinal environment, so the considerable change in dietary habits over the past century could explain the rising incidence of IBD. Several studies that have analyzed the preillness diets of patients with CD have found they habitually eat more refined sugar, chemically modified fats, and fast food and less raw fruits, vegetables, omega-3–rich foods, and dietary fiber than do healthy people (Table 186.1).[10–14] In one study, the preillness intake of refined sugar in patients with CD was nearly twice that in controls (122 g/day vs. 65 g/day).[14] One researcher found that before the onset of disease, patients with CD had eaten cornflakes more frequently than controls.[16] Although other researchers could not verify this specific finding, cornflakes are high in refined carbohydrates and are derived from a very common allergen (corn). Much of controversy over the role of preillness diet in the etiology of CD is largely due to the fact that the only way to assess this diet is from postdiagnostic interviews. Studies in which the interview has taken place within the first 6 months of diagnosis tend to be more supportive than studies in which the interview was conducted more than 7 months after diagnosis. Increased refined sugar intake and high overall carbohydrate intake precede the development of CD.[17] Along these lines, patients with UC show higher consumption of refined carbohydrates than do control subjects.[18] Increased consumption of chemically modified fats (e.g., those found in margarine) may be involved in the etiology of UC.[19] Interestingly, high consumption of a fast-food diet is an antecedent of both UC and CD.[20]

Another important dietary factor that is entirely overlooked in the standard texts is the role of food allergy. Support for this hypothesis is offered in clinical studies that have used an elemental diet, total parenteral nutrition, or an exclusion diet with great success in the treatment of IBD.[16,21–25] The role of food allergy is discussed in greater detail later in the chapter, as is the effect of dietary fiber in the etiology and treatment of IBD (see "Therapeutic Considerations").

A reduced intake of omega-3 oils and an increased intake of omega-6 oils are also being linked with the growing rise of CD in Japan. Because the genetic background of the Japanese is relatively homogeneous, this higher incidence is most likely due to the incorporation of Western foods in the diet. To examine the contribution of diet to the increased incidence of CD in Japan, the incidence and daily intake of a number of dietary components were compared annually between 1966 and 1985. The analysis showed that the greater incidence of CD was strongly correlated with increased dietary intake of total fat, animal fat, omega-6 fatty acids, animal protein, milk protein, and the ratio of omega-6 to omega-3 fatty acids. It was less correlated with intake of total protein, was not correlated with fish protein, and was inversely correlated with vegetable protein. Multivariate analysis showed that higher intake of animal protein was the strongest independent factor, followed by an increased ratio of omega-6 to omega-3 fatty acids.[26] Correction of this increased ratio by reduction of omega-6 oil intake and an increase of omega-3 oil intake may lead to significant clinical benefit through an effect on eicosanoid metabolism (discussed later).

Miscellaneous Factors

Psychosomatic factors such as mental and emotional stress can promote exacerbation of IBD, so stress management techniques may prove useful for some patients.[27]

THERAPEUTIC CONSIDERATIONS

IBD is the end result of a complex interplay of several factors. This section discusses the key nutritional, microbial, and toxic issues that must be addressed for the successful management of this difficult disease.

Control of Causative Factors

Natural History of Crohn's Disease

Little is known about the natural course of CD because virtually all patients with the disease undergo standard medical care (drugs and/or surgery) or alternative therapy. The only exceptions are patients in clinical trials who are assigned to the placebo group.[28–30] However, even these patients do not represent the natural course of the disease because they are seen frequently by physicians and other members of a healthcare team and are taking medication, even if it is only in the form of a placebo. If proper evaluation of therapies for IBD is to occur, there must be a greater understanding of its natural history. This is particularly important for alternative practitioners because it is commonly believed that standard medical care often interferes with the normal efforts of the body to restore health. Some aspects of the "natural" course of CD support this idea, especially when coupled with the limited efficacy of current medications and surgery and their known toxicity. However, heroic measures do have their place in many instances and should be used when appropriate.

Researchers in the National Cooperative Crohn's Disease Study (NCCDS) reviewed 77 patients who received placebo therapy in part 1 of

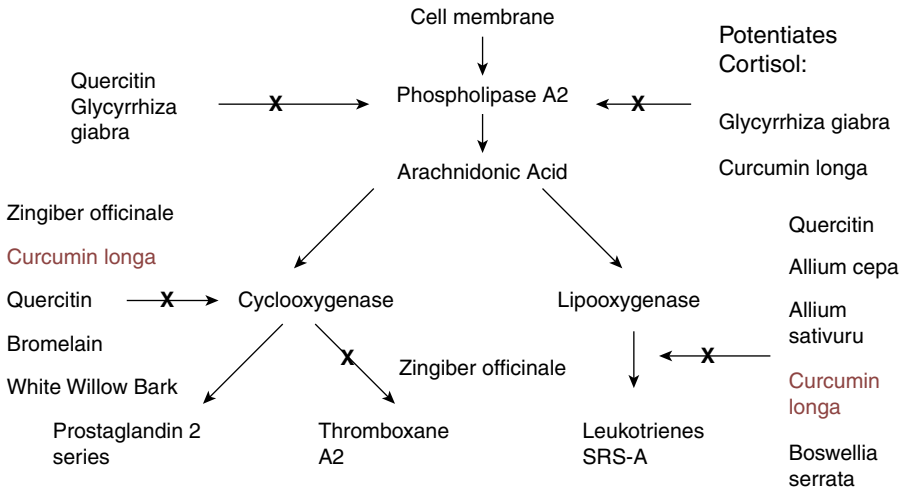

Fig. 186.2 Botanical Modulation of the Arachidonic Cascade. This figure illustrates the pathway by which arachidonic acid in plasma membranes is metabolized to proinflammatory eicosanoids such as PGE2, thromboxane A2, and so forth. Medications that are given for IBD work in large part by their ability to attenuate this pathway. However, botanicals found in nature and food at therapeutic doses can work on the exact same pathways and block the metabolism of arachidonic acid into proinflammatory mediators.

the 17-week study.[28,29] They all had active disease, as defined by a CD activity index (CDAI) higher than 150. Of the patients completing the study:

- None died.
- Only 7 (9%) suffered a major worsening of their disease (i.e., either a major fistula developed or the patient required abdominal surgery).
- Twenty-five (32%) suffered a lesser worsening (increase in the CDAI to >450 or presence of fever of 100°F for 2 weeks).
- Treatment was considered to have failed in 25 (32%) because their CDAIs remained higher than 150.
- Twenty (26%) achieved clinical remission.

On at least one occasion during the 17 weeks of therapy, 49% of the patients were found to have a CDAI lower than 150.

The patients who showed a favorable response to the placebo continued to be observed with placebo therapy for up to 2 years (part 1, Phase II). Interestingly, although none of these patients' intestinal radiographs showed worsening during Phase I or Phase II, 18% showed improvement. Of the patients whose disease responded to placebo (20; 26% of the 77), the majority (70%) remained in remission at 1 year, and a fair number (45%) remained in remission at 2 years. These results indicate that many patients undergo spontaneous remission, approximately 20% at 1 year and 12% at 2 years. However, when another factor is considered, the "success" of placebo therapy rises dramatically. Of patients in the placebo group who had no previous history of steroid therapy, 41% achieved remission after 17 weeks. In addition, 23% of this group continued in remission after 2 years, compared with only 4% of the group with a history of steroid use.

The European Cooperative Crohn's Disease Study (ECCDS), although different in some methodological details, is quite similar to the NCCDS.[28,30] In the ECCDS, 110 patients constituted the placebo group, 68 patients with prior treatment and 42 patients with no prior treatment. The results of the study showed that 55% of the total placebo group achieved remission by 100 days, 34% remained in remission at 300 days, and 21% remained in remission at 700 days. Like the NCCDS, the ECCDS demonstrated that patients with no prior therapy have a greater likelihood of remission.

Although one group of researchers did not advocate placebo therapy, they did carefully point out that once remission was achieved, 75% of the patients continued in remission at the end of 1 year and up to 63% at 2 years regardless of the maintenance therapy used. These results would suggest that the key is achieving remission, which, once attained, can be maintained by conservative nondrug therapy rather than the "medicines we are currently using with their limited efficacy and known toxicity."[28]

Eicosanoid Metabolism in Inflammatory Bowel Disease

Patients with IBD show greatly increased levels of inflammatory chemicals in the colonic mucosa, serum, and stool samples. Specifically, these patients show an increase in the synthesis of the lipoxygenase products, leukotrienes, and mono-hydroxyeicosatetraenoic acids (mono-HETEs).[31–35] These compounds are produced by neutrophils and are known to amplify the inflammatory process and cause smooth muscle contraction. Release of lipoxygenase products is promoted by activation of the alternative complement pathway. The therapeutic efficacy of sulfasalazine and corticosteroids is due to their effect on eicosanoid metabolism. Sulfasalazine is an inhibitor of both cyclooxygenase and neutrophil lipoxygenase, whereas corticosteroids inhibit phospholipase A_2 and thus block the release of arachidonic acid from the membrane phospholipid pool. Sulfasalazine also inhibits the degranulation of mast cells. Several naturally occurring compounds, such as the polyphenols (quercetin, curcumin, resveratrol, etc.), also interact favorably with these enzymes (Fig. 186.2).

The formation of these inflammatory compounds can be decreased by reducing or eliminating the consumption of omega-6–rich foods (corn, beef, liver, pork, lamb, and milk/dairy products) and increasing the consumption of omega-3 fatty acids through a higher intake of cold-water fish (salmon, mackerel, herring, and halibut). These fish are good sources of the longer-chain omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

Meta-analyses of double-blind studies with fish oil supplements (2.7–5.1 g total omega-3 oils) have demonstrated an ability to prevent or delay relapses in both CD and UC.[36,37] The Cochrane Collaboration recently published a systematic review evaluating 214 publications and identified only 15 randomized controlled trials (RCT). Only four studies were of sufficient quality to be included in the analysis. Enteric-coated omega-3 essential fatty acid (EFA) supplementation reduced the 1-year relapse rate by half, with an absolute risk reduction of 31% and a number needed to treat (NNT) of only 3. A much larger RCT asked whether omega-3 fatty acids could sustain remission once it was achieved. Two randomized, double-blind, placebo-controlled studies (Epanova Program in Crohn's Study 1 [EPIC-1] and EPIC-2) were conducted between January 2003 and February 2007 at 98 centers in Canada, Europe, Israel, and the United

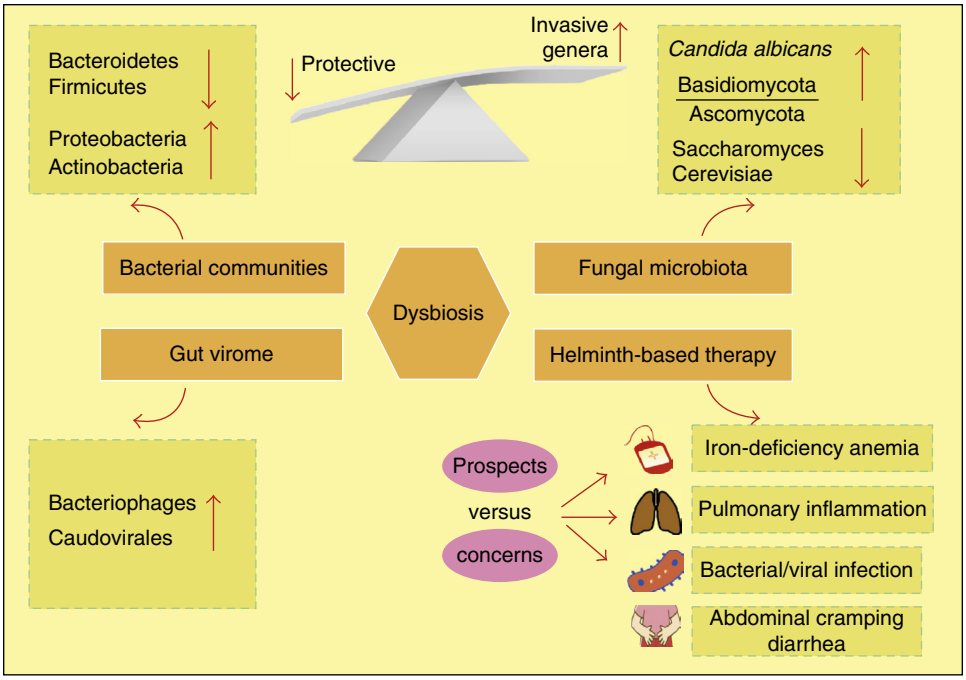

Fig. 186.3 Gut Microbiota Alteration and Immune Responses in Inflammatory Bowel Disease (IBD). The gut microbes, including bacteria, viruses and fungi, and dysfunctional immune responses, engaging Tregs, T-helper 1 (Th1), and Th17, are implicated in IBD pathogenesis. During homestasis, gut microbes induce an immune tolerance phenotype in the host, whilst in inflammatory conditions like IBD, antigens from dysbiotic microbes activate Th1 and Th17 cells, resulting in tissue injury, decreased mucus layer, and microbial penetration and persistence in the intestinal tissues. This mucosal injury results in further uptake of microbial antigens, TLR ligands, and viable organisms that perpetuate the immune responses. *DC, Dendritic cell; MMP,* matrix metalloproteinase; TGF, Transforming growth factor. States. Data from 363 and 375 patients with quiescent CD were evaluated in EPIC-1 and EPIC-2, respectively. Patients with a CDAI score of less than 150 were randomly assigned to receive either 4 g/day of omega-3 free fatty acids or placebo for up to 58 weeks. No other treatments for CD were permitted. Clinical relapse is defined by a CDAI score of 150 points or greater and an increase of more than 70 points from the baseline value, or initiation of treatment for active CD. In both EPIC-1 and EPIC-2, there were no significant differences in the CD relapse rate for placebo versus fish oils.[38] Flaxseed oil is also of value. Flaxseed oil contains alpha-linolenic acid, an essential omega-3 fatty acid that has anti-inflammatory effects and can be converted to EPA in limited amounts.[39]

Mucin Defects in Ulcerative Colitis

Mucins are an ill-defined class of high-molecular-weight, carbohydrate-rich (85% by weight of *N*-acetylgalactosamine, galactose, sialic acids, *N*-acetylglucosamine, and fructose) glycoproteins thought to be largely responsible for the viscous and elastic characteristics of secreted mucus. Alterations in mucin composition and content in the colonic mucosa have been reported in patients with UC.[39–42] The factors responsible for these changes appear to be a dramatic drop in the mucous content of the goblet cells (proportional to the severity of the disease) and a diminution of the major sulfomucin subfraction (designated "species IV," according to diethylaminoethanol-cellulose differentiation). In contrast, these abnormalities are not found in patients with CD. It is significant that although the mucin content of the goblet cells returns to normal during remission, the sulfomucin deficiency does not. The specific components of the sulfomucin and the cause of its lower concentration have not yet been determined. These mucin abnormalities are also thought to be a major factor in these patients' higher risk of colon cancer.

Many of the herbs used historically in the treatment of UC are demulcents; that is, agents that soothe irritated mucous membranes and promote the secretion of mucus. This effect appears to be very beneficial and supports the use of demulcents in UC.

Intestinal Microflora

The intestinal microflora is extraordinarily complex and contains more than 400 distinct microbial species.[43,44] Accurate simultaneous quantification of all possible species is not possible with current conventional culture techniques. In addition, measurement techniques such as stool cultures do not indicate bacterial metabolic activity, locations of growth within the gastrointestinal tract, or turnover rates. These last two factors may prove to be the more important determinants of the role of the intestinal bacterial flora in IBD than the actual numbers of specific bacterial species. In an effort to describe a nonspecific (qualitative or quantitative) alteration in the intestinal flora, the term *dysbiosis* is often used (see Chapters 9 and 28 for a full discussion of this important topic).[43]

The fecal flora of patients with IBD has been found to contain higher numbers of gram-positive anaerobic coccoid rods and *Bacteroides vulgatus*, a gram-negative rod.[43] Studies have indicated that these alterations in fecal flora are not secondary to the disease, and alterations in the metabolic activity of the various bacteria are thought to be more important than alterations in the number of bacteria per se. In addition, specific bacterial cell components (which vary even within the same species) are thought to be responsible for promoting lymphocyte cytotoxic activity against the colonic epithelial cells.[43,44] Fig. 186.3 illustrates the potential role of gut dysbiosis in IBD disease pathogenesis, and Fig. 186.4 demonstrates the interaction of dietary factors with the gut microbiome in disease risk.

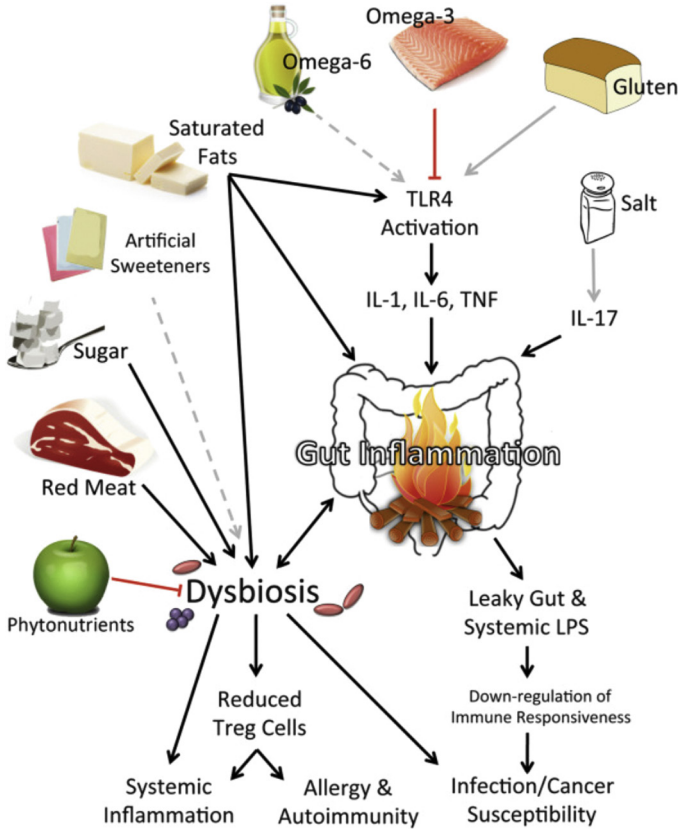

Fig. 186.4 Diagrammatic overview of the current mechanisms for macro-components of the modern diet altering susceptibility to infection, allergy, and autoimmunity. Solid black lines indicate that direct human evidence for enhancement is present; solid red lines indicate that direct human evidence of inhibition exists; gray lines indicate that only in vitro or animal model evidence exists currently; dotted lines indicate significant disagreement within the scientific literature. *IL-*, Interleukin; *TLR4,* Toll-like receptor 4; *TNF,* tumor necrosis factor; *Treg,* T-regulatory cell. Carrageenan

Interestingly, researchers investigating the intestinal flora of UC often use the carrageenan (a sulfated polymer of galactose and D-anhydrogalactose extracted from red seaweeds, principally *Eucheuma spinosum* and *Chondrus crispus*) model to induce the disease in animals experimentally. In the initial experiments reported by Marcus and Watt[45] in 1969, 1% and 5% carrageenan solutions were provided as the exclusive source of oral fluids for guinea pigs. Over a period of several days, the animals lost weight, demonstrated anemia, and had bloody diarrhea. Gross anatomic studies after sacrifice at 20 and 45 days revealed a loss of haustral folds, mucosal granularity, pseudopolyps, and strictures; microscopic examination showed crypt abscesses, lymphocytic infiltration, capillary congestion of the lamina propria, and gross ulcerations. These results have since been confirmed by numerous investigators and in studies involving other animal species, including primates.[46–49]

In its native state, the carrageenan polymer has a molecular weight of 100,000 to 800,000 Da, but in the studies, it is degraded by mild acidic hydrolysis to yield products with weights in the vicinity of 30,000 Da. Carrageen compounds are used by the food industry as stabilizing and suspending agents, with polymers of different molecular weights being used for a variety of purposes. Typically, carrageenans used in the food industry have a molecular weight greater than 100,000 Da. Carrageenan is widely used in milk and chocolate milk products (e.g., ice cream, cottage cheese, milk chocolate) because of its ability to stabilize milk proteins.

As suggestive as the animal studies are in linking UC with carrageenan and despite the higher consumption of carrageenan in Western diets, at this time there appears to be no correlation between the human consumption of carrageenan and the development of UC. In one study, no lesions of IBD were observed in healthy human subjects fed enormous quantities of degraded carrageenan.[50] However, differences in intestinal bacterial flora are probably responsible for this discrepancy, because germ-free animals do not display carrageenan-induced damage.

On further examination, it was discovered that the bacterium linked to the carrageenan-induced damage in animals is a strain of *B. vulgatus.*[43] As mentioned earlier, this organism is found in much higher concentrations (six times as high) in the fecal cultures of patients with IBD. When all the data are evaluated, they appear to imply that although carrageenan can be metabolized into nondamaging components in most human subjects, those individuals with an overgrowth of *B. vulgatus* may be at risk. Strict avoidance of carrageenan appears warranted at this time for patients with IBD until further research clarifies its safety for them.

Aspirin and Intestinal Permeability

A very interesting study evaluated 30 patients with CD and 37 first-degree relatives of patients with CD for intestinal permeability by means of the lactulose/mannitol ratio. First-degree relatives had a 110% higher intestinal permeability after ingesting acetylsalicylic acid, compared with an increase of 57% in the control subjects. Thirty-five percent were "hyperresponders."[51] A familial permeability defect causing increased permeability would be a significant predisposing factor for CD, because a leaky gut is associated with a higher incidence of food allergy and greater absorption of intestinal toxins (see Chapter 19).

Endotoxemia and the Alternative Complement Pathway

Endotoxemia is associated with both CD and UC.[51,52] Endotoxemia-induced activation of the alternative complement pathway could explain some of the extraintestinal (i.e., outside the gastrointestinal tract) manifestations of IBD (discussed later). Whole-gut irrigation significantly reduces the endotoxin pool in the gut and has been shown to have a very beneficial antiendotoxemia effect.[53] Colonic irrigation may offer similar benefit. However, colonic irrigation during an acute inflammatory flare may be contraindicated.

Extraintestinal Manifestations

More than 100 disorders, known as extraintestinal lesions (EILs), constitute a diverse group of systemic complications of IBD.[54,55] The most common EIL in adults is arthritis, which is found in about 25% of patients. Two types are typically described, the more common being peripheral arthritis affecting the knees, ankles, and wrists. Arthritis is more common in patients with colon involvement. The severity of symptoms is typically proportional to disease activity.[54,55]

Less frequently, arthritis primarily affects the spine. Symptoms are low back pain and stiffness, with eventual limitation of motion. This EIL occurs predominantly in men with human leukocyte (HLA)-B_{27} and is fairly indistinguishable from typical ankylosing spondylitis. In fact, it may antedate the bowel symptoms by several years. There is probably a consistent underlying factor in both the progression of ankylosing spondylitis and IBD.[54,55]

Skin manifestations are also common, being seen in approximately 15% of patients. Typical lesions are erythema nodosum, pyoderma gangrenosum, and aphthous ulcerations. Recurrent aphthous stomatitis occurs in approximately 10% of patients.[54,55]

BOX 186.1 Causes of Malnutrition in Inflammatory Bowel Disease

Decreased oral intake
- Disease-induced (pain, diarrhea, nausea, anorexia)
- Iatrogenic (restrictive diets without supplementation)

Malabsorption (with corresponding diagnostic tests)
- Decreased absorptive surface due to disease or resection (D-xylose testing)
- Bile salt deficiency after resection (fecal bile acids, Mayo Clinic)
- Bacterial overgrowth (lactulose or glucose breath hydrogen and methane testing)
- Drugs (e.g., corticosteroids, sulfasalazine, cholestyramine)

Increased secretion and nutrient loss
- Protein-losing enteropathy (fecal alpha-1 antitrypsin 24 h clearance)
- Electrolyte, mineral, and trace mineral loss in diarrhea

Increased utilization and increased requirements
- Inflammation, fever, infection
- Increased intestinal cell turnover

Serious liver disease (i.e., sclerosing cholangitis, chronic active hepatitis, cirrhosis) is also a common EIL, affecting 3% to 7% of the patients with IBD. It probably relates to the increased endotoxin load associated with IBD. If patients are demonstrating liver enzyme abnormalities, hepatoprotection appears indicated, with botanical medicines such as *Silybum marianum* (i.e., silymarin) and curcumin.[56–58]

Other common EILs are as follows[54,55]:
- Thrombophlebitis
- Finger clubbing
- Ocular manifestations (episcleritis, iritis, and uveitis)
- Nephrolithiasis
- Cholelithiasis
- In children: failure to grow, thrive, and mature normally

Malnutrition

Many nutritional complications occur during the course of IBD.[59–61] Because these complications can have a significant influence on the morbidity and perhaps also the mortality of these patients, every effort should be made to ensure optimal nutritional status. The major mechanisms that contribute to nutritional depletion in patients with IBD are listed in Box 186.1.

A decreased food intake is the most important mechanism of nutritional deficiency in patients with IBD, and a deficient calorie intake is the most common nutritional deficit in patients requiring hospitalization. Often the patient feels significant pain, diarrhea, nausea, and/or other symptoms after a meal, resulting in a subtle diminution in dietary intake. Protein-calorie malnutrition and associated weight loss are prevalent in 65% to 75% of patients with IBD.[59]

Malabsorption can be anticipated in patients with extensive mucosal involvement of the small intestine and in those who have undergone resection of segments of the small intestine. Particularly common is fat malabsorption, which results in significant loss of calories as well as the loss of fat-soluble vitamins and minerals. Involvement of the ileum or surgical resection of that area typically leads to malabsorption of vitamins (in particular vitamin B_{12}) and bile acid. Because of the cathartic effect of bile acids on the colon, the malabsorption may result in chronic watery diarrhea. Electrolyte and trace mineral deficiencies should be suspected in patients with a history of chronic diarrhea, whereas calcium and magnesium deficiencies may be a result of chronic steatorrhea.

Increased secretion of protein into the intestinal lumen and nutrient loss due to the exudative and inflammatory nature of IBD are common. In particular, there is a significant loss of plasma proteins across the damaged and inflamed mucosa. The loss of protein may exceed the ability of the liver to replace plasma proteins despite a high protein intake. The chronic loss of blood often leads to iron depletion and anemia.

TABLE 186.2 Prevalence of Nutritional Deficiencies in Hospitalized Patients With Inflammatory Bowel Disease

Deficiency	Prevalence (%)
Hypoalbuminemia	25–80
Anemia	60–80
Iron deficiency	40
Low serum vitamin B_{12}	48
Low serum folate	54–64
Low serum magnesium	14–33
Low serum potassium	6–20
Low serum retinol	21
Low serum ascorbate	12
Low serum 25-OH-vitamin D	25–65
Low serum zinc	40–50

Data from Aoki K. A study of endotoxemia in ulcerative colitis and Crohn's disease. I. Clinical study. *Acta Med Okayama* 1978;32:147–158.

The drugs most commonly used in the allopathic treatment of IBD are corticosteroids and sulfasalazine, both of which increase nutritional needs. Corticosteroids are known to have the following effects:
- Stimulate protein catabolism
- Depress protein synthesis
- Decrease the absorption of calcium and phosphorus
- Increase the urinary excretion of ascorbic acid, calcium, potassium, and zinc
- Increase blood glucose, serum triglyceride, and serum cholesterol levels
- Increase the requirements for vitamin B_6, ascorbic acid, folate, and vitamin D
- Decrease bone formation
- Impair wound healing

Sulfasalazine has been shown to have the following effects[62]:
- Inhibits the absorption and transport of folate
- Decreases serum folate and iron
- Increases the urinary excretion of ascorbic acid

The last consideration in the causes of nutrient deficiency in patients with IBD involves the nutritional consequences of a chronic inflammatory and/or infectious disease. This topic has not been fully investigated; the only conclusion that currently can be drawn is that protein requirements may be raised in patients with acute exacerbations of IBD. An elevated erythrocyte sedimentation rate signifies a rise in both protein breakdown and protein synthesis. Typically, patients with IBD require perhaps as much as 25% more protein than the usual recommended allowance.[59–61]

Prevalence of Nutritional Deficiencies

The prevalence of nutritional deficiencies is quite high in hospitalized patients with IBD. Although it is generally agreed that the prevalence of nutritional deficiencies is greater in hospitalized patients (who typically are more severely ill) than in outpatients, a great number of ambulatory patients with CD display one or more nutrient deficiencies as well.[63] In addition to the deficiencies listed in Table 186.2, low levels of vitamin K, copper, niacin, and vitamin E have been reported.[59]

TABLE 186.3 Dietary Therapies for Inflammatory Bowel Disease

Diet	Rationale	Plan	Evidence
Elimination	Lower antigenic burden—up to 66% of patients with CD report food intolerances.	Eliminate known and suspected provocative foods for 2–4 weeks, then reintroduce one new food per day; process may take 2–3 months.	143,144
Enteral Nutrition	Multifactorial: lower antigenic stimulation	Enteral feeds via tube feed or ONS; induction/maintenance	145
Specific Carbohydrate Diet	Eliminate poorly digestible carbohydrates to limit fermentation in small bowel. Avoid complex carbohydrates.	Allowed: meat, fish, eggs, vegetables, nuts, low-sugar fruits, oils, honey Avoid: starches, grains, pasta, legumes, and breads	146,147
Low FODMAP	Decrease fermentable carbohydrates, poorly transported di-saccharides, gas production, osmotic diarrhea, etc.	Limit fructose, lactose, fructans, galactans, and sugar-alcohols.	148,149

CD, Crohn's disease; *FODMAP,* fermentable oligo-, di-, mono-saccharides and polyols; *ONS,* oral nutrition supplement.

Diet

The importance of correcting nutritional deficiencies in patients with IBD cannot be overstated. Deficiencies of both macronutrients and micronutrients cause alterations in gastrointestinal function and structure, which may lead to a vicious cycle—the secondary effects of malnutrition on gastrointestinal tract function and structure may further exacerbate malabsorption, further reducing nutrient status. Foremost in nutritional therapy is providing adequate caloric intake. It should be assumed that the majority of patients suffer from micronutrient deficiency, although the deficiency is often subclinical and can be detected only by appropriate laboratory investigation.

In general, patients with IBD should be started on therapeutic vitamin supplements of at least five times the recommended dietary allowances (RDAs). Several minerals may also have to be supplemented at equally high levels. Dietary treatment involves the use of either an elemental diet or an elimination diet (described later).

Elemental Diet

The elemental diet has been shown to be an effective nontoxic alternative to corticosteroids as the primary treatment of acute IBD (Table 186.3).[16,21–23] Such a diet is one that is purported to contain all essential nutrients, with protein being provided only as predigested or free-form amino acids. The improvements noted on an elemental diet, however, are probably not primarily related to nutritional improvement but could be a result of alterations in the intestinal flora (which have been noted to occur in patients consuming an elemental diet). A stronger case could be made for a secondary immune mechanism being bypassed during elemental feeding: the elemental diet is serving as an allergy-elimination diet.

The main drawbacks of the widespread use of elemental diets are their poor palatability and their hyperosmolality, which often result in diarrhea. In addition, hospitalization is often required for satisfactory administration, and relapse is quite common when patients resume normal eating. An elimination diet, rather than an elemental diet, may be a more acceptable alternative in the treatment of acute and particularly of chronic IBD.

Elimination (Oligoantigenic) Diet

Although food allergy has long been considered an important etiological factor in the pathogenesis of IBD, studies using an elimination diet in the treatment of IBD have been performed only recently (elimination diets are described in Chapter 14).[24–26] These studies demonstrate that an elimination diet is the primary therapy of choice in the treatment of chronic IBD. The most common offending foods were found to be wheat and dairy products.

An alternative approach is to determine the actual allergens with laboratory methods, preferably a method that measures reactions mediated by both immunoglobulins G (IgG) and E (IgE). The allergens are then avoided, or a rotary diversified diet is used as appropriate (see Chapter 46).

Minerals

Zinc

Zinc deficiency, a well-known complication of CD, occurs in approximately 45% of patients with the disorder.[64] Low serum zinc concentrations, low hair zinc levels, malabsorption of zinc, altered urinary excretion of zinc, and impaired taste acuity are commonly found in patients with CD.[60,64] The deficiency of zinc is due to low dietary intake, poor absorption, and excess fecal losses.[60–62,64] Zinc deficiency may be the direct cause of the following complications of CD[64–66]:

- Poor healing of fissures and fistulas
- Skin lesions (acrodermatitis)
- Hypogonadism
- Growth retardation
- Retinal dysfunction
- Depressed cell-mediated immunity
- Anorexia
- Chronic diarrhea

Many patients with CD show no response to oral or intravenous zinc supplementation because such patients appear to have a defect in the tissue transport of zinc. Intravenous supplementation results in a tremendous rise in urinary zinc excretion but insignificant clinical results. Several clinical trials using oral zinc sulfate have shown the same lack of positive effect.[67]

Administration of zinc in the oral picolinate form may be more advantageous than other forms of zinc, possibly improving both intestinal absorption and tissue transport, although one study displayed no significant difference in zinc absorption between zinc sulfate and zinc picolinate in patients with pancreatic insufficiency.[68] Zinc citrate may also be an appropriate alternative. In any event, every attempt should be made to ensure that adequate tissue stores of zinc are maintained because disease activity is correlated with zinc deficiency. Parenteral zinc administration may be needed in some cases. Although less than ideal, intravenous administration of zinc is often the only way to attain even marginal zinc levels in patients with CD.[67]

Magnesium

Magnesium deficiency is often seen in patients with IBD.[60,69,70] However, a poor correlation exists between serum magnesium levels—which may be low in only a few patients— and intracellular magnesium levels, which are commonly decreased in patients with IBD.[60]

Patients with low intracellular magnesium levels may present with the following problems[60]:

- Weakness
- Anorexia
- Hypotension
- Confusion
- Hyperirritability
- Tetany
- Convulsions
- Electrocardiographic or electroencephalographic abnormalities

These symptoms are generally responsive to parenteral magnesium supplementation.

A daily intravenous dose of 200 to 400 mg of elemental magnesium may be necessary for patients not responding to oral supplementation. Patients with IBD may require this route of supplementation owing to magnesium's somewhat cathartic action and poor absorption in those with a short bowel. Oral supplementation should be with magnesium chelates (i.e., citrate, aspartate) rather than inorganic magnesium salts (i.e., carbonate).

Iron

Iron deficiency anemia is very common in IBD, largely because of chronic blood loss through the gut.[60] Serum ferritin levels are the most useful indices of iron status. A serum ferritin concentration of greater than 55 ng/mL indicates adequate iron reserves in bone marrow, whereas a concentration of less than 18 ng/mL is highly predictive of iron deficiency (see Chapter 23 for further discussion). The clinician should attempt to increase the patient's iron stores by improving absorption, as with supplemental vitamin C, rather than through direct iron supplementation, which promotes intestinal infection.[71]

Calcium

Patients with IBD are also at risk for the development of calcium deficiency, probably owing to the following factors[60]:

- Loss of absorptive surfaces
- Steatorrhea
- Corticosteroid use
- Vitamin D deficiency

Potassium

Diarrheal diseases are often associated with potassium and other electrolyte deficiencies. Although symptoms of potassium deficiency are quite rare in patients with IBD, levels of this mineral are probably below optimum. In one study, nutritional support to correct potassium deficiency resulted in significantly reduced rates of surgical complications.[72]

Vitamins

Vitamin A

Low serum retinol levels are found in approximately 20% of patients with CD and are correlated with the activity of the disease.[60,66] Vitamin A can profoundly affect the metabolism and differentiation of the intestinal epithelial mucosa because it can increase the number of goblet cells, the production of mucins, and the secretion of mucus; moreover, it can restore normal barrier function. Preliminary case reports indicated that vitamin A may be of therapeutic use in CD.[73,74] However, long-term controlled trials have shown that vitamin A (50,000 IU twice daily) has no therapeutic effect in the majority of patient with CD.[75,76] It should be kept in mind, however, that certain individuals may respond to vitamin A therapy and that zinc supplementation will often normalize disturbances of vitamin A metabolism because zinc is a necessary component of retinol-binding protein.[66]

Vitamin D

Vitamin D deficiency is quite common in IBD, with laboratory evidence of this in 75% of patients with CD and 35% of patients with UC.[60,77] It is probably due to decreased absorption of 25-hydroxyvitamin D. Patients with IBD are at increased risk for the development of metabolic bone diseases such as osteoporosis and osteomalacia. This relates to previously mentioned factors in calcium deficiency. Vitamin D plays an important role in supporting proper immune regulation, much like probiotics; both influence T-regulatory cell function and dampen proinflammatory cytokines produced in animal models of IBD. Clinical studies using vitamin D at supraphysiological doses are under way.

Vitamin E

Vitamin E deficiency can occur in IBD, as observed in one case report.[78] The patient had a 25-year history of CD and had undergone multiple small bowel resections. Presenting symptoms relating to vitamin E deficiency were as follows:

- Bilateral visual field scotomata
- Generalized motor weakness
- A broad-based gait with marked ataxia
- Brisk reflexes
- A bilateral Babinski response

This patient's serum vitamin E concentration was 0.03 mg/dL (normal is 0.8–1.2 mg/dL), and in vitro peroxide hemolysis was 100% (normal is <10%). Supplementation with 270 IU/day of vitamin E eventually brought complete recovery over a period of 2 years.

Vitamin E supplementation is also indicated because of its ability to inhibit the formation of leukotrienes and reduce free-radical damage.[79]

Vitamin K

Vitamin K deficiency, resulting in the formation of abnormal prothrombin (deficient in gamma-carboxyglutamic acid), is quite common in patients with IBD.[80,81] It also contributes to the osteoporosis and osteopenia that are so often seen in patients with CD.[82] The best laboratory test to diagnose early vitamin K deficiency before lowered serum levels is to measure the incomplete gamma-carboxylation of specific serum proteins such as osteocalcin and prothrombin. Low vitamin K status has been linked to bone disease by incomplete carboxylation of osteocalcin and coronary artery disease by unknown mechanisms. Vitamin K_2 deficiency is tested my measuring PIVKA II (protein in the absence of vitamin K carboxylation) and/or uncarboxylated osteocalcin by laboratories such as Quest and LabCorp as well as many designer specialty laboratories.

Folic Acid

Low serum concentrations of folic acid are common in IBD, with reports of occurrence ranging between 25% and 64% of cases.[60,82–84] The drug sulfasalazine exacerbates the condition by interfering with folate-dependent enzymes and with the intestinal folate transport system.[85] A folate deficiency promotes further malabsorption through alteration in the structure of the intestinal mucosal cells.[86] These cells have a very rapid turnover (1–4 days) compared with red blood cells (RBCs; 3–4 months); therefore deficiency affects mucosal cells much earlier than RBCs. Testing CD patients for elevations in serum homocysteine or single-nucleotide polymorphisms (SNPs) for enzymes involved in the methylation of folate, such as methyl-tetrahydrofolate reductase, may provide valuable diagnostic tools for the early detection of aberrant folate metabolism in patients with CD. Patients with UC, on the other hand, require supplemental folate to reduce their higher risk of colon cancer.

TABLE 186.4 Randomized Controlled Clinical Trials of Curcumin in Ulcerative Colitis (UC)

Author	Design/#	Method	Control	Duration	Results
150	DBRCT Refractory Left-Sided UC	*Enema curcuma longa* (140 mg in 20 mL of water QD for 8 weeks) + 800 oral mesalamine BID *N* = 45	Oral Mesalamine plus placebo (enema)	8 wk	Induction of remission superior with curcumin 43% herb vs. 23% placebo
151	DBRCT Stable UC	Oral 1 gm BID curcumin *N* = 89	Mesalamine 2.4 gm daily or placebo	26 wk	Maintenance of remission superior with curcumin
152	DBRCT Mild to moderate UC refractory to maximal oral and topical doses of mesalamine	Oral 3 gm curcumin daily *N* = 50	Mesalamine (oral and topical same doses continue) or placebo oral and topical	4 wk	All superior in combined group 65% response $p < 0.001$; 35% endoscopic remission. Adverse events rare.

DBRCT, Double-blind, randomized controlled trial.

Vitamin B_{12}

There is a significant correlation between vitamin B_{12} absorption and the extent of terminal ileal disease and/or resection.[60,87] Overall, abnormal Schilling test results are found in 48% of patients with CD. When ileal resection exceeds 90 cm, the Schilling test result is abnormal in all patients and does not improve with time. If the length of the resection or the extent of the inflammatory lesion is less than 60 cm, adequate absorption may occur.

Ascorbic Acid

A low vitamin C intake is common in patients with IBD, particularly in those on a low-fiber diet.[60,88] Ascorbic acid levels in serum and leukocytes are significantly lower in patients with CD than in matched controls.[60,88] Vitamin C is thought to be particularly important in the prevention of fistula formation. It has been shown that patients with fistulas have lower ascorbic acid levels than patients without them.[89]

Antioxidant Defenses

Increased oxidative stress and decreased antioxidant defenses in the mucosa are hallmark features of IBD.[90] Patients with IBD have heightened oxidative stress and associated protein and DNA oxidative damage).[90] Likewise, IBD patients have serum and mucosal deficiencies in antioxidant defenses such as selenium-dependent glutathione peroxidase and copper-zinc superoxide dismutase, along with cofactors for these enzyme systems (i.e., zinc, copper) and others (i.e., ascorbate, vitamin E, vitamin A), as previously described in this chapter.[90]

Other Nutrients

Obviously, patients with IBD are at risk for the development of any nutrient deficiency, including nutrients not discussed here. However, there is probably no real need for laboratory investigation to determine micronutrient deficiencies other than for the nutrients discussed here.[60]

Recommendation for a High-Potency Multivitamin/Multimineral Formula

It is absolutely essential that patients with IBD take a high-potency multivitamin/multimineral supplement comprising all the known vitamins and minerals. Table 186.4 lists recommendations for an optimal intake range.

In addition, patients with IBD should consume additional antioxidants (rationale provided previously). The two primary antioxidants in the human body are vitamins C and E. Vitamin C is an "aqueous phase" antioxidant, whereas vitamin E is a "lipid phase" antioxidant. Recommended doses in patients with IBD are as follows:

- Vitamin E (mixed tocopherols with approximately 40% gamma-tocopherol): 400 to 800 IU
- Vitamin C (ascorbic acid): 1000 to 3000 mg

Botanical Medicines

Curcumin

Turmeric, the major spice in curry, is a natural spice made from the herb *Curcuma longa,* a member of the ginger family. In addition to being a culinary staple, it has been used in Ayurvedic medicine since ancient times. The major chemical constituents of turmeric are curcuminoids, the most prominent of which is curcumin. Recently, the investigational focus has shifted toward the role of curcumin as an intracellular signaling agent, and studies have demonstrated that, much like green tea polyphenols, curcumin is an inhibitor of nuclear factor (NF)-κB and leads to downstream regulation and inhibition of proinflammatory genes and cytokines (see Fig. 186.2).[91] Administration of curcumin has also been reported to modulate a host of other cytokines and signaling pathways, including iNOS, MMP-9, tumor necrosis factor-alpha (TNF-α), JNK, p38, AKT, JAK, ERK, and PKC.[92] Four studies involving curcumin administration in murine colitis models showed clinical and histopathological improvement and, where measured, decreased inflammatory cytokine production.[93–95] These findings were echoed in three further studies involving rodent models of colitis.[96–98]

In 2005 Holt and colleagues reported the preliminary results of a pilot study involving open-label administration of a curcumin preparation to five patients with UC and five patients with CD. Of these 10 patients, 9 reported improvement at the conclusion of the 2-month study. Of the five patients with UC, four were able to decrease or eliminate their medications.[99] In a larger randomized, double-blind, multicenter trial involving 89 patients with quiescent UC, administration of 1 g of curcumin twice daily resulted in both clinical improvement and a statistically significant decrease in the rate of relapse.[100] Given its excellent safety profile, its plausible mechanism for affecting inflammation, and the results just described, curcumin is poised to have a prominent role in the future management of IBD. Table 186.5 summarizes the results of the randomized controlled clinical trials for curcumin in ulcerative colitis.

Boswellia

The Ayurvedic herb *Boswellia serrata* (Indian frankincense) contains boswellic acids, which inhibit leukotriene biosynthesis in neutrophilic granulocytes by noncompetitive inhibition of 5-lipoxygenase.[101] During a small 6-week trial, 350 mg three times a day of *Boswellia* gum

TABLE 186.5 Optimal Range of Nutrients

Nutrient	Range for Adults
Vitamins	
Vitamin A (retinol)	5000 IU[a]
Vitamin A (from beta-carotene)	5000–25,000 IU
Vitamin D	100–400 IU
Vitamin E (D-alpha tocopherol)	100–200 IU
Vitamin K (phytonadione)	60–300 mcg
Vitamin C (ascorbic acid)	100–1000 mg
Vitamin B_1 (thiamin)	10–100 mg
Vitamin B_2 (riboflavin)	10–50 mg
Niacin	10–100 mg
Niacinamide	10–30 mg
Vitamin B_6 (pyridoxine)	25–100 mg
Biotin	100–300 mcg
Pantothenic acid	5–100 mg
Folic acid	400 mcg
Vitamin B_{12}	400 mcg
Choline	10–100 mg
Inositol	10–100 mg
Minerals	
Boron	1–6 mg
Calcium	250–500 mg
Chromium	200–400 mcg
Copper	1–2 mg
Iodine	50–150 mcg
Iron	15–30 mg[b]
Magnesium	250–500 mg
Manganese	10–15 mg
Molybdenum	10–25 mcg
Potassium	200–500 mg
Selenium	100–200 mcg
Silica	1–25 mg
Vanadium	50–100 mcg
Zinc	15–45 mg

[a]Women of childbearing age for whom becoming pregnant is a possibility should not take more than 2500 IU/day of retinol because of the possible risk of birth defects.
[b]Men and postmenopausal women rarely need supplemental iron.

resin was as effective as sulfasalazine (1000 mg three times a day) in reducing symptoms or laboratory abnormalities of patients with active UC.[102] The rate of remission was 82% with *Boswellia* and 75% with sulfasalazine.[103] In a randomized, double-blind study from Germany, a proprietary *Boswellia* extract, H15, was found as effective as mesalazine in improving symptoms of active CD.[104] Table 186.6 summarizes the results of the randomized controlled clinical trials for *Boswellia* in inflammatory bowel disease.

Quercetin

The plant flavonoid quercetin appears to be particularly indicated in the treatment of IBD. Flavonoids in general are considered natural biological response modifiers.[105,106] Quercetin, as perhaps the most pharmacologically active flavonoid, has remarkable effects on a variety

TABLE 186.6 Randomized Controlled Clinical Trials of *Boswellia* in Inflammatory Bowel Disease

Author	Design/#	Disease	Control	Duration

DBRCT, Double-blind, randomized controlled trial; *CD,* Chron's disease; *UC,* ulcerative colitis.

of enzyme systems,[105,106] and many of the enzymes thus affected are important in the secretory, contractile, and motility processes associated with the inflammatory response: the release of histamine and other inflammatory mediators from mast cells, basophils, neutrophils, and macrophages; migration and infiltration of leukocytes; and smooth muscle contraction.

Quercetin's effect on these enzymes and processes is likely due to a common action—antagonizing calmodulin.[107] When bound to calmodulin, calcium activates a great variety of enzymes, including those involved in cyclic nucleotide metabolism, protein phosphorylation, secretory function, muscle contraction, microtubule assembly, glycogen metabolism, and calcium flux. Quercetin is believed to interact directly with calmodulin and calcium channels. This has been shown in many experimental studies and would explain quercetin's effect on such a wide number of enzymes.

Quercetin and many other flavonoids have been shown to be potent inhibitors of mast cell and basophil degranulation.[108–111] A generally accepted hypothesis for this action is that quercetin inhibits receptor-mediated calcium influx, thereby inhibiting the primary signal for degranulation. However, quercetin is also active under conditions in which the calcium channel mechanism is not operative, indicating that other mechanisms are responsible as well.

Quercetin has been shown to inhibit many of the inflammatory processes attributed to activated neutrophils.[112] This is probably due to its membrane-stabilizing action, potent antioxidant effect (which prevents the production of free radicals and inflammatory leukotrienes), and inhibition of the enzyme hyaluronidase (thus preventing the breakdown of the collagen matrix of connective tissue and ground substance). Quercetin's membrane-stabilizing effect could also account for its action in preventing mast cell and basophil degranulation. The effect also inhibits inflammation by decreasing neutrophil lysosomal enzyme secretion.[112] (Neutrophils and monocytes contain lysosomes that, on secretion of their contents, contribute greatly to the inflammatory process.)

Quercetin has been shown to inhibit many steps in eicosanoid metabolism. Probably of most significance in IBD is its inhibition of phospholipase A_2 and lipoxygenase enzymes.[105,106,113] The net result is a significant reduction in the formation of leukotrienes. Excessive leukotriene formation has been linked to asthma, psoriasis, atopic dermatitis, gout, and possibly cancer as well as IBD.[114,115] The leukotrienes C_4, D_4, and E_4 (composing the slow-reacting substances of

anaphylaxis [SRS-A]) are derived from arachidonic acid and are 1000 times as potent as histamine in promoting inflammation. Leukotrienes promote inflammation by causing vasoconstriction (thereby increasing vascular permeability) and other smooth muscle contraction and by promoting white blood cell (WBC) chemotaxis and aggregation. The reduction of leukotriene formation has significant anti-inflammatory effects, particularly in IBD. (For more information on quercetin, see Chapter 81). Despite the overwhelming evidence supporting the role of quercetin in preventing and improving inflammation in IBD, only three of six animal model–based studies showed a positive effect. Authors have speculated that the methylation of quercetin in the gut is variable in IBD, which could explain the inconsistent results observed thus far. Clinical trials in humans are thus far lacking, so no conclusions can be drawn.

Aloe Vera

Aloe vera gel has a dose-dependent inhibitory effect on the production of the reactive oxygen metabolites prostaglandin E2 and (at high doses) interleukin (IL)-8 by human colonic epithelial cells grown in tissue culture.[116] When administered via the oral route, aloe vera gel at 100 mL twice a day for 4 weeks produced a clinical response significantly more often than placebo (response ratio 5.6) in patients with UC.[117] Remission occurred in 30% of patients taking aloe vera gel and 7% of those receiving a placebo. In this clinical trial, aloe also reduced histological disease activity, whereas placebo did not. No significant side effects were described in the aforementioned trials on aloe vera for UC, although it should be noted that aloe vera gel is often used as a laxative. Acemannan, an extract of aloe vera, concentrated to a mucopolysaccharide (MPS) concentration of 30% of solid weight, has been demonstrated to reduce symptoms and indices of inflammation in controlled studies of patients with UC.[118]

Bastyr Formula (Modified Robert Formula)

Although no research has been done to document its efficacy, an old naturopathic remedy, the Robert formula or its modification (Bastyr formula), has a long history of use in IBD (Box 186.2). It is composed of the following botanical medicines:

- *Althea officinalis* (also known as marshmallow root)—a demulcent with soothing effects on the mucous membranes
- *Baptisia tinctora* (also known as wild indigo)—used for gastrointestinal infections
- *Echinacea angustifolia* (also known as purple coneflower)—antibacterial and used to promote normalization of the immune system (see Chapter 75)
- *Geranium maculatum*—a gastrointestinal hemostatic
- *Hydrastis canadensis* (also known as goldenseal)—inhibits the growth of many enteropathic bacteria (see Chapter 86)
- *Phytolacca americana* (also known as poke root)—used for healing ulcerations of the intestinal mucosa
- *Symphytum offinale* (also known as comfrey)—anti-inflammatory and a promoter of tissue growth and wound healing
- *Ulmus fulva* (also known as slippery elm)—a demulcent

The cabbage powder is used because of its documented ability to heal gastrointestinal ulcers (see Chapter 207), pancreatin is used to assist in the digestive process (see Chapter 100), niacinamide is used for its anti-inflammatory effects, and duodenal substance is used because it also heals gastrointestinal ulcers.

Butyrate Enemas in Ulcerative Colitis

The short-chain fatty acids (SCFAs)—mainly acetate, propionate, and butyrate—arise in the colon as end products of bacterial carbohydrate fermentation. These SCFAs function as primary energy sources for the luminal colon cells, especially in the distal segments. Decreased levels or decreased utilization of SCFAs leading to impaired cellular energetics have been hypothesized to play a major role in UC (Fig. 186.5). On the basis of this hypothesis, several clinical trials have been conducted with enemas providing SCFAs (usually composed of either butyrate as a sole agent in concentrations ranging from 80 to 100 mmol/L or SCFA combinations composed of acetate 60 mmol/L, propionate 25 mmol/L, and butyrate 40 mmol/L; Table 186.7). Excellent preliminary results in pilot studies have led to a well-designed double-blind study.[73,119]

In this study, 47 patients with distal UC randomly received either a combination of SCFAs, butyrate, or a placebo in an enema form retained for 30 minutes twice daily.[73] The primary end point of the study was the disease activity index composed of stool frequency, rectal bleeding, mucosal appearance, and physician rating of disease activity as well as endoscopic examination. After 8 weeks of therapy, there was a drop in activity in all three groups, with the butyrate group showing the lowest disease activity. Endoscopic examination demonstrated less disease in the butyrate and SCFA combination groups. Complete remission occurred in 47% receiving SCFAs, 38% receiving butyrate, and 25% receiving placebo. This study and others indicate that butyrate and SCFA enemas may prove to be useful adjuncts in the treatment of UC. There is a total of four studies demonstrating improved healing of patients with left-sided UC that is refractory to standard medical therapy.

Prebiotics

Prebiotics are nondigestible food ingredients that stimulate the growth or modify the metabolic activity of intestinal bacterial species that have the potential to improve the health of their human host. The criteria associated with the notion that a food ingredient should be classified as a prebiotic are that it remain undigested and unabsorbed as it passes through the upper part of the gastrointestinal tract and that it be a selective substrate for the growth of specific strains of beneficial bacteria (usually lactobacilli or bifidobacteria) rather than for all colonic bacteria. Prebiotic food ingredients include bran, psyllium husk, resistant (high-amylose) starch, inulin (a polymer of fructofuranose), lactulose, and various natural or synthetic oligosaccharides, which consist of short-chain complexes of sucrose, galactose, fructose, glucose, maltose, or xylose. The best-known effect of prebiotics is to increase fecal water content, relieving constipation. Bacterial fermentation of prebiotics yields SCFAs like butyrate. Several studies have suggested benefits of various prebiotics for the treatment of patients with UC. For instance, when oat bran at 60 g/day (supplying 20 g of dietary fiber) was given to patients with UC, fecal butyrate was increased by 36%, and abdominal pain improved.[120] A dietary supplement containing fish oil and two types of indigestible carbohydrate, FOS and xanthan gum,

BOX 186.2 Composition of the Bastyr Formula

- Eight parts *Althea officinalis*
- Four parts *Baptisia tinctora*
- Eight parts *Echinacea angustifolia*
- Eight parts *Geranium maculatum*
- Eight parts *Hydrastis canadensis*
- Eight parts *Phytolacca americana*
- Eight parts *Ulmus fulva*
- Eight parts cabbage powder
- Two parts pancreatin
- One part niacinamide
- Two parts duodenal substance

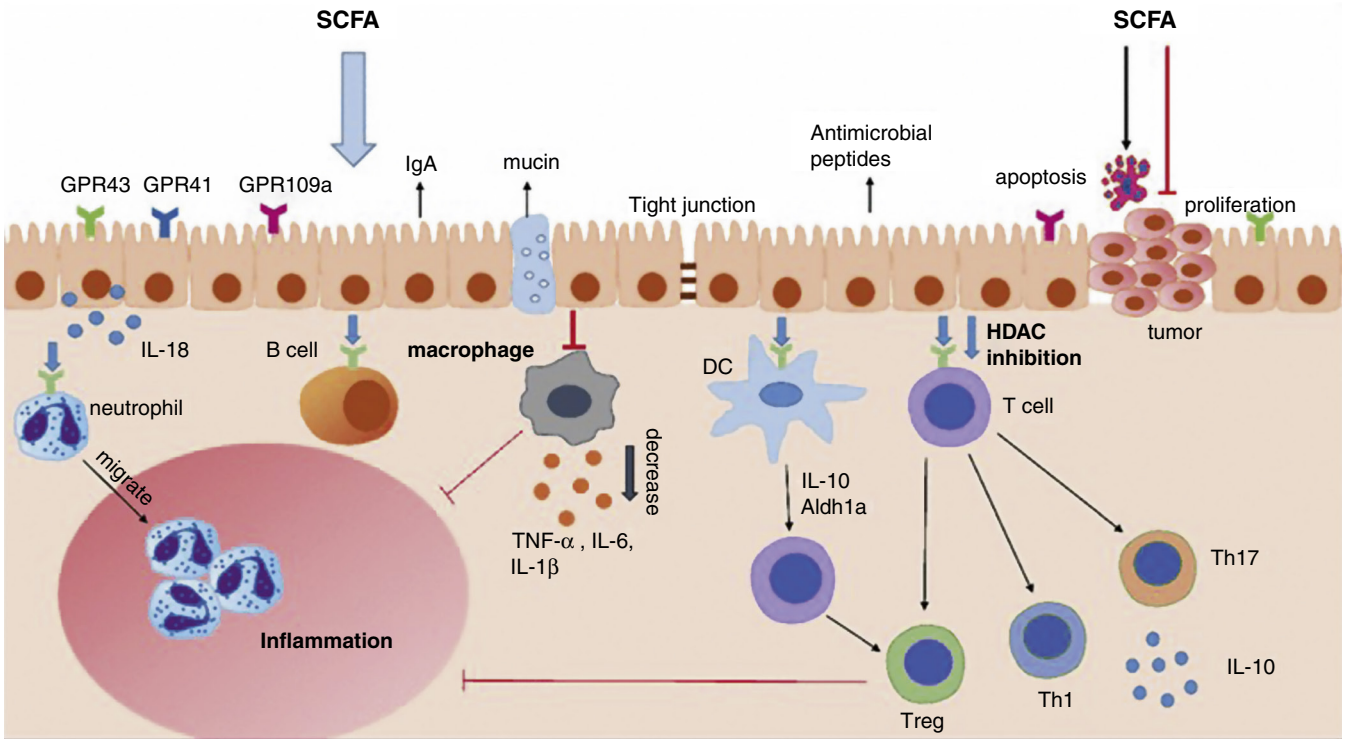

Fig. 186.5 Role of short-chain fatty acids (SCFAs) in the regulation of mucosal immune responses. SCFAs regulate intestinal mucosal immunity by exerting their effects on various immune cells. SCFAs regulate intestinal barrier integrity by inducing intestinal epithelial cell secretion of interleukin-18 (IL-18), antimicrobial peptides, and mucin and upregulating the expression of tight junctions. SCFAs induce neutrophil migration to inflammatory sites and enhance their phagocytosis ability. SCFAs regulate T-cell function not only through the GPCR pathway but also through the inhibition of histone deacetylases (HDAC). The differentiation of T cells is mediated both by SCFA regulation of dendritic cells (DCs) and the direct action of SCFAs on T cells. SCFAs regulate the generation of T-helper type-1 (Th1), T-helper type-17 (Th17), and regulatory T cells (Tregs) in different cytokine milieu. SCFAs also inhibit intestinal macrophage production of proinflamamtory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), and interleukin-1 beta (IL-1β), through inhibition of HDAC, and possibly induce intestinal immunoglobulin A (IgA) production by B cells. Moreover, SCFAs inhibit carcinogenesis by promoting apoptosis and suppressing the proliferation of tumor cells. (Original figure published in Sun M, et al. Microbiota metabolite short chain fatty acids, GPCR, and inflammatory bowel diseases.*J Gastroenterol*. 2017 Jan;52[1]:1–8. https://doi.org/10.1007/s00535-016-1242-9. CD, Chron's disease; *LGG,* Lactobacillus rhamnosus *GG; SCB,* Saccharomyces boulardii*; UC,* ulcerative colitis.

allowed a reduction of glucocorticoid dose as compared with a placebo in patients with steroid-dependent UC.[121] Other prebiotic trials for UC included a Japanese germinated barley foodstuff (GBF) containing hemicellulose-rich fiber; given at a dose of 20 to 30 g/day, it was found to increase stool butyrate concentration,[122] decrease the clinical activity index of patients with active disease,[123] and prolong remission in patients with inactive disease.[124] A mixture of *Bifidobacterium longum* and inulin-derived FOS administered for 1 month as monotherapy to patients with UC produced improvement in sigmoidoscopic appearance, histology, and several biochemical indices of tissue inflammation versus a placebo control.[125]

Probiotics in Inflammatory Bowel Disease

The term *probiotics* refers to beneficial bacteria and yeasts that can be administered orally to achieve a therapeutic benefit. The results of studies for the use of probiotics in IBD are summarized in Table 186.8. Overall, patients with UC do benefit from using probiotics during an active flare of their disease, and there is a benefit of probiotics for maintaining remissions. The studies to date have shown inconsistent results with all strains of probiotics for CD overall. However, supplementation with the beneficial yeast *Saccharomyces boulardii* is a safe and effective treatment for patients with CD, helping reduce diarrhea, intestinal inflammation, and the risk of relapse.[126,127] Common doses of *S. boulardii* are 250 mg three to four times a day. Likewise, supplementation with *Lactobacillus-GG* has proved to be of benefit in patients with CD; the customary dose is 10^{10} colony-forming units (CFUs) in enteric-coated tablets twice a day.[128,129]

THERAPEUTIC MONITORING AND EVALUATION

Fecal Calprotectin

Calprotectin is a protein secreted into the intestinal lumen in direct proportion to inflammation. Measurement of calprotectin in stool samples has been shown to be a sensitive and specific noninvasive assessment for inflammation in patients with IBD, and the test is helpful for distinguishing IBD from other, noninflammatory gastrointestinal conditions, such as irritable bowel syndrome.[130]

Crohn's Disease Activity Index

The CDAI was developed as a monitoring tool in the NCCDS.[131] It met the basic requirements necessary for the study—providing uniform clinical parameters that could be assessed and producing a consistent numerical index for recording the results of the study of several centers over several years.

In general, CDAI scores below 150 indicate a better prognosis than higher scores. The CDAI is a very useful way to monitor the progress of therapy.

BOX 186.3 Monitoring of the Pediatric Patient With Inflammatory Bowel Disease

History
- Appetite, extracurricular activities
- Type and duration of inflammatory bowel disease, frequency of relapses
- Severity and extent of ongoing symptoms
- Medication history

3-Day Diet Diary

Physical Examination
- Height, weight, arm circumference, triceps skinfold measurements
- Loss of subcutaneous fat, muscle wasting, edema, pallor, skin rash, hepatomegaly

Laboratory Tests
- Complete blood count and differential, reticulocyte and platelet counts, sedimentation rate, urinalysis
- Serum total proteins, albumin, globulin, and retinol-binding protein
- Serum electrolytes, calcium, phosphate, ferritin, folate, carotenes, tocopherol, and vitamin B_{12}
- Leukocyte ascorbate, magnesium, and zinc
- Creatinine height index, blood urea nitrogen/creatinine ratio

Monitoring of the Pediatric Patient

Pediatric patients with IBD present a particularly difficult problem in that it is often very difficult for them to achieve normal growth and development. Growth failure occurs in 75% of children with CD and in 25% of children with UC.[62] The pediatric patient with IBD should be evaluated at least twice yearly. Evaluation should include a pertinent history, clinical anthropometry, Tanner staging, and appropriate laboratory testing. Box 186.3 outlines the necessary components of a comprehensive, twice-yearly nutritional evaluation in pediatric patients with IBD. An aggressive nutritional program should be instituted, including supplements (it may be necessary to use enteral or parenteral methods in some patients), which is similar to the approach outlined for the adult patient, with the doses adjusted as appropriate.

The CDAI is not as accurate in monitoring the disease in children as it is in adults. To overcome this shortcoming, Lloyd-Still and Green[132] devised a clinical scoring system for IBD in children. It is divided into five major divisions (the maximum score is in parentheses): general activity (10), physical examination and clinical complications (30), nutrition (20), radiography (15), and laboratory (25). An elevated score (i.e., scores in the 80s) represents good status, whereas scores in the 30s and 40s represent severe disease.

THERAPEUTIC APPROACH

It is important to recognize that in some patients, CD and UC are life-threatening diseases that at times require emergency treatment. A small percentage of patients who have severe colitis may experience severe exacerbations requiring hospitalization. This is more common in patients with UC, who typically present with a fever of 101°F or higher; profuse, constant, loose, bloody stools; anorexia; and apathy and prostration; and although abdominal signs may be normal, physical examination will uncover a distended abdomen, tympany, absence of bowel sounds, and even rebound tenderness.

For the typical patient, IBD is a chronic disease requiring long-term therapy and follow-up. The first step is to identify and remove all factors that may be initiating or aggravating the inflammatory reaction, such as food allergens and carrageenan. The patient is started on a diet that maximizes macronutrients and micronutrients while minimizing aggravating foods and nonfoods.

A broad-based, individualized nutritional supplementation plan is necessary for all patients with IBD. Particularly important are the nutrients zinc, magnesium, folic acid, and vitamin A. Nutritional supplements are used as appropriate to correct deficiencies, normalize the inflammatory process, and promote healing of the damaged mucosa. Botanical medicines are used to promote healing and normalize the intestinal flora.

Diet

All allergens—as well as wheat, corn, dairy products, and carrageenan-containing foods—should be eliminated. The diet should be high in complex carbohydrates and low in sugar and refined carbohydrates. Fiber is poorly tolerated in Crohn's disease with luminal narrowing, whereas complex carbohydrates are prebiotic for fostering healthy enteric flora and have been shown to be helpful for ulcerative colitis.[133]

Supplements

- Multivitamin and mineral supplements with trace mineral cofactors for antioxidant systems
- Magnesium: 200 mg/day. Higher dosages may be required.
- Zinc picolinate or carnosine: 37.5 mg of zinc L carnosine or 50 mg of picolinate. Please be cautioned that long-term use of zinc supplements can deplete the body's copper storage and lead to neurologic problems.
- Vitamin E: 400 to 800 IU/day mixed tocopherols
- Fish oil: 4,000-5,000 mg of combined EPA/DHA daily.
- Choose one of the following:
  - Quercetin: 400 mg 20 minutes before meals
  - Grape seed extract (>95% procyanidolic oligomers): 150 to 300 mg/day
  - Pine bark extract (>90% procyanidolic oligomers): 150 to 300 mg/day
- Prebiotics (inulin, fructose oligosaccharides, etc.): 5 g/day
- Short-chain fatty acid enemas (60 mL of 80–100 mmol/L) nightly for left-sided colitis

Botanical Medicines

- Curcumin from turmeric (*C. longa*): 1000 two to three times a day before meals
- *Boswellia* extract: equivalent to 400 mg boswellic acids three times a day
- Aloe vera: Choose one of the following:
  - Aloe vera gel: oral preparations can be consumed at a dose of 100 mL a day . Diarrhea is a potential side effect. The preparation needs to be a "latex-free" distilled preparation that is 100% pure aloe gel. Otherwise there is a risk of toxicity.
  - Aloe vera juice: a variety of different preparations types and concentrations make accurate dose recommendations difficult. They can be consumed orally as a beverage or tonic.
  - Acemannan: 400 to 800 mg/day
- Bastyr formula: 2 to 3 "00" capsules with each meal

Insomnia and Other Sleep Disorders

John Nowicki, ND, and *Michael T. Murray, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Difficulty falling asleep (sleep-onset insomnia)
- Frequent or early awakening (sleep-maintenance insomnia)
- Early wakening
- Daytime symptoms such as fatigue, cognitive problems, mood disorders, and impaired psychomotor performance
- Affects one of every four people in the United States

GENERAL CONSIDERATIONS

Insomnia is one of the most common complaints seen by physicians. Within the course of a year, up to 30% of the population suffers from insomnia, and roughly 10% of the adult population has chronic insomnia (Fig. 187.1).[1] Many use over-the-counter (OTC) medications to combat the problem, and others seek stronger sedatives. Approximately 12.5% of the adult population uses a prescribed anxiolytic or sedative-hypnotic in the course of a year; about 2% of the population takes one on any given day. More than one half of these drugs, especially benzodiazepines, are prescribed by primary care physicians. Nearly 100 million prescriptions are written each year for these drugs.[2]

A thorough history and physical examination are indicated in the patient presenting with insomnia because it is a symptom that can have many causes (Table 187.1). Psychological factors account for 50% of all insomnias evaluated in sleep laboratories.[1] Insomnia is closely associated with affective disorders (see Chapter 142), and cognitive-behavioral therapy can produce effective improvements in sleep quality.[3] A detailed recreational, prescription, and nonprescription drug-use history, along with a dietary and beverage history, are also required to determine whether the patient is consuming any agents known to interfere with sleep. Examples are shown in Table 187.2. The listing of marijuana may seem confusing because users report improved sleep with use. However, this improved sleep appears primarily with occasional use. Chronic use has been consistently shown to increase sleep disorders. The mechanism is likely similar to that seen with alcohol—rebound and withdrawal.[4]

Sleep apnea is the most common example of sleep-disordered breathing. A high prevalence of insomnia has been observed in individuals with sleep apnea. First described in 1965, sleep apnea is a breathing disorder characterized by brief interruptions of breathing with subsequent hypoxia during sleep. These breathing pauses are almost always accompanied by snoring between apneic episodes, although not everyone who snores has this condition. Sleep apnea can also be characterized by choking sensations. Sleep apnea may happen several times an hour, ensuring the individual is never fully rested. The frequent interruptions of deep, restorative sleep often lead to excessive daytime sleepiness and may be associated with an early-morning headache. Approximately 18 million Americans are thought to suffer from sleep apnea.

Early recognition and treatment of sleep apnea are important because it is associated with marked daytime fatigue, irregular heartbeat, high blood pressure, heart attack, and stroke as well as memory loss and other intellectual capabilities. The patient usually does not know he or she has a problem and may not believe it when told. If a person snores heavily or if their sleep partner reports the individual has periods of interrupted breathing during sleep, it is important to consult a doctor. Sleep apnea should also be considered in anyone with significant daytime drowsiness or changes in intellectual function. Sleep apnea can be properly diagnosed through the services of a sleep disorder specialist, usually in a sleep laboratory. Home sleep studies are also available but require a sleep specialist for interpretation of the results.

Sleep apnea is most often caused by narrowing of the airway by pharyngeal structures, causing obstructive sleep apnea. With a narrowed airway, the person continues efforts to breathe, but air cannot easily flow into or out of the nose or mouth. This narrowing results in heavy snoring, periods of no breathing, and frequent arousals (causing abrupt changes from deep sleep to light sleep). Ingestion of alcohol and sleeping pills increases the frequency and duration of breathing pauses in people with sleep apnea. In some cases, sleep apnea occurs even if no airway obstruction or snoring is present. This form of sleep apnea, central sleep apnea, is caused by a loss of perfect control over breathing by the brain.

TABLE 187.1 Causes of Insomnia[a]

Sleep-onset Insomnia	Sleep-maintenance Insomnia
Anxiety or tension	Depression
Environmental change	Environmental change
Emotional arousal	Sleep apnea
Fear of insomnia	Nocturnal myoclonus
Phobia of sleep	Hypoglycemia
Disruptive environment	Parasomnias
Pain or discomfort	Pain or discomfort
Caffeine	Drugs
Alcohol	Alcohol

[a]The boundary between the categories is not entirely distinct.

TABLE 187.2 Common Agents Known to Interfere With Sleep

- Alcohol
- Beta blockers
- Chocolate
- Coffee
- Marijuana
- Oral contraceptives
- Tea
- Thyroid preparations

In both obstructive and central sleep apnea, obesity is the major risk factor, and weight loss is the most important aspect of long-term management. People with sleep apnea experience periods of anoxia (oxygen deprivation of the brain) with each apneic episode, which ends in arousal and a reinitiation of breathing. Seldom does the sufferer awaken enough to be aware of the problem. However, the combination of frequent periods of oxygen deprivation (20 to several hundred times per night) and the greatly disturbed sleep can significantly diminish the sufferer's quality of life and lead to serious problems.[5]

The most common treatment of sleep apnea is the use of nasal continuous positive airway pressure (CPAP). In this procedure, the patient wears a mask over the nose during sleep, and pressure from an air blower forces air through the nasal passages. The air pressure is adjusted so that it is just enough to prevent the throat from collapsing during sleep. The pressure is constant and continuous. Nasal CPAP prevents airway closure while in use, but episodes of apnea return when CPAP is stopped or used improperly. Surgery to reduce soft tissue in the throat or soft palate should be used only as a last resort because it is often unsuccessful and may aggravate the condition. Laser-assisted uvulopalatoplasty is a highly promoted surgical option. In this procedure, lasers are used to surgically remove excessive soft tissue from the back of the throat and the palate. About 90% of sleep apnea sufferers receive benefit initially. However, within a year, many people regress or end up worse than before the procedure as a result of the formation of scar tissue.[5]

Normal Sleep Patterns

Human sleep is perhaps one of the least understood physiological processes. Its value to human health and proper functioning is without question. Sleep is absolutely essential to both the body and the mind. Impaired sleep, altered sleep patterns, and sleep deprivation impair mental and physical function.

Normal adult sleep–wake patterns repeat themselves on an approximately 24-hour cycle, of which sleep constitutes one third. Exactly how much sleep is required varies from one person to the next. Sleep tends to decrease with age, but whether this tendency is a normal or abnormal progression is unknown. A 1-year-old baby requires about 14 hours of sleep a day, a 5-year-old about 12 hours, and adults about 7 to 9 hours. Women tend to require more sleep than men. The elderly tend to sleep less at night but doze more during the day than do younger adults.

From observations of eye movement and electroencephalographic (EEG) recordings, sleep is divided into two distinct types: rapid eye movement (REM) sleep and non-REM sleep. During REM sleep, the eyes move rapidly and dreaming takes place. When people are awakened during non-REM sleep, they report that they were thinking about everyday matters but rarely report dreams.

Non-REM sleep is divided into stages 1 through 4 according to the level of EEG activity and ease of arousal. As sleep progresses, there is a deepening of sleep and slower brainwave activity until REM sleep ensues, when suddenly the brain becomes much more active. In adults, the first REM sleep cycle is usually triggered 90 minutes after going to sleep and lasts about 5 to 10 minutes. After the flurry of activity, brainwave patterns return to those of non-REM sleep for another 90-minute sleep cycle.

Each night, most adults experience five or more sleep cycles. REM sleep periods grow progressively longer as sleep continues; the last sleep cycle may produce a REM sleep period that can last about an hour. Non-REM sleep lasts approximately 50% of this 90-minute sleep cycle in infants and about 80% in adults. As people age, in addition to less REM sleep, they tend to awaken at the transition from non-REM to REM sleep.

The Importance of Adequate Sleep

Adequate sleep is absolutely necessary for long-term health and regeneration. Many physiological processes occur during sleep, but perhaps the most important are the increased secretion of growth hormone (GH) and the scavenging of free radicals in the brain.

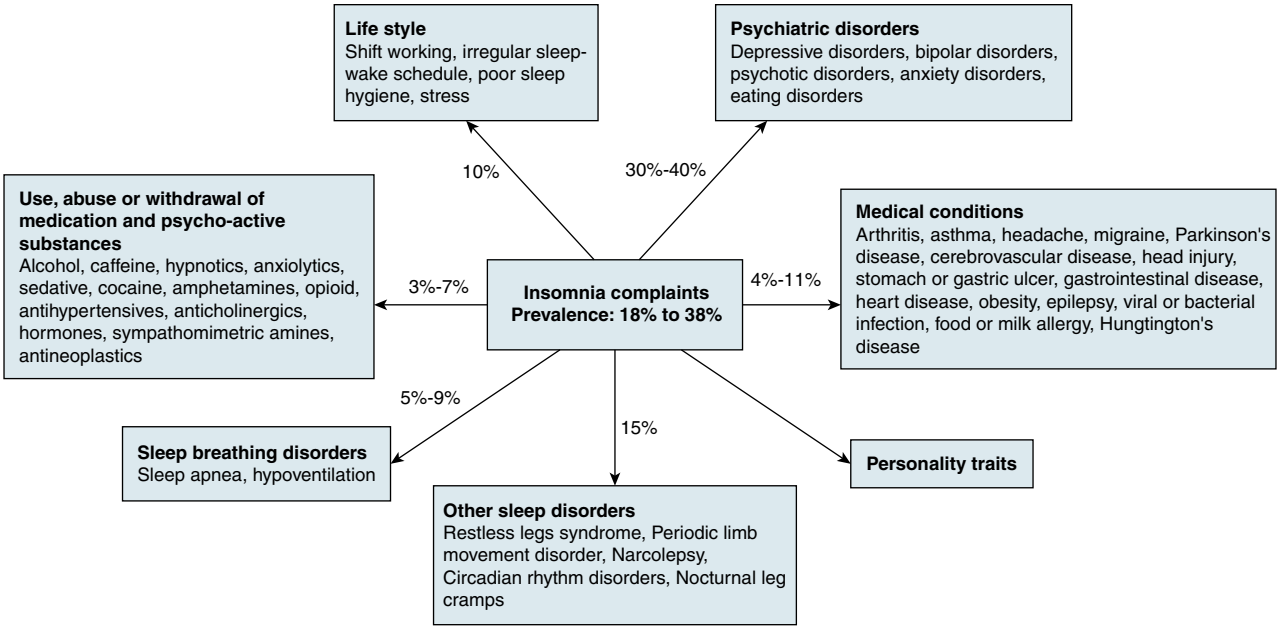

Fig. 187.2 Factors associated with insomnia. (From https://www.sleepeval.com/dyssomnia/impact.html.)

Many of the benefits of sleep are probably mediated through GH. As an anabolic hormone, GH has been called by some the "antiaging" hormone. GH stimulates tissue regeneration, liver regeneration, muscle building, breakdown of fat stores, normalization of blood sugar, and a host of other beneficial processes in the body. It also helps convert fat to muscle. Small amounts of GH are secreted at various times during the day, but essentially all secretion of GH occurs during sleep.

Sleep is required to ensure minimal neuronal damage from free radicals accumulated during waking. Most people can tolerate a few days without sleep and fully recover. However, chronic sleep deprivation accelerates aging of the brain, causes neuronal damage, and produces nighttime elevations in cortisol.[6]

THERAPEUTIC CONSIDERATIONS

Insomnia is initiated or maintained by several psychological and physiological factors, which should be addressed before inducing sleep pharmacologically (Fig. 187.2). Counseling and/or stress-reduction techniques (including biofeedback and hypnosis) may be indicated in many cases. The following topics are discussed in this chapter as they relate to the promotion of sleep:

- Exercise
- Progressive relaxation
- Nocturnal glucose levels
- Serotonin precursor and cofactor therapy
- 5-Hydroxytryptophan (5-HTP)
- Cofactors for serotonin synthesis
- Melatonin
- Restless legs syndrome and nocturnal myoclonus
- Botanicals with sedative properties

Lifestyle

Exercise

Regular physical exercise is known to improve general well-being and promote improvement in sleep quality.[3] Exercise should be performed in the morning or early evening, not before bedtime, and should be of moderate intensity. Usually 20 minutes of aerobic exercise at a heart rate between 60% and 75% of maximum (maximum heart rate is approximately 220 minus the patient's age in years) is sufficient.

Progressive Relaxation

Progressive relaxation is based on a simple procedure comparing tension with relaxation. Each muscle is first forcefully contracted for a period of 1 to 2 seconds and then relaxed. Because the procedure goes progressively through all the muscles of the body, a deep state of relaxation results. The procedure begins with contraction of the muscles of the face and neck, with the contraction held for at least 1 or 2 seconds. Next, the upper arms and chest are contracted and then relaxed, followed by the lower arms and hands. The process is repeated progressively down the body—abdomen, buttocks, thighs, calves, and feet. This whole practice is repeated two or three times or until sleep is produced.

Nocturnal Glucose Levels

Increased nocturnal blood glucose volatility may be an important cause of sleep-maintenance insomnia, especially when there are rapid drops in blood glucose levels. The brain is highly dependent on glucose as an energy substrate, and a quick drop in blood glucose level promotes awakening via the release of glucose regulatory hormones (e.g., epinephrine, glucagon, cortisol, and GH). Increased nocturnal blood glucose volatility and/or hypoglycemia must be ruled out in maintenance-type insomnia (see Chapter 181).

Serotonin Precursor and Cofactor Therapy

Serotonin is an important initiator of sleep. The synthesis of central nervous system (CNS) serotonin depends on the availability of tryptophan (discussed in more detail in Chapter 76, 5-HTP).

Tryptophan

L-Tryptophan has shown modest effects in the treatment of insomnia,[7–9] and although not every patient responded to L-tryptophan in clinical trials, those who have experienced dramatic relief. It is generally more effective in sleep-onset insomnia and less effective in sleep-maintenance insomnia. Advantages of L-tryptophan versus over-the-counter (OTC) and prescription pills include limited distortions

of normal sleep processes and no withdrawal symptoms. Doses smaller than 2000 mg are generally ineffective.

The sleep-promoting effect of L-tryptophan is believed to be due to enhanced serotonin synthesis, but there is evidence to suggest that other mechanisms may also be responsible or contributory, including L-tryptophan–enhanced melatonin synthesis. Administration of L-tryptophan causes a massive elevation of plasma melatonin concentration.[10] Although L-tryptophan reduces sleep latency, it exerts effects in normal subjects that are at odds with the serotonin system, such as reducing REM sleep and increasing non-REM sleep.[11,12] Drugs that prevent the conversion of tryptophan to serotonin enhance these effects. From this information, it is concluded that some of L-tryptophan's effects on sleep do not involve the serotonin or melatonin system. As discussed in Chapter 87, the effects of L-tryptophan can be negated by conversion via the kynurenine pathway. This conversion can be partially inhibited by niacin (30 mg is an appropriate dose), thereby enhancing the effects of L-tryptophan.

The insomnia-relieving and sleep-promoting actions of L-tryptophan appear to be cumulative, because it often takes a few nights for L-tryptophan to start working. In a double-blind study, the effects of 3 g of L-tryptophan on sleep performance, arousal threshold, and brain electrical activity during sleep were assessed in 20 males with chronic sleep-onset insomnia.[13] After a sleep laboratory screening night, all subjects received placebo for three consecutive nights; then 10 subjects received L-tryptophan and 10 received a placebo for six nights. All subjects received placebo on two withdrawal nights. L-Tryptophan had no effect on sleep latency during the first three nights of administration. However, on nights four through six of administration, sleep latency was significantly reduced. Consistent with other studies, this study found that unlike sleeping pills (benzodiazepines especially), L-tryptophan did not alter sleep stages, impair performance, or alter brain electrical activity during sleep. This study indicates that L-tryptophan should be used for a minimum of 1 week to gauge its effectiveness in chronic insomnia. Administration of high-dose L-tryptophan (4 g) during the day can promote sleep. This indicates that the consumption of foods high in tryptophan during the day may contribute to daytime sleepiness, and an evening meal high in tryptophan in relation to competing amino acids may promote sleep.

The important cofactors vitamin B_6, niacin, and magnesium should be administered along with the tryptophan to ensure its conversion to serotonin. Also, because other amino acids compete with tryptophan for transport into the CNS across the blood–brain barrier and insulin increases tryptophan uptake by the CNS, protein consumption should be avoided near administration, and a carbohydrate source such as fruit or fruit juice should accompany the tryptophan.

5-Hydroxytryptophan

5-HTP is one step closer to serotonin than L-tryptophan and does not depend on a transport system for entry into the brain. Several clinical studies have shown 5-HTP to produce dramatically better results than L-tryptophan in promoting and maintaining sleep.[14–17]

One of the key benefits of 5-HTP is its ability to increase REM sleep (typically by about 25%) while increasing deep sleep stages 3 and 4 without lengthening total sleep time.[11,12] The dosage recommendation of 5-HTP is 100 to 300 mg, 30 to 45 minutes before retiring. The patient should start with the lower dose for at least 3 days before increasing it. For more information, see Chapter 87.

Vitamin B Complex

B vitamins play a significant role in the manufacture of serotonin, and deficiencies can affect both sleep quality and sleep quantity. Niacin has been reported to have a sedative effect, probably owing to its peripheral dilating action and shunting of tryptophan metabolism toward serotonin synthesis. Cross-sectional data from the National Health and Nutrition Examination Surveys (NHANES) 2005–2006 found independent inverse associations between serum vitamin B_{12} and sleep duration as well as between folate and sleep disturbance.[18] A study of 87 adults aged 21 to 45 years found that insomniacs consumed significantly less energy, carbohydrates, folic acid, and vitamin B_{12} than normal sleepers.[19] Further, intakes of protein, fat, and thiamine were significantly different in insomniacs.

Magnesium

Magnesium is a cofactor in the synthesis of serotonin as well as an *N*-methyl-D-aspartic acid (NMDA) antagonist and gamma-aminobutyric acid (GABA) agonists and seems to play a key role in the regulation of sleep. One double-blind, randomized clinical trial was conducted to determine the efficacy of magnesium supplementation to improve insomnia in elderly individuals.[20] Forty-six elderly subjects randomly allocated into the magnesium or the placebo group received 500 mg magnesium or a placebo daily for 8 weeks. Compared with the placebo group, in the experimental group, dietary magnesium supplementation brought about statistically significant increases in sleep time, sleep efficiency, and concentration of serum melatonin and also resulted in a significant decrease in sleep-onset latency and serum cortisol concentration.

Melatonin

Melatonin is secreted by the pineal gland, and its production is based on light cues, increased at night and inhibited during the day. Supplementation with melatonin has been shown in several studies to be effective in helping induce and maintain sleep in children and adults, people with normal sleep patterns, and those with insomnia. However, the sleep-promoting effects of melatonin are most apparent only if melatonin levels are low.[21] In other words, melatonin has a sedative effect only when endogenous melatonin levels are low. Melatonin appears to be most effective in treating insomnia in the elderly, in whom low melatonin levels are common.[22]

In one study, 26 elderly insomniacs with lower-than-normal melatonin levels were given 1 to 2 mg of melatonin 2 hours before the desired bedtime for 1 week. Rapid- and slow-release melatonin preparations were used. Both sleep latency and sleep quality were evaluated. Although there was no discernible difference in sleep onset or sleep efficiency (time asleep as a percentage of total time in bed) between the two forms, the slow-release form yielded better effects on sleep maintenance.[23] A 2017 meta-analysis assessed the therapeutic effects of exogenous melatonin in treating primary sleep disorders.[24] The results showed that melatonin had significant effects on sleep-onset latency in primary insomnia, delayed-sleep-phase syndrome, and regulation of the non-24 sleep–wake syndrome compared with placebo.

Doses as low as 0.1 and 0.3 mg have been shown to produce a sedative effect when melatonin levels are low.[25] Common doses of melatonin range from 0.2 to 3 mg. Although melatonin appears to have no serious side effects at recommended doses, melatonin supplementation could conceivably disrupt the normal circadian rhythm. In one study, a dosage of 8 mg/day for only 4 days resulted in significant alterations in hormone secretions.[26] For more information, see Chapter 92.

Restless Legs Syndrome and Nocturnal Myoclonus

Restless legs syndrome and nocturnal myoclonus are significant causes of insomnia. Restless legs syndrome is characterized during waking by an irresistible urge to move the legs. Almost all patients with restless legs syndrome have nocturnal myoclonus,[1] a neuromuscular disorder characterized by repeated contractions of one or more muscle groups,

typically of the leg, during sleep. Each jerk usually lasts less than 10 seconds. The patient is normally unaware of the myoclonus and complains only of either frequent nocturnal awakenings or excessive daytime sleepiness, but questioning of the sleep partner often discovers the myoclonus.

If there is a family history of restless legs syndrome (present in about one third of all cases of the syndrome), high-dose folic acid, 35 to 60 mg daily, can be helpful.[27] Doses in this range require a prescription because the U.S. Food and Drug Administration limits the amount available per capsule to 800 mcg. Restless legs syndrome is also a common finding in patients with malabsorption syndromes.[27]

Serum ferritin levels should also be measured to determine iron stores. The association between low iron levels and restless legs syndrome was documented in clinical studies more than 30 years ago. One study reproduced these observations, finding serum ferritin levels to be lower in 18 patients with restless legs syndrome than in 18 control subjects.[28] Serum iron, vitamin B_{12}, folic acid, and hemoglobin levels did not differ in the two groups. A rating scale with a maximum score of 10 was used to assess the severity of symptoms of restless legs syndrome. Serum ferritin levels were inversely correlated with the severity of symptoms. Fifteen of the patients with the syndrome were treated with iron (ferrous sulfate) at a dosage of 200 mg three times daily for 2 months. The severity of restless legs syndrome improved by an average of 4 points in 16 patients with an initial ferritin level lower than 18 mg/L, by 3 points in 4 patients with ferritin levels between 18 and 45 mg/L, and by 1 point in 5 patients with ferritin levels between 45 and 100 mg/L. The conclusion of the study is an important contribution to the understanding of the development of restless legs syndrome in elderly patients, and iron supplements were found to produce a significant reduction in symptoms.

In addition to restless legs syndrome, low serum ferritin levels have been found in psychiatric patients experiencing a condition called akathisia, coming from a Greek word meaning "cannot sit down." Akathisia is a drug-induced state of agitation and can significantly impair restful sleep. The drugs that most commonly produce akathisia are antidepressants, such as fluoxetine (Paxil, Prozac) and sertraline (Zoloft). The level of iron depletion correlates with the severity of akathisia. Anyone suffering from drug-induced akathisia should ask his or her physician to perform a serum ferritin assessment. If serum ferritin levels are below 35 mg/L, the physician should recommend that the patient take 30 mg of iron bound to either succinate or fumarate twice daily between meals. If this recommendation causes abdominal discomfort, the patient should try 30 mg with meals three times daily.

Botanicals With Sedative Properties

Numerous plants have sedative action. Plants commonly prescribed as aids in promoting sleep include the following:

- *Valeriana officinalis*
- *Passiflora incarnata*
- *Humulus lupulus*
- *Scutellaria lateriflora*
- *Matricaria chamomilla*

Of the herbs listed, the one with the most clinical research is *Valeriana officinalis* (see Chapter 123). More than 20 double-blind clinical studies have substantiated valerian's ability to improve sleep quality and relieve insomnia.[29,30] Additional research is warranted, but these studies show that extracts of valerian root improve sleep quality and sleep latency. The studies demonstrated that valerian was as effective in reducing sleep latency as small doses of barbiturates or benzodiazepines. Although these latter compounds also increase morning sleepiness, valerian usually reduces morning sleepiness.

THERAPEUTIC APPROACH

Treatment should be conservative and include some means of addressing the psychological factors contributing to insomnia. Metabolically, the foremost component of treatment is the elimination of any factors known to disrupt normal sleep patterns, including the following:

- Stimulants (e.g., coffee, tea, chocolate, coffee-flavored ice cream)
- Alcohol
- Hypoglycemia
- Stimulant-containing herbs (e.g., ephedra, guarana)
- Marijuana and other recreational drugs
- Numerous OTC medications
- Prescription drugs

If this approach produces no response, more aggressive measures can be taken. Once a normal sleep pattern has been established, the recommended supplements and botanicals should be slowly decreased. If the patient suffers from restless legs syndrome, 5 to 10 mg/day of folic acid should be added to the therapy. Nocturnal myoclonus can be aided with 400 IU/day of natural vitamin E.

Lifestyle

The patient should institute a regular exercise program that elevates the heart rate to 60% to 75% of maximum for at least 20 minutes a day.

Supplements

The following supplements should be taken 45 minutes before bedtime:

- Niacin: 100 mg (decrease dose if uncomfortable flushing interferes with sleep induction)
- Vitamin B_6: 50 mg (if unresponsive, use P5'P)
- Magnesium: 250 to 500 mg
- Tryptophan: 3 to 5 g, or 5-HTP, 100 to 300 mg
- Melatonin: 3 mg

Botanical Medicines

The following botanical medicines should also be taken 45 minutes before bedtime:

Valeriana officinalis

- Dried root (or as tea): 2 to 3 g
- Tincture (1:5): 4 to 6 mL (1 to 1½ tsp)
- Fluid extract (1:1): 2 to 4 mL (½ to 1 tsp)
- Dry powdered extract (0.8% valerenic acid): 150 to 300 mg

Intestinal Protozoan Infestation and Systemic Illness

Helen (Verhesen) Messier, and *Leo Galland*, AB, MD*

OUTLINE

INTRODUCTION

The gastrointestinal tract is the largest organ of immune surveillance in the body, home to two thirds of the total lymphocyte population.[1] Regulatory T cells play a crucial role among the lymphocytes responding to protozoan infestation, so parasitical infestation may alter the immune response environment, exerting a major effect on systemic responses, including allergy and autoimmunity.[2] Systemic immunological reactivity may occur in the absence of digestive complaints.[3–7]

PROTOZOA

Giardia spp.

Human giardiasis may provoke asthma,[8,9] urticaria,[10–14] arthritis,[5,14–17] and uveitis,[18] presumably by inducing immunological hypersensitivity. Urticaria induced by *Giardia* has been associated with specific anti-*Giardia* immunoglobulin-E (IgE), which is not found in patients with intestinal symptoms only. IgE production is associated with increased activity of vascular and intercellular adhesion molecules.[19] Using proteomics, *Giardia* has recently been found to release a number of specific proteins, known as excretory-secretory products (ESPs), which affect gene expression, secretion, signaling, metabolism, and immune responses in intestinal epithelial cells (Fig. 188.1).[20]

During *Giardia*–host cell interactions in vitro, specific proteins are released into the growth medium. The same types of proteins, mainly enzymes, are released from both the host and parasite (*black* in Fig. 188.1), but there are also parasite-specific proteins being released (*blue* in Fig. 188.1).[20]

Giardia may also provoke systemic illness through malabsorption or protein loss, which can occur without diarrhea.[21] Iron deficiency[22,23]; low levels of carotene and folate[24]; and abnormal absorption of vitamin A,[25–27] folic acid, and vitamin B_{12}[21] can result from chronic giardiasis and add to the burden of illness, even in patients who appear well nourished.[26] Giardiasis may also induce small intestinal bacterial overgrowth[21,28] and jejunal candidosis,[29] each of which may independently cause systemic symptoms. *G. lamblia* may also act as a vector for double-stranded RNA viruses.[30]

Giardiasis was identified in 61 of 218 consecutive patients presenting to the author's medical clinic with a chief complaint of chronic fatigue.[31] The symptoms of patients with and without giardiasis are shown in Table 188.1. Giardiasis was strongly associated with myalgia, muscle weakness, flu-like feelings, sweats, adenopathy, and a previous diagnosis of chronic fatigue immune dysfunction syndrome (CFIDS). Cure of giardiasis resulted in the clearing of fatigue and related "viral" symptoms (myalgia, sweats, flu-like feelings) in 70% of cases and in some palliation of fatigue in 18%. In 2012 a waterborne outbreak of giardiasis occurred in which more than 1200 individuals were exposed. Over a threefold increase in the risk for irritable bowel syndrome (IBS) and a fourfold risk for chronic fatigue was reported in the 3 years after the acute exposure.[32] Evidence of CD4 T-cell activation at least 5 years after exposure has also been documented among these individuals.[33] The association between intestinal protozoa and chronic fatigue in patients without prominent digestive complaints may not be limited to giardiasis. In an unpublished presentation, the author reported that 80% of patients with a diagnosis of CFIDS who were infected with the protozoan *Blastocystis hominis* showed significant improvement of fatigue associated with treatment that cleared the protozoa from stool specimens.[34] As in giardiasis, infestation with *B. hominis* has also been associated with several patterns of urticaria: acute, chronic, and pressure induced.[35–37]

Entamoeba histolytica

Chronic infestation with *Entamoeba histolytica* has been associated with autoimmune phenomena, including the appearance of antibodies to colonic epithelial cells[38] and the development of ulcerative colitis after the cure of amebic colitis.[39] Extraintestinal autoimmune reactions to intestinal amebiasis include a case of antiphospholipid antibody syndrome with deep vein thrombosis and pulmonary embolism[40] and the development of symmetrical polyarthritis mimicking rheumatoid arthritis.[5,41–44] Diarrhea, polyarthritis, and circulating antinuclear

*Previous edition contributor

antibodies developed in a U.S. serviceman heavily infested with *Endolimax nana*, an allegedly nonpathogenic ameba.[45] Metronidazole rapidly reversed all abnormalities. Amebic arthritis may be an example of parasitical rheumatism, an inflammatory polyarthropathy produced by circulating antigen–antibody complexes.[46,47] Reiter syndrome (arthritis, uveitis, and urethritis) has been reported as a complication of infection with two other intestinal protozoa, *Cryptosporidium*[48–50] and *Cyclospora*.[51] *Cyclospora cayetanensis* has also provoked Guillain-Barré syndrome, a severe autoimmune neuropathy.[52] Chagas heart disease, caused by the protozoan parasite *Trypanosoma cruzi*, may also have an autoimmune etiology because some individuals clearly produce autoantibodies and autoreactive T cells during infection.[53]

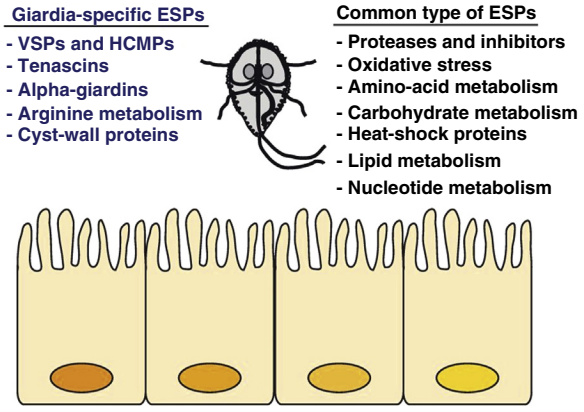

Fig. 188.1 Proteins secreted during *Giardia*–host cell interactions.

TABLE 188.1 Systemic Symptoms of Patients with Chronic Fatigue Immune Dysfunction Syndrome

Symptom	With Giardiasis (%) (*n* = 63)	Without Giardiasis (%) (*n* = 157)
Depression	61	41
Muscle weakness	46	19
Headache	41	36
Sore throat	41	11
Lymphadenopathy	36	8
Arthralgia	36	27
Myalgia	34	18
Flu-like symptoms	34	6
Poor exercise tolerance	30	10

Modified from Galland L, Lee M, Bueno H, et al. *Giardia lamblia* infection as a cause of chronic fatigue. *J Nutr Med.* 1990;2:27–32.

E. histolytica contains a soluble lectin that is mitogenic for T lymphocytes.[54,55] Activation of helper T cells by this lectin may induce replication of human immunodeficiency virus (HIV) in vivo. In one report, soluble *E. histolytica* protein, although not mitogenic itself, induced HIV replication in tissue culture of lymphocytes obtained from three of seven men with chronic HIV infection.[56] Infection with *E. histolytica* and other parasites may promote the development of acquired immunodeficiency syndrome in HIV-infected individuals.[57,58] Epidemiological evidence associated preexisting intestinal protozoan infection with the appearance of Kaposi's sarcoma among homosexual men in the United States.[59] Although the influence of treating intestinal protozoan infection on the course of HIV infection has not been systematically studied, the treatment of intestinal helminth infestation decreased the HIV viral load among African patients with AIDS.[60] Synergism between intestinal parasites and other lymphotrophic retroviruses was considered an explanation for the pathogenesis of Burkitt lymphoma[61] and adult T-cell leukemia and/or lymphoma.[62]

Helminths and Immune Modulation

In recent years, the potential for beneficial immune modulation with specific parasites has also emerged. Helminths, or multicellular organisms that are either parasitical or free-living, appear to downmodulate both the innate and adaptive immune systems and may block the same inflammatory pathways that are responsible for allergies and autoimmunity (Fig. 188.2).

Infection with parasitical worms causes the host immune system to polarize into a Th2 response (preventing Th1 or Th17 immune response) characterized by Th2 cytokines. Helminth ES products can cause the differentiation of macrophages toward the M2 phenotype, resulting in a Th2 immune response. ES products can also prevent dendritic cell synthesis of proinflammatory cytokines and promote the production of immunoregulatory molecules such as interleukin (IL)-10 and transforming growth factor-beta (TGF-β). A regulatory T cell (Treg) phenotype is also induced, promoting the protection/

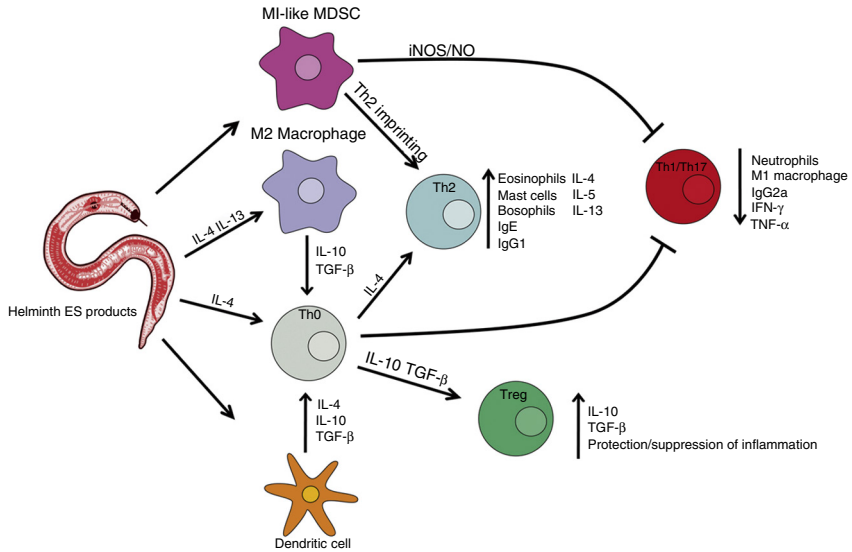

Fig. 188.2 Helminth excretory/secretory (ES) products effect on host immune cells.

suppression of inflammation produced by a Th1 autoimmune disease. Myeloid-derived suppressor cells (MDSCs) function as immunoregulators, producing reactive oxygen/nitrogen species that inhibit the function of T cells.[63]

Currently, one fourth of the world's population may be infected with helminths, and it has been proposed that for much of human history, this rate would have been near 100%, which has sparked the "old friends" hypothesis—that is, that humans have coevolved with various organisms, including helminths, that act as inducers of immunoregulatory circuits. Areas with higher infections rates also have lower rates of autoimmune disease, and human and animal trials are suggestive of a potential benefit in the treatment of inflammatory bowel disease (IBD), type 1 diabetes, multiple sclerosis, asthma, and celiac disease.[64,65] As the excretory products are better understood, it may be that specific molecular therapy can replace the use of live organisms, although clinical trials have generally proven safe.

DIAGNOSTIC CONSIDERATIONS

Protozoan infection may be diagnosed with stool examination; however, comparison of the results of stool microscopy and duodenal aspiration has consistently shown that stool may fail to contain identifiable parasites even at the height of acute giardiasis.[66,67] Some authorities have suggested empirical treatment for intestinal parasites in high-risk groups, such as immigrants to the United States from Asia, the Middle East, sub-Saharan Africa, Eastern Europe, Latin America, and the Caribbean, and have justified this approach on a cost-effective basis, given the safety of current medical therapies.[68] A similar case might be made for treating chronically ill patients at high risk for parasitical infection because of residence, travel, sexual practices, or the context in which illness occurred. Specific recommendations for laboratory testing are also available, including the recommendation for the use of a *Giardia/Cryptosporidium* enzyme immunoassay in areas where *Giardia* is more common and the use of a modified acid-fast stain when *Cryptosporidium, Cyclospora,* or *Cystoisospora* are suspected, for example.[69]

THERAPEUTIC CONSIDERATIONS

Artemisia annua

Numerous naturally occurring substances have antiprotozoan activity. The most extensively studied is *Artemisia annua* (sweet Annie or qinghao), a plant that yields the lactone artemisinin (qinghaosu), which is the basis for a new class of antimalarial compounds widely used in Asia and Africa.[70] Artemisinin is thought to owe its antiprotozoan effects to its content of endoperoxides and killing of parasites through oxidation. Its activity, at least in the treatment of Simian malaria, is enhanced by coadministration of cod liver oil and diminished by coadministration of vitamin E. Artemisinin has low toxicity. In addition to its antibiotic activity, it stimulates macrophages, an important component of the immune response to protozoan infestation.[71] It has demonstrated antiparasitical activity against protozoan parasites such as *Leishmania* spp., *Trypanosoma* spp., *Toxoplasma gondii, Neospora caninum, Eimeria tenella, Acanthamoeba castellanii, Naegleria fowleri, Cryptosporidium parvum, Giardia lamblia,* and *Babesia* spp., with both low cost and low toxicity.[72] Artemisinin may induce abortion if given during pregnancy.

Berberine

The alkaloid berberine can be extracted from the roots of several plant species, notably *Berberis aquifolium* (Oregon grape), *Hydrastis canadensis* (goldenseal) root, and *Coptis chinensis* (goldthread). Berberine has protostatic and protocidal activity against *E. histolytica, G. lamblia,* and *B. hominis.*[73–75] It has shown benefit in the treatment of giardiasis in children.[76]

Allium sativum and *Juglans nigra*

Allium sativum (garlic) and *Juglans nigra* (black walnut) have a long history of use as antimicrobials. Allicin inhibits the growth of *E. histolytica* in culture[77] and may be responsible for the antimicrobial activity of garlic.[78] Human studies on the efficacy of garlic and black walnut in treatment of protozoan infections are lacking.

Intestinal Bacterial Milieu

The intestinal bacterial milieu may be important in the treatment of protozoan infestation, especially for colonic organisms like *E. histolytica.* Pathogenic strains of *E. histolytica* are able to evade lysis by both classic and alternative pathways of complement. Intestinal bacteria, *Escherichia coli* in particular, are necessary for complement resistance and for amebic virulence.[79] Additionally, children with very high rates of infection with *E. histolytica* are more likely to be symptomatic (diarrheal disease) depending on the composition of their microflora, specifically an increase in *Prevotella copri* colonization.[80] Gitler and Mirelman[81] suggested that ingested bacteria lowered the redox potential within the parasite and allowed the amebae to escape destruction by oxidative enzymes.[81]

Animal studies have also documented that dysbiosis is associated with a decrease in the surface expression of CXCR2 on neutrophils, impairing neutrophil recruitment to the site of infection.[82] Mirelman et al.[83] reported that one can reversibly change the zymodeme patterns of *E. histolytica* isolates from nonpathogenic to invasive by culturing amebae with the gut flora of patients who have either invasive disease or no symptoms. Optimal treatment of protozoan infection requires not only the administration of antimicrobial substances but also strategies aimed at enhancing the function of intestinal resistance factors such as secretory immunoglobulin A (IgA), both neutrophil and phagocyte function, and the creation of a bacterial milieu that is not parasite friendly.

CONCLUSION

Intestinal protozoan infestation is a significantly underrecognized cause of systemic illness. Undiagnosed infestations with *Giardia* spp., *E. histolytica,* and other organisms have been associated with diverse diseases, such as arthritis; asthma; Reiter syndrome; urticaria and uveitis; CFIDS; increased rate of progression of HIV infection; and a wide range of systemic dysfunction, such as fatigue, malabsorption, muscle weakness, and myalgia. Effective eradication of protozoa can result in surprisingly quick and complete clinical response.

Irritable Bowel Syndrome

Gerard E. Mullin, MD

OUTLINE

DIAGNOSTIC SUMMARY

Irritable bowel syndrome (IBS) is a functional disorder of the large intestine with no evidence of accompanying structural defect; it is characterized by some combination of:

- Abdominal pain
- Altered bowel function, constipation, or diarrhea
- Hypersecretion of colonic mucus
- Dyspeptic symptoms (flatulence, nausea, anorexia)
- Varying degrees of anxiety or depression
- In some cases, also extraintestinal manifestations such as restless legs syndrome (RLS), migraine headaches, chronic fatigue, irritable bladder syndrome, and dyspareunia

IBS is presently diagnosed according to the Rome IV criteria (Box 189.1).

Less acceptable synonyms are *nervous indigestion, spastic colitis, mucous colitis,* and *intestinal neurosis.* Splenic flexure syndrome is a variant of IBS in which gas in the bowel leads to pain in the lower chest or the left shoulder. Many patients with IBS also have extraintestinal symptoms, including sexual dysfunction, fibromyalgia, dyspareunia, urinary frequency and urgency, poor sleep, menstrual difficulties, lower back pain, headaches, chronic fatigue, RLS, and insomnia. These conditions tend to increase in number with the severity of IBS. The pathophysiology of IBS is complex, but it is known to involve genetic factors, intolerance to food(s), gastrointestinal dysbiosis, altered gut motility, decreased intestinal barrier integrity, visceral hypersensitivity, and altered mucosal immune responses (Fig. 189.1). Extraintestinal symptoms (EISs) are important to recognize in patients with IBS because increased EISs portends a higher likelihood of greater IBS severity (Fig. 189.2).[1]

GENERAL CONSIDERATIONS

IBS is the most common gastrointestinal disorder seen in general practice, representing 30% to 50% of all referrals to gastroenterologists.[2,3] Determining incidence or prevalence figures is virtually impossible because many sufferers never seek medical attention. It has been estimated, however, that approximately 15% of the population has complaints of IBS, with women predominating in a ratio of 2:1 (it is likely that an equal number of men have IBS but that they do not report symptoms as often). The etiology of the greater colonic motility seen in IBS has been attributed to physiologic, psychological, and dietary factors.

Although IBS is often a diagnosis of exclusion, clinical judgment must be used to determine the extent of the diagnostic process required. A detailed history and physical examination has been shown to eliminate much of the vagueness involved in diagnosing IBS.[4] Distention, relief of pain with bowel movements, and the onset of loose or more frequent bowel movements with pain seem to correlate best with the diagnosis of IBS (any three, $P = 0.84$; just one, $P = 0.25$).[2]

In most cases, a comprehensive stool and digestive analysis (see Chapter 28, Stool Analysis), with special attention to dysbiosis, complete blood count, and measurements of erythrocyte sedimentation rate, free thyroid T3 hormone level, and celiac testing (antiendomysial antibody test; see Chapter 157, Celiac Disease), should be performed to establish the diagnosis and exclude other diseases. If diarrhea-predominant IBS symptoms are more pervasive, panendoscopy with duodenal, colonic, and terminal ileal biopsies should be obtained to rule out autoimmune conditions such as celiac disease, inflammatory bowel disease, lymphocytic colitis, and collagenous colitis. If food allergy is suspected as a contributor, stool testing for eosinophilic cationic protein should be considered (for a more complete discussion of laboratory tests to evaluate food allergy and/or adverse reactions, see Chapter 14, Food Hypersensitivities). If no discernible cause can be identified, screening for occult fecal blood and flexible sigmoidoscopy are indicated in patients younger than 50 years and colonoscopy in older patients.

THERAPEUTIC CONSIDERATIONS

Once other chronic conditions have been ruled out, there appear to be three major treatments to consider in the formulation of a therapeutic regimen for IBS:

- Increasing dietary fiber
- Eliminating allergic/intolerant foods

BOX 189.1 Rome IV Criteria for Irritable Bowel Syndrome

According to Rome IV, a diagnosis of IBS can be made if recurrent abdominal pain (at least once weekly) is associated with two or more of the following:

- Related to defecation;
- Associated with a change in frequency of stool; or
- Associated with a change in form (appearance) of stool.

The patient needs to have none of the following warning signs:

- Are greater than 50 years of age at onset, no previous colon cancer screening, and with the presence of symptoms.
- Recent change in bowel habit.
- Evidence of overt GI bleeding (i.e., melena or hematochezia).
- Nocturnal pain or passage of stools.
- Unintentional weight loss.
- Family history of colorectal cancer or inflammatory bowel disease.
- Palpable abdominal mass or lymphadenopathy.
- Evidence of iron-deficiency anemia on blood testing.
- Positive test for fecal occult blood.

GI, Gastrointestinal; *IBS,* irritable bowel syndrome.Data from Palsson OS, Whitehead WE, van Tilburg MA, et al. Rome IV diagnostic questionnaires and tables for investigators and clinicians. *Gastroenterology*. 2016;150:6:1481–1491.

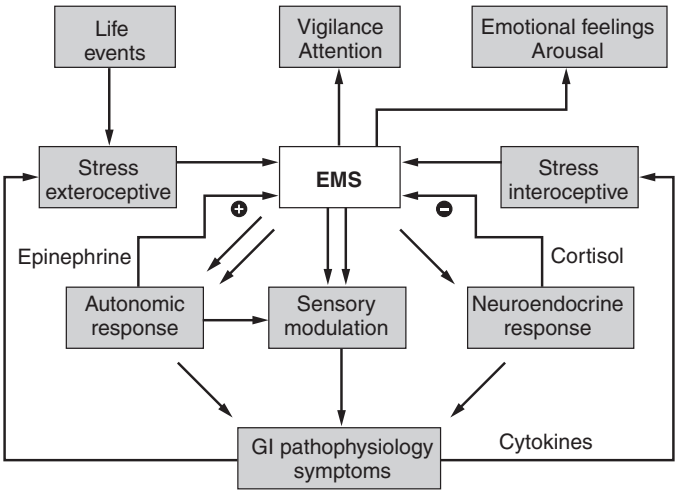

Fig. 189.1 Current understanding of irritable bowel syndrome (IBS) pathophysiology. Stress, abuse, and emotional feelings influence bowel symptoms via activation of the brain's central circuitry called the emotional motor system (EMS) to produce autonomic and neuroendocrine responses. Bowel symptoms then cause more distress, triggering the release of mediators (cytokines, cortisol, and adrenaline) that act on the EMS, producing a feed-forward cycle of bowel symptoms and emotional distress.

- Controlling psychological components
- Peppermint oil for spastic colon
- Acupuncture for pain modulation and motility regulation
- Melatonin as a stress adaptogen, as a mood stabilizer, and to promote restful sleep
- Small intestinal bacterial overgrowth, intestinal dysbiosis, and food allergies may be silent triggers of the disease.
- Dietary fermentable oligo-, di-, and monosaccharides and polyols (FODMAPS) appear to play a role in promoting disease activity and should be limited in IBS.

Diet

Dietary Fiber

The treatment of IBS through an increase in dietary fiber has a long, though irregular, history.[2] Patients with constipation are much more likely to show a response to dietary fiber than are those with diarrhea. One problem that has not been addressed in studies on the therapeutic use of dietary fiber is the role of food allergy. The type of fiber often used in both research and clinical practice is wheat bran.[5] Wheat and other grains are among the most commonly implicated foods in malabsorptive and allergic conditions, and food allergy is a significant etiological factor in IBS, so the use of wheat bran is usually contraindicated.

Increasing dietary fiber from fruit and vegetable sources rather than cereal sources may offer more benefit to some individuals, although in one uncontrolled clinical study, there was no significant difference in improvement when a diet composed of 30 g of fruit and vegetable fiber and 10 g of cereal fiber was compared with a diet consisting of the opposite ratio.[6] Although the two diets resulted in similar significant improvements in abdominal pain, bowel habits, and state of well-being, the presence of large quantities of potentially allergenic cereal fiber in both diets would probably have obscured any differences.

One type of fiber that may be useful and that is without the allergenic component of a wheat-based fiber is partially hydrolyzed guar gum (PHGG). The guar plant, *Cyamopsis tetragonolobus,* has been grown in India and Pakistan since ancient times. PHGG is a natural water-soluble dietary fiber derived from the guar plant.[7] One study of 134 patients found that consumption of 6 g/day of PHGG decreased the frequency of IBS symptoms such as abdominal spasms, flatulence, and abdominal tension.[8] The researchers concluded that PHGG works well in cases of altered intestinal motility and is easy to use because of its nongelling properties, unlike unhydrolyzed gum, which is much higher in viscosity and more difficult to incorporate into the diet. A recent study has shown that the guar gums when combined with the antibiotic rifaximin (Rifaxam) provide an additional benefit to eradicating dysbiosis in small intestinal bacterial overgrowth (SIBO) associated with IBS.[9] Put simply, for most cases of IBS, nonwheat sources of fiber, such as vegetables and fruits, may be the best choice to help reduce symptoms. For some cases of IBS, especially those with a strong diarrheal component, cooked vegetables in small quantities at first may be most helpful. Because each case is unique, clinical judgment and close patient monitoring are needed. In some cases, fiber may aggravate diarrhea and is therefore contraindicated. For a more detailed explanation of dietary fiber, see Chapter 132.

Food Allergy/Intolerance

The importance of food allergies in the etiology of IBS has been recognized since the early 1900s.[10,11] Later studies have further documented the association between food allergy and the irritable bowel.[12–15] The type of food allergy most significant in IBS is believed to be nonimmunologic, so food intolerance rather than food allergy may be a more appropriate diagnosis. According to double-blind challenge methodologies, the majority of patients with IBS (approximately two thirds) have at least one food intolerance, and some have multiple intolerances.[12] Foods rich in carbohydrates, as well as fatty food, coffee, alcohol, and hot spices, are most frequently reported to cause symptoms.[1] The most common allergens are dairy products (40%–44%) and grains (40%–60%).[14] Because in most cases the reaction appears to be related to prostaglandin synthesis or immunoglobulin G (IgG)–mediated rather than immunoglobulin E (IgE)–mediated reactions, skin tests and the IgE-radioallergosorbent test are poor indicators of food intolerance in these patients. The enzyme-linked immunosorbent assay (ELISA) allergen challenge test or ELISA IgE/IgG_4 may be a better indicator (see

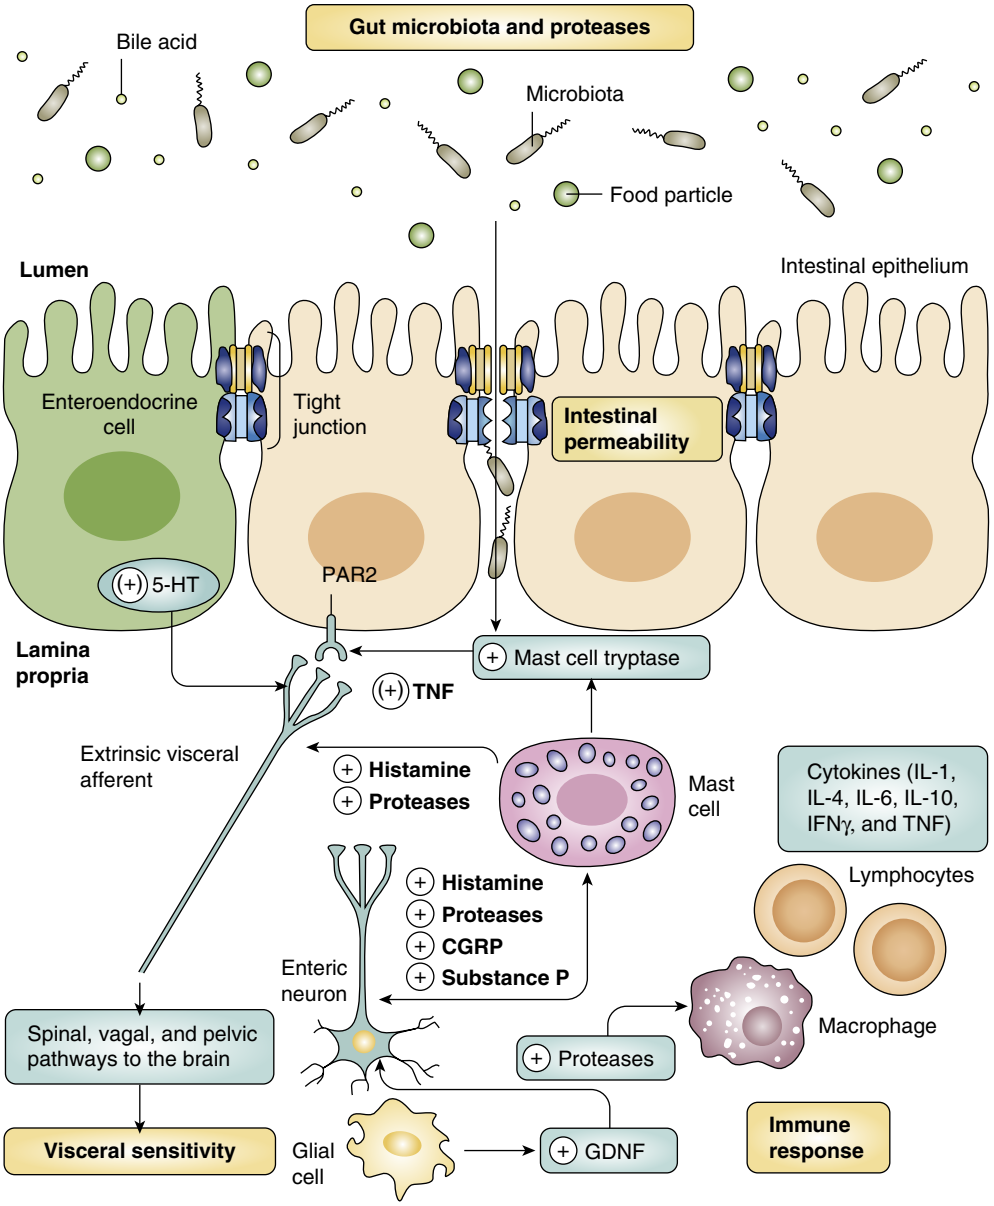

Fig. 189.2 Overview of the pathophysiology of irritable bowel syndrome (IBS). Although the etiology of IBS has not yet been completely elucidated, various factors have a role, including the composition of the gut microbiota, intestinal permeability, immune cell reactivity and sensitivity of the enteric nervous system, the brain–gut axis (spinal, vagal, or pelvic pathways), and the brain. The figure highlights those mediators that are probably involved in IBS pathology. The plus symbols indicate whether a mediator activates or inhibits its target cell; those in parentheses denote actions established in animal models, and those without parentheses are effects demonstrated in humans (human tissue). *5-HT,* 5-hydroxytryptamine (also known as serotonin); *CGRP,* calcitonin gene-related peptide; *GDNF,* glial cell-derived neurotrophic factor; *IL,* interleukin; *PAR2,* proteinase-activated receptor 2; *TNF,* tumor necrosis factor. (Figure and text obtained from Enck P, Aziz Q, Barbara G, et al. Irritable bowel syndrome. *Nat Rev Dis Primers.* 2016;2. https://doi.org/10.1038/nrdp.2016.14; with permission.)

Chapter 14, Food Hypersensitivities), although many sensitivities may still be undetectable by currently available laboratory procedures.[16] Many patients have noted marked clinical improvement with the use of elimination diets.[12-15,17]

Interestingly, many patients with IBS have associated symptoms suggestive of vasomotor instability (e.g., palpitations, hyperventilation, fatigue, excessive sweating, and headaches), which is consistent with food allergy/intolerance reactions.

Sugar

Meals high in refined sugar can contribute to IBS as well as small intestinal bacterial overgrowth by decreasing intestinal motility.[18] When blood glucose levels rise too rapidly, gastrointestinal tract peristalsis slows down. Because glucose is absorbed primarily in the duodenum and jejunum, the message affects this portion of the gastrointestinal tract most strongly. The result is that the duodenum and jejunum become atonic. A diet high in refined sugar may be the

most important reason that IBS is such a common condition in the United States.

Dietary FODMAPs

FODMAPs are short-chain carbohydrates that are osmotically active and fermentable (degradable by intestinal bacteria yielding large amount of gases, like hydrogen or carbon dioxide, thus causing abdominal bloating). FODMAPs include oligosaccharides such as fructans, which are chains of fructose with one glucose molecule on the end. Only minimal amounts of fructans may be absorbed in the human intestine. They may interfere with the absorption of fructose, thus aggravating symptoms in fructose malabsorption. Foods rich in fructans are wheat (white bread, pasta, pastries, cookies), onions, and artichokes; other not commonly problematic foods containing fructans are asparagus, leeks, garlic, chicory roots, and chicory-based coffee substitutes. Fructans with more than 10 molecules of fructose in a chain are known as inulins, and those with fewer than 10 fructoses are referred to as *fructo-oligosaccharides* or *oligofructoses*. Fructans cause problems mainly in fructose malabsorption. Galactans (e.g., stachyose and raffinose) are chains of fructose with one galactose molecule on the end. They act much like fructans. The main foods rich in galactans are legumes (soy, beans, chickpeas, lentils), cabbage, and brussels sprouts.[58-60]

Disaccharides. Lactose (milk sugar). Lactose is found in dairy products, but it may also be found in chocolate and other sweets, beer, preprepared soups and sauces, and so on. Lactose is poorly absorbed by individuals with lactose intolerance, SIBO, and small intestinal inflammation (Crohn's disease, celiac disease).

Monosaccharides. Fructose (fruit sugar). Fructose-rich foods include honey, dried fruits (prunes, figs, dates, or raisins), apples, pears, sweet cherries, peaches, agave syrup, watermelon, and papaya. Fructose is often added to commercial foods and drinks as high-fructose corn syrup. Fructose causes symptoms even in healthy people if ingested in excess and especially in those with fructose malabsorption or SIBO.

Polyols. These are also known as sugar alcohols (appearing as artificial sweeteners in commercial foods and drinks). Sorbitol may appear in "sugar-free chewing gum" and "low-calorie foods"; it appears naturally in stone fruits (peaches, apricots, and plums). Xylitol naturally appears in some berries. A pack of chewing gum containing sorbitol or xylitol may cause bloating or diarrhea in a healthy child and especially in persons with fructose malabsorption or SIBO. Other polyols—like mannitol, isomalt, erythritol, arabitol, erythritol, glycol, glycerol, lactitol, and ribitol—may be problematic in fructose malabsorption and SIBO.

Recent work indicates that FODMAP short-chain carbohydrates that are poorly absorbed in the small intestine are important triggers of functional gut symptoms. Open studies have suggested that three out of four patients with IBS will respond well symptomatically to the restriction of FODMAP intake,[19] as confirmed by a randomized, placebo-controlled rechallenge trial.[20] Breath hydrogen testing helps identify which specific sugars behave as FODMAPs in the individual. Due to a recent series of articles on the low-FODMAP diet in IBS, a number of systematic reviews and meta-analyses have been published, all showing efficacy for reducing IBS symptoms (Table 189.1).[18–20]

Nutritional Supplements

Probiotics

Probiotics are dietary supplements containing live microorganisms that, when ingested, exert a beneficial effect on the host. Among the most commonly used and studied species are *Lactobacillus, Bifidobacterium,* and *Saccharomyces boulardii.* The association between IBS and SIBO is well established.[21] Pimentel and colleagues have demonstrated that successful treatment of SIBO with antibiotics improved IBS symptoms.

The results of a meta-analysis of randomized controlled clinical trials using probiotics to treat IBS symptoms are shown in Figs. 189.3, 189.4, and 189.5.[21] Zhang and colleagues looked at a number of issues related to strain, duration, and dosing of probiotics. The authors report in their methodology section that 1392 randomized clinical trials were eligible using the Rome III criteria for the diagnosis of IBS. Of these, 21 met criteria for inclusion, and 17 were used for data synthesis. IBS symptoms and quality of life were improved for both single strains and multistrain formulations. IBS symptom improvement was not different whether the probiotic was administered for less than or greater than 8 weeks. Likewise, IBS symptom improvement was not different according to whether the probiotic daily dose was greater or less than 10 billion colony forming units.[61]

In summary, probiotics may prove to be key components in the comprehensive approach to treating IBS. Probiotic supplementation appears to be indicated in IBS (see Chapter 105, Probiotics).

Botanical Medicines

Enteric-Coated Volatile Oils

Peppermint oil, and presumably similar volatile oils, inhibits gastrointestinal smooth muscle action in both laboratory animal preparations and humans. Clinically, peppermint oil has been used to reduce colonic spasms during endoscopy,[27] and an enteric-coated peppermint oil (ECPO) capsule has been used in the treatment of IBS.[28] Enteric coating is believed to be necessary because menthol (the major constituent of peppermint oil) and other plant monoterpenes in peppermint oil are rapidly absorbed.[29] This rapid absorption tends to limit effects to the upper intestine, resulting in relaxation of the cardioesophageal sphincter and common side effects, such as esophageal reflux and heartburn, after administration. A transient hot, burning sensation in the rectum during defecation, due to unabsorbed menthol, has been noted by some patients taking the ECPO.

Most of the studies have used ECPO at a dosage of 0.2 mL twice daily between meals.[67] A meta-analysis of five studies supported the efficacy of peppermint oil in IBS.[30] A well-designed study of ECPO involved 110 patients with symptoms of IBS.[31] The patients took one capsule of either ECPO (0.2 mL) or a placebo three to four times daily 15 to 30 minutes before meals for 1 month. The effects of peppermint oil on IBS are summarized in Table 189.2. A summary of the findings of a meta-analysis conducted by the author and colleagues demonstrating the effects of ECPO on the major symptoms of IBS and associated adverse events is provided in Table 189.3. These results are impressive, especially given the safety of ECPO.

Herbal Formulas

For centuries, botanicals have been used for medicinal purposes; they are now a commonly used remedy for IBS. The appeal of botanicals likely stems from their accessibility and perceived safety as "natural" products. Various botanical preparations have been studied in IBS, with varied results. Of the 75 randomized trials for combination herbal therapy identified in one systematic review, only three double-blind, placebo-controlled trials were considered to be high quality. In a study of 116 patients, both standard and individualized combination Chinese herbal medicine significantly improved bowel symptoms. The benefit of individualized herbal treatment was maintained at 14 weeks after completion of treatment. Another study in 208 patients demonstrated efficacy with the herbal preparations STW 5 and STW 5-II.[32] The most recent of the three trials randomized 119 patients to a standard preparation of traditional Chinese medicine extracts containing 11 herbs or

TABLE 189.1 Studies of Randomized Trials of Low FODMAPs Dietary Intervention in Irritable Bowel Syndrome

First Author, Year, Reference No.	Country	Design	Sample Size	Intervention/Time	Definition of Response/Primary Outcome
Bohn, 2014[69]	Sweden	Parallel, multicenter	82	LFD vs. THD diet 4 weeks No follow-up	>50% reduction in IBS-SSS. LFD reduced the IBS-SSS from 337 (287–382) (median [25th–75th percentile]) to 231 (154–350) ($p = .001$). THD reduced the symptom score from 312 (250–346) to 240 (171–296) ($p < .001$). No difference in reduction.
Bohn, 2015[70]	Sweden	Parallel, single center	75	LFD vs. NICE diet guidelines 4 weeks No follow-up	>50% reduction in IBS-SSS. Change in IBS-SSS LFD vs. NICE was similar between groups ($P = 0.62$).
Eswaran, 2016[71]	USA	Parallel, single center	92	LFD vs. NICE diet guidelines 4 weeks No follow-up	Adequate relief of symptoms >50% of last 2 weeks of study. 52% of the LDF vs. 41% of the NICE group reported adequate relief of their IBS-D symptoms ($P = 0.31$).
Halmos, 2014[72]	Australia	Crossover with washout at least 21 days, single center	30	LFD vs. typical Australian diet 3 weeks of each diet with ≥3-week washout	10-mm difference on 100-mm VAS scale considered clinically significant. LFD had significant improvements in global symptoms compared with control diet for IBS (all $P < 0.001$).
McIntosh, 2017[73]	UK	Parallel, single center	40	LFD vs. HFD 3 weeks No follow-up	Symptoms were assessed using the IIBS-SSS. The IBS-SSS was reduced in the low-FODMAP diet group ($p < 0.001$) but not the high-FODMAP group.
Laatikainen, 2016[74]	UK	Crossover design, single center 4 weeks	87	Low-FODMAP (LF) rye bread vs. High-FODMAP (HF) rye bread.	IBS-SSS and VAS were used to assess individual symptoms. Abdominal pain, wind, and bloating improved on LF rye ($p < 0.05$) but IBS-SSS no different vs. HF rye.
Ong, 2010[62]	Australia	Crossover with washout, single center 7 days	15	LFD vs HFD 2 days No follow-up	Composite scale of GI symptoms based on 3-point Likert scale. HFD has higher scalae of symptoms (wind, abdominal pain, bloating; median 6; range 1–9) vs. LFD (2, 0–7), $p = 0.002$.
Pedersen, 2014[63]	Denmark	Parallel, single center	123 Web-based app	Dietary advice or probiotics: Intervention = LFD Control = probiotic (LGG)[a] or normal Danish diet 6 weeks No follow-up	>50% reduction in IBS-SSS. Reduction of IBS-SSS for LFD vs. control at 6 weeks (75; 95% CI 24–126; $P < 0.01$) but not for LGG vs. control (32; 95% CI 18–80; $P = 0.2$).
Peters, 2016[64]	UK	Parallel, single center	74	Gut-directed hypnotherapy, LFD vs. both. 6 weeks therapy 6 months follow-up	>20-mm improvement on 100-mm VAS for GI symptoms. Improvements in overall symptoms were observed from baseline to week 6 for hypnotherapy (mean difference [95% CI]: –33 [–41 to –25]), diet (–30 [–42 to –19]), and combination (–36 [–45 to –27]]). There were no differences across groups ($P = 0.67$).
Staudacher, 2012[65]	UK	Parallel, single center	41	LFD vs. Australian habitual diet 4 weeks No follow-up	Global symptoms rating scale not defined. Low-FODMAP diet had significant improvements in global symptoms ($P = 0.006$).
Staudacher, 2017[66]	UK	Crossover 2 × 2 factorial design, 2 centers	104	LFD or sham diet (placebo) vs. probiotic VSL#3 or placebo 4 weeks Follow-up period unclear	Mean IBS-SSS scores were lower for patients on the LFD (173±95) than sham (224 ± 89) ($P = .001$). LFD had a trend toward adequate symptom relief (57%) vs. the sham diet group (38%) ($P = .051$).

placebo. However, the use of this herbal formulation for diarrhea-predominant IBS did not improve symptoms.

Although no research has been done to document its efficacy, an old naturopathic remedy called Robert's formula has a long history of use in this condition. The Tibetan herbal formula known as Padma Lax also showed efficacy for patients with constipation-predominant IBS in one 3-month double-blind, randomized pilot study. A small number of patients did have loose stools with this formula, but this effect was easily remedied by lowering the dosage.[33]

Miscellaneous Considerations

Psychological Factors

Mental/emotional problems—anxiety, fatigue, hostile feelings, depression, and sleep disturbances—are reported by almost all patients with IBS.[34] The severity and frequency of such symptoms tend to correlate with these psychological factors. Anxiety predicts a high degree of food-related symptoms in IBS.[1] Especially significant is sleep quality; poor sleep quality results in a rise in symptom severity.[35]

Several theories link psychological factors with the symptoms of IBS. The "learning model" holds that when exposed to stressful situations, some children learn to develop gastrointestinal symptoms to cope with the stress. Another theory holds that IBS is a manifestation of depression, chronic anxiety, or both. Personality assessments of IBS sufferers have shown them to have higher anxiety levels and a greater feeling of depression.[36] However, these studies were based on postmorbid personality assessments, and it has since been determined, with premorbid personality assessment, that IBS sufferers have normal personality profiles. Therefore many of the psychological symptoms may be either secondary to the bowel disturbances (particularly malabsorption) or due to a common etiological factor (e.g., stress, food allergy, or gut microbial dysbiosis; Figs. 189.6 and 189.7).[68]

Greater colonic motility during exposure to stressful situations has been shown to occur in both normal subjects and sufferers of IBS.[37] This finding apparently accounts for the greater abdominal pain and irregular bowel function seen in patients with IBS and normal subjects during periods of emotional stress. Distressed patients with IBS are also known to have decreased immune function, as evidenced by lower percentages of activated T cells and natural killer cells.[38] This finding suggests that patients with long-term IBS have lowered immune function, which may leave them susceptible to a host of other illnesses. Some researchers believe that IBS sufferers have difficulty adapting to life events, although this belief has not been well demonstrated in clinical studies. Psychotherapy, in the form of relaxation therapy,[39] biofeedback,[40] hypnosis,[40] counseling,[41] or stress-management training,[42] has been shown to reduce symptom frequency and severity and to enhance the results of standard medical treatment of IBS. Hypnosis, which the

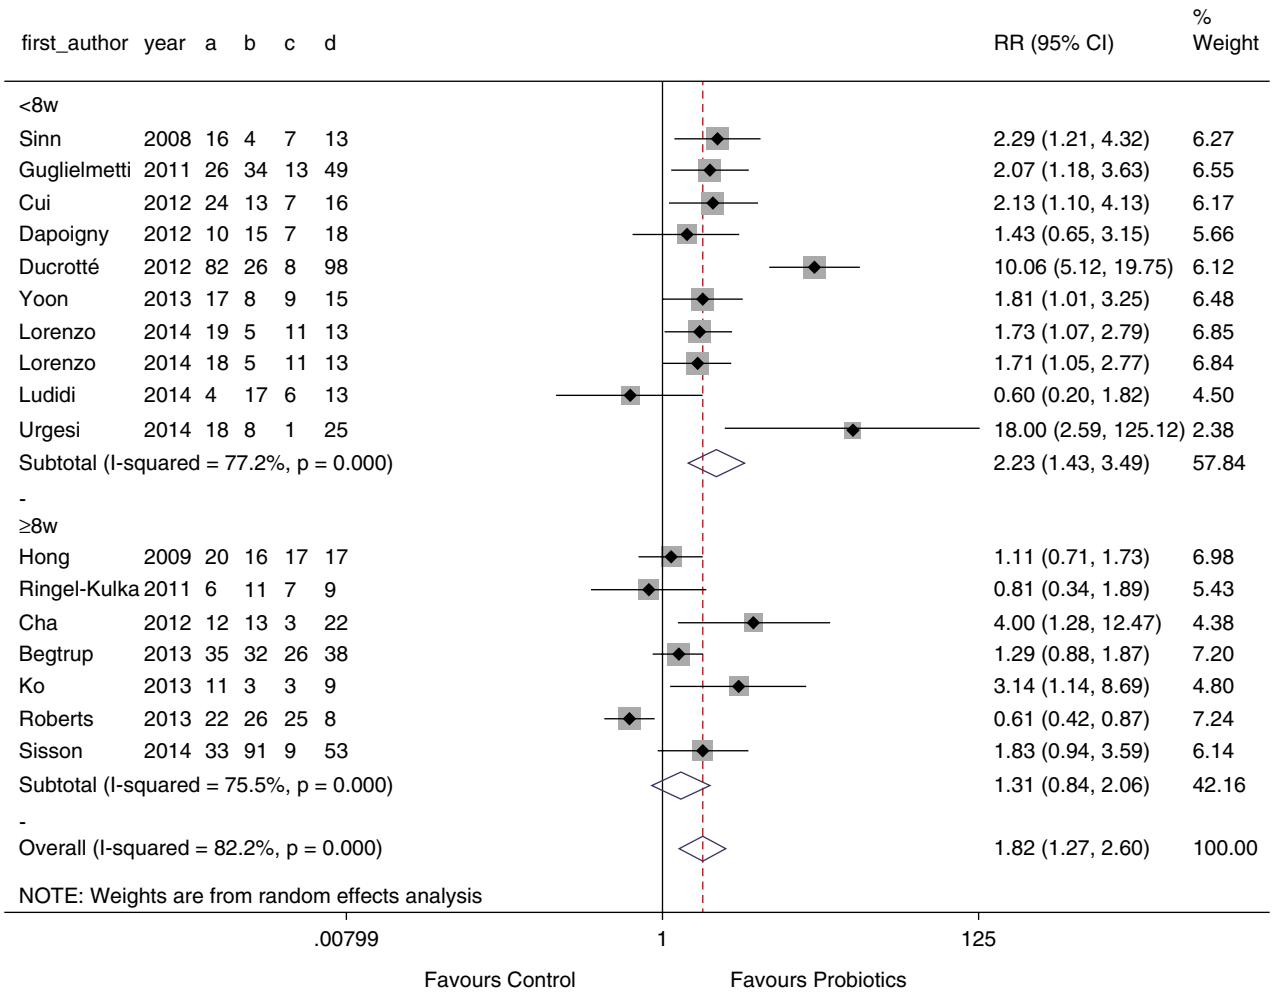

Fig. 189.4 Forrest plot of overall symptom response in patients with irritable bowel syndrome (IBS): subgroup probiotics duration. Overall, probiotics improved symptoms response in patients with IBS (n = 17 studies, relative risk [RR] 1.82, 95% confidence interval [CI] [1.27, 2.60]). Subgroup analysis shows that patients with IBS have improved symptom response irrespective of the duration of probiotics; intervention with benefit was demonstrated in patients receiving treatment for less than 8 weeks or greater than 8 weeks. (Figure obtained from Zhang Y, Li L, Guo C, Mu D, Feng B, Zuo X, Yanging L. Effects of probiotic type, dose, and treatment duration on irritable bowel syndrome diagnosed by Rome III criteria: a meta-analysis. *BMC Gastroenterology*. 2016;16:62. https://doi.org/10.1186/s12876-016-0470-z.)

patient may practice at home using simple compact disc recording equipment,[43] has been shown to reduce both fasting colonic motility[44] and rectal sensitivity.[45] In contrast to psychotherapeutic modalities, the use of anxiolytic drugs, a combination of tranquilizers and antispasmodics, or antidepressants has not yielded effective results.

Physical Medicine

An increase in physical exercise also appears helpful for patients with IBS. Many find that daily leisurely walks markedly reduce symptoms, probably owing to the known stress-reducing effects of exercise. A specific massage therapy known as foot reflexology was evaluated in a small study of 34 individuals; no benefit for patients with IBS was found.[46]

THERAPEUTIC APPROACH

Because IBS is a multifactorial disease, the approach to the patient requires consideration and integration of the following factors:

- Dietary fiber
- Determination and elimination of food allergies/intolerances
- Stress reduction
- Exercise

As necessary, peppermint oil and Robert's formula may be used to temporarily ameliorate symptoms. Also, because the diagnosis is typically made by exclusion, a careful diagnostic evaluation is always indicated.

Diet

Fiber-rich foods (see Chapter 132, Dietary Fiber) are to be increased, and foods that are allergenic, contain refined sugar, or are highly processed are to be eliminated, along with FODMAPs.

Supplements

Lactobacillus acidophilus: 1 to 2 billion live organisms per day

Botanical Medicine

Enteric-coated volatile oil preparations (e.g., peppermint oil): 0.2 mL caps once to twice daily between meals is the recommended protocol

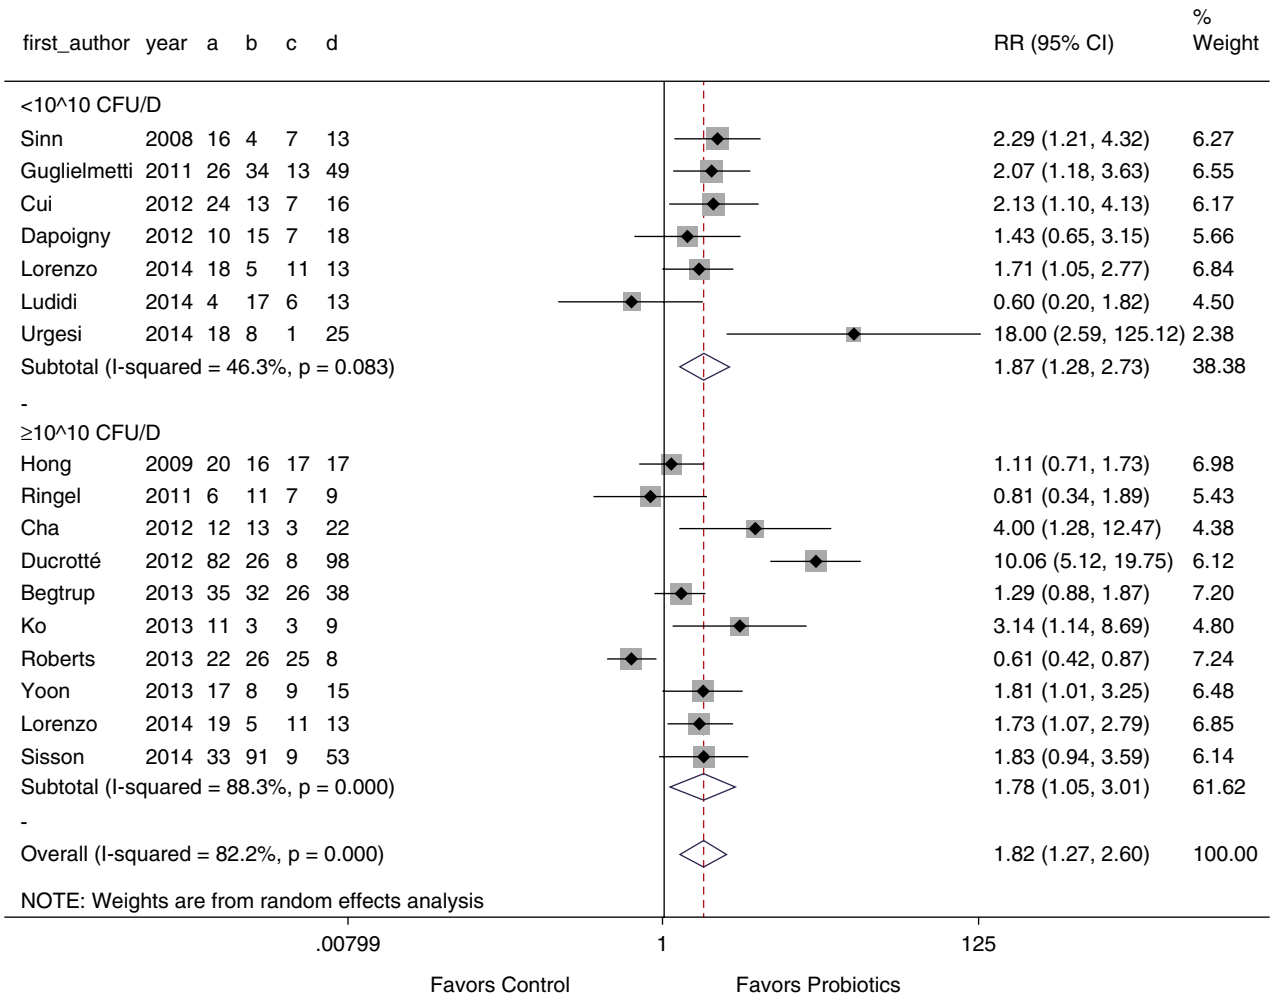

Fig. 189.5 Forrest plot of overall symptom response in patients with irritable bowel syndrome (IBS): subgroup probiotics dose. Overall, probiotics improved symptoms response in patients with IBS (n = 17 studies, relative risk [RR] 1.82, 95% confidence interval [CI)] [1.27, 2.60]). Subgroup analysis shows that patients with IBS have improved symptom response irrespective of the dose of probiotics; intervention with benefit was demonstrated in patients receiving treatment of less than 10^{41} colony-forming units (CFU) per day (n = 7 studies, RR 1.87, 95% CI [1.28, 2.73]) or greater than 10^{41} CFU per day (n = 10 studies, RR 1.78, 95% CI [1.05, 2.60]). (Figure obtained from Zhang Y, Li L, Guo C, Mu D, Feng B, Zuo X, Yanging L. Effects of probiotic type, dose and treatment duration on irritable bowel syndrome diagnosed by Rome III criteria: a meta-analysis. *BMC Gastroenterology*. 2016;16:62. https://doi.org/10.1186/s12876-016-0470-z.)

TABLE 189.3 Summary of Findings for Enteric-Coated Peppermint Oil in Irritable Bowel Syndrome

Peppermint Oil Versus Placebo for Treatment of IBS
Patient or Population: Patients With Active IBS
Settings: Outpatients
Intervention: Enteric-Coated Peppermint Oil Capsules Versus Placebo

Illustrative Comparative Risk[a]

(95% CI)

Assumed

	RISK			CORRESPONDING RISK		
Outcomes NNT	Control	Peppermint Oil Versus Placebo	Risk Ratio (95% CI)	No. Participants (Studies)	Quality of the Evidence (GRADE)	
Global improvement in IBS symptoms	250 per 1000[b]	598 per 1000 (483–743)	RR 2.39(1.93–2.97)	507 (7 studies)	⊕⊕⊕⊕ High[c]	3 (2–4)
Improvement in abdominal	303 per	539 per 1000 (433–666)	RR 1.78 (1.43–2.20)	556 (6 studies)	⊕⊕⊕◯	4 (3–8)
pain	1000[b]				Moderate[d]	
Adverse events	21 per 1000[b]	29 per 1000 (18–47)	RR 1.40 (0.87–2.26)	671(8 studies)	⊕⊕◯◯ Low[e]	125 (29–∞)

GRADE Working Group grades of evidence: *high quality,* further research is very unlikely to change our confidence in the estimate of effect; *moderate quality,* further research is likely to have an important effect on our confidence in the estimate of effect and may change the estimate; *low quality,* further research is very likely to have an important effect on our confidence in the estimate of effect and is likely to change the estimate; *very low quality* we are very uncertain about the estimate.

[a]The basis for the assumed risk (e.g., the median control group risk across studies) is provided in footnotes. The corresponding risk (and its 95% CI) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).

[b]Control group risk estimates come from control arm of meta-analysis, based on included trials.

[c]⊕⊕⊕⊕ High: downgraded on risk of bias, upgraded on large magnitude of effect.

[d]⊕⊕⊕◯ Moderate: downgraded on risk of bias.

[e]⊕⊕◯◯ Low: downgraded on risk of bias and imprecision.

CI, Confidence interval; *IBS,* irritable bowel syndrome; *NNT,* number needed to treat; *RR,* relative risk.

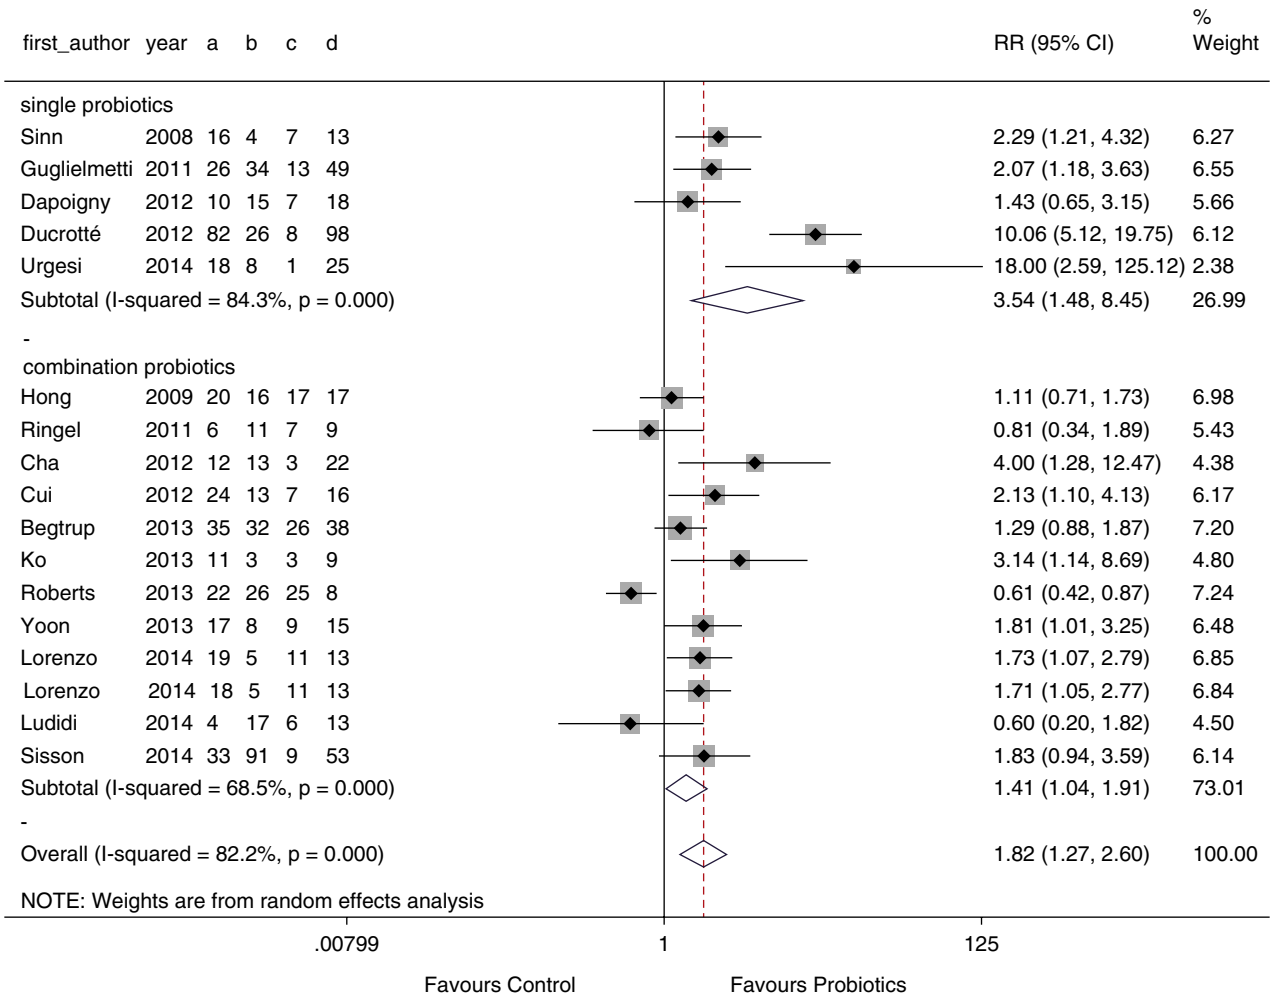

Fig. 189.6 Forrest plot of overall symptom response in patients with irritable bowel syndrome (IBS): subgroup probiotics duration. Overall, probiotics improved symptom response in patients with IBS (n = 17 studies, relative risk [RR] 1.82; 95% confidence interval [CI] [1.27, 2.60]). Subgroup analysis shows that patients with IBS have improved symptom response irrespective of the strain of probiotics used for the intervention. Benefit was demonstrated in patients receiving treatment with single strain (n = 5, RR 3.54, 95% CI [1.48, 8.45]) or multistrain probiotics (n = 12, RR 1.41, 95% CI [1.04, 1.91]). (Figure obtained from Y, Li L, Guo C, Mu D, Feng B, Zuo X, Yanging L. Effects of probiotic type, dose and treatment duration on irritable bowel syndrome diagnosed by Rome III criteria: a meta-analysis. *BMC Gastroenterology*. 2016;16:62. https://doi.org/10.1186/s12876-016-0470-z.)

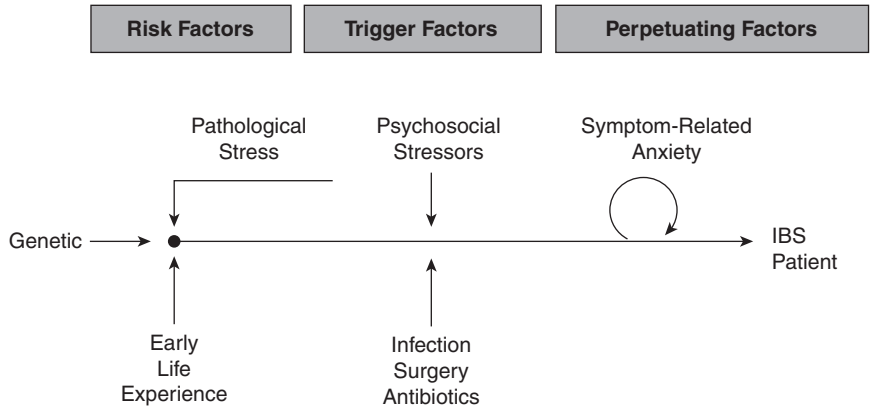

Fig. 189.7 Role of stress in the development and modulation of irritable bowel syndrome (IBS) symptoms. Different types of stressors may play a role in the permanent biasing of stress responsiveness, in transient activation of the stress response, and in the persistence of symptoms. (Figure and caption reprinted with permission from Mayer EA, Naliboff BD, Chang L, Coutinho SV. Stress and irritable bowel syndrome. *Am J Phy-Gastroint Liver Physiol*. 2001;280:G519–G524. https://doi.org/10.1152/ajpgi.2001.280.4.G519.)

Physical Therapy

The patient may be advised to take leisurely 20-minute walks daily.

Counseling

The clinician should help the patient develop an effective stress reduction program. Biofeedback may be particularly useful for patients with IBS.

Kidney Disease

Thomas A. Kruzel, MT, ND

OUTLINE

DIAGNOSTIC SUMMARY

- General symptoms of fatigue, malaise, lethargy, decreased mental sharpness
- Skin may become ruddy, dry, itchy
- Edema, loss of appetite, nausea, vomiting, polyneuropathy, chest pain, dyspnea, muscle cramping, insomnia, electrolyte imbalance, unintentional weight loss, changes in urination
- Microalbuminuria with a normal glomerular filtration rate (GFR) in early disease
- Hypertension; abnormal heart and lung sounds
- Change in slope of serum creatinine levels over time correlates with disease process
- Worsening of GFR, casts, albumin, blood on urinalysis
- Progressive if not addressed, resulting in end-stage renal failure

GENERAL CONSIDERATIONS

Physiology of Kidney Function

Human kidneys are described as bean shaped and lie in the retroperitoneal space near the vertebrae. An adult kidney weighs approximately 125 to 170 g in males and between 115 and 155 g in females, and the kidneys are about 11 cm (4.3 in.) in length.

About 20% of the plasma entering the glomerulus is filtered at any given moment, with the kidneys filtering about 180 liters/day (125 mL/min). This means that approximately 3 liters of blood plasma is filtered 60 times/day, which allows the kidneys to maintain close control on the internal environment. The kidneys, in conjunction with the lungs, maintain tight control on blood pH to preserve the delicate balance between metabolic acidosis and alkalosis.

The renal corpuscles filtration barrier consists of three layers composed of the capillary endothelium, a basement membrane, and a single cell layer that comprises Bowman's capsule. The glomerular basement membrane (GBM) is a gel-like cellular meshwork of glycoproteins and proteoglycans surrounded by cells termed podocytes because of their intrusion, like filaments, into the spaces. The slits between the endothelial cells and the foot processes (podocytes) and Bowman's space constitute the path through which the filtrate passes. An electrical charge partially occludes the slits and provide selective barriers through which materials are filtered (Fig. 190.1).

Reabsorption and secretion are the primary functions of the renal corpuscle, and when the direction of flow is from the lumen to the peritubular capillaries, it is termed tubular reabsorption; movement in the opposite direction is termed *tubular secretion*. This must not be confused with secretion, which occurs when substances are pumped into the lumen against a gradient. As a rule, more substances undergo reabsorption than secretion.

The kidneys perform five major functions:

1. They regulate volume, osmolality, mineral composition, and acidity of the body while balancing ions such as sodium, potassium, chloride, calcium, magnesium, sulfate, phosphate, and hydrogen.
2. They excrete metabolic wastes, including urea, uric acid, creatinine, end products of hemoglobin metabolism, hormone metabolites, and other solutes.

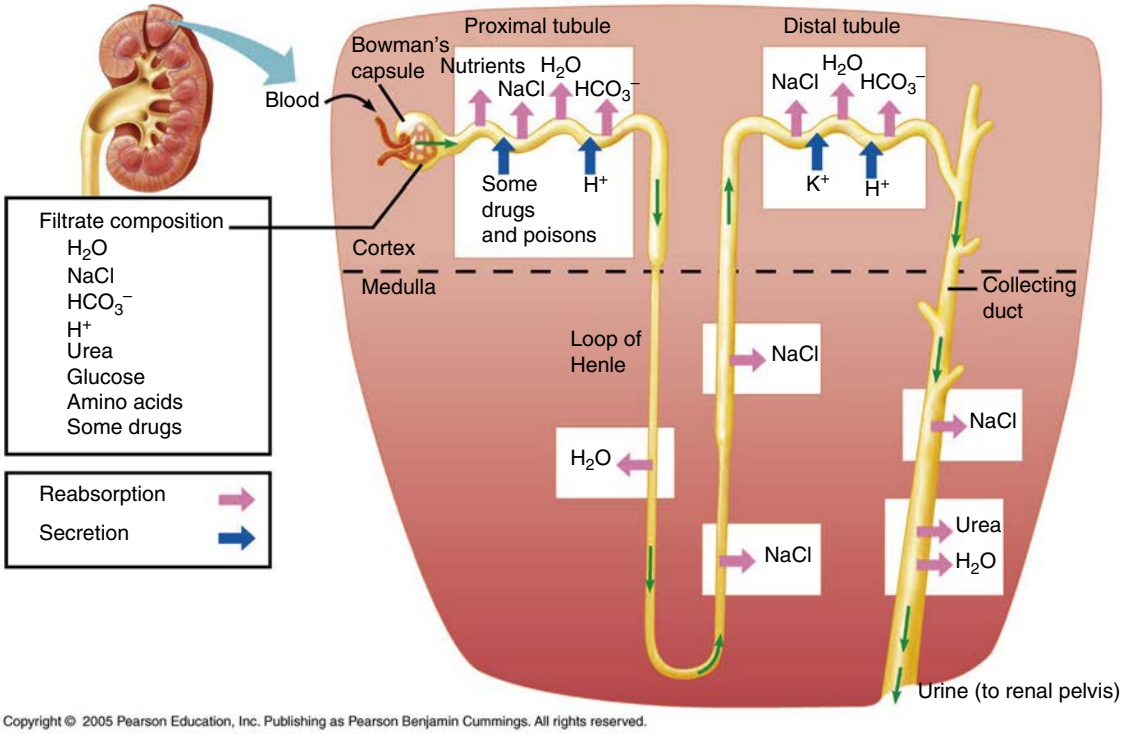

Fig. 190.1 Kidney excretion of toxins. (Copyright © 2005 Pearson Education, Inc. Publishing as Pearson Benjamin Cummings. All rights reserved.)

3. They regulate the excretion of foreign substances, such as chemicals, drugs, pesticides, food additives, and other metabolic waste products.
4. They are involved in gluconeogenesis, especially during prolonged fasting, and can supply up to 20% of the glucose from gluconeogenesis
5. They contribute to endocrine function conversion of 25(OU)D3 to 1,25-dihydroxyvitiman D3, erythropoietin, and renin.[1,2]

Prevalence

Chronic kidney disease is recognized as a public health problem worldwide. In the United States, the prevalence of chronic kidney disease (CKD) in the general population is approximately 14%. More than 30 million, or about 15% of, Americans have some form of CKD, and as shown in Fig. 190.2, the rate is increasing relentlessly. CKD, regardless of the type or cause, leads to complications of decreased kidney function, kidney failure, and cardiovascular disease (CVD). African Americans and Mexican Americans are more likely to develop CKD than Caucasians.[3–5]

End-stage renal disease (ESRD) is defined as the last stage (stage 5) of CKD. The number of persons progressing to ESRD continues to rise by about 21,000 cases per year, making it one of the most expensive diseases to manage medically.[6] African Americans are about 3.5 times more likely to develop ESRD than Caucasians, and Hispanics are 1.5 times more likely to develop ESRD than non-Hispanics.[7,8]

In children, the main causes of kidney disease are birth defects, hereditary disease, infections, systemic diseases, nephrotic syndrome, trauma, and blockage of the urinary tract or reflux. Kidney failure in children from birth to age 4 is usually the result of birth defects and inherited conditions, with hereditary diseases, nephrotic syndrome, and the effects of systemic disease seen between the ages of 5 to 14 years. Glomerular function diseases primarily affect older children, up to age 19.

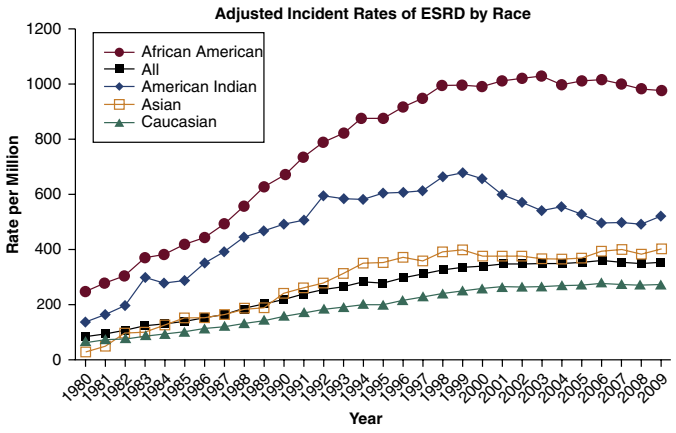

Fig. 190.2 Increasing prevalence of kidney disease. (https://www.google.com/url?sa=i&source=images&cd=&cad=rja&uact=8&ved=2ahUKEwjt363iu97cAhVHJDQIHeJvCEcQjRx6BAgBEAU&url=https%3A%2F%2Fcolumbusblack.com%2Fblog-series-vol-1%2Fdr-chris-brown%2Fnot-the-end-but-a-new-beginning-end-stage-renal-disease-esrd.html&psig=AOvVaw0ytVQcZNM8zKwhsb02rcs0&ust=1533852312484646.)

Kidney disease affects children in various ways, ranging from treatable disorders without long-term consequences to life-threatening conditions to acute kidney disease that develops suddenly, lasts a short time, and then resolves. The effects of both acute and chronic kidney disease can be serious, with long-lasting consequences, or completely clear once the underlying cause has been treated. Children with CKD face additional challenges, such as negative self-image; behavioral, learning, and relationship problems; and delayed language and motor skills.[9]

In the allopathic model, the belief is that CKD generally does not go away with treatment and tends to become worse over time, eventually

leading to kidney failure. This is because symptoms are managed with medications in hopes of slowing down the progression of the disease. In contrast, naturopathic therapies act to remove the cause and restore normal homeostasis as per the laws of healing and the therapeutic order.[10]

One of the reasons CKD is increasing is that many patients do not have symptoms until later stages of the disease process. Additionally, many early cases are missed as a result of a lack of screening on routine physical examinations and/or adequate screening laboratory studies.

Risk Factors

Although CKD and ESRD are found universally, certain ethnic groups exhibit faster rates of disease progression than others. In a study comparing estimated creatinine clearance rates (eGFRcreat) and cystatin C levels, the authors found that kidney function decline varied significantly by race/ethnicity, and these differences were present even among those without albuminuria upon initial evaluation.[11] Overall, blacks and Hispanics had higher rates of decline compared with whites, whereas Chinese and whites had similar rates of kidney function decline. Additionally, in Hispanics, researchers found that rates of decline varied significantly by country of origin, with the highest among Dominicans and Puerto Ricans. Sociodemographics and comorbidities were not found to be a factor.[12]

In a review article by Stenvinkel, the rate of prevalence of CKD was significantly higher in men compared with women. Women with CKD are more likely to be found in stages 1 to 4 compared with men.[13] Obesity was found to convey a threefold risk of developing CKD compared with hypertension and diabetes. Several other studies looked at hyperlipidemia, hypertension, changes in estimated glomerular filtration (eGFR) rates, and inflammation and their relationship to development of CKD.[14–16]

Comorbid conditions, such as cardiovascular disease and diabetes, can accelerate the rate of decline in CKD, and CKD itself contributes to the acceleration of CVD and diabetes.

The GFR is estimated to decline about 1.0 mL min^{-1} per year in the elderly, and therefore deterioration of renal function can be considered a "normal" aging process. Rates of decline in the elderly are highly variable and depend on lifestyle, diet, and overall health status.

The decline in the eGFR depends on the CKD stage and baseline values, with a faster decline the higher the baseline eGFR and a slower rate of decline with lower baseline eGFRs. Baseline eGFR values are a better predictor of CKD progression than age, gender, and stage of renal disease.[17] It has also been suggested that social isolation, loneliness, and poverty may also contribute to deterioration in kidney function as well as other diseases.[18]

An association of blood type and the development of CKD has been examined, with the most prevalent blood group among renal failure patients being blood group A (45.7%), followed by blood group O (30.4%), blood group B (17.3%), and blood group AB (6.6%). This is due to the presence of lectins that stimulate the production of antibodies, with the circulating immune complexes affecting glomerular basement membrane function. The disruption causes changes that contribute to filtration and eventual loss of kidney function.[19,20]

ENVIRONMENTAL EXPOSURE AND KIDNEY DYSFUNCTION

Excessive Salt in Diet

Excessive salt consumption is another significant factor contributing to the degeneration of the kidneys.[21] Mean intake of sodium in a global population is estimated at 3.95 g/day (equivalent to 10.06 g/day of salt), and in the United States, the average intake of sodium is 3.4 g/day (equivalent to 8.7 g/day of salt).[22] Studies have shown a connection between NaCl intake and acid–base balance, with high-salt diets causing a decrease in pH and moderate metabolic acidosis.[23,24] In response to acidosis, the kidney implements adaptive processes to restore the acid–base balance. These include the removal of the nonmetabolizable anions, the conservation of citrate, the enhancement of kidney ammoniagenesis, and urinary excretion of ammonium ions, resulting in the lowering of urinary pH, hypocitraturia, hypercalciuria, and nitrogen and phosphate wasting.[25] Some researchers have hypothesized that excessive salt in the diet is a significant contributor to loss of kidney function with aging.

Excessive Phosphates in Diet

The primary sources of "hidden" phosphates are additives used as processing aids, such as acid balancing (especially in carbonated beverages), leavening of bread, color and moisture retention, anticaking, and flavorings. It appears that a substantial portion of the population consumes more than the tolerable upper limit of 4000 mg/d and significantly more than the Recommended Dietary Allowance (RDA) of 700 mg/d for adults. Eliminating phosphates is difficult for the kidneys. Excessive intake of phosphates damages the tubules, increases fibrosis, which blocks the blood vessels, and decreases the GFR. Increasing phosphate levels in the blood is one of the early signs of kidney failure.[26] Serum phosphorous levels in the "high-normal" range (≥4.0 mg/dL but < 4.5mg/dL) have been associated with a twofold-higher risk of developing new-onset CKD and ESRD in the general population.[27] An observational study showed that every 0.5-mg/dL increase in serum phosphorous demonstrated a 40% greater risk for incident ESRD.[28]

Toxic Metals

Cadmium, chromium, lead, mercury, platinum, and uranium are all nephrotoxic. Although each is significant, the most common, as well as the most researched, are cadmium and mercury.

Cadmium is a significant kidney toxicant. It has a worrisome half-life of over 10 years, making it very difficult to excrete. The kidney holds 50% of the total body burden of cadmium, which increases the nephrotoxicity. The current cadmium exposure experienced by individuals living in the United States has reached levels that adversely affect kidney health in a significant proportion of the population.[29] As the kidneys degenerate, they not only lose their ability to excrete toxins but are less able to perform other normal physiological functions.

The kidneys have a high affinity for mercury. Within a few hours of exposure, 50% of the mercury that gets into the blood ends up in the kidneys. Mercury damages both the glomeruli and the tubules. Proximal tubular necrosis, especially along the straight renal segments in the inner cortex and outer stripe of the outer medulla, is a prominent feature of inorganic mercury nephrotoxicity.[30] Much of the tissue damage appears to result from poisoning of the kidney mitochondria, so there is not enough adenosine triphosphate (ATP) for the cells to protect themselves from the toxins they are excreting.[31]

Persistent Organic Pollutants

Because persistent organic pollutants (POPs) are mostly fat soluble, they are particularly damaging to the kidneys. Many of these chemicals are classified as halogenated hydrocarbons and are so difficult to detoxify or excrete that they have half-lives measured in months to years.

Fluorinated hydrocarbons (e.g., polytetrafluoroethylene [PTFE] polymers such as Teflon, perfluorooctanoic acid [PFOA], and perflourooctanesulfonic acid [PFOS]) damage the kidneys by passive diffusion into the tubules, where they poison the mitochondria. The resulting damage creates inadequate energy production, impairing active excretion; increases oxidative stress as the damaged mitochondria leak highly oxidative electrons and oxygen; and causes cell death, producing progressive loss of kidney function.[32]

Glyphosate

Epidemiological research has found a strong correlation between glyphosate use and the kidney failure epidemic. Of course, association does not prove causation. Animal research shows that chronic exposure at very low dosages causes kidney damage. A 2-year study that involved 0.1 ppb of glyphosate in rats' drinking water resulted in cellular kidney abnormalities and significant chronic kidney deficiencies.[33] Research conducted in Sri Lanka found that those who drank well water contaminated with glyphosate had a higher incidence of kidney failure in proportion to concentrations starting at 0.7 ppb, and farmers spraying glyphosates in the fields had a 5.4-fold increased incidence of kidney disease.[34] The European standard for water contamination is 0.1 ppb, whereas the U.S. Environmental Protection Agency (EPA) standard is an inexplicable 700 ppb.[35]

Nonsteroidal Anti-Inflammatory Drugs

Most nonsteroidal anti-inflammatory drugs (NSAIDs) were initially available only by prescription. Later, when the patents expired, NSAIDs became available over the counter. Acetaminophen, aspirin, ibuprofen, naproxen, indomethacin, and COX-2 inhibitors have all been shown to cause kidney damage when used chronically.[36–38,74,75]

Chronic consumption (>3 years) of single and/or combinations of NSAIDs is known to cause irreversible analgesic nephropathy.[39] Fig. 190.3 summarizes the risks. As can be seen, these drugs greatly increase the risk of kidney failure. Note that this is kidney failure; loss of kidney function is much more prevalent. Discontinuing the use of NSAIDs results in some recovery of function even in patients with kidney failure. After 6 months of stopping NSAIDs, those with the most damaged kidneys still had a doubling of kidney function.

CLASSIFICATIONS OF CHRONIC KIDNEY DISEASE

There are several classifications of kidney disease, each with their own characteristics. Understanding the etiology of CKD is helpful in determining the therapy needed. This is specifically important in naturopathic medicine due to the large number of therapeutic options available to the clinician.

Minimal-Change Nephropathy

Minimal-change nephropathy, also termed minimal-change disease (MCD), is believed to be primarily a disease of children but is found in adults as well. It is most often seen between the ages of 24 to 36 months, with males showing a higher incidence. The male-to-female predominance changes, as well as the incidence of development, with advances in age.

The onset of the disease is insidious and usually discovered after the development of edema. Kidney biopsy shows minimal changes in the glomerular structure, tubules, and interstitial areas, and thus the name minimal-change nephropathy. Hypertension and a reduction in renal function are usually not seen, nor is hematuria or the presence of red cell casts found with glomerulonephritis. A low serum albumin and proteinuria, an elevated serum cholesterol, and edema are the hallmarks of this disease.

MCD is associated with primary idiopathic nephrotic syndrome but can be secondary to NSAID use; exposure to heavy metals, such as mercury and lead; and in children with AIDS. Additionally, Hodgkin's disease and lymphoproliferative disorders must also be kept in mind with a presentation of MCD.

Membrane-Proliferative Glomerulonephritis

Membrane-proliferative glomerulonephritis (MPGN) is generally considered to be an immune complex disorder characterized by mesangial cell proliferation and deposits in the basement membrane of the C3 component of complement and immunoglobulins. The condition can further be divided into types I and II depending on the morphological presentation, age of onset, serum concentrations of C3, and the presence of serum nephritic factors and lipodystrophy. As with many of the renal diseases, there are disagreements as to whether these are separate entities or part of a natural history of the disease.

Type I MPGN is the most common presentation and is a slowly progressive disease. About 30% to 40% of individuals affected will remain clinically stable even with persistent proteinuria. Type I disease is characterized by a persistent 1+ to 2+ proteinuria and urinary sediments, which may contain low levels of erythrocytes and red blood cell (RBC) casts. Occasionally, a marked hematuria along with higher levels of protein will be seen at the beginning of the disease, which will revert to chronic levels after the initial insult.

In type II MPGN disease, an acute nephritis with macroscopic hematuria is the most common presentation. This presentation is more likely to have accompanying edema, hypertension, and signs of renal failure compared with an acute type I episode. Because of this, type II MPGN disease progresses more rapidly to renal failure than type I. About 20% of patients will remain stable for considerable periods of time despite the larger protein losses and low levels of uremia.

MPGN may also be associated with other diseases, such as immune-complex diseases (systemic lupus erythematosus [SLE], mixed cryoimmunoglobulinemia), malignancy (leukemia, lymphomas, light-chain disease), chronic liver disease (chronic active hepatitis, cirrhosis), and infectious diseases (bacterial, endocarditis, AIDS), and with Down syndrome, drug addiction, sarcoidosis and sickle cell disease.

Membranous Nephropathy

Membranous nephropathy is the most common form of nephropathy found in adults (usually over 30) with an unexplained or idiopathic proteinuria. The diagnosis is made after renal biopsy, which shows a thickened glomerular basement membrane and subendothelial deposits. Medications or an associated systemic illness seem to play a role, and the disease may be present for years before it is detected.

The first presentation may be heavy proteinuria, followed soon after by the signs and symptoms of progressive renal failure. Microscopical hematuria may also be present in a few cases. Males are affected more often than females, and hypertension and azotemia may not be present until later in the disease process.

The subsequent nephrotic syndrome presents with malaise, edema, and anorexia. Occasionally anasarca is also present. Elevated cholesterol and triglyceride levels are found, and there may be a predisposition to the formation of thrombosis, especially of the renal veins.

Membranous nephropathy is believed to be an immune-mediated disease because immunoglobulin G (IgG) and complement C3 are found with special staining. These could be formed locally or be deposits of circulating immune complexes. Secondary antigens have been found associated with hepatitis B surface and e antigens as well as thyroid antigens associated with thyroiditis.

Immunoglobulin A Nephropathy

Immunoglobulin A (IgA) nephropathy, otherwise known as Berger's disease, represents about 10% of all patients who reach end-stage renal failure and is the most common form of primary glomerulonephritis found worldwide. The histopathological findings are similar to those of Henoch–Schönlein purpura, which may represent a more systemic form, and together with glomerulonephritis are termed primary IgA nephropathy. Secondary forms are the result of conditions in which circulating IgA becomes deposited in the glomerulus. This

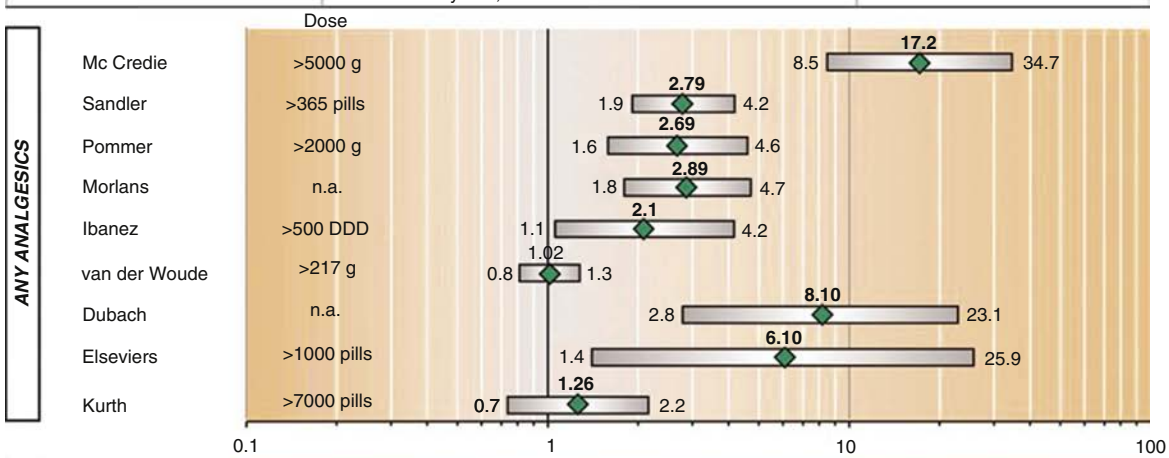
B



C

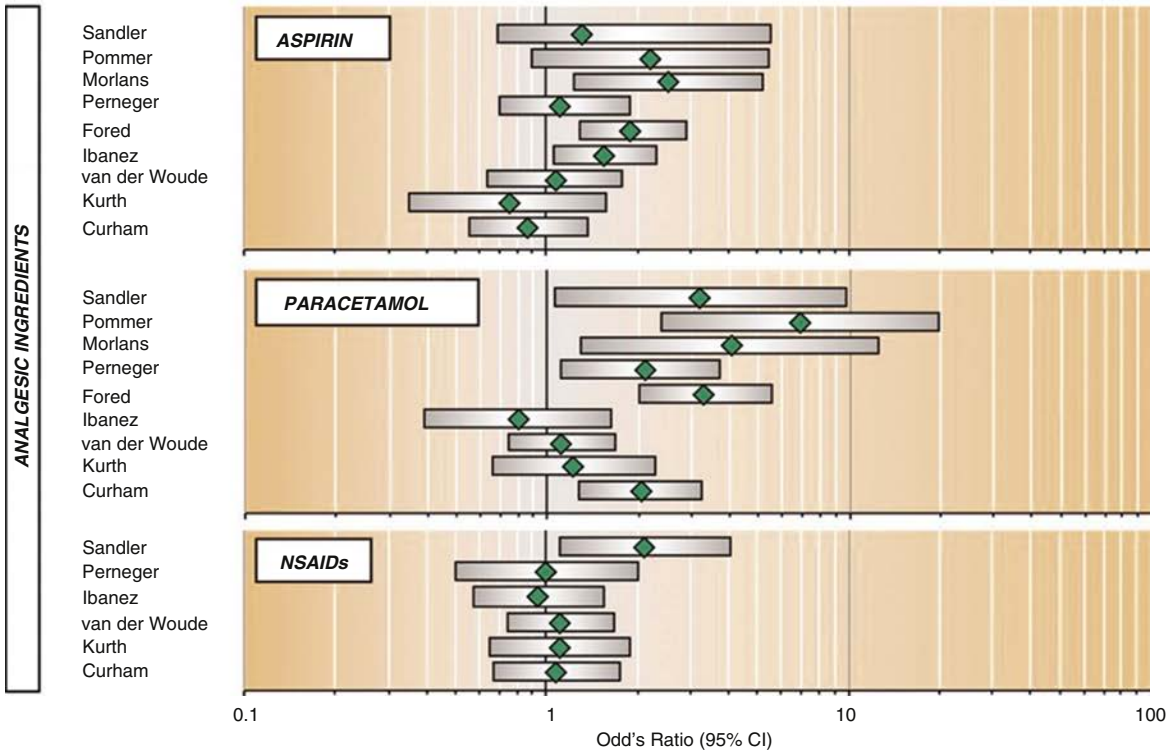


Fig. 190.3 Risk of kidney failure from long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs). (From Wei L, MacDonald TM, Jennings C, et al. Estimated GFR reporting is associated with decreased nonsteroidal anti-inflammatory drug prescribing and increased renal function. *Kidney Int.* 2013 Jul;84[1]:174–178.)

is commonly seen with celiac disease, chronic liver disease, dermatitis herpetiformis, psoriasis, ankylosing spondylitis, inflammatory bowel disease, IgA monoclonal gammopathies, HIV infection, certain cancers, and mycosis fungoides.

Although the disease is found in all age groups, children and young adults are more commonly affected, with a higher ratio of males to females. Most commonly, the person will present with macroscopic hematuria along with an upper respiratory tract infection. The person is usually asymptomatic but may present with fatigue, malaise, or muscle soreness or pain. Children and some adults may complain of loin pain. A distinction from post-streptococcal nephritis (PSN) can be made because the symptoms usually occur 10 to 14 days after infection, and the patient may have had a fever before the onset. Additionally, hypertension and peripheral edema, commonly seen with PSN, are usually not seen with IgA nephropathy.

Hematuria may last hours to days and may become intermittent with periods of no bleeding and then recur several months or years later after a febrile illness. Occasionally the hematuria is also accompanied by proteinuria of varying degrees, usually less than 1 g/day.

Henoch–Schönlein purpura, which is found more often in children, may also have associated arthralgia with a lack of joint swelling and inflammation; a skin rash primarily over the legs and lower trunk that rapidly becomes purpuric; and severe abdominal pain, ileus, and bloody diarrhea. Less commonly, the presentation will be a nephrotic syndrome with renal insufficiency and hypertension.

Acute Post-Streptococcal and Postinfectious Nephropathy

Acute post-streptococcal and post-infectious glomerulonephritis are a result of the deposition of circulating immune complexes in the glomerulus. This is often due to the presence of group A beta hemolytic streptococcus (BHS) after pharyngitis or a skin infection (cellulitis, impetigo). Other microorganisms, such as bacteria, viruses, and parasites, have been implicated as well.

Post-streptococcal glomerulonephritis (PSGN) is the most commonly encountered form of glomerulonephritis in children, with subclinical asymptomatic cases occurring 4 times more frequently than acute disease. There is some association with disease development in families, which may also be due to blood type and the presence of certain human leukocyte antigens (HLAs).[19,20] There appears to be a 2:1 male-to-female ratio even though susceptibility to BHS infection is not sex related.

The onset of the disease is usually abrupt and follows an infection with group A BHS. There is a latent period of 7 to 21 days after the infection before symptoms, such as edema and hematuria, occur. Periorbital edema is commonly observed. Hypertension may be present, resulting in headaches, visual disturbances, and altered sensorial states. Coma and convulsions may occur in severe cases. Circulatory congestion due to fluid retention results in dyspnea, cough, orthopnea, and cardiac and pulmonary changes suggesting pulmonary edema and congestive heart failure. PSGN should always be considered in patients presenting with cardiovascular or upper respiratory diseases of rapid onset.

Diagnosis is made by urinalysis positive for hematuria and RBC casts. However, white blood cell (WBC), tubular epithelial, and granular casts are also commonly found and reflect the degree of pathology present. Serum creatinine levels tend to remain stable, but blood urea nitrogen (BUN) levels may rise somewhat. Changes in electrolyte balance will parallel changes in metabolic acidosis or alkalosis and need to be monitored frequently. Anti-streptolysin O (ASO) titers begin to rise about 10 to 14 days post–streptococcal pharyngitis, peak at about 4 weeks, and return to normal levels between 1 and 6 months later. The magnitude of the titer does not seem to correlate to the degree of kidney involvement. Depression of hemolytic complement activity (C3) is present almost 100% of the time but also does not correlate to the degree of kidney involvement.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is defined as an idiopathic primary glomerular disease characterized by a rapidly progressing deterioration in renal function over a period of days to weeks to a few months. The definition is somewhat complicated because a rapid deterioration of kidney function can occur with a variety of illnesses. The cause of illness must be ruled out before a diagnosis of RPGN can be obtained. If untreated, the condition will commonly progress to end-stage kidney failure or death.

Diagnosis is by kidney biopsy confirming renal failure to be related to circulating antiglomerular basement membrane antibodies. A relationship to primary alveolar disease, such as Goodpasture's disease, has been suggested but not proven. The disease can be divided into three types, suggesting a vasculitis type of disease, circulating immune complexes as a pathogenesis, and possibly a relationship to HLA antigens and specific disease activity.[40,41]

Nephrotic Syndrome

Nephrotic syndrome (NS) is a recognized condition that can be the result of several diseases and is not considered a disease itself but rather a collection of symptoms due to kidney failure. Nephrotic syndrome is characterized by very high levels of urinary protein, low levels of serum total protein, swelling of the extremities (especially around the eyes), and high serum cholesterol.

Nephrotic syndrome can be caused by diseases that affect the glomerular filtration of the kidneys, such as focal segmental glomerulosclerosis (FSGS) or membranous nephropathy and are termed primary NS. Systemic diseases such as diabetes or lupus (secondary NS) can also cause nephrotic syndrome. Most cases of nephrotic syndrome in adults have secondary causes, with diabetes being the most common.[42,43]

DIAGNOSIS OF CHRONIC KIDNEY DISEASE

As previously mentioned, many patients with CKD have no knowledge of its presence until it is at somewhat of an advanced stage. This is because of the body's substantial organ reserve and ability to adapt to chronic conditions, or the person believes that it is due to another disease or part of the aging process.

Signs and symptoms may be minimal at first, and the patient may complain of feeling run-down or fatigued. The skin may become ruddy, dry, itchy, and perhaps yellowish in color. Mental processes and movements may become slower, and as the disease advances, the person may become anorexic and have cramping, numbness, and tingling of the extremities and may complain of insomnia.

At a minimum, a fasting chemistry screen and lipid levels should be ordered and include BUN, creatinine, and uric acid levels to assess kidney filtration. A complete blood count (CBC) to determine whether there is anemia, along with a fasting glucose, hemoglobin A1c, and insulin level to rule out metabolic syndrome or diabetes, and inflammatory markers such as serum ferritin, high-sensitivity C-reactive protein (hsCRP), and erythrocyte sedimentation rate (ESR) should also be considered.

Additionally, a routine urinalysis with microscopical examination should be performed, and if albumin is present, then a total protein/creatinine ratio is required to assess protein loss. A 24-hour urine creatinine clearance can follow this to establish a baseline to evaluate patient response to therapy.[44]

Several parameters, if noted early on, suggest developing kidney disease. One of the earliest manifestations is the development of microalbuminuria with a normal (calculated) GFR.[45]

A change in the slope of serum creatinine levels over time is a predictor of decreasing kidney function, with a greater slope correlating with a greater decrease in function. The association of low serum albumin corresponding with a faster rate of GFR decline was more consistently noted in studies of diabetic patients than nondiabetic patients.

The effect that dyslipidemia has on kidney decline is based on high levels of total cholesterol, triglycerides, or low-density lipoprotein and low levels of high-density lipoprotein. Several studies looking at individual or the totality of these parameters showed varying results, suggesting that there may be some association.

Smoking seems to have an effect on changes in GFR, with smokers being found to have a greater rate of deterioration.[45]

The GFR can be estimated from serum creatinine levels by using prediction equations that also account for age, sex, race, and body size. Two such equations are the Cockcroft–Gault and the Abbreviated MDRD study equations. The MDRD equation has largely replaced the Cockcroft–Gault equation because it is believed to be more accurate and precise for persons with a GFR of less than approximately 90 mL/min per 1.73 m^2 and does not require height and weight. Thus it is easily calculated and can be included with routine laboratory panels.

$$C_{Cr} = \left\{ \frac{(140 - \text{age}) \times \text{weight}}{(72 \times S_{Cr})} \right\} \times 0.85 \text{ (if female)}:$$

(The Cockcroft and Gault formula (1973))

$$\text{eGFR} = 175 \times (S_{Cr})^{-10154^{\circ}} \times (\text{age})^{-0.203^{\circ}} \times 0.742 \text{ [if female]} \times 1.212 \text{ [if Black]}: \text{(MDRD equation)}$$

$$C_{Cr}^{\circ}\text{(creatinine clearance)} = {}^{\text{mL}}/_{\text{minute}}$$

$$\text{Age} = \text{years}$$

$$\text{Weight} = \text{kg}$$

$$\text{SCr (serum creatinine)} = {}^{\text{mg}}/_{\text{dL}}$$

Although both equations are good for screening for potential kidney disease development, there is some question as to the validity of the MDRD equation in diabetic kidney disease, in patients with serious comorbid conditions, in "normal" patients, or in patients older than 70 years of age. In these cases, the Cockcroft–Gault equation may provide a better assessment.

The value of using both equations is in individuals with extremes of age and body size, severe malnutrition or obesity, diseases of skeletal muscle, paraplegia or quadriplegia, vegetarian diet, or rapidly changing kidney function. They can also be used to determine the dose of potentially toxic drugs that are excreted by the kidneys.

Other screening parameters of note are the serum calcium/phosphorus ratio and calcium X phosphorus, which is an assessment of the kidney's ability to balance calcium and phosphorus as well as to assess parathyroid function, response to vitamin D, and renal calcinosis. As serum calcium levels fall, there is a rise in phosphorus, resulting in symptoms of hypocalcemia. However, changes noted over time on routing chemistry screens may provide a clue for developing kidney disease. The normal calcium/phosphorus ratio = (2.5 ± 0.4), and the normal calcium X phosphorus = (N = < 40 and abnormal = 60 or >).

STAGES OF CHRONIC KIDNEY DISEASE

Kidney disease is recognized as a chronic, progressive disease and is classified according to the following stages:

Stage 1—Signs of mild kidney disease but with normal or better GFR (greater than 90% kidney function)

Stage 2—Signs of mild kidney disease with reduced GFR (indicating 60%–89% kidney function).

Stage 3—Signs of moderate chronic renal insufficiency (where the GFR indicates 40%–59% kidney function)

Stage 4—Signs of severe chronic renal insufficiency (where the GFR indicates 15%–29% kidney function).

Stage 5—Signs of end-stage renal failure (where the GFR indicates less than 15% kidney function).

THERAPEUTIC APPROACH

Case Management

Considering the many different causes of chronic kidney disease, comorbid disease management is as important as the management of the kidney disease itself. This has been one of the challenges facing physicians as medicine has become more compartmentalized, with specialists treating isolated organ systems. Polypharmacy is increasingly recognized as contributing to morbidity, negative health outcomes, and decreasing the quality of life.[46] Polypharmacy is particularly relevant to kidney function because many of these drugs, such as antihypertensive medications, directly affect kidney function.

In children affected with any type of kidney disease, it is important to consider that the kidney is still maturing. This may present a dilemma. In prolonged cases, severe damage can take place, altering kidney-centered parameters and affecting growth and development, as well as predisposing the person to an earlier development of kidney failure. However, in a disease state of shorter duration, a developing kidney has a greater chance of complete recovery if recognized and treated early.

A treatment regimen that considers the type of kidney disease, precipitating etiology, duration, and expected changes in the pathophysiology of the disease must be developed. This may consist of dietary modifications, allergen identification, and control of hypertension and diabetes if present. The goal of treatment is to relieve the perturbing insult on the kidney and allow healing and restoration of normal function to occur. Therefore periodic follow-up visits are needed once the initial insult has been eliminated or has reached equilibrium.

Education of the patient as to the possible course of the disease, the patient's susceptibility to it, and the significance of prevention to maintain the disease or the recovered level of health is important. A periodic routine urinalysis is beneficial for screening, especially after any febrile or respiratory illness.

Dialysis

Patients on renal dialysis present additional challenges for the clinician because each requires different levels of monitoring and follow-up. Hemodialysis is commonly performed 3 times per week, requiring the patient to be connected to a dialyzer that cleans the blood. This procedure takes between 3 and 5 hours and requires frequent blood testing to monitor electrolyte and protein balance. Peritoneal dialysis,

on the other hand, is carried out at home by the patient and is achieved through continuous ambulatory peritoneal dialysis (CAPD) or continuous cycling peritoneal dialysis (CCPD).

From a holistic perspective, it is much easier for the clinician to treat patients on CAPD and CCPD than hemodialysis simply because the mechanism of dialysis CAPD and CCPD works with the body's alternative filtering mechanism, the omentum, to achieve dialysis rather than filtering the blood, which necessitates a rebalancing of blood chemistry.

However, both methods increase the likelihood of sepsis due to contamination of fluids. Therapies to prevent sepsis seem to work better with CAPD and CCPD than hemodialysis. Additionally, the balancing of blood chemistry and working with the patient's dietary requirements are also easier to address.[47]

NUTRITIONAL CONSIDERATIONS IN ACUTE AND CHRONIC RENAL FAILURE

The goals of nutritional therapy in ESRD are to maintain the body's chemical composition as close to that of normal to preserve protein stores until renal function is normalized. Nutritional therapy in acute renal failure (ARF) is complicated because of the rapid and fluctuating progression of the disease, in contrast to ESRD, which is slower and more predictable.

Diets with high-quality protein and high carbohydrate (2200 calories) intake, with an excess of 500 mL of water above the daily output, are desired. Intake of water, electrolytes, and minerals must be closely monitored, especially in patients undergoing dialysis, to avoid fluid overload while minimizing abnormal concentrations of these substances. Protein restriction must occur to decrease the accumulation of nitrogenous wastes as well as other inorganic ions, such as sulfates and phosphates, which result from protein metabolism. A sufficient intake of calories and vitamins is needed to minimize catabolism of protein stores. High-carbohydrate diets in patients with renal failure were found to reduce endogenous protein catabolism, decreasing the BUN.

Water and Mineral Balance

Patients with ARF often show greater impairment of water, mineral, and electrolyte excretion than do patients with ESRD, even though the creatinine clearances may be similar. This is due to an inability of the body to adjust to the rapid changes occurring with ARF as opposed to the slower rate of change with ESRD. Water intake may need to be negative to balance the serum ion concentration.

Water loss must account for the patient's temperature, any surface loss through burns or open wounds, the rate of ventilation, and the humidity of the air. In afebrile patients without burns, fluid losses of 400 to 600 mL/day are seen. Water loss can be monitored by measuring weight changes and the differences between fluid intake and output, as well as calculation from body composition analysis.

Edema and hypernatremia indicate an excess of salt and water, whereas postural hypotension suggests volume loss. In patients with edema, hypernatremia requires water and salt restriction until the serum sodium concentration is normalized and the edema is reduced. In patients with postural hypotension, careful use of salt and/or blood or colloid is needed to correct the volume deficit. Hyperkalemia usually requires dialysis to remove potassium because it is primarily due to renal impairment.

Dietary Protein Requirements

Patients with ESRD are in neutral or positive nitrogen balance with ingestion of 40 g/day of high-quality protein but can go into negative balance with only 20 g/day. It has been shown that 0.5 to 0.8 gm/kg/day of protein is needed to maintain a neutral nitrogen balance and that higher amounts are needed with patients on dialysis. Patients on hemodialysis need higher protein amounts due to loss from the procedure. This also includes peritoneal dialysis. One g/kg/day is needed, and if the person is restricted to less, he or she will go into negative nitrogen balance.

Essential amino acids (AAs) need to be part of the regimen because a person lacking only one of the essentials AAs will develop a negative nitrogen balance as the rate of protein synthesis decreases in the absence of the amino acid. Branched-chain AAs have been shown to increase muscle protein synthesis while decreasing muscle degradation. Branched-chain AAs, which include leucine, isoleucine, and valine, showed a decline in degradation, especially leucine, which, by itself, can decrease catabolism. Protein-sparing effects were noted not only during the administration of the amino acid solution but up to a week after administration.

General Principles of Nutrient Administration

1. Adequate calories and nitrogen should be administered with a minimal amount of water.
2. High-quality protein should be administered in sufficient amounts to achieve neutral nitrogen balance but not so high as to increase urea nitrogen levels.
3. Sodium intake should be adjusted to achieve sodium output unless edema is present. If edema is present, then sodium should be restricted to a quantity less than the daily excretion. Potassium, calcium, magnesium, and phosphate should be monitored to make sure adequate serum concentrations are maintained.
4. Patients should be encouraged to eat, and the minimal dietary requirements for renal insufficiency should be followed unless there is a catabolic illness requiring a greater intake of protein.

Nutritional Therapies for Chronic Kidney Disease

There are a considerable number of natural therapies that can be used for patients with CKD, not only to support kidney function and decrease rates of decline but also to support the other emunctories that must compensate for decreased kidney function. Therefore liver and skin support for detoxification and elimination are important to address as part of a comprehensive CKD program. As with all natural therapies, individualization of treatment plans is important because patients with CKD will present with their own unique presentations due to the stressors of the disease process.

Most of the causes of kidney damage can be controlled by helping people make better choices. The key environmental nephrotoxic agents include cadmium, mercury, fluorinated hydrocarbons, and glyphosate. Decreasing exposure is primarily accomplished by modifying lifestyle choices. This includes eliminating or significantly reducing consumption of conventionally grown foods (e.g., soybeans), eliminating tobacco smoking, avoiding genetically modified organism (GMO) foods, eliminating or reducing consumption of large fish (e.g., tuna), avoiding nonstick coatings on pots and pans, and avoiding clothing that is waterproof but breathable. Some of the most immediate benefits can be seen by decreasing toxins of choice, such as excessive dietary salt, excessive dietary phosphates, and drugs such as NSAIDs. Organic, mostly plant-based foods should be consumed when possible. Eating organic foods has been shown to measurably decrease POP levels within 3 days.[48]

Vitamin C

Vitamin C supplementation in patients with CKD, especially those on dialysis, has been reviewed in several studies looking at its antioxidant effects for lipid peroxidation, enhancement of cellular function, and

its role in mobilizing iron to form hemoglobin. Because there is a high turnover of RBCs in patients with CKD, iron stores will increase due to chronic inflammation and loss from dialysis. Vitamin C plays a key role in mobilizing iron for hemoglobin formation. However, in CKD, an increase in oxidation may occur because of ascorbate, causing additional stress to already-uremic patients. Depending on the study, levels of 60 to 300 mg per day or 1 to 1½ g per week are recommended above intake from food sources.[49,50]

Vitamin D

Patients with CKD show reduced levels of 1-α hydroxylase, the enzyme that converts calcifediol/25-hydroxyvitamin D (25[OH]D) to its more active form, calcitriol/1,25-dihydroxyvitamin D ($1,25[OH]_2D$). Because of this, patients with CKD are most often supplemented with a vitamin D replacement of the active form of 1,25-dihydroxvitamin D.[51] Because extra-renal 1-α hydroxylation does occur, some nephrologists recommend supplementing with the unactivated form of vitamin D, allowing the extra-renal sites to regulate calcium and phosphorus balance.[52]

The half-life of calcifediol/25-hydroxyvitamin D (25[OH]D) is 2 to 3 weeks except in renal failure, where it will last up to 2 to 3 times that. The half-life of calcitriol/1,25-dihydroxyvitamin D ($1,25[OH]_2D$ is 3 to 6 hours, but the pharmacological activity can last 3 to 6 days. When administering vitamin D, the serum calcium and phosphorus levels should be checked monthly to adjust dietary intake because of changes in kidney production as well as supplementation. In dialysis patients, they should be checked weekly.[51,53]

Vitamin E

Vitamin E has been shown to be an excellent protector and stabilizer of cell membranes, especially in RBCs and lung tissue. This is because of its antioxidant properties, anti-inflammatory, and anti–platelet aggregation effects. Vitamin E was shown in one study to lower the protein/creatinine ratios while somewhat increasing the mean GFR.[54,55] Asymmetrical dimethylarginine (ADMA), an inhibitor of endothelial nitric oxide synthase, is elevated in CKD and is considered a risk factor for the development of arteriosclerosis. A study evaluating the effects of ADMA concluded that vitamin E supplementation increased the bioavailability of nitric oxide, lowering the risk of arteriosclerosis.[56]

Fish Oil

Consumption of fish, either in the diet or supplemented fish oils, shows a reduction in the development of CKD.[57] Fish oil supports kidney function through anti-inflammatory effects and the regulation of blood pressure.[55] Fish oil has also been found to slow the progress of kidney disease in patients with IgA nephropathy. Fish oils have also been found to protect renal function in patients undergoing Cyclosporin therapy for psoriasis as well as with renal transplant.[58,59]

Flax Oil

Flax oil, a source of alpha-linoleic acid, has been found to be beneficial because it reduces renal injury in experimental polycystic kidney disease by decreasing associated interstitial nephritis.[60] This is due in large part to its anti-inflammatory properties and its ability to alter the renal content of polyunsaturated fatty acids, which promotes the formation of less inflammatory classes of renal prostanoids.[61]

N-Acetylcysteine

N-Acetylcysteine (NAC) is believed to promote the production of glutathione, an antioxidant that prevents damage to important cellular components caused by free radicals, lipid peroxidation, and heavy metals. NAC is used for the treatment of acetaminophen toxicity as well as a mucolytic in patients with cystic fibrosis and chronic obstructive pulmonary disease. NAC also provides protection in patients with CKD by increasing glutathione production and reducing exposure to acetaminophen and contrast dyes.[62,63] Additionally, NAC has been shown, along with the iron chelator deferoxamine and *Ginkgo biloba* extract, to protect against cisplatin lipid peroxidation, with NAC and deferoxamine having the greatest effect.[64]

Alpha-Lipoic Acid

Alpha-lipoic acid (ALP) has been shown to attenuate the effects of other antioxidants, such as vitamins C and E, especially in patients with diabetic nephropathy. Additionally, ALP increased renal cortical glutathione levels in patients with diabetes.[65] Another study looked at the effects of ALP on doxorubicin-induced renal damage and found that there was greater mitigation of oxidative stress, inflammation, and apoptosis parameters with pretreatment with ALP. These studies suggest that ALP, used in conjunction with other antioxidants, provides additional protection against oxidative stress in CKD.[66]

Carnitine

Carnitine supplementation slows the rate of kidney function loss while improving skeletal and cardiac muscle function as well as decreasing anemia, all found in CKD patients. Carnitine slows the rate of kidney function loss, and its deficiency is a common occurrence in dialysis patients, where supplementation has been shown to decrease hospital use in this group.[67,68]

Curcumin

Curcuma longa is a potent antioxidant that protects against protein loss, albuminuria, and hyperlipidemia as well as decreasing kidney damage due to free-radical formation. Additionally, it was found to increase glutathione and glutathione peroxidase activity while eliminating kidney microsomal and mitochondrial lipid peroxidation.[69,70]

Glandulars

Dietary use of renal protomorphogen (kidney tissue extract) helps decrease circulating immune-complex damage in autoimmune disease as well as provide nutrients and growth factors for renal regeneration. Many cultures use organ-specific nutrients when treating specific disease conditions like CKD, as well as to support normal growth and development.

Homeopathy

Homeopathic prescriptions for patients with CKD have, in many cases, slowed, stopped, or reversed the progress of the disease. This is particularly seen in patients with acute kidney failure whose course is often rapid and severe, requiring lesional, fundamental, and constitutional prescriptions. In patients with CKD, prescriptions are more often constitutional or miasmic due to the slowly evolving nature of the disease. Often used in conjunction with other natural therapies, a wide variety of homeopathic medicines are used to direct the healing process or with dialysis patients to reduce the risk of sepsis and toxemia.[71]

Botanical Medicines

Botanical medicines, such as *Aconite napellis, Arctostaphylos uva ursi, Atropa belladonna, Eupatorium purpureum, Juniperus officinalis, Galium aparine, Rheum palmatum, Salviae militorrhizae,* and *Solidago odora,* are commonly used for CKD. Botanical medicines work differently than drugs in that they contain several different constituents that affect a variety of parameters of kidney function.[72–74]

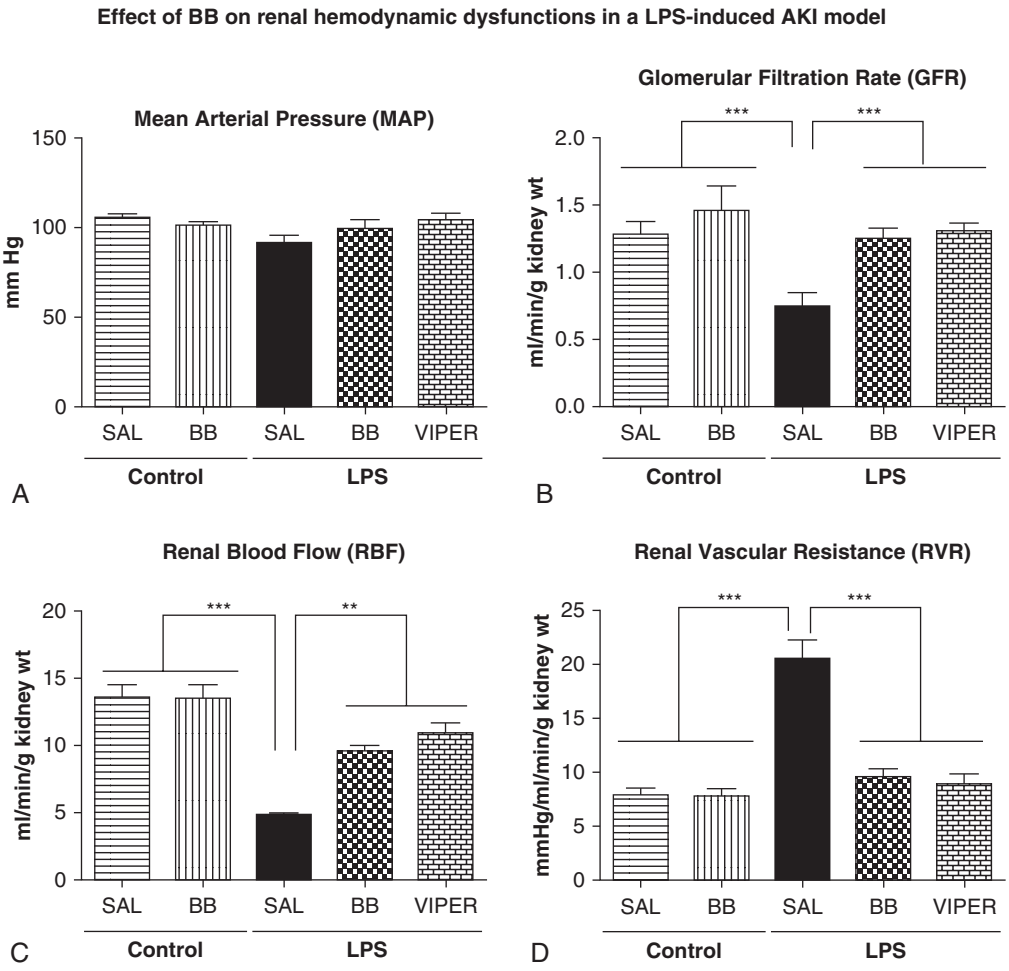

Fig. 190.4 Blueberries protect the kidneys from gut-derived toxins.

Salvia Militorrhizae

As an example, *Salvia militorrhizae* increases blood flow to the kidney by decreasing platelet adhesion, enhances urea and creatinine clearance, stabilizes the glomerular basement membrane by enhancing electrical charge, provides antioxidant and free-radical neutralization, and decreases lipid peroxidation due to the presence of magnesium lithospermate B. It also affects blood pressure by enhancing prostaglandin E2 for vasodilation while limiting the effects of thromboxane A2 that contribute to vasoconstriction.[75]

Hydrastis, Phytolacca, Bryonia, and Baptisia

Herbal medicines such as *Echinacea, Hydrastis, Phytolacca, Bryonia,* and *Baptisia,* when used in combination, reduce the risk of the development of sepsis in dialysis patients. The combination is taken prophylactically and at an increased dosage at the first signs of developing sepsis. The formula is often used in conjunction with homeopathic *Pyrogenum* and/or *Echinacea* and has been found to quickly restore normal homeostasis.[76]

Gotu kola

Traditional Chinese medicine has used *Gotu kola* to treat kidney diseases for centuries. Asiaticoside has been shown to improve microcirculation and reverse fibrosis in humans with varicose veins. Its direct benefits for the kidneys have only been shown in animals but are encouraging. In rats, *G. kola* showed a protective effect for Adriamycin-induced nephropathy, resulting in dramatically improved kidney function.[77] Another study combined *G. kola* in conjunction with naringenin and showed decreased fibrosis formation in the kidneys.[78]

Dark Chocolate

Dark chocolate consumption improves oxygenation of the kidneys in all individuals. The benefit is directly proportional to catechin levels.[79] Animal research has shown that catechins also protect the kidneys from oxidative stress from toxic drugs like cyclosporine.[80]

Blueberry

Blueberry anthocyanins specifically protect the kidneys from bowel-derived endotoxins. Fig. 190.4 shows how blueberries increase the GFR in normal kidneys (but the increase is not statistically significant) and completely protect the kidneys from the dramatic lowering of GFR caused by gut toxins in those with impaired function.[81]

Zingiber officinale

There is ample animal research showing that *Zingiber officinale* not only improves kidney function but is especially beneficial in protecting the kidney from cadmium. The primary mechanism of protection appears to be ginger's ability to decrease inflammation and oxidative damage to kidney tissue exposed to a variety of toxins. The anti-inflammatory benefits of ginger in the kidney result from its antioxidant properties and the epigenetic downregulation of proinflammatory genes.[82] Several animal studies have shown that ginger can protect the kidneys from cadmium. One study found the anti-inflammatory effects

Effect of administration of polyphenols from ginger on kidney function parameters of normal and streptozotocin-diabetic rats.

Group	Kidney function test	
	Urea (mg/dL)	Creatinine (mg/dL)
Control	14.82 ± 1.99[a]	1.72 ± 0.26[a]
Diabetic untreated	50.61 ± 6.82[b]	2.52 ± 0.53[a]
Diabetic + Free	22.63 ± 2.09[c]	2.01 ± 0.29[a]
Diabetic + Bound	27.05 ± 2.12[c]	2.83 ± 0.71[a]
Diabetic + Glibenclamide	35.82 ± 3.87[c]	2.11 ± 0.23[a]

Values are mean ± S.E.M. of 8 rats per group. Test values down the vertical columns carrying different superscripts are significantly different ($p < 0.05$).

Fig. 190.5 Ginger partially restores kidney function in diabetic rats.

of ginger to be strong enough to prevent most of the kidney damage from cadmium.[83] Another found almost no histological kidney damage when ginger was fed along with cadmium.[84] Animal research has also shown kidney protection from alcohol, malathion, carbon tetrachloride, chromates, fructose, gentamycin, ischemia, lead, and cancer drugs.[85–87] Fig. 190.5 shows restoration of kidney function in rats that already had diabetes.[87]

Herbal medicines have also been found to contribute to the development of CKD when used incorrectly, misidentified, or contaminated. Consulting a botanical material medica before prescribing for CKD is highly recommended.[88]

THERAPEUTIC APPROACH

There is no substitute for vigorously avoiding all causes of kidney damage, especially environmental toxins and NSAIDs.

Supplements

Vitamin C: 500 mg/d
Vitamin E: 1000 IU mixed tocopherols/d
Fish oil: 3 g/d
NAC: 500 mg/d

Botanical Medicines

G. kola extract: 30 to 90 mg/d
Dark chocolate: to tolerance
Blueberry extract: 1000 mg/d

Kidney Stones

Geovanni Espinosa, ND, LAc, IFMCP, CNS, and
Ralph Esposito, ND, LAc

OUTLINE

DIAGNOSTIC SUMMARY

- Usually asymptomatic
- Diagnosed adventitiously or from acute symptoms if urinary tract obstruction
- Excruciating, intermittent, radiating pain to the groin area originating in the flank or kidney
- Nausea, vomiting, and abdominal distention
- Chills, fever, and urinary frequency if infection present

GENERAL CONSIDERATIONS

Stone formation in the urinary tract has been recognized for thousands of years; during the past few decades, however, both the pattern and incidence of the disease have changed markedly. In the past, stone formation occurred almost exclusively in the bladder, but today most stones form in the upper urinary tract (Fig. 191.1). Males have a 3:1 ratio in the formation of kidney stones compared with females except in the sixth decade, where the incidence falls in men but rises in women—a trend toward gender equivalence.[1]

Once a kidney stone does form, there is a 50% chance of recurrence within 5 to 7 years if there is no treatment. Kidney stones are not limited to any cultural, geographical, or racial groups. In the United States, 1 of every 11 Americans is affected by kidney stones, with the emergency department (ED) being the most common resource for patients. Of these, 11% return within the first 30 days after an ED visit.[2] The incidence has been steadily growing, paralleling the rise in other diseases associated with the so-called Western diet—ischemic heart disease, cholelithiasis, hypertension, and diabetes.

In the western hemisphere, over 80% of kidney stones are usually composed of calcium salts, uric acid (5%–8%), or struvite (10%–15%). Molecular research is beginning to link certain mutations in the genes responsible for handling renal chloride, which can lead to hypercalciuria. Other identified genetic changes are being linked to excess urinary excretions of oxalate, cystine, and uric acid.[3] A recent systematic review found that 20 genes and more than 42 single-nucleotide polymorphisms (SNPs) may relate to stone matrix, calcium and phosphate regulation, inflammation, and oxidative stress, all of which contribute to stone formation. The complexities of genomics are not yet completely solidified; thus suggesting that the cause of stones is primarily related to an SNP is premature. However, this still provides us with a deeper insight as further research emerges.[4]

The incidence of renal stones varies geographically, reflecting differences in environmental factors, diet, and components of drinking water. Human urine is supersaturated with respect to calcium oxalate, uric acid, and phosphates. These substances normally remain in solution because of pH control and the secretion of inhibitors of crystal growth.

The following primary and secondary metabolic diseases cause kidney stones and must be ruled out early in the clinical process:

- Hyperparathyroidism
- Cystinuria
- Vitamin D excess
- Milk-alkali syndrome
- Destructive bone disease
- Primary oxaluria
- Cushing syndrome
- Sarcoidosis
- Acid-forming diet

Evolving research is showing that acid-forming diets (i.e., diets whose constituents require a metabolic response to neutralize and increase excretion of acids) appear to underlie many of the dietary factors—especially salt and foods with sulfur-containing amino acids—and have been shown to play a key role in the formation of both calcium and urate stones. This finding also helps explain the protective effects of a diet high in fruits and vegetables.

DIAGNOSTIC CONSIDERATIONS

Stone Formation

Conditions favoring stone formation can be divided into two groups: factors increasing the concentration of stone crystalloids and factors favoring stone formation at normal urinary concentrations (Fig. 191.2). The first group includes a reduction in urine volume (dehydration) and an increased rate of excretion of stone constituents. The second group is related to urinary stasis, pH changes, foreign bodies, and reduction of normal substances that solubilize stone constituents. See Tables 191.1 and 191.2 for an outline of the diagnostic possibilities.

THERAPEUTIC CONSIDERATIONS

Stone Composition

Diagnosing the type of kidney stone is critical to identifying the appropriate therapy. Careful evaluation of the following criteria usually determines the composition of the stone if one is not available for chemical analysis:

- Diet
- Underlying metabolic or disease factors
- Serum and urinary calcium, uric acid, creatinine, and electrolyte levels
- Urinalysis
- Urine culture

Table 191.3 summarizes the findings in the major types of kidney stones.

Dietary Factors

Calcium-containing stones are composed of calcium oxalate, calcium oxalate mixed with calcium phosphate, or very rarely calcium phosphate alone. The high incidence of calcium-containing stones in affluent societies is directly associated with the following dietary patterns:

- Low amounts of fiber[5]
- Intake of highly refined carbohydrates[6,7]

TABLE 191.1 Causes of Excessive Excretion of Relatively Insoluble Urinary Constituents

Constituent	Cause of Excess Excretion	Laboratory Findings
Calcium	(>250 mg/day excreted)	Low serum PO_4
	Absorptive hypercalciuria	30%–40% of all stone formers
	Renal hypercalciuria (renal tubular acidosis)	High serum parathyroid hormone
	Primary hyperparathyroidism	High urinary cyclic AMP
	Hyperthyroidism	High serum calcium
	High vitamin D intake	High $1,25(OH)_2D_3$
	Excess intake of milk and alkali	Low serum phosphate
	Aluminum salt intake	High $1,25(OH)_2D_3$
	Destructive bone disease	
	Sarcoidosis	
	Prolonged immobility	
	Methoxyflurane anesthesia	
Oxalate	Familial oxaluria	Rare
	Ileal disease, resection, or bypass	Vitamin B_6 deficiency or abnormal oxalate metabolism
	Steatorrhea	
	High oxalate intake	
	Ethylene glycol poisoning	
	Vitamin C excess (extremely unlikely)	
Uric acid	(<750 mg/day excreted)	Rapid cell destruction
	Gout	
	Idiopathic hyperuricosuria	
	Excess purine intake	
	Anticancer drugs	
	Myeloproliferative disease	
Cystine	Hereditary cystinuria	

TABLE 191.2 Physical Changes in Urine and the Kidneys

Condition	Possible Cause
Increased concentration	Dehydration
	Stasis
	Obstruction
	Foreign-body concretions
Urinary pH	Low—uric acid, cystine
	High—calcium oxalate and PO_4
Infection	*Proteus*—struvite
Uricosuria	Crystals of uric acid initiate precipitation of calcium oxalate from solution
Nuclei for stone formation	Cells, bacteria, blood clots, etc., initiate precipitation
	Sponge kidney
Deformities of kidney	Horseshoe kidney
	Caliceal obstruction or defect

AMP, Adenosine monophosphate

- High alcohol consumption[8]
- Large amounts of animal protein[8,9]
- High intake of fat[10]
- High intake of soft drinks[11]
- High intake of fructose[12]

The classification of most stones as either "idiopathic" or "hypercalciuria" reflects an ignorance of the dietary factors that induce hyperuricemia, hypercalciuria, and stone formation. The cumulative effect of these dietary factors is undoubtedly the reason for the rising incidence of kidney stones.

As a group, vegetarians have a lower risk of stone development. Studies have shown that even among meat eaters, those who ate higher amounts of fresh fruits and vegetables had a lower incidence of stones.[13] Bran supplementation, as well as the simple change from white to whole-wheat bread, has resulted in lower urinary calcium levels.[5]

Dietary factors may also play a role in acidifying or alkalinizing urine. Depending on the type of stone, this ability to alter urinary pH may help treat and prevent stones.[14] In one study, 12 healthy men were given a standardized diet plus cranberry, black currant, or plum juice. These subjects then provided 24-hour urine collections for evaluation. The researchers found that cranberry juice decreased the urinary pH and significantly increased the excretion of oxalic acid and the relative supersaturation for uric acid. Black currant juice increased urinary pH, excretion of citric acid, and loss of oxalic acid. Plum juice effected no change.[15] The researchers concluded that black currant juice could support the treatment and prevention of uric acid stones through its alkalizing effect. Conversely, because cranberry juice acidifies urine, it could be useful in the treatment of brushite and struvite stones as well as for urinary tract infections.[16]

Increased fluid intake has been recognized as one of the main approaches to decrease urine supersaturation. An increase in the urine volume results in a decrease in stone prevalence. Numerous randomized controlled trials (RCTs) have found that consumption of more than 2 L/day of water[17] or increased fluid intake to achieve a urine output of more than 2.5 L/day[18] lowers the long-term risk of kidney stone recurrence by approximately 60% versus no treatment.

One trial, conducted in stone-forming men with a baseline soft drink consumption of more than 160 mL/day, reported a reduction in self-reported physician-confirmed episodes of renal colic in those randomized and advised to abstain from soft drink intake versus no intervention for 3 years. Total fluid intake was similar in both groups.[11]

TABLE 191.3 Chemical and Physical Characteristics of Urinary Stones

Composition	Crystal Name	Frequency (%)	X-Ray Appearance	Urine Characteristics	Crystal Characteristics
Calcium oxalate	Whewellite	30–35	Opaque	Nonspecific	Small, hempseed- or mulberry-shaped, brown or black
Calcium oxalate + calcium phosphate		30–35	Opaque	pH > 5.5	Small, hempseed- or mulberry-shaped, brown or black
Calcium phosphate	Apatite	6–8	Opaque	pH > 5.5	Staghorn configuration, light in color
Magnesium ammonium phosphate	Struvite triple phosphate	15–20	Opaque	pH > 6.2 Infection	Staghorn configuration, light in color
Uric acid		6–10	Translucent	pH < 6.0	Ellipsoid, tan or red-brown
Cystine		2–3	Opaque	pH < 7.2	Multiple, faceted, maple syrup color

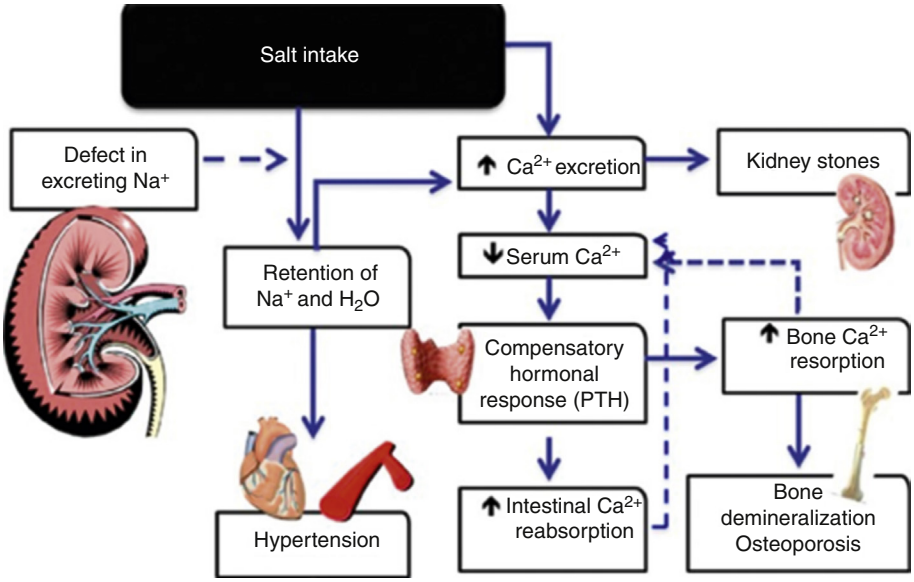

Fig. 191.3 Schematic representation of the effects of salt intake on calcium metabolism and its implications for kidney stone formation and bone health. (From Cappuccio FP. Cardiovascular and other effects of salt consumption. *Kidney Int Suppl.* 2013;3[4]: 312–315. PubMed PMID: 25019010. https://openi.nlm.nih.gov/detailedresult.php?img=PMC4089690_kisup201365f1&req=4.)

DIET

In one study, high levels of dietary calcium in men younger than age 60 were associated with decreased stone formation, but there was no effect in men older than age 60, nor was a supplemental dietary intake of more than 500 mg of calcium associated with an increased risk of stones.[19]

The specific type of stone was not elucidated in this study, and it was assumed that the majority of kidney stones reported by the cohort population consisted predominantly of calcium oxalate, as in the general population. The cause of this age-specific difference is unclear. Dietary calcium may bind to dietary oxalate in the intestine, thereby reducing oxalate absorption and the subsequent concentration of urinary oxalate. Both vitamin D deficiency and a diminished ability to absorb dietary calcium are more prevalent in older people.[19]

Sodium and Salt

Regarding dietary salt content, observational studies suggested a strong relation between sodium consumption and hypercalciuria, but more recent evidence has challenged this idea. High sodium intake is known to reduce renal tubular reabsorption of calcium, thereby increasing the amount of calcium excreted in the urine (Fig. 191.3).[20] Also, a high-sodium diet is known to increase urine pH and has been proposed to reduce urine citrate.[21] Other studies show a positive association between urinary sodium and calcium excretion and suggest that stone formers may be more sensitive to the calciuric effect of sodium.[22]

Nouvenne et al.[23] found that when patients with idiopathic calcium stones were treated with sodium restriction (60 mmol/day) and high fluid intake, a reduction of 100 mmol of urinary sodium was accompanied by a reduction of 64 mg/day in urinary calcium, with 30% of patients achieving normal urine calcium.

In contrast, other data, specifically in patients with hypocitraturia (not hypercalciuria), demonstrated that dietary sodium supplementation resulted in increased voided volume and decreased calcium-oxalate supersaturation.[24] This must be carefully examined because these patients were followed for only a short period of time and were already using pharmacological interventions for stone

disease. Although results continue to be conflicting, reduced dietary sodium is a general recommendation given to most patients with a history of kidney stones.

Fructose

Sports drinks have become increasingly popular within the past decade. The content of citrate in such beverages would be expected to increase urine citrate excretion and urine pH, providing protection against both calcium and uric acid stones. However, the purposely high sodium content of sports drinks, promoted as useful for "rehydration" in athletes, might be associated with increases in urine calcium excretion. In addition, the ingestion of significant amounts of sucrose and fructose in these drinks could also be associated with increases in calcium excretion.[7] Fructose, a component of corn syrup frequently added to sports drinks and sodas as a sweetener, would also be an undesirable way for most stone formers to increase urine volume, given its recent links to hyperuricemia, metabolic syndrome, and stones.[25,26]

Citrate is an important inhibitor of the aggregation and growth of calcium-oxalate and calcium-phosphate crystals. In the past, dietary interventions to increase citrate have included lemonade and orange juice.[27,28] The results with lemonade are conflicting, with one study showing an increase in urine volume but not in urine citrate.[29] Another citrus juice, grapefruit, may prove to be effective in increasing urinary citrate levels and reducing the BONN risk index score, suggesting an overall protective effect on crystallization. Although the urinary oxalate levels may be increased, crystallization is decreased and offset by increased citrate.[30–32]

Regular consumption of grapefruit juice should be avoided, however. In one large-scale study, women drinking 8 oz of grapefruit juice daily increased their risk of stones by 44%.

Hyperoxaluria is a metabolic risk factor for stone disease. Dietary oxalate may contribute as much as 80% of the urine oxalate.[33,34] Therefore a low-oxalate diet may provide benefit for patients with hyperoxaluria. In addition, adequate dietary calcium to minimize intestinal oxalate absorption has been shown to be beneficial. Borghi et al.,[35] in a randomized trial in men with recurrent calcium-oxalate stones, achieved a significant reduction in oxalate excretion and the incidence of recurrent stones for patients on a normal-calcium (1200 mg/day), low-animal-protein, low-salt diet compared with a low-calcium diet (400 mg/day).

Dietary Recommendations for Patients With High Urine Oxalate

Low-Oxalate Diet

A low-oxalate diet is a common prescription for recurrent calcium-oxalate kidney stones. The ultimate goal is to reduce the level of oxalic acid being excreted in the urine. It appears that people with recurrent kidney stones have a tendency to absorb higher levels of dietary oxalates, up to 50%,[33] compared with normal subjects not prone to kidney stones, who absorb only 3% to 8% of dietary oxalate. A low-oxalate diet is usually defined as less than 50 mg of oxalate per day, so foods in the high- and moderate-oxalate categories have to be curtailed. Box 191.1 provides an estimate of the oxalate content of food, which is highly variable. The level of oxalate in a particular food in published reports can vary twofold to fifteenfold. Differences in climate, soil quality, state of ripeness, or even which part of the plant is analyzed will also affect the value.

Although the role of oxalates in the development and risk of kidney stones is unclear, with some research showing only a modest correlation, clinically it would be prudent for stone formers to reduce intake. However, the stringency of following a low-oxalate diet must be considered and tailored to the patient and his or her potential comorbidities.[36]

Weight and Carbohydrate Metabolism

Weight control and the correction of carbohydrate metabolism are important because excess weight and insulin insensitivity lead to hypercalciuria and are high-risk factors for stone formation.[37,38] After glucose ingestion, there is a rise in urinary calcium, and phosphate reabsorption decreases. This leads to a low plasma phosphate concentration, which stimulates the production of 1,25-dihydroxycholecalciferol and results in increased intestinal absorption of calcium; concurrently; it also causes hypercalciuria. The ingestion of sucrose and other simple sugars causes an exaggerated rise in the urinary calcium-oxalate content in approximately 70% of people with recurrent kidney stones.[39]

Gut Flora

Studies are beginning to find a correlation between the proper balance of intestinal flora and a lower risk of oxalate kidney stones. Oxalate homeostasis depends in part on the intestinal anaerobic bacterium *Oxalobacter formigenes.* It now appears that *O. formigenes* contributes to oxalic acid homeostasis and that its absence may predispose individuals to idiopathic calcium-oxalate kidney stone disease.[39] This bacterium is found primarily in the colon, and its loss through prolonged, widespread use of antibiotics is associated with an increased risk of hyperoxaluria and calcium-oxalate stone formation.[40] Studies in animals and human volunteers have indicated that, when administered therapeutically, *O. formigenes* can repopulate the gut and reduce the urinary oxalate concentration after an oxalate load, hence reducing the incidence of calcium-oxalate kidney stone formation.[41] More recent human studies have developed showing an inverse correlation with *O. formigenes* colonization and recurrent nephrolithiasis, inflammatory bowel disease, and idiopathic calcium nephrolithiasis, thus suggesting this unique commensal may confer some protection against future kidney stone disease.[42]

Nutrients

Magnesium and Vitamin B_6

A magnesium-deficient diet accelerates the deposition of calcium in renal tubules in rats.[43] Magnesium has been shown to increase the solubility of calcium oxalate and inhibit the precipitation of both calcium phosphate and calcium oxalate.[44–46] A low ratio of urinary magnesium to calcium is an independent risk factor for stone formation.[47] Supplemental magnesium alone has been shown to be effective in preventing recurrences of kidney stones.

When magnesium is used in conjunction with vitamin B_6, an even greater effect is noted.[48,49] Pyridoxine is known to reduce the endogenous production and urinary excretion of oxalates,[50,51] and patients with recurrent oxalate stones have abnormal activation levels of erythrocyte glutamate pyruvate transaminase, erythrocyte glutamic-oxaloacetic transaminase (EGOT), urinary glutamic-pyruvic acid transaminase, and urinary glutamic-oxaloacetic transaminase, indicating clinical insufficiency of vitamin B_6 as a cofactor and impaired glutamic acid synthesis. These levels return to normal after 3 months of treatment.[51] Induced pyridoxine deficiency in rats has been shown to produce oxaluria and calcium-oxalate lithiasis (which is prevented by magnesium supplementation).[50]

Several studies have confirmed the benefits of vitamin B_6 as a sole agent in reducing urine oxalate, albeit with a small population size. Doses between 200 to 500 mg have been shown to normalized hyperoxaluria in those with calcium-oxalate stones. However, other studies have questioned the benefit of B_6 as a sole agent, with a large review

BOX 191.1 Oxalate Content of Select Foods

Vegetables

High Oxalate, >10 mg per Serving

Beets—greens or root[a]
Celery
Collards
Dandelion greens
Eggplant
Escarole
Green beans
Kale
Leeks
Okra[b]
Parsley
Parsnips
Peppers, green
Potatoes
Pumpkin
Spinach[a]
Squash, yellow summer
Sweet potatoes
Swiss chard[a]
Tomato sauce, canned
Turnip greens
Watercress

Moderate Oxalate, <10 mg per Serving

Asparagus
Artichokes
Broccoli
Brussels sprouts
Carrots
Cucumber
Garlic
Lettuce
Mushrooms
Mustard greens
Onions
Peppers, green
Potato chips
Potato salad (¼ cup)
Pumpkin
Radishes
Snow peas
Tomato, fresh[c]
Tomato sauce, canned (¼ cup)

Low Oxalate, 2–5 mg per Serving

Acorn squash
Arugula
Ketchup (1 tbsp)
Onions
Pepper, red
Zucchini squash

Fruits

High Oxalate, >10 mg per Serving

Concord grapes
Figs, dried[b]
Kiwi
Lemon peel
Lime peel
Orange peel
Rhubarb[a]

Moderate Oxalate, <10 mg per Serving

Apples
Apricots
Berries (¼ cup)
Blackberries
Blueberries
Cherries, red sour
Cranberries, dried
Currants, black
Oranges
Peaches
Pears
Pineapple
Plums
Prunes, Italian
Red raspberries
Tangerines

Low Oxalate, 2–5 mg per Serving

Apples, peeled
Avocado
Cantaloupe
Cherries, bing
Cranberries
Grapes
Lemon juice (1 cup)
Lemons
Lime juice (1 cup)
Raisins

Grains

High Oxalate, >10 mg per Serving

Bread, whole wheat
Buckwheat[c]
Oatmeal
Popcorn
Spelt
Stone-ground flour
Wheat bran
Wheat germ
Whole-wheat flour

Moderate Oxalate, <10 mg per Serving

Bagel (1 medium)
Barley, cooked
Bread, white (2 slices)
Corn
Corn tortilla (1 moderate)
Cornbread
Cornmeal, yellow (1 cup dry)
Cornstarch (¼ cup)
Pasta
Rice, brown
Spaghetti
Wheat, white flour

Continued

BOX 191.1 Oxalate Content of Select Foods—cont'd

Low Oxalate, 2–5 mg per Serving
Rice, white
Rice, wild
Rye bread

Legumes
High Oxalate, >10 mg per Serving
Garbanzo beans
Lentils
Soy and all soy products

Moderate Oxalate, <10 mg per Serving
Lima beans
Split peas

Low Oxalate, 2–5 mg per Serving
Peas, green

Nuts and Seeds
High Oxalate, >10 mg per Serving
Almonds
Brazil nuts
Hazelnuts
Peanuts
Peanut butter
Pecans
Sesame seeds
Sunflower seeds

Moderate Oxalate, <10 mg per Serving
Cashews
Flaxseed
Walnuts

Low Oxalate, 2–5 mg per Serving
Coconut

Herbs
Moderate Oxalate, <10 mg per Serving
Cinnamon, ground (11/2 tsp)
Ginger, powdered (1 tbsp)
Pepper, black (1 tsp per day)
Thyme, dried (1 tsp)

Low Oxalate, 2–5 mg per Serving
Basil, fresh (1 tbsp)
Dill (1 tbsp)
Ginger, raw, sliced (1 tsp)
Malt, powder (1 tbsp)
Mustard, Dijon (1/2 cup)
Nutmeg (1 tbsp)
Pepper (1 tsp)

Miscellaneous
High Oxalate, >10 mg per Serving
Beer
Chocolate
Cocoa
Soy sauce (1 tbsp)
Tea, black
Tea, green

Moderate Oxalate, <10 mg per Serving
Coffee
Red wine
Sardines
Tea, rosehip

Low Oxalate, 2–5 mg per Serving
Beef
Chicken
Corned beef, canned
Eggs
Fish, haddock, plaice, and flounder
Ham
Hamburger
Lamb
Pork
Turkey
Venison

[a]Greater than 200 mg per serving.
[b]Greater than 50 mg per serving.
[c]Greater than 100 mg per serving.

showing no risk association with vitamin B_6 and kidney stone incident.[52] In this large review, the cohorts with the highest vitamin B_6 intake also had the highest use of calcium supplementation, which was not accounted for in the risk incidence of nephrolithiasis. Calcium may have provided a protective effect and altered the risk association.

Glutamic Acid

Depressed levels of glutamic acid (from vitamin B_6 deficiency or for other reasons) are significant in the formation of kidney stones because a higher concentration of glutamic acid in the urine induces precipitation of calcium oxalate. Glutamic acid supplementation in rats significantly reduces the incidence of calculi, and it may do so in humans as well.[53] Supplementation with glutamic acid may, however, be superfluous if adequate vitamin B_6 levels are attained.

Calcium

Although most doctors still tell their patients with kidney stones to avoid calcium supplements, this advice is mostly outdated. A strong body of evidence has emerged refuting the general trend to restrict calcium supplementation in patients with kidney stones.

One study has even shown that calcium supplementation reduces oxalate excretion.[54] This study measured urinary oxalate excretion after calcium supplementation and the administration of oxalic acid. Calcium was given in the form of calcium carbonate or calcium citrate malate at a dose of 300 mg elemental calcium daily. Compared with baseline assessment, calcium supplementation significantly reduced oxalate absorption and excretion.

Another study evaluated calcium intake and the dietary profiles in 37 outpatients with kidney stones and 45 control subjects. Dietary calcium, assessed from 4-day dietary records, was significantly lower for patients with urinary calculi.[55] A third study further supporting the benefits of calcium intake is a 5-year randomized trial comparing the effect of two diets in 120 men with recurrent calcium-oxalate stones and hypercalciuria.[56] Upon completion, the men consuming the normal-calcium diet experienced a 51% reduction in the risk of stone recurrence. During follow-up, urinary calcium levels dropped

significantly in both groups, but urinary oxalate was reduced in the normal-calcium-intake group and increased in the low-calcium-intake group. Finally, one large prospective epidemiological investigation also reported that kidney stones were more likely to manifest in individuals with the lowest daily calcium intakes (516 mg) than in those with the highest daily calcium intakes (1326 mg).[57]

These studies clearly demonstrate that calcium supplementation (300–1000 mg daily) may prove to be an effective preventive measure against calcium-oxalate kidney stones.

One large trial, however, of more than 36,000 postmenopausal women with no history of kidney stones showed, compared with placebo, a 17% increased risk of self-reported urinary tract stones in women who consumed 1000 mg of calcium carbonate plus 400 IU of vitamin D daily. For postmenopausal women, the implications of calcium carbonate ingestion may differ from those for younger women and men, for unknown reasons. Calcium absorbability comes into question in this population of women, particularly when the elemental form used is carbonate.[58] This study contradicts other data indicating that vitamin D supplementation can be provided to postmenopausal women who are not stone formers and who are vitamin D–insufficient without fear of an increased risk of kidney stones.[59]

Citrate

Low urinary citrate excretion is known to pose a risk for nephrolithiasis.[60] Although urinary calcium rises in patients consuming calcium citrate, some of citrate's effects inhibit the formation of kidney stones. Specifically, citrate has the ability to reduce urinary saturation of calcium oxalate and calcium phosphate and to retard the nucleation and crystal growth of calcium salts. The use of potassium or sodium citrate in the treatment of recurrent urinary saturation of calcium oxalate has been shown to be effective in clinical studies, ending stone formation in nearly 90% of the subjects.[61] For example, in one study, 31 mmol/day of potassium citrate provided to recurrent stone formers who were also hypocitraturic resulted in a drop of stone formation from 0.7 to 0.13 per year.[62]

Another 3-year, double-blind study of 57 people with a history of calcium stones and low urinary citrate levels revealed that those given potassium citrate developed fewer kidney stones than they had previously. In comparison, the group given a placebo had no change in their rate of stone formation.[63]

However, rather than potassium or sodium citrate, magnesium citrate appears to offer the greatest benefit.

Magnesium citrate slows the growth rate of brushite crystals, nucleation rate, and supersaturation of urine. In addition, because magnesium competes with calcium in binding oxalates in both the gut and urine, the ratio of magnesium to calcium in the urine is used in estimating stone risk.[64]

Vitamin K

The urinary glycoprotein, a powerful inhibitor of calcium-oxalate monohydrate growth, requires posttranscriptional carboxylation of glutamic acid to form gamma-carboxyglutamic acid. Vitamin K is an essential factor for this carboxylation to occur.[65] Impairment of glutamic acid formation or a vitamin K deficiency reduces the formation of this glycoprotein. The presence of vitamin K in green leafy vegetables may contribute to the lower incidence of kidney stones among vegetarians.[66]

Uric Acid Metabolism

The level of dietary purine consumption is linearly related to the rate of urinary uric acid excretion.[67] This relationship is important because hyperuricosuria is a causative factor in recurrent calcium-oxalate stones. High levels of supplemental folic acid promote purine-scavenging and xanthine oxidase inhibition, resulting in decreased excretion of uric acid (see Chapter 174). Higher urine pH also helps with uric acid solubility[68]; however, manipulation of urine pH is a complex task because it will be affected not only by diet and hydration status but also by weight and body mass index (BMI). Higher BMIs have been associated with lower urine pH.[69,70] Including a weight-reduction goal when appropriate may benefit patients with uric acid stones or low urine pH, although the long-term benefits are unknown.

Botanical Medicines

There are limited clinical trials with the use of medicinal herbs for kidney stones, and those that exist are poorly designed. We focus briefly on the traditional in vitro and in vivo use of a number of botanicals.

Anthraquinones isolated from the *Rubia, Cassia,* and *Aloe* species bind calcium and significantly reduce the growth rate of urinary crystals when used in oral doses lower than the laxative dose.[71,72] *Rubia tinctura, Rumex, Rheum, Polygonum aviculare, Aloe,*[73] *Senna, Rhamnus alnus,* and *Mitchella repens* are sources of these anthraquinones and may be used to prevent stone formation; during acute attacks, they may help reduce the size of the stone.

The furanocoumarin-containing herb *Ammi visnaga* has been shown to be unusually effective in relaxing the ureter and allowing the stone to pass.[74] This action is due to its calcium channel–blocking capabilities, which act primarily on the ureters. Atropine and papaverine have similar but less active smooth muscle–relaxing effects. *Peucedanum, Leptotania, Ruta graveolens,* and *Hydrangea* contain similar furanocoumarins that also promote smooth muscle relaxation, and all of these herbs have historical uses in the treatment of kidney stones.

Eupatorium purpureum (gravel root), as its name implies, has traditionally been used for treating urinary stones ("gravel"). The Eclectics, physicians who employed natural therapies at the end of the 19th and beginning of the 20th centuries, considered it as mildly astringent, a stimulant, and a tonic with a specific action on the urinary tract.[66] It was said to have the power to dissolve concretions.

One of several reasons why kidney stones are painful when they are passed is because they produce spasm in the ureters. Spasmolytic herbs have been clinically effective for controlling ureteral spasm in such cases, whereas diuretic herbs are also used to push sufficiently small stones through the ureters more slowly and tolerably. Currently, the use of these herbs is more dependent on tradition than on scientific data.

Some of the more popular spasmolytic herbs that have been reliably effective in this realm include *Ammi visnaga* (khella) fruit, which is also strong enough to use for angina pectoris and acute asthma, and *Lobelia, Piscidia piscipula* (Jamaican dogwood) bark, *gelsemium,* and western pasque flower. *Hyoscyamus niger* (henbane) herb is also useful; it is an even stronger anticholinergic antispasmodic—like belladonna but with an affinity for the genitourinary tract.[75]

In two clinical trials, participants with a history of nephrolithiasis and with radiographic stones present at baseline were randomized to *Orthosiphon grandiflorus* extract 2.5 g in tea twice daily or to sodium-potassium citrate 5 to 10 g three times daily for 18 months.[24] Serial ultrasound was used to measure mean annualized reduction in stone diameter at 18 months. The two treatments were equally effective at reducing stone size over a year's time, with far fewer adverse effects in the tea group.[76]

Phyllanthus niruri has been shown to inhibit calcium-oxalate crystallization in the test tube. Although reportedly diuretic in rodent and human studies,[77,78] low-dose studies find that it is not significantly diuretic in rats, although it still significantly dissolves stones.[78]

In one clinical trial, 69 subjects were randomized to extract capsules 450 mg of *Phyllanthus* three times daily or to placebo for 3 months.[79] Among those randomized to receive *P. niruri,* there was a reduction of hypercalciuria in those patients who had this problem initially, but no significant effect on calculus elimination or calculus size was observed.

Lifestyle

Sleep Position

Even though the etiology of recurrent unilateral kidney stones is unclear, patients with recurrent renal calculi most often present with calculi on the same side. Data from the literature support the notion that sleep posture may contribute to alterations of renal hemodynamics. Researchers studied 110 patients who suffered from kidney stones confined to one side of their bodies. Of these patients, 93 consistently favored sleeping with one side in a dependent position. Further study showed that the side of the stone was identical to the dependent sleep side in 76%, with positive predictive values of right-side-down and left-side-down sleep postures for ipsilateral stone formation at 82% and 70%, respectively.[80]

Stress

One case-control study of 200 patients with symptomatic kidney stones and 200 matched controls demonstrated a statistically significantly higher rate of kidney stone formation in people who had more stressful life events. Such events were defined as those that the subjects perceived as highly stressful by inflicting an intense emotional effect on them, with apprehension and distress, for at least 1 week.[81] It is hypothesized that stressful events may encourage the loss of litholytic urinary constituents such as magnesium and citrate.[82] The sympathetic "fight-or-flight" response may increase vasopressin release, thus contributing to a more hypertonic urine.[83] Furthermore, the stress response results in a stimulation of the hypothalamic–pituitary axis, resulting in increased release of not only vasopressin but also adrenocorticotropic hormone (ACTH). This stress response and increased ACTH can directly increase parathyroid hormone, resulting in hypercalcemia and subsequent hypercalciuria.[84] Furthermore, the stress adaptation response via the hypothalamic–pituitary–adrenal axis may chronically increase cortisol secretion, which has a similar physiological effect as vasopressin on the renal tubules, thus further contributing to hypertonic urine.

Miscellaneous

Toxin Exposure

Hair mineral analysis may be of value because many heavy metals (mercury, gold, uranium, and cadmium) are nephrotoxic. Cadmium, in particular, has been shown to greatly increase the incidence of kidney stones. A prospective study of coppersmiths showed a 40% incidence of kidney stones, which correlated with elevations of serum cadmium concentration.[85] Additional studies analyzed populations living in cadmium-contaminated environments and found that higher urinary calcium excretion correlated with higher urinary cadmium levels and an increased risk of urinary stone disease.[86,87]

Polyaromatic hydrocarbons (PAHs) constitute a group of chemicals generated from vehicle exhaust, asphalt, coal tar, wildfires, agricultural burning, soil, charbroiled foods, and tobacco smoke. Data from the U.S. National Health and Nutrition Examination Surveys (NHANES III), 2011–2012 examined the potential link between urinary PAH and kidney stones.[88] In 5560 American adults aged 20 to 80, urinary 2-hydroxyfluorene (odds ratio [OR] 1.35, 95% confidence interval [CI]; 1,02–1.78), 3-hydroxyfluorene (OR = 1.35, 95% CI; 1.07–1.70), 1-hydroxyphenanthrene (OR = 1.48, 95% CI; 1.08–2.03), 1-hydroxypyrene (OR = 1.36, 95% CI; 1.05–1.77), and 2-hydroxynaphthalene (OR = 1.25, 95% CI; 1.00–1.58) were significantly associated with kidney stones.

Interestingly, researchers examining data from NHANES III found that individuals with the highest dietary zinc intake (>15 mg/day) were associated with a significantly increased risk of kidney stone disease compared with those with lower dietary zinc intake (<7 mg/day).[89]

Vitamin C and the Risk of Oxalate Stones

Vitamin C is often cited in the medical literature as a potential factor in the development of calcium-oxalate kidney stones. Numerous studies have now demonstrated that in persons not undergoing hemodialysis or suffering from recurrent kidney stones, severe kidney disease, or gout, high-dose vitamin C therapy does not cause kidney stones. Vitamin C ingestion of up to 10 g/day has not had any effect on urinary oxalate levels.[90,91]

On the contrary, several human trials consistently indicate that a large percentage of individuals—regardless of kidney stone history, age, gender, and race—ingesting 1000 to 2000 mg of ascorbic acid for only short periods experience hyperoxaluria to some degree.

A more recent clinical study concurs with previous studies in demonstrating mean increases in total oxalate excretion with ascorbic acid supplementation.[91]

Another recent double-blind, crossover RCT of 50 healthy adults compared vitamin C with metabolites (Ester-C) to ascorbic acid. Only 41% of subjects on vitamin C with metabolites experienced an increase in 24-hour oxalate, which is 25% fewer compared with ascorbic acid. This implies that if one needs to consume vitamin C, Ester-C may be most beneficial for stone formers; however, the beneficial effects of Ester-C are still controversial.[92]

Inositol Hexaphosphate

Inositol hexaphosphate (also known as phytic acid or IP6), a naturally occurring compound found in whole grains, cereals, legumes, seeds, and nuts, is known for its antineoplastic activity. One trial showed that the use of 120 mg per day of IP-6 significantly reduced, within in 15 days, the formation of calcium-oxalate crystals in the urine of people with a history of kidney stones.[93] One literature review reported several human studies demonstrating the effectiveness of phytic acid against four types of kidney stones.[94]

THERAPEUTIC APPROACH

Effective treatment of kidney stones requires accurate differentiation between the various stone types and recognition and control of any underlying metabolic diseases or structural abnormalities of the urinary tract. Tables 191.1 and 191.2 list diagnosable causes of kidney stones.

Prevention of recurrence is the therapeutic aim in the treatment of kidney stones. Because dietary management is effective, inexpensive, and free of side effects, it is the treatment of choice. The specific treatment is determined by the type of stone and may include the following:

- Reducing urinary calcium
- Reducing purine intake
- Avoiding foods high in oxalate
- Increasing intake of foods with a high magnesium/calcium ratio
- Increasing intake of vitamin K–rich foods

For all types of stones, increasing urine flow to dilute the urine is vital. Enough fluids should be consumed to produce urine with a specific gravity lower than 1.015 and urinary volume of at least 2000 mL daily.

As far as lifestyle changes are concerned, if stones occur on one side only, it may be helpful to avoid sleeping on that side. Stress-reduction techniques and counseling should be considered for anyone with stones and a history of significant stress.

Acute Obstruction

Surgical removal or lithotripsy may be necessary; the following agents may also be used:

- *Ammi visnaga* extract (12% khellin content): 250 mg three times a day
- *Rubia tinctura, Rumex crispus,* or *A. vera* at doses lower than used for laxative effect

Calcium Stones

Diet

- Increase intake of fiber, complex carbohydrates, and green leafy vegetables.
- Decrease intake of simple carbohydrates and purines (meat, fish, poultry, yeast).
- Increase consumption of foods with high magnesium/calcium ratios (barley, bran, corn, buckwheat, rye, soy, oats, brown rice, avocados, bananas, cashews, coconut, peanuts, sesame seeds, lima beans, potatoes).
- If the stones are oxalate, reduce consumption of oxalate-containing foods (black tea, cocoa, spinach, beet leaves, rhubarb, parsley, cranberries, nuts).
- Limit consumption of dairy products.

Supplements

- Vitamin B_6: 25 mg/day
- Vitamin K: 2 mg/day
- Magnesium: 600 mg/day
- Calcium: 300 to 1000 mg/day
- IP6: 120 mg/day

Botanicals

Use any of the following agents in a dose less than that used for laxative effect:

- *R. tinctura*
- *R. crispus*
- *A. vera*

Miscellaneous

Avoid aluminum compounds and alkalis.

Uric Acid Stones

Diet

- Decrease consumption of purines (see list given for calcium stones).
- Ensure adequate fluid intake and a high alkali load, with plenty of fruits and vegetables.

Supplements

Folic acid: 5 mg/day

Miscellaneous

Alkalinize urine: citrate, bicarbonate, black currant juice.

Magnesium–Ammonium–Phosphate Stones

Miscellaneous

- Eradicate infection (see Chapter 163).
- Acidify urine with ammonium chloride (100–200 mg three times a day).

Cystine Stones

Diet

Avoid methionine-rich foods (soy, wheat, dairy products except whole milk, fish, meat, lima beans, garbanzo beans, and mushrooms; all nuts except coconut, hazelnut, and sunflower seeds).

Miscellaneous

Alkalinize urine: optimal pH is 7.5 to 8.

Brushite and Struvite Stones

Acidify urine with cranberry juice.

Leukoplakia

Michael Traub, ND, DHANP, FABNO

OUTLINE

DIAGNOSTIC SUMMARY

- Adherent white patch or plaque appearing anywhere on the oral mucosa
- Asymptomatic until ulceration, fissuring, or malignant transformation occurs
- Diagnosis confirmed by biopsy

GENERAL CONSIDERATIONS

Leukoplakia is a clinical term signifying a white, plaque-like lesion occurring anywhere on the oral mucosa. It is generally a reaction to irritation, such as cigarette smoking or tobacco or areca (betel) nut chewing, as well as an early sign of human immunodeficiency virus (HIV) infection. It appears most commonly in men 50 to 70 years of age. In 90% of cases, leukoplakia represents epithelial hyperkeratosis and hyperplasia.[1] In the remaining 10%, there is also epithelial dysplasia; these lesions are considered precancerous.

Prompt workup and effective treatment of these lesions can reduce the risk of malignant transformation and provide early diagnosis of invasive cancer. A biopsy should be performed of any persistent or suspicious leukoplakia, and appropriate therapy should be provided based on histological features. Benign lesions can be observed or treated with oral or topical therapy, and dysplastic lesions should be excised. The risk of malignant transformation remains even after treatment, and patients should be followed closely. Oral squamous cell carcinoma is an aggressive malignancy that most often results from malignant evolution of oral leukoplakia. These tumors are primarily treated with surgical resection and adjuvant radiation or chemoradiation.[2]

Oral cancer is among the most common malignant neoplasms, with nearly 50,000 new cases and 12,000 deaths reported in the United States alone each year. Survival rates for patients undergoing surgery and chemoradiation have not significantly changed in the past few decades. Success in preventing death due to oral cancer is achieved through the prevention of oral cancer. Abstinence from tobacco and a higher intake of antioxidant nutrients are the primary preventive measures. However, the risk of oral squamous cell carcinoma remains elevated even after alcohol and tobacco cessation and may take up to 20 years to reach baseline levels.[3]

Areca (betel) nut chewing is practiced by 10% to 20% of the world's population and is a major cause of oral cancer in the Asia-Pacific region. The betel nut, from the *Areca catechu* palm tree, when chewed, is considered the fourth most commonly used addictive substance in the world after tobacco, alcohol, and caffeine. The highest incidence of oral cancers is found in Melanesia, including Papua New Guinea and the Solomon Islands, and in Guam, where the oral cancer mortality rate among native Chamorro people is six times higher than that in the United States.[4]

Significantly increased lipid peroxidation and decreased antioxidant levels have been observed in the plasma of patients with leukoplakia. Glutathione deficiency is thought to play a critical role in malignant transformation.[5]

It has recently been demonstrated that CD8+ and CD163+ tumor-infiltrating cells and the inhibitory checkpoint programmed cell death ligand 1 (PD-L1) are overexpressed in oral squamous cell carcinoma and oral leukoplakia, thus evading host immune response. This finding suggests a possible therapeutic benefit to checkpoint-inhibiting agents.[6]

Serum ceruloplasmin is also significantly increased in oral leukoplakia and oral carcinoma. Copper chelating agents may similarly be potentially therapeutic in both conditions.[7] Environmental nickel exposure is correlated with an increased risk of oral carcinoma in patients with oral leukoplakia as well.[8]

THERAPEUTIC CONSIDERATIONS

The treatment of leukoplakia involves the removal of all irritants. Electrodesiccation, cryosurgery, and proteolytic enzymes have not given predictably favorable results.[9] Photodynamic therapy, vitamin A, beta-carotene, and lycopene have shown clinical resolution rates higher than 50%.[10]

VITAMIN A AND BETA-CAROTENE

Historically, vitamin A supplementation and, more recently, beta-carotene supplementation have been clinically effective in the treatment of leukoplakia.[11–16] Stich et al.,[15,16] using the micronucleus test

to monitor efficacy, were among the first to evaluate vitamin A and beta-carotene for leukoplakia. The micronucleus test is a useful indicator of the neoplastic tendency of epithelial cells because it provides immediate information about genotoxic damage. Micronuclei are formed during chromatid or chromosomal breakage, with the rate of formation tied closely to carcinogenesis in the oral cavity. This rate is a good predictor of cancer, which typically takes years or decades to generate clinically recognizable signs. On the basis of the results of the micronucleus test, Stich et al. found that these two dietary factors, particularly beta-carotene, were effective in decreasing the mean proportion of cells with micronuclei on the buccal mucosa in those who chew Asian betel nut and tobacco.[15,16] The subjects continued to chew betel nut and tobacco during the study.

The epidemiological and experimental data documenting the protective effect of carotenoids and retinoids against epithelial cancers are overwhelming. The inverse relationship between serum retinol and carotene levels and cancer incidence holds true for oral carcinomas as well.[17,18]

Dosages used in clinical studies testing vitamin A in the treatment of leukoplakia generally were fairly high (i.e., 150,000–900,000 IU/day) but extremely effective.[11–14] Because beta-carotene appears to be as effective as retinol in decreasing the levels of micronuclei and has a much higher therapeutic index, beta-carotene should probably be the treatment of choice for this condition. (Note: Vulvar leukoplakia is also responsive to retinol and could therefore respond to beta-carotene as well.)[19,20] However, the only head-to-head comparison study of the two supplements did find an advantage for retinol (see Table 192.1). In this study, 160 men and women with leukoplakia were randomly assigned to receive oral vitamin A (retinyl acetate 300,000 IU/week for 12 months; $n = 50$), oral beta-carotene (360 mg/week for 12 months; $n = 55$), or placebo ($n = 55$).[21] The complete regression rates were 10% in the placebo arm, 52% with vitamin A, and 33% with beta-carotene. Homogeneous leukoplakias and smaller lesions responded better than nonhomogeneous and larger lesions. No major toxicities were observed even in the group given prolonged vitamin A supplementation.

LYCOPENE

A randomized controlled trial of the carotenoid lycopene conducted over 5 months found no significant difference in the clinical response of subjects taking 8 mg lycopene orally twice daily compared with those taking 4 mg twice daily. Both groups had significantly greater responses than those in the control group. Histological assessment was significantly better in the group taking 8 mg of lycopene.[22]

OTHER ANTIOXIDANTS

Antioxidants in addition to beta-carotene may be helpful in treating leukoplakia. For example, studies have shown alpha-tocopherol (400 IU twice daily for 24 weeks) to produce a 65% response rate.[23] However, it makes the most sense to use a combination of antioxidant nutrients (including using mixed tocopherols rather than just one of the eight isomers), given their beneficial interactions and their limitations as monotherapy. Preliminary results using a combination of vitamin C (1000 mg/day), beta-carotene (30 mg/day), and vitamin E (400 IU/day) are encouraging.[24]

TABLE 192.1 Beta-Carotene Trials

Study	Dosage	Response Rate (%)
Stich et al.[15]	180 mg/week	15
Stich et al.[16]	180 mg/week	27
Garewal et al.[27]	30 mg/day	71
Brandt et al.[28]	90 mg/day	60
Toma et al.[29]	90 mg/day	44
Malaker et al.[30]	30 mg/day	50
Garewal et al.[31]	60 mg/day	56
Sankaranarayanan et al.[21]	360 mg/week	33

CURCUMIN

Curcumin has recently shown promise in vitro as a chemopreventive agent for leukoplakia.[25]

ANTHOCYANINS

Black raspberry extract has demonstrated reduction of DNA damage and mutagenesis in cell studies of oral leukoplakia, supporting a role for this anthocyanin in the inhibition of oral carcinogenesis.[26]

THERAPEUTIC APPROACH

Because leukoplakia is due to a combination of excessive carcinogenic irritation in the context of marginal or low levels of vitamin A, the approach is simple: eliminate all sources of irritation and establish optimal vitamin A, beta-carotene, and antioxidant levels. Particularly significant irritation results from the smoking or chewing of tobacco, the chewing of betel nut, and exposure to ultraviolet light.

SUPPLEMENTS

- Vitamin A: 25,000 IU/day
- Beta-carotene: 30 to 90 mg/day
- Lycopene 8 mg twice daily
- Vitamin C: 1000 to 3000 mg/day
- Vitamin E (mixed tocopherols): 400 IU/day
- Curcumin: 500 mg twice daily
- Black raspberry extract: 500 mg daily

Lichen Planus

John Nowicki, ND, and *Sam Russo**, *ND, LAc, RMSK*

OUTLINE

DIAGNOSTIC SUMMARY

- Lichen planus is an inflammatory, pruritic disease of the skin and mucous membranes described by the "six P's": pruritic, polygonal, planar (flat-topped), purple papules, and plaques. Intense pruritus is commonly the primary complaint, although lesions can present without pruritus.
- Skin lesions are flat-topped, violaceous to purple, polygonal or oval papules 1 to 10 mm wide with sharply defined edges and shiny. Lesions may be grouped, linear (Koebner phenomenon), annular, or disseminated when generalized. White lines (Wickham striae) may be present. A handheld lens and application of a clear oil over a lesion intensify the visibility of the striae. In dark-skinned patients, postinflammatory hyperpigmentation commonly occurs. Skin lesions may occur anywhere, with a predilection for the trunk and flexor surfaces, particularly the wrists as well as the lumbar region, eyelids, shins, scalp, glans penis, and mouth.
- Oral lesions appear inflamed, with leukohyperkeratosis, manifesting as reticulated white puncta or papules and lines in a lacelike pattern. Plaques may form and can become hyperkeratotic. Erosions with blisters may occur. Both buccal mucosae are usually affected, although the tongue, lips, and gingivae may be as well. Skin lesions occur in 10% to 60% of cases of oral lichen planus. Biopsy should be performed if there is doubt about the diagnosis or if blisters, plaques, or erosions occur in oral lichen planus.
- Other locations include (1) the genitalia, as papular, annular, or erosive lesions on the penis, scrotum, labia majora, labia minora, and vagina; (2) the scalp, with atrophic skin and scarring alopecia; and (3) the nails, with destruction of the nail fold and bed and with longitudinal splintering.

GENERAL CONSIDERATIONS

Lichen planus (LP) is an immune-mediated inflammatory disease primarily affecting the skin and mucous membranes, including the oral, vulvovaginal, esophageal, laryngeal, and conjunctival mucosa. Variants are based on the morphology of the lesions and the site of involvement and include the following:

- Hypertrophic: Large, thick plaques on the feet and shins; more common in African American males. Hypertrophic lesions may become hyperkeratotic.
- Follicular: Individual keratotic-follicular papules and plaques that lead to cicatricial alopecia. Graham Little syndrome is the complex of spinous follicular lesions, any lichen planus, and cicatricial alopecia.
- Vesicular: Development of vesicular or bullous lesions within or independent of lesions. In the latter, direct immunofluorescence is consistent with bullous pemphigoid, and patients have bullous pemphigoid immunoglobulin (Ig) G autoantibodies.
- Actinicus: Papular lesions in sun-exposed areas, especially the dorsa of the hands and arms.
- Ulcerative: Therapy-resistant ulcers, particularly on the soles, requiring skin grafting.

Despite these numerous clinical attributes, histological findings remain characteristic in the variants, ensuring the correct diagnosis. One of the primary histopathological features of LP is the vacuolar degeneration of the keratinocytes in the basal layer.[1]

Although the etiology is often unknown, trigger factors such as drugs, metals, or infection (hepatitis C virus) resulting in the alteration of cell-mediated immunity appear to play a role. Human leukocyte antigen–associated genetic susceptibility explains a predisposition in some patients. The immune system plays a role, as evidenced by two findings: first, immunoglobulins (primarily IgM; possibly also IgA and IgG) and complement (C3) are found at the dermal-epidermal junction in 95% of lichen planus lesions; second, lesions are associated with certain pathological immune conditions, such as autoimmune diseases, graft-versus-host disease reactions, dermatomyositis, viral infections, and as cutaneous manifestations of malignant lymphoma. The primary immune factor involved appears to be T-cell–mediated processes, but the responsible antigen remains unidentified.[2] In early lesions, activated helper T (T_H) cells target basal cells, which may have antigenic alterations. Suppressor T (T_s) cells predominate in older lesions.

Epidemiological studies have demonstrated a higher prevalence of hepatitis C virus infection in patients with lichen planus than in the normal population. Most studies show that the lesions are the result of

* Previous edition contributor

the host immune response to the viral components and not the result of the direct action of the virus.[3] However, the mechanisms involved have not been clearly elucidated, and a pathogenic relationship has yet to be established.

Incidence, Onset, and Course

Although not common, lichen planus occurs in 6 per 1000 patients seen by dermatologists, with an annual prevalence of 4.4 per 1000 people in the United States. However, oral lichen planus may be the most common cause of white lesions in the mouth, occurring in 0.5% to 1% of dental patients. Women tend to be affected more than men, and the age at onset is 30 to 60 years.

Onset can be acute or insidious, with lesions remaining for months to years. Diagnosis is commonly made via history, physical examination, and biopsy if necessary. The course of oral lichen planus may be chronic, lasting from months to years. Approximately two thirds of patients experience spontaneous resolution within 1 year. Recurrence is uncommon in both forms, being seen in less than 20% of patients. Patients with mucous membrane involvement usually have a more prolonged course, possibly lasting months to decades, although 50% experience remission within 2 years. The incidence of oral squamous cell carcinoma in individuals with oral lichen planus is 5% higher than in those with lesions in other locations. A significant increase of malignant transformation risk has been noted among smokers (odds ratio [OR] = 2, 95% confidence interval [CI]; 1.25–3.22), alcoholics (OR = 3.52, 95% CI; 1.54–8.03), and HCV-infected patients (OR = 5, 95% CI; 1.56–16.07), compared with patients without these risk factors.[4] The list of possible causative medications is long. The most common are gold, antimalarial agents, penicillamine, thiazide diuretics, beta blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), quinidine, and angiotensin-converting enzyme (ACE) inhibitors.[5] The interval between administration of the offending agent and the development of lichenoid drug eruptions is usually a few months, ranging from 10 days to several years.[5]

THERAPEUTIC CONSIDERATIONS

Dental Amalgams

Dental amalgams appear to play a role in the etiology of oral lichen planus. In one study, 161 patients with chronic lichenoid reactions (142) or oral lichen planus (19) underwent replacement of mercury amalgam fillings with alternative substances. Five patients served as controls, receiving no restoration. Evaluation 6 to 12 months after restoration showed that 95% of the patients with chronic lichenoid reactions had marked improvement or complete restoration of normal mucosa. The effect was more apparent for those with gold crowns than those with CM (palladium-based) crowns. In the oral lichen planus group, those areas of lesions in contact with amalgam showed an improvement in 63% of patients, but lesions at other sites were not affected.[6] A second study found that if gold crowns are already present, patients should undergo patch testing for gold allergy; removal of the crowns should be considered in those with positive results.[7] The former study downplays the significance of patch testing for mercury because many patch-negative patients still responded to amalgam removal. However, in cases of positive patch-test reactions to mercury compounds, partial or complete replacement of amalgam fillings will lead to a significant improvement in nearly all patients.[8,9]

Photodynamic Therapy

Phototherapy, especially with narrow-band ultraviolet B (NB-UVB), is effective, but caution must be taken because of the risk of keobnerization (i.e., injury to the skin can cause further formation).[10] A retrospective analysis of 50 patients with generalized cutaneous lichen planus treated by broad-band ($n = 7$) or narrow-band ($n = 43$) ultraviolet B radiation showed a complete response in 70%; 85% of these responders were still in remission after a median of 34.7 months.[11] Another report involves a 64-year-old man with lichen planus of the penis that did not respond to steroids.[12] In this case, photodynamic therapy was preceded (4 hours before treatment) by application of 5-aminolevulinic acid (20%) ointment. The area was irradiated with a Paterson-Whitehurst lamp (Paterson Institute, Christie Hospital, Manchester, United Kingdom) at a center wavelength of 630 nm and a rectangular passband of 27 nm. The dose was gradually increased to 50 J/cm^2 at a fluence rate of 55 mW/cm^2 to prevent edema and phimosis. Treatment was repeated after 6 weeks. The lesions resolved completely after another 4 weeks, with no recurrence at 6 months. Photodynamic therapy with medium-dose ultraviolet A-1 has successfully treated ulcerative lichen planus of the feet in another case.[13]

Supplements and Botanical Medicines

Vitamin Deficiencies

Correction of low levels of vitamins B_1 and B_6 in patients with oral lichen planus (OLP) resulted in both clinical and subjective improvement in the majority treated but did not produce complete remission of the lesions.[14]

In 77 patients with lichen planus (cutaneous lichen planus [CLP], 49 cases; OLP, 28 cases), compared with the control group (19.82 mg/dL), the level of ascorbic acid was significantly lower, both in patients with CLP (8.47 mg/dL, p = 0.001) and in those with OLP (8.04 mg/dL, p = 0.001).[15] In patients with lichen planus, it was found that the deficiency of ascorbic acid increases with age. In addition, the urinary concentrations of ascorbic acid were significantly lower in patients with lichen planus associated with infections, compared with patients with lichen planus without infections.

An additional study found that patients with OLP had a significantly higher frequency of deficiencies in hemoglobin (men < 13 g/dL, women < 12 g/dL), iron (<60 μg/dL), and/or vitamin B_{12} (< 200 pg/mL) and abnormally elevated blood homocysteine levels than healthy control participants.[16]

Vitamin A and Beta-Carotene

Six patients with hypertrophic lichen planus of the palms or soles used topical retinoic acid (0.1% in petroleum jelly base) three times daily for 3 weeks. This frequency caused irritation, so application was switched to two to three times every other day. Regression occurred after 2 to 3 weeks. The duration of treatment was unspecified in the study report. Two cases showed slight recurrences after 3 to 4 months.[17]

A second study compared topical retinoic acid 0.05% (RA) and fluocinolone acetonide 0.1% (FA) applied four times daily. Thirty-three patients with varying stages of OLP were alternately given RA (15) or FA (18); 56% of patients receiving FA improved, but only 13% of patients receiving RA improved. The extent of change was greater in the FA group as well.[18] Small doses of vitamin A acid locally applied produced improvement or regression in hypertrophic lichen planus of the palms or soles in a small number of patients.[19] Retinaldehyde gel 0.1% showed good clinical efficacy in 17 patients with OLP, resulting in 6% disappearance and 82% improvement of lesions, confirmed by the downregulation of filaggrin and CK-10 as markers of terminal differentiation.[20] In a trial of seven patients with lichen planus of either the penis or anal region, application of 0.1% retinoic acid in Orabase overnight and 10 mg (33,330 IU) of oral retinoic acid three to four times daily for 3 days to 3 weeks resulted in improvement or resolution in all cases.[21]

In another study, 18 patients with mucosal dysplasia (10 leukoplakia, 4 lichen planus, 3 erythroplasia, 1 leukokeratosis) were evaluated for serum vitamin A, beta-carotene, and levels of cis-retinoic acid,

which were low normal. All patients received beta-carotene 30 mg four times daily. Disease worsened in one patient, remained stable in nine, and improved in eight, with eventual complete resolution in six of those with improvement. Patients with stable disease were then treated with isotretinoin (Accutane 10 mg three times daily) in conjunction with beta-carotene; three showed improvement. The response to treatment was much higher in smokers (30 packs per year or more) than in nonsmokers.[22]

Synthetic Retinoids

After topical therapy with 0.1% 13-cis-retinoic acid for 8 weeks, restoration of physiological cell morphology was observed in a small group of patients with OLP.[23] Both 0.05% and 0.18% isotretinoin also appear to be effective in significantly improving atrophic-erosive OLP.[24]

A prospective, open-label, single-arm pilot study was performed to assess the efficacy and safety of oral alitretinoin taken at 30 mg once daily for up to 24 weeks in the treatment of severe OLP refractory to standard topical therapy.[25] At the end of treatment, 40% of patients had a >50% reduction in disease severity as measured by the Escudier severity score. Therapy was well tolerated. Adverse events were mild and included headache, mucocutaneous dryness, musculoskeletal pain, increased thyroid-stimulating hormone, and dyslipidemia.

Glycyrrhizin

Seventeen patients with OLP and hepatitis C were divided into two groups; nine received intravenous glycyrrhizin, and eight were given information on dental hygiene. The treatment group received 40 mL of a 0.2% solution of glycyrrhizin daily for 4 consecutive weeks. Six of the nine treated patients demonstrated clinical improvement. The patients who responded tended to have only mildly raised serum alanine transaminase (ALT) and aspartate transaminase (AST).[26]

Aloe Vera

Thirty-four women with vulval lichen planus, with erosive and ulcerative lesions in 83% and 17%, respectively, were randomized into two groups to receive either topical aloe gel or placebo. Of 17 patients treated with *Aloe vera,* 14 (82%) improved clinically by at least 50% after 8 weeks of treatment, whereas 1 (5%) of 17 placebo-treated patients had a similar response ($P < 0.001$). Neither group experienced side effects.[27]

Hyaluronic Acid

A total of 124 patients with erosive OLP participated in a randomized, placebo-controlled, double-blind trial to evaluate the efficacy of a topical 0.2% hyaluronic acid (HA) preparation for 28 days. Application of topical HA produced a significant reduction ($P < 0.05$) in soreness scores compared with placebo for up to 4 hours postapplication; there was also a significant reduction ($P < 0.05$) in the size of the erosive/ulcerated area after 28 days of treatment compared with baseline. Very frequent applications should be considered to obtain a more significant clinical benefit.[28]

Purslane

Twenty patients with OLP received 235 mg of purslane per day for 3 months, and 17 received a placebo. Approximately 83% of the purslane patients responded with partial or complete clinical improvement, compared with partial improvement in 17% of the placebo group. According to visual analog scale (VAS) scores, a partial or complete response was observed in all purslane-treated patients, whereas 71% of the controls demonstrated partial responses ($P < 0.001$).[29]

THERAPEUTIC APPROACH

If the lesions are oral and the patient has significant metal-based fillings, heavy-metal detoxification and replacement of the metal fillings should be considered.

Correction of vitamin and mineral deficiencies may aid in treatment benefit.

Topical Treatments

Apply four times a day:

- Vitamin A (0.1% solution): May cause inflammation and mildly increase pain temporarily.
- Hyaluronic acid gel
- *A. vera* gel
- Glycyrrhizin: topical application

Oral Treatments

- Vitamin A: 33,330 IU three to four times a day for 3 days to 3 weeks while monitoring liver enzymes or beta-carotene 30 mg four times a day
- Purslane: 235 mg dried herb per day

Intravenous Treatments

- Glycyrrhizin: 40 mL of a 0.2% solution a day for 4 consecutive weeks

Lower Urinary Tract Symptoms, Overactive Bladder Syndrome, and Urinary Incontinence (LUTS, OAB, and UI)

Tracey Seipel, FANPA, ABC, and *Alexander G. Schauss, PhD*

OUTLINE

DIAGNOSTIC SUMMARY

The diagnostic summary data are modified from the International Continence Society and the National Society for Continence.[1,2]

LOWER URINARY TRACT SYMPTOMS

Lower urinary tract symptoms (LUTS) are categorized according to the three stages of the bladder cycle:

Storage/Filling Symptoms
- Frequency (more than 8 micturitions in a 24-hour period)[3,6]
- Urgency[3,6]
- Nocturia (more than once per night)[3,6]
- Urgency incontinence[3]
- Stress incontinence
- Nocturnal enuresis/incontinence
- Bladder/urethral pain
- Absent or impaired sensation

Emptying/Voiding Symptoms
- Hesitancy[6]
- Straining to void
- Poor stream[4]
- Dysuria[6]
- Intermittency
- Terminal dribble

Post-Voiding Symptoms
- Postmicturition dribble
- Feeling of incomplete emptying[6]
- Postmicturition incontinence

Overactive Bladder

Urinary urgency with or without urinary frequency, nocturia, and urgency urinary incontinence and in the absence of urinary tract infection or other obvious pathology.

Urinary Incontinence

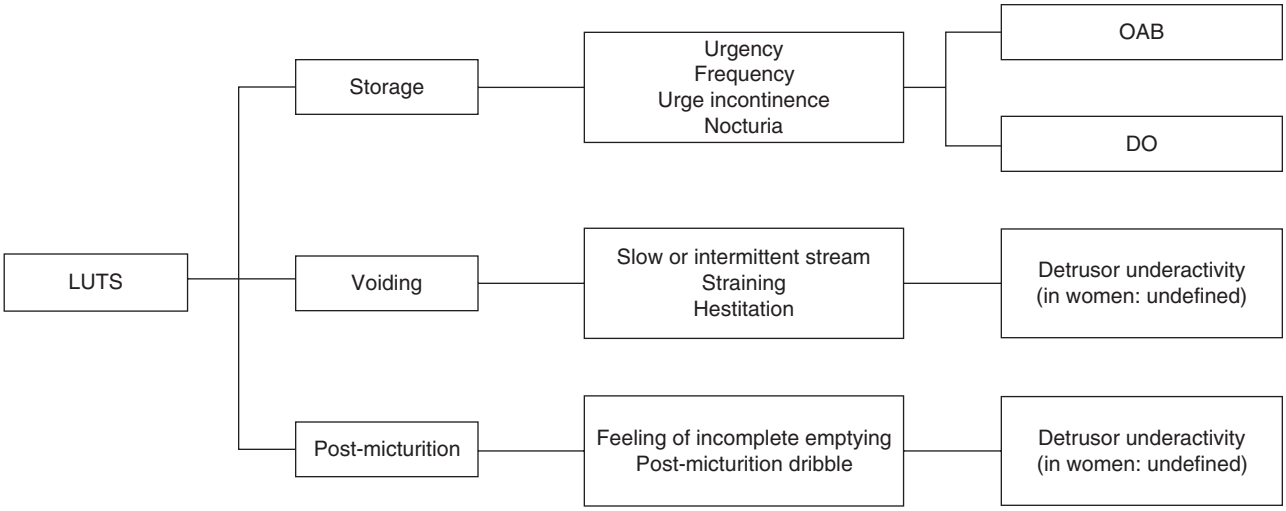
Stress Urinary Incontinence

Involuntary urine loss with stress urinary incontinence (SUI) occurs without warning when pressure is exerted on the pelvic floor muscles, for example, with coughing, laughing, jumping, and sneezing or with heavy lifting.

Urgency Urinary Incontinence

Urine loss with urgency urinary incontinence (UUI) occurs with warning when the individual has an urgency sensation of the need to urinate and cannot reach the restroom in time.

Mixed urinary incontinence (MUI) is a combination of stress and urge incontinence. Overflow incontinence refers to leakage that occurs when the quantity of urine produced exceeds the bladder's holding



Distribution for LUTS as assessed in the EpiLUTS study indicating overlapping or nonoverlapping symptoms. Storage LUTS include the following symptoms: micturition frequency, nocturia, urinary urgency, and urinary incontinence. Voiding LUTS include slow or weak stream, hesitancy, and terminal dribble. Post-micturition LUTS include sensation of incomplete emptying and post-micturition dribble (n = 15 861 women)

NO LUTS	25.3%
Voiding only	5.2%
Storage only	22.4%
Post-micturition only	0.9%
Voiding and storage	14.8%
Voiding and post-micturition	2.0%
Storage and post-micturition	3.6%
Voiding storage and post-micturition	26.0%

OAB – overactive bladder, DO – detrusor overactivity

Fig. 194.1 Lower urinary tract symptoms (LUTS) by type, key symptoms, underlying pathophysiology, and relation to disease entity. (Adapted from Perabo FGE. Drug development for LUTS – the challenge for industry. Drug Discov Today Ther Strat. 2012;9:E5-E14; Sexton CC, Coyne KS, Kopp ZS, et al. The overlap of storage, voiding and postmicturition symptoms and implications for treatment seeking in the USA, UK and Sweden: EpiLUTS. BJU Int 2009;103 (Suppl 3):12–23.)

capacity. Enuresis is overnight incontinence or bedwetting. Other, less common forms of urinary incontinence include continual incontinence and situational incontinence.

GENERAL CONSIDERATIONS

From the mid-1990s, the term *lower urinary tract symptoms* (LUTS) was increasingly used for women and replaced with the term *prostatism* in men. In 2002 the International Continence Society (ICS) categorized the term *overactive bladder syndrome* or *overactive bladder* (OAB) to cover the increasingly more prevalent symptom picture of urinary urgency, with or without day frequency, nocturia, and urinary incontinence (Fig. 194.1). In the United States, the 2018 International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) codes used to indicate a diagnosis for reimbursement purposes are as follows: R32 for unspecified urinary incontinence; N39.3 and N39.4 for stress incontinence and stress incontinence and other specific urinary incontinence, respectively; N39.44 for nocturnal enuresis; R35.0 for urinary frequency (micturition); F98.0) for nonorganic enuresis; and R39.81 for functional urinary incontinence, as well as urinary incontinence associated with cognitive impairment. Other codes for symptoms and signs involving the genitourinary system in ICD-10-CM are found between R30 and R39.

OAB with UUI is also called OAB wet, and OAB without UUI is also called OAB dry. With time, OAB dry tends to progress to OAB wet. OAB and UUI are considered to be due to overactivity or excessive neural stimulation of the detrusor muscle. This excessive contraction of the detrusor muscle results in the sensation of needing to void. Detrusor overactivity can be determined through urodynamic testing.

SUI occurs when the pelvic floor muscles that support the organs and structures of the lower abdomen are weakened and fail to support the internal and external urethral sphincters. The most common causes of stress incontinence among women are pregnancies involving multiple vaginal deliveries, during which time the sphincter and pelvic muscles are stretched and weakened.

OAB and urinary incontinence (UI) are psychologically distressing conditions that negatively affect physical and emotional status and health-related quality of life (HR-QOL) in those affected, resulting in greatly increased healthcare costs.[7–11] Millions of individuals worldwide are affected by UI, yet the associated embarrassment results in the condition being underreported and underdiagnosed.

The prevalence of UI can be challenging to determine. Current estimates suggest it may be as high as one in five people with UI and 15% with OAB.[11] The National Association for Continence estimates that 33 million Americans suffer from OAB, with 12.2 million experiencing concomitant urgency incontinence.[2]

The 2002 EPIC study included five Western countries (i.e., Canada, Germany, Italy, Sweden, and the United Kingdom) and demonstrated an average OAB prevalence of 11.8% (11% men and 13% women) and an

UI of 9.4%.[10] Women are more likely to experience UI, predominantly SUI, whereas men more commonly experience UUI.[12] Data analyzed on 17,580 adults surveyed in the 2001 and 2008 cycles of the National Health and Nutrition Examination Survey (NHANES) found that the prevalence of UI was 51.1% in women and 13.9% in men, with increasing prevalence rates observed for both men and women from the first survey to the second survey.[13] In a 2010 prevalence study of incontinence in Australia, 4.2 million (19%) Australians aged 15 years and over had urinary incontinence, and 1.3 million had fecal incontinence, with an economic burden of AUS $42.9 billion, or approximately AUS $9014 per person.[14] The prevalence rate jumps much higher in the residential aged care community, where 70.9% were found to have urinary or fecal incontinence (or both), with the prevalence projected to rise to 250,000 by 2030.[14]

A 2009 population-based survey conducted to estimate the prevalence rate of UI in China found the prevalence rate to be 22.1%, with SUI at 12.9%, UUI at 1.7%, and MUI at 7.5%).[15] The authors of the China study concluded that UI is a common disorder in Chinese women owing to numerous risk factors besides pregnancy. In a cross-sectional survey that included 19,024 women, the overall prevalence rate of UI was 30.9%, with estimates of SUI, UUI, and MUI being 18.9%, 2.6%, and 9.4%, and a corresponding proportional distribution of 61%, 8%, and 31%, respectively.[16] The study found that only 25% of women reported consulting health practitioners about this issue. In a randomly sampled prevalence survey performed in Fuzhou, Fujian Province, China, 19.0% of women were found to have UI, with the prevalence of SUI, UUI, and MUI at 16.6%, 10.0%, and 7.7%, respectively.[17] Prevalence increased significantly with age. It is not surprising that the prevalence of UI and OAB syndrome is lower in Occidental women, because women in China have given birth to fewer children in their lifetime.[17]

Many individuals with LUTS do not tell their doctor or even their partner about their condition.[8] Women often view UI as a "normal" part of being female.[18] Doctors do not often question about patients' bladder control; 50% to 75% of incontinent community-dwelling patients never describe their symptoms to physicians.[7,19] In a 2017 review paper on medical/surgical options and complications for women affected by UI, although 10% to 20% of women and up to 77% of those residing in nursing homes have UI, only 25% were found to seek or receive treatment for the condition.[20]

Individuals affected by UI tend to modify their lifestyle to cope, wearing adult pads/diapers/absorbent underwear and traveling no more than 1 hour at a time in case of the need to change the pad/diaper or find a restroom. They tend to stop socializing and exercising for fear of having an accident in public, which negatively affects mental and cardiovascular health. They have increased issues with intimacy. Those affected often experience interrupted sleep and resultant daytime fatigue because of frequent nocturia. They typically stop visiting and staying overnight with family or friends for fear of having an accident or disrupting people who may be asleep in the household. With time, sufferers can become reclusive and isolated and have a significant reduction in quality of life. Urinary incontinence is a leading cause of elderly admittance to nursing care.

The etiology of male LUTS is multifactorial, with BPH being a common cause. However, in men, bladder dysfunction can occur independently of the prostate (Fig. 194.2). Less than 50% of cases of bladder dysfunction in men have urodynamically proven bladder outlet obstruction that may be attributed to BPH or other obstructive causes.[9,21] A differential diagnosis of non–prostate-related OAB needs to be ruled out when assessing BPH symptoms.

For men, the occurrence of LUTS, OAB, and UI increases with age. Research shows that 11% of men over the age of 40 have experienced a UI episode in the past year. For men over the age of 60 years, daily UI may be as high as 11%, and in men over the age of 80 years, daily UI is 32%.[22]

For women, UI affects approximately 25% at reproductive age, 50% postmenopause, and 50% to 75% of women in nursing homes.[8,23]

LUTS negatively affect HR-QOL and are associated with high healthcare costs.[9,10,24] OAB and UI are highly prevalent and progress over time, and the severity of UI symptoms increases over time. The number of people affected by poor bladder control is comparable to the number affected by arthritis.

In summary, the problem is widespread and affects people of all ages, including children and young adults. The National Association for Continence (NAFC) estimates that 25 million adult Americans experience transient or chronic UI, increasing to more than 50 million Americans when including OAB sufferers.[2]

Causes/Contributing Factors

OAB: overactivity of the detrusor (bladder) muscle
SUI: weakened pelvic floor (supporting) muscles

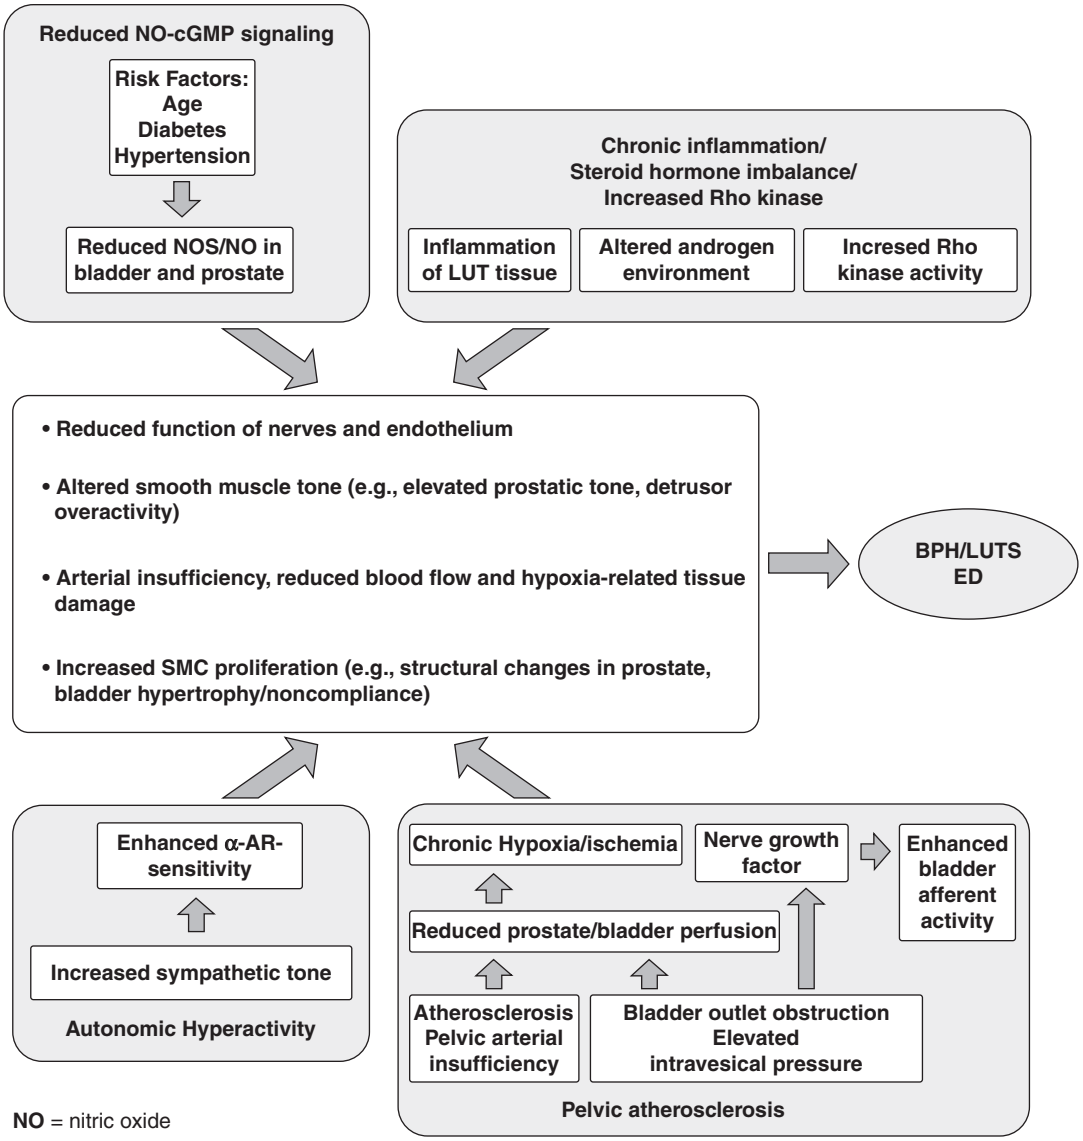
Considerations (Causes, Contributing/Interacting Factors)

- Childbirth (40% of women suffer some form of leaking urine for many months after bearing children)[25]
- High body mass index (places strain on the pelvic floor)
- Constipation and other bowel symptoms (places strain on the pelvic floor)
- History of surgery such as hysterectomy, prostatectomy, or prolapse repair[26]
- Increasing age
- BPH (can lead to secondary OAB due to the strain on the bladder)
- Diabetes mellitus (greater risk of developing OAB)
- Stroke
- Multiple sclerosis
- Alzheimer's disease
- Parkinson's disease
- Poor bladder habits: urinating "just in case" before the bladder has sufficiently filled teaches the bladder that it can only hold a smaller volume of urine and needs to empty before completely necessary.
- Waiting too long to urinate can also interfere with the natural bladder-emptying signals.
- Spinal cord injury
- Medications (antihypertensives, heart medications, diuretics, muscle relaxants, antihistamines, sedatives, and antidepressants)
- Bladder abnormalities, such as tumors or bladder stones
- Declining cognitive function due to aging, which may make it more difficult for the bladder to understand the signals it receives from the brain
- Poor mobility (can lead to urinary urgency)
- High alcohol intake—more than 7 standard drinks/week
- Age-related changes in the lower urinary tract
- Urinary tract infection
- Bladder cancer
- Declining mental health and depression

Addressing the underlying disease is the most effective treatment; however, the cause of OAB and/or UI often cannot be determined.

Chemical irritants, including bacterial lipopolysaccharide (LPS), acid, turpentine, mustard oil, croton oil, and acrolein, directly damage the urothelium and other cells of the bladder, resulting in various degrees of erosion of the mucosa, edema, hemorrhage, and leukocyte infiltration of the bladder wall.[27] Although the cause of chronic bladder pain is yet unknown, it is plausible that irritants may contribute to the etiology.

The elderly may have combined difficulty with bladder-storage problems and bladder emptying. Incomplete emptying may exacerbate urgency, and OAB may require specialist assessment.



NO = nitric oxide
cGMP = cyclic guanosine monophosphate
NOS = nitric oxide synthase
Rho kinases = (ROCKs) are serine/threonine kinases that are important in fundamental processes of cell migration, cell proliferation and cell survival.
SMC = smooth muscle cell

DIAGNOSIS

Due to the underreporting of bladder symptoms, it is important that questions about bladder control, frequency, urgency, and nocturia are included in the initial naturopathic consultation. A thorough history needs to be taken to identify possible causes of LUTS and associated comorbidities, including medications that may contribute to hyperactivity of the bladder.

LUTS Questionnaires

Refer to the LUTS chart at the start of this chapter, undertake a differential diagnosis, and then provide a referral if required.

A bladder symptom diary can capture fluid intake and urinary frequency, urinary urgency, incontinence, nocturia, and enuresis; assist in diagnosis; and serve as a record to gauge improvement with treatment (see Fig. 194.3).

Validated quality-of-life questionnaires for overactive bladder are available and are useful to track improvement with treatment (e.g., Overactive Bladder Short Form [OAB-SF], Urinary Distress Inventory [UDI], and Incontinence Impact Questionnaire [IIQ] questionnaires; see Figs. 194.4–194.6).

Referral to a urinary specialist may be required to complete the physical examination of the abdomen and external genitalia and digital

Bladder Symptom Diary (Frequency and Urgency)

Start Date: _____

Name: _____

Total number of episodes: Please place amount/number/tally marks as each symptom occurs

SYMPTOM	NUMBER (per day 1)	NUMBER (per day 2)	NUMBER (per day 3)
# Times urinating in day			
Average volume/voiding			
# Times get out of bed to urinate			
Night time bladder accidents			
Urge incontinence			
Stress incontinence			
Other incontinence			

Day 3 -

rectal examination. Referral may also be necessary if the symptoms are complicated by recurrent or persistent urinary tract infection, urinary retention, renal impairment that is suspected to be caused by lower urinary tract dysfunction, or suspected urological cancer or for cystoscopy or imaging.

Although urodynamic studies for determining the underlying pathophysiology of LUTS are standard, they have not advanced in decades and are limited due to their invasiveness. Research showing no change in outcome whether performing or not performing the invasive urodynamic testing before treatment calls into question the

OAB-SF Questionnaire

6-Item Symptom Bother Scale Short Form

During the past 4 weeks how bothered were you by…	Not at all	A little bit	Some-what	Quite a bit	A great deal	A very great deal
1. An uncomfortable urge to urinate?	1	2	3	4	5	6
2. A sudden urge to urinate with little or no warning?	1	2	3	4	5	6
3. Accidental loss of small amounts of urine?	1	2	3	4	5	6
4. Night-time urination?	1	2	3	4	5	6
5. Waking up at night because you had to urinate?	1	2	3	4	5	6
6. Urine loss associated with a strong desire to urinate?	1	2	3	4	5	6

OAB-SF Questionnaire

12-Item Symptom Bother Scale Short Form

During the past 4 weeks, how often have your bladder symptoms...	Not at all	A little bit	Some-what	Quite a bit	A great deal	A very great deal
7. Caused you to plan “escape routes” to restrooms in public places?	1	2	3	4	5	6
8. Made you feel like there is something wrong with you?	1	2	3	4	5	6
9. Interfered with your ability to get a good night’s rest?	1	2	3	4	5	6
10. Caused you to decrease your physical activities (exercising, sports, etc.)?	1	2	3	4	5	6
11. Made you avoid activities away from restrooms (walks, running, hiking)?	1	2	3	4	5	6
12. Made you frustrated or annoyed about the amount of time you spend in the restroom?	1	2	3	4	5	6
13. Awakened you during sleep?	1	2	3	4	5	6
14. Made you uncomfortable while travelling with others because of needing to stop for a restroom?	1	2	3	4	5	6
15. Affected your relationships with family and friends?	1	2	3	4	5	6
16. Caused you embarrassment?	1	2	3	4	5	6
17. Interfered with getting the amount of sleep you needed?	1	2	3	4	5	6
18. Caused you to have problems with your partner or spouse?	1	2	3	4	5	6
19. Caused you to locate the closest restroom as soon as you arrive at a place you have never been?	1	2	3	4	5	6

Fig. 194.4 Overactive Bladder–Short Form (OAB-SF) questionnaire. (Coyne K, Revicke D, Hunt T, Corey R, Stewart W, Bentkover J, et al. Psychometric validation of an overactive bladder symptom and health-related quality of life questionnaire: the OAB-q. Qual Life Res. 2002;11(6):563–74. Matza L, Thompson C, Krasnow J, Brewster-Jordan J, Zyczynski T, Coyne K. Test-retest reliability of four questionnaires for patients with overactive bladder: the overactive bladder questionnaire (OAB-q), patient perception of bladder condition (PPBC), urgency questionnaire (UQ), and the primary OAB symptom questionnaire (POSQ). Neurourol Urodyn. 2005;24(3):215–25.)

Incontinence Impact Questionnaire (IIQ)

Has urine leakage affected the following:

	Not at all	Slightly	Moderately	Greatly
1. Household chores	1	2	3	4
2. Physical recreation	1	2	3	4
3. Entertainment activities	1	2	3	4
4. Travel >30 minutes away from home	1	2	3	4
5. Social activities	1	2	3	4
6. Emotional health (nervousness, depression etc.)	1	2	3	4
7. Feeling frustrated	1	2	3	4

Fig. 194.5 Incontinence Impact Questionnaire (IIQ). (Robinson J, Shea J. Development and testing of a measure of health-related quality of life for men with urinary incontinence. J Am Geriatr Soc. 2002;50(5):335–45.)

Urogenital Distress Inventory

Do you experience, and if so, how much are you bothered by the following:

	Not at all	Slightly	Moderately	Greatly
1. Frequent urination	1	2	3	4
2. Leakage related to feeling of urgency	1	2	3	4
3. Leakage related to activity, coughing, sneezing	1	2	3	4
4. Small amounts of leakage (drops)	1	2	3	4
5. Difficulty emptying bladder	1	2	3	4
6. Pain or discomfort in lower abdominal or genital area	1	2	3	4

Fig. 194.6 Urinary Distress Inventory (UDI) questionnaire. (Robinson J, Shea J. Development and testing of a measure of health-related quality of life for men with urinary incontinence. J Am Geriatr Soc. 2002;50(5):335–45.)

treatment-outcome benefits of using these procedures. Emerging noninvasive diagnostic tools include imaging, external condom catheter method, penile cuff test, and near-infrared spectroscopy.[28]

DIFFERENTIAL DIAGNOSIS

- Benign prostatic hyperplasia (BPH):
  - Use of the International Prostate Symptom Score (IPSS) assists
  - Specialist assessment may be required
  - Prostate-specific antigen (bound and unbound) may be requested
- Interstitial/nonbacterial cystitis
- Urinary tract infection (UTI)
- Diabetes mellitus
- Stroke
- Parkinson's disease
- Multiple sclerosis
- Bladder or renal stones
- Diabetes insipidus
- Renal impairment:
  - Check urinalysis dipstick for blood, glucose, protein, leukocytes, and nitrites; pathology for serum creatinine and glomerular filtration rate (GFR).
- Nocturnal polyuria syndrome
- Bladder cancer
- Bladder polyps

THERAPEUTIC CONSIDERATIONS

Pharmaceutical

Anticholinergic/Antimuscarinic and Beta 3-Adrenergic Agonists

Acetylcholine is the primary excitatory neurotransmitter involved in bladder emptying. The two medication classes commonly used are anticholinergic/antimuscarinic (e.g., oxybutynin, tolterodine, solifenacin) and beta 3-adrenergic agonists (e.g., mirabegron). These medications reduce symptoms of OAB and UI with variable outcomes.[29,30] A 2017 study found that prescribing of medications with anticholinergic properties to nursing home residents is common, despite "an association with an increased risk of falls, delirium, and other [adverse] outcomes."[31]

A systematic literature review of randomized controlled trials between 1966 and 2011 evaluating fesoterodine, tolterodine, oxybutynin, solifenacin, and trospium concluded that approximately 13% of participants achieved continence, and approximately 6% of participants discontinued treatment due to the severity of adverse effects (e.g., dry mouth, constipation, blurry vision, drowsiness, and cognitive issues such as confusion and memory loss).[32] Improved quality of life was limited.

The newer medications, such as darifenacin, solifenacin, and trospium, are more targeted for bladder tissue, whereas transdermal delivery systems still produce unwanted anticholinergic effects in tissues other than the bladder.[32]

Significantly, a growing body of research shows a positive association between anticholinergic/antimuscarinic medications and memory

loss that was originally thought to be temporal in nature. One reported study in *JAMA* highlighted the negative effect of these medications on dementia. A 2018 *BMJ* study that analyzed 40,770 patients aged 65 to 99 with a diagnosis of dementia between April 2006 and July 2015, compared with 283,933 controls without dementia, found that the use of anticholinergics is associated with impaired cognition in the short term and in the long term was linked to increased risk of dementia incidence, with associations persisting up to 20 years after exposure.[33,34]

Mirabegron, a drug used to treat OAB, is a beta-3 adrenergic agonist that activates the beta-3 adrenergic receptor in the detrusor muscle in the bladder, which can lead to muscle relaxation and increased bladder capacity.[35] Postsurveillance data show side effects, including elevated blood pressure (hypertension) in more than 10% of individuals, and in 1% to 10% of users, side effects include nasopharyngitis, UTI, dry mouth, joint pain, cystitis, back pain, upper respiratory tract infections, sinusitis, headache, dizziness, diarrhea and constipation, tachycardia, and urinary retention.[36] The overall incidence of drug-related adverse events reported in a randomized clinical trial of mirabegron was 15.8%.[37]

Botox

Sacral nerve stimulation and OnabotulinumtoxinA (Botox, Dysport, Xeomin) are options prescribed by some physicians for UI and OAB. The rationale proposed for the use of OnabotulinumtoxinA involves the drug's ability to inhibit the calcium-mediated release of acetylcholine vesicles at the presynaptic neuromuscular junction in peripheral nerve endings, resulting in temporary flaccid paralysis of the bladder muscle.[38] Botox is the most commonly known drug of the seven antigenically distinct forms of botulinum toxin.[39] In one study, 35 patients (29 women; 6 men) with symptoms of bladder frequency, urgency, and/or urge incontinence in whom previous anticholinergic therapy had failed were administered 300 U of botulinum-A toxin injected transurethrally at 30 sites within the bladder.[40] Of participants, 60% experienced improvement in UDI and IIQ scores and a slight to complete improvement in bladder symptoms by 3 weeks that lasted for up to 6 months. Thereafter, a repeat of the procedure would be needed, and as often as needed, in the hope of a lasting resolution. Mild hematuria, pelvic pain, and dysuria were experienced in 20% of participants. Urinary retention, UTI, hematuria, insomnia, and fatigue following Botox injections are the most common serious side effects reported within the initial 12 weeks after injections are administered.

Surgery

More invasive therapies include surgery with augmentation cystoplasty or detrusor myectomy (removing part or all of the outer muscle layer surrounding the bladder). Detrusor myectomy has been used for years for bladder augmentation in treating refractory detrusor overactivity.[41] This procedure may improve the compliance of the bladder to limit or prevent upper tract damage due to high bladder pressures. In a 1-year postsurgical follow-up of detrusor myectomy for detrusor overactivity, 17 of 27 patients studied experience an overall improvement, with those with idiopathic instability (12 of 17) experiencing a higher rate of success.[42] In a 2-year follow-up study of detrusor myectomy, it was found to be successful in nearly 80% of patients with idiopathic detrusor overactivity in a review of 30 consecutive patients, although "detrusor contractility is affected in most and almost half of the patients required clean intermittent self-catheterization afterward," with 45% of patients needing to start clean intermittent self-catheterization after surgery.[43]

Sling procedures, bulking injections (such as certain collagens), and other surgical procedures support or move the bladder to improve continence. Selective bladder denervation to treat OAB syndrome using radiofrequency ablation is also an option,[44] and the tension-free vaginal tape procedure in women with stress UI can be performed as yet another option, although "the possibility of persistent overactive bladder symptoms" following treatment should be considered.[45]

Physical Therapy

Pelvic Muscle Rehabilitation

Pelvic floor muscle or Kegel exercises (see Box 194.1). Arnold Kegel first advocated pelvic floor muscle strengthening and retraining to treat SUI. Kegel's program has shown some promise.[46,47] Regular, daily exercising of pelvic floor muscles can improve, and even prevent, SUI and MUI. This is particularly helpful for younger women.[48] A specialist physiotherapist or physical therapist can help ensure Kegel exercises are being performed correctly.

Research supports the effectiveness of home-based Kegel exercises, with no supervision, for SUI and MUI. In one study, 72 women with urodynamically proven UI were divided into SUI and MUI groups.[49] The women undertook Kegel exercise, consisting of 10 repetitions of 10 sets of contractions/day, for at least 8 weeks. There were statistically significant improvements in both IIQ and UDI scores, with better results in the SUI group than in the MUI group.

Vaginal weight training. Small weights are held within the vagina by tightening the vaginal muscles. This exercise should be performed for 15 minutes, twice daily, for 4 to 6 weeks before effectiveness can be assessed.

Biofeedback

Used in conjunction with Kegel exercises, biofeedback using sensors to detect if the muscles are contracting helps the individual gain awareness and control of the pelvic floor muscles.

Pelvic Floor Electrical and Magnetic Stimulation

In this type of therapy, mild electrical pulses stimulate muscle contractions. This stimulation is best used in conjunction with Kegel exercises.

Posture

General good posture helps to support the inner and outer abdominal muscles to position correctly and, thereby, also the pelvic floor muscles. During urination, changes in posture can help with more complete bladder emptying. After urination feels complete, structurally (with a straight back), bend forward after urination to move the position of bladder so that it is more likely to be above the urethral sphincter. This may help to eliminate any residual urine volume.

Neural Reflex for Overactive Bladder

Plantar flexion (or pressing the toes into the ground) stimulates the tibial nerve and setting off a somatovesical neural reflex to the bladder, reducing the symptom of urinary urgency.

Transcutaneous Tibial Nerve Stimulation

Transcutaneous tibial nerve stimulation can result in improvement in symptoms of OAB and UI.[50]

Urge-Suppression Techniques

- Stop and sit down
- Apply pressure to the perineum either manually or by crossing the legs
- Practice breathing from the diaphragm
- Raise the pelvic floor muscles.
- Distract mentally (e.g., by thinking of a "happy," peaceful place or counting backward from 50.

Behavioral Therapy

Bladder Retraining

Bladder retraining (see Box 194.2) teaches the bladder to adequately fill and then empty. It involves modifying habits of urinating too much, "just in case," and teaches people to resist the urge to void and, over time, extend the timeframe between voids. A schedule for voiding is developed to allow the person to resist the urge and develop more control over the urge. The mechanisms to explain how bladder training works, when it does, are not fully understood. However, the behavioral interventions that have been reported to have some benefit in managing urinary symptoms to promote bladder health include habit (lifestyle) changes and training techniques. The former is discussed in the section on lifestyle.

Behavioral interventions using training techniques to manage symptoms would include urgency control methods that incorporate deep breathing and mental tasks that try to delay or ignore urgency, bladder training that progressively increases the intervals between voidings and timing to urination, pelvic floor muscle training, and delayed voiding through progressive increases between the onset of urgency and voiding.

Although a 1999 study reported in *Neurourology Urodynamics* failed to find any objective benefit of behavioral therapy and bladder training or pelvic floor muscle training by itself, or a combination training program of both, on urodynamic parameters in women with UI, subjective reports by participants indicated that some improvement occurred immediately after treatment.[51,52]

Botanical Medicines

Crateva nurvala/Crateva magna (Varuna, Three-Leaf Caper)

Crateva is documented in traditional Ayurvedic herbal texts and in research as effective for improving and normalizing the tone of the bladder wall (as assessed by cystometric studies), beneficial for neurogenic bladder and postprostatectomic atony of the bladder.[53–58] Crateva can benefit men with hypotonic bladder due to BPH and decreases residual urine volume. Research with dogs shows that *Crateva* increases the tone of both smooth and skeletal muscle in vitro. Forty days of treatment with *Crateva* resulted in hypertonic curves of the urinary bladder compared with initial curves.[53,58]

Equisetum arvense (Horsetail)

Western herbal medicine traditionally recommends *Equisetum arvense* as a genito-urinary astringent, likely due to the silica content, for UI and enuresis in children.[58,59] *Equisetum* has also been shown to have anti-inflammatory, antibacterial, and antilithogenic effects.[60,61] Note that *Equisteum* extracted with alcohol or heat will destroy the naturally occurring thiaminase.

Crateva and *Equisetum* Combined

A randomized controlled trial with 120 male and female participants using a proprietary blend of *C. nurvala* (equivalent to 6000 mg dry bark) and *E. arvense* (equivalent to 3000 mg dry herb) resulted in statistically significant reductions in day frequency and UI and improved quality of life within 2 months of treatment; however, dropout was high (23%).[62] There were no anticholinergic side effects.

Lindera aggregata/L strychnifolia (Japanese Evergreen Spicebush, Benzoin, Wuyao)

Lindera is documented for use with frequent urination and UI due to cold from a deficient bladder.[63] It promotes the movement of chi or energy and blood and disperses cold, especially in the lower abdomen.

Urox (*Crateva, Equisetum,* and *Lindera*)

Urox is a proprietary blend of concentrated extracts of *Crateva, Equisetum,* and *Lindera.* An 8-week randomized controlled trial with 150 male and female participants showed that 840 mg Urox daily resulted in significant reductions in day frequency, nocturia, urinary urgency, and UI.[64]

Results showed that by 8 weeks, 60% of participants had returned to normal day frequency (8 or fewer micturitions/day); nocturia incidence halved, with 24% of participants experiencing normal nighttime urination; 20% were free from urinary urgency; and 23% had resolution of their UI (both SUI and UUI). A corresponding reduction in adult diaper/pad usage occurred for 75% of study participants. The correlated benefits of less interrupted sleep were also considered clinically relevant. There were significant improvements in HR-QOL. No anticholinergic/antimuscarinic side effects were observed, and no side effects resulted in withdrawal from the study.

Urox produces faster and better results for OAB and UI than any other herbal assessed in randomized controlled research. Urox is the only herbal shown to produce statistically significant reductions in both SUI and UUI in both men and women.

Pumpkin Seed (*Cucurbita pepo*) and Soy

Pumpkin seeds contain zinc and act as 5-alpha-reductase inhibitors to assist with bladder symptoms associated with BPH and prostate health. Soy is typically recommended for hormone-balancing effects.

A 12-week randomized controlled trial in 120 women with LUTS of OAB participated in this study to assess the effectiveness of Cucuflavone (97.5% pumpkin seed extract, EFLA 940 and 12.5% soy germ, SOYLIFE 40 combination).[65] The daily dosage equated to 875 mg pumpkin seed extract and 125 mg soy germ extract for 12 weeks. Urinary frequency reached the normal range by 12 weeks, nocturia was reduced by 31%, and urinary urgency was reduced by 31%. There was a 30% dropout rate, which might have been due to the length of time for symptoms to improve. There was no statistically significant improvement in UI symptoms.

Angelica archangelica (Garden Angelica, Wild Celery)

Angelica archangelica is recommended for bladder control and has a large usage in Europe. An 8-week randomized trial with men ($n = 69$) using two tablets daily of *A. archangelica* (Sagapro) was assessed for its effects on nocturnal bladder symptoms.[66] There was no significant reduction in overall nocturia, although subgroup analysis of only those with a decreased bladder capacity reached significance. Men with BPH were included, which may explain some of the variations in results.

Vaccinium macrocarpon (Cranberry)

Cranberry is typically recommended for UTI. A randomized controlled trial in 69 male participants assessed the effectiveness of 1500 mg whole cranberry *(Vaccinium macrocarpon)* fruit powder for 6 months in men with both LUTS and nonbacterial prostatitis.[67] These men did not fit the typical picture of OAB or UI, although results showed a statistically significant reduction for urinary urgency at 3 and 6 months and for frequency and nocturia at 6 months.

Other Herbals

Agathosma betulina (buchu)
Zea mays (cornsilk)
Galium aparine (cleavers)
Agrimonia eupatoria (agrimony)
Cinnamomum cassia (cinnamon)
Rhus aromatica (fragrant sumach)
Humulus lupus (hops)
Ephedra viridis (Mormon tea)
Chimaphila umbellate (Pipsissewa)

Chinese and Japanese Herbal Medicine

Hachi-mi-jio-gan. Hachi-mi-jio-gan extract (Harncare; HE) contains the ancient traditional Chinese medicine (TCM) herbal mixture Ba-Wei-Die-Huang-Wan. The daily dose contains 4.4 g of the eight-ingredient formula with concentrated extracts equivalent to the following:

- *Rehmannia glutinosa* root 5 g
- *Cornus* fruit 3 g
- *Dioscorea* rhizome 3 g
- *Alismatis* rhizome 3 g
- *Moutan* bark 3 g
- Cinnamon bark 1 g
- Hoelen *(Poria cocus)* 3 g
- Heat-processed lateral root of aconite 1 g

Gosha-jinki-gan. Gosha-jinki-gan (GJG) contains the same type and amount of concentrated extracts as Hachi-mi-jio-gan, with the addition of two concentrated extracts equivalent to Achyranthis Radix (3 g) and Plantaginis Semen (3 g).

An observational study assessed the effectiveness of 7.5 g/day GJG for 8 weeks in 44 Japanese women diagnosed with OAB. Urinary frequency, nocturia, International Prostate Symptom Score (IPSS) index scores, and HR-QOL index scores were all significantly reduced, with adverse reactions observed in 9%.[68]

Rat studies have confirmed that GJG partially reduces the tachykinins and TRPV1 and P2X3 purine receptors (receptors responsible for hypersensitivity) in the bladder without destroying the nerve fibers.[69] GJG has an inhibitory effect on the bladder and maintains the balance of the sympathetic and parasympathetic nervous systems.[70]

A study with 45 female rats assessing the mechanism of Harncare showed that it reduced the bladder expression of tachykinins and P2X3 and TRPV1 receptors and inhibited adenosine triphosphate (ATP)–induced detrusor overactivity, which may explain part of its beneficial effects on LUTS.[71]

Further rat studies showed that treatment with Harncare for 4 weeks significantly inhibited, in a dose-dependent manner, the acetylcholine-induced contraction of isolated rat bladder strips, with a 7-times-greater affinity for purinergic receptors than for muscarinic and 1,4-DHP receptors, with little or no effect on the level and activity of hepatic CYP, which would indicate minimal pharmacokinetic interaction with drugs.[72]

Sixty male participants with LUTS and cold sensitivity and who were unresponsive to alpha-1 blockers or antimuscarinic drugs were given either a mixture of Harncare or GJG for 12 weeks in addition to alpha-1 adrenergic receptor blockers or antimuscarinic drugs as add-on therapy. The IPSS and HR-QOL scores, Benign Prostatic Hyperplasia Impact Index score, and the number of nocturnal voids were statistically much improved, with no change in maximal urinary flow rate and postvoid residual urine. Mild adverse reactions were observed in 8.3% of patients.[73]

Both Harncare and GJG mixtures seem safe and effective potential therapeutic alternatives in patients with LUTS and cold sensitivity unresponsive to alpha-1 blockers or antimuscarinic drugs.

Alpinia oxyphylla

Alpinia oxyphylla (Zingiberaceae) is a Chinese medicinal herb, and the fruit is commonly used in TCM for the treatment of LUTS of OAB. In vitro testing of 95% ethanol extract of the capsular fruits exhibited significant dose-dependent antimuscarinic activity against carbachol-induced contraction of the rat detrusor muscle.[74]

Dietary/Nutritional

Minerals play an important role in connective tissue structural integrity and neuromuscular signaling.

Magnesium at therapeutic doses can be of benefit in OAB, as may calcium. Forty women who had sensory urgency or detrusor instability participated in a randomized, double-blind, placebo-controlled study to compare the effect of magnesium hydroxide or placebo on symptoms, frequency/volume changes, and cystometric results. Magnesium was well tolerated, and 11 of 20 subjects in the magnesium group reported subjective improvements, compared with only 5 taking placebo, yet there was no statistically significant improvement in pre- and posttreatment urodynamic parameters.[75] A better-absorbed form of magnesium, such as chelate, orotate, or diglycinate, is recommended. Regarding whether magnesium and calcium serum levels are different in women with detrusor overactivity or urodynamic stress incontinence, investigation of blood levels determined there were no differences.[76]

Diet

Bladder stimulants include diuretics such as caffeine and alcohol, and bladder irritants include certain acidic fruits, spices, and tomato-based products. When 10 studies, including 2 randomized controlled trials, were analyzed to examine the role of the diet in OAB, the analysis found that "diet seems to have an impact on OAB, particularly caffeine consumption, which increases storage symptoms."[77] Similar results were found in a study of caffeine, alcohol, and carbonated drinks, which concluded that "in addition to fluid intake, there is some evidence to support a role of caffeine, alcohol, and carbonated beverages in the pathogenesis of OAB and lower urinary tract dysfunction."[78]

Hence, caffeine has been the subject of studies on its effects on UI in women. In a study conducted in the United States of women who participated in the 2005 to 2006 and 2007 to 2008 NHANES, a cross-sectional nationally representative survey, the U.S. prevalence for any UI was 41.0%, and the prevalence was 16.5% for moderate/severe UI, with SUI being the most common UI type (36.6%). The women surveyed consumed a mean caffeine intake of 126 mg a day. Caffeine intake equal to or exceeding 204 mg a day was associated with any UI, but not moderate/severe UI, after controlling for multiple factors.[79] An 8-oz cup of brewed coffee can contain from 95 to 165 mg of caffeine per cup, whereas a 12-oz serving of a carbonated cola soda can contain as much as 46 mg of caffeine. An 8-oz energy drink can contain from 27 to 164 mg of caffeine, and an "energy shot" can contain 40 to 100 mg per ounce.[80] By comparison, in a survey of men aged 20 years or older, a significant association was found between caffeine intake and moderate to severe UI. Men with a caffeine intake at the upper 75th percentile (234 mg or more a day) and 90th percentile (392 mg or more per day) were significantly more likely to experience moderate to severe UI even after adjusting for prostate condition.[81] These findings support the need to reduce caffeine intake in men with UI.

Nevertheless, quite the opposite conclusion was reported after a meta-analysis of observational studies examining the association between coffee and caffeine intake and the risk of UI. The meta-analysis found "no evidence for an association between coffee/caffeine consumption and the risk of UI."[82] Similarly, a prospective cohort study in 21,564 women with moderate UI enrolled in the Nurses' Health Study II did not find an association between the risk of UI progression over 2 years among women with moderate incontinence, even when comparing women consuming 450 mg or more to those consuming 150 mg or less of caffeine per day.[83] The study did not examine the acute effects of caffeine on UI.

Potential foods known to be bladder irritants include:

- Coffee, tea, and chocolate (containing caffeine, a diuretic)
- Alcohol (diuretic)

- Carbonated drinks
- Artificial sweeteners (e.g., aspartame [NutraSweet], saccharin), corn sweeteners, fructose
- Acidic fruits and juices, including lemon, lime, grapefruit, and orange
- Spicy foods (e.g., chili)
- Watermelon
- Tomato-based products (e.g., tomato juice)

It is recommended to remove them from the diet and then, after 2 weeks, slowly and individually reintroduce each food to determine whether it is contributing to bladder symptoms. Additional common foods that have been reported to be bladder irritants include apples and apple juice, cantaloupe, citrus fruits, cranberries and cranberry juice, grapes, guava, cow's milk and its by-products (cheese, cottage cheese, ice cream, yogurt), peaches, pineapples, plums, strawberries, sugar (sucrose), and vinegar.[84,85] This list of possible bladder irritants includes foods that may or may not affect a patient's bladder symptoms.

Fluid

With age, the thirst reflex reduces. Many individuals with OAB and UI restrict their water intake to help manage their condition. It is important to maintain a fluid intake of 1.5 to 2 L/day and manage bladder control through healthy bladder habits and supplements. Dehydration may cause additional strain on the kidneys and bladder.

Medications That Increase Urgency

There are medications that can increase the frequency or urgency to urinate. Among them are antihypertensives and medications to reduce muscular pain (relaxants). Among the medications to treat hypertension are diuretics such as hydrochlorothiazide and furosemide; alpha-antagonists, including doxazosin maleate and prazosin; and angiotensin-converting enzyme (ACE) inhibitors such as captopril and enalapril maleate.

Lifestyle

Habit changes involve lifestyle modifications. Modifications include changes in diet, fluid intake, and food and beverage choices; weight management; and smoking cessation. Lifestyle changes can also include timed voiding using a bladder diary.

Increasing age is a risk factor for OAB and UI; however, most risk factors are modifiable, including the following:

- Excess weight; obesity[86]
- Lack of physical activity[86]
- Smoking[86]
- Stress[2]
- Heavy alcohol intake (more than 7 standard drinks per week)[2]
- Caffeine, a dietary diuretic that can increase urinary frequency
- Constipation (pressure and bearing down)
- Vertebral misalignment
- Medications (antihypertensives, heart medications, diuretics, muscle relaxants, antihistamines, sedatives, and antidepressants)

Elderly individuals may have combined difficulty with bladder storage problems and bladder emptying. Incomplete emptying may exacerbate urgency and OAB and may require specialist assessment.

Erectile dysfunction is correlated with LUTS, but no evidence has been produced that shows a causal relationship. Preclinical evidence that both develop due to several common pathophysiological mechanisms has been proposed.[87]

It is important for practitioners to discuss sexual function in male patients presenting for LUTS because epidemiological evidence, based on well-powered multivariate analyses, provides compelling evidence of an association between LUTS and erectile dysfunction in men. This is even more important to discuss with the patient because men with LUTS have an increased risk of all-cause mortality, particularly for older males with nocturia.[88]

Other Holistic Treatments

Hypnotherapy

Hypnotherapy may be of benefit based on the early work of Freeman and Baxby reported in 1982.[89] In their study, 50 incontinent women with detrusor instability completed 12 sessions of hypnotherapy over a 1-month period. Thereafter, the patients continued the treatment using a prerecorded cassette tape and were followed up for at least 6 months. Of the 50 patients, 29 claimed to be entirely symptom-free, 6 showed no objective improvement, and 14 reported some improvement. Well-controlled clinical studies of the efficacy of hypnotherapy are lacking, although case histories continue to appear in the literature attesting to its benefit.[90]

Physiotherapy

Specialist physiotherapists can correctly instruct for Kegel/pelvic floor exercises and posture during urination and can assist with any structural contributing factors. A multicenter, randomized clinical trial compared physiotherapy to midurethral-sling surgery in women with SUI.[91] In the study, 230 women were randomly assigned to the physiotherapy group and an equal number to the surgery group. Forty-nine percent of the women in the physiotherapy group and 11.2% of the women in the surgery group crossed over to the other treatment. Using an intention-to-treat analysis that analyzed the outcome for all participants (including those who dropped out of the study before completing the assigned group), "subject improvement was reported by 90.8% of women in the surgery group and 64.4% of women in the physiotherapy group" after 1 year. The rates of subjective resolution were 85.2% in the surgery group and 53.4% in the physiotherapy group, and the rates of an objective "cure" were 76.5% and 58.8%, respectively. These results are associated with the broad variation in the rates of success for physiotherapy reported in the literature, which vary from 53% to 97% when measuring subjective success and from 5% to 49% when measured by objective means.[92]

Acupuncture

To assess the effectiveness of acupuncture for SUI in adults, a review was performed, and the results of randomized and quasi-randomized controlled trials were analyzed.[93] The analysis of the studies selected for inclusion in the review was not conclusive as to whether acupuncture in adults with SUI was more effective than medications or other treatment options.

Another approach taken to assess the efficacy of acupuncture was undertaken by experts in acupuncture familiar with the ancient literature in the 4th edition of the *Canon of Chinese Medicine* that discusses the use of acupuncture for urinary incontinence. This led to the reviewers identifying 356 articles reporting on the use of this treatment for UI involving 41 acupoints. The results of this group analysis showed that "urinary incontinence belongs to external genitalia diseases, which should be treated from yin, indicating more yin-meridians be used and special acupoints be focused on."[94] A randomized, multicenter clinical trial to determine the efficacy of electroacupuncture in the treatment of SUI in women, compared with pelvic floor muscle training, is underway in China, but the results are unknown at this time. A description of the study is published.[95]

A randomized controlled trial involved 240 women with OAB using weekly acupuncture compared with daily oral tolterodine tartrate 2 mg twice daily, over 4 weeks. Both groups showed statistically significant decreases in urinary urgency, UI, urinary frequency, and nocturia and an increase in volume voided per micturition. There was no difference in the changes in OAB symptoms between groups.[74]

Chiropractic

Vertebral misalignment can contribute to poor bladder control, and if appropriate, chiropractic treatment can be beneficial. Current observations by chiropractors indicate that some patients with SUI may have imbalances in several lumbopelvic muscles that inhibit the pelvic floor muscles and joints, leading to incontinence.[96] Comorbidities between incontinence, lumbopelvic pain, and breathing difficulties have also been suggested. [96,97]

A retrospective case-series study using chiropractic management of UI that included 21 women, 13 to 90 years of age, with UI found that 13 patients had lumbosacral dysfunction. Chiropractic manipulative (high-velocity, low-amplitude manipulation; Cox flexion distraction manipulation; and/or use of percussion instrument treatment for myofascial trigger points) and soft tissue treatments were used to address soft tissue and articular dysfunctions. UI symptoms resolved in 10 patients, 7 improved, and 4 showed only slight improvement.[98]

Case studies reporting on the resolution of various bladder-related disorders abound in the literature. In one case, a 13-year-old female developed unpredictable UI and right hip pain immediately after emergency open appendectomy surgery. The UI persisted for 10 months, forcing the patient to wear a pad throughout the day and night. A combination of chiropractic therapy and applied kinesiology methods was used to diagnose and treat the patient. Muscle impairments were identified in the lumbar spine and pelvis, which, upon treatment, resulted in rapid resolution of UI and hip pain. A 6-year follow-up confirmed continued resolution.[99]

Therapeutic Approach

A key aspect of the therapeutic approach for patients suffering any of the forms of LUTS, OAB, and UI is fully exploring and eliminating as many causative, irritant, or contributing factors as possible. Eliminate or find alternatives for any drug that may aggravate.

Weight should be achieved.

Diet

Reduce bladder stimulants, including diuretics such as caffeine and alcohol, and bladder irritants, such as certain acidic fruits, spices, and tomato-based products, to determine whether there is an improvement in symptoms. Gradually reintroduce foods to determine which are problematic. Ensure adequate fluid intake.

Nutritional Supplements

Magnesium citrate: 250 mg bid

Botanical Medicines

C. *nurvala:* dose should be equivalent to 6000 mg dry bark daily
Urox (*Crateva, Equisetum,* and *Lindera* blend) 840 mg daily

BOX 194.1 Kegel Exercises

Identify the muscles by stopping urination midstream. Then, when not urinating, contract/tighten these muscles for 2 to 3 seconds and then release for 2 to 3 seconds. These exercises can be done when sitting, standing, or lying down.

Slowly increase the duration of the contraction up to 10 seconds. Ideally, build up to performing three sets of 10 contractions (10-second duration each) three times a day. It may take up to 8 weeks to see benefits.

If in doubt regarding the correct muscles to contract, return to squeezing the lower urinary muscles as required to stop urination midstream.

BOX 194.2 Bladder Retraining

A bladder symptom diary (See Fig. 194.3) is kept to determine the voiding pattern throughout the day and evening.

The aim of the bladder training/retraining program is to extend the timeframe between voiding by 15 min per week, gradually lengthening the time between toilet visits so that the person can hold urine in the bladder for up to 4 hours.

It is important to gradually increase the intervals between micturitions and to record the timing and voiding volume of each micturition. If a relapse occurs, remain positive and manage the relapse. Then forge forward with increasing voiding-interval timeframes and, ideally, volume-holding capacity.

Management techniques such as relaxation, meditation, and so forth can assist. It is important to "teach" the bladder that it can hold urine for longer periods of time.

In the event of an accident, breaking the program is fine, but then return to the schedule with the aim of expanding the voiding-interval timeframe.

Pumpkin seed extract (875 mg) and soy extract (125 mg) daily
Cranberry whole fruit powder 1500 mg daily

Physical Medicine

Kegel exercises (Box 194.1)
Acupuncture as appropriate
Chiropractic as appropriate

Behavioral Therapy

Bladder retraining (Box 194.2)

Macular Degeneration

John Nowicki, ND, and *Michael T. Murray, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Progressive visual loss occurs due to degeneration of the macula.
- Ophthalmological examination may show spots of pigment near the macula and blurring of the macular borders.

GENERAL CONSIDERATIONS

The *macula,* the area of the retina where most images focus, is the portion of the eye responsible for fine vision. Degeneration of the macula is the leading cause of severe visual loss in the United States and Europe in persons 55 years and older and is second only to cataracts as a cause of decreased vision in persons older than 65 years. It is estimated that more than 150,000 Americans are legally blind from age-related macular degeneration (ARMD), with 20,000 new cases occurring each year.[1,2]

Types of Macular Degeneration

The two most common types of ARMD are the atrophic (dry) form, by far the more common, and the neovascular (wet) form. In either form, patients may experience blurred vision. The patient may note that straight objects appear distorted or bent; the presence of a dark spot near or around the center of the visual field; and, while reading, that parts of words are missing.

Dry Age-Related Macular Degeneration

Between 80% and 95% of people with ARMD have the dry form of the disease.

The primary lesions are atrophic changes in the retinal pigmented epithelium (RPE), which constitutes the innermost layer of the retina. Beginning in early life and continuing throughout life, cells of the RPE gradually accumulate sacs of cellular debris (lipofuscin). The lipofuscin bodies are either remnants of incompletely degraded abnormal molecules from damaged RPE cells or derivatives of phagocytized rod and cone membranes. Progressive engorgement of the RPE cells with lipofuscin is associated with the extrusion of tissue components like hyaline, sialomucin, and cerebroside. The hallmark excrescences beneath the RPE apparent on ophthalmoscopic examination are referred to as drusen. The formation of drusen is a result of free-radical damage similar to the type of damage that induces cataracts (see Chapter 219). However, decreases in nutrient, blood, and oxygen supply to the retina are the harbinger of the development of drusen and subsequent macular degeneration.

The presence of complement and other inflammatory mediators in drusen, along with the identification of ARMD-susceptibility genes encoding complement factors, supports the concept that local inflammation and immune-mediated processes play a key role in ARMD pathogenesis. This may be further accelerated through systemic immune activation, and increased levels of C-reactive protein (CRP) have been associated with a higher risk of ARMD. Aside from being an inflammatory risk marker, CRP may also play a role in the progression of the disease because it has been identified in drusen.[3] Oxidative stress and inflammation in the microenvironment of the local circulation certainly contribute to the disease process. However, conditions such as ARMD may also be indicative of a more systemic disease process.

Although identified nearly three decades ago, reticular psuedodrusen (RPD) have been recently recognized as a distinctive phenotype and are strongly associated with late ARMD. Unlike drusen, RPD are located in the subretinal space. Identification is not straightforward at fundus examination, and at least two different imaging modalities (i.e., spectral-domain optical coherence tomography [SD-OCT], infrared [IR] reflectivity, multicolor imaging) should be considered for more accurate diagnosis.[4] Although ARMD and RPD share several nonocular risk factors, such as older age, female sex, current smoking, and high body mass index (BMI), other reported risk factors for RPD included less education, B–vitamin complex use, history of steroid eye drop use, and glaucoma.[5]

The disease progresses slowly, and only central vision is lost; peripheral vision remains intact. Although it is rare for anyone to become blind from dry ARMD, in the late stages of ARMD, there is excessive recruitment of scar tissue that leads to irreversible destruction of photoreceptors. Currently, there is no standard medical treatment for this common form of ARMD, although the use of nutritional supplements designed to address the underlying oxidative damage is becoming the "unofficial" standard of care.

Wet Age-Related Macular Degeneration

Wet ARMD is also known as the neovascular form or advanced ARMD. It affects 5% to 20% of persons with ARMD. Wet ARMD is characterized by the growth of abnormal blood vessels. A common early symptom of wet ARMD is straight lines that appear wavy. Because the disease can rapidly progress to a point at which surgery cannot be used, treatment should begin as soon as possible.

Wet ARMD can be treated quite effectively in the early stages with laser photocoagulation therapy. Photodynamic therapy using photosensitive drugs (verteporfin) and a low-powered laser or low-dose radiation therapy are also alternatives.[6,7] Antiangiogenics or anti–vascular endothelial growth factor (anti-VEGF) agents are also used. These drugs can cause regression of the abnormal blood vessels and improvement of vision when injected directly into the vitreous humor of the eye. The injections have to be repeated on a monthly or bimonthly basis. Examples of these agents include ranibizumab (Lucentis), bevacizumab (Avastin), and pegaptanib (Macugen).[1,2]

THERAPEUTIC CONSIDERATIONS

The primary treatment goal of the dry form and prevention of the wet form of ARMD involve the use of antioxidants and natural substances that correct the underlying pathophysiology—free-radical damage and poor oxygenation of the macula. This can be accomplished by reducing the risk factors for ARMD, focusing on preventive factors against atherosclerosis, increasing dietary intake of fresh fruits and vegetables, and supplementing with nutritional and botanical antioxidants.

In particular, tobacco smoking greatly increases the risk of ARMD.[8] Smoking a pack of cigarettes a day for any significant length of time increases the risk for ARMD by two to three times compared with someone who has never smoked.[8,9] This risk does not return to the control rate until a person has stopped smoking for 15 years.[9]

There is also a strong genetic component to consider. Although a number of genetic markers have been identified, a family history may be the most convenient screening method. The lifetime risk of developing late-stage macular degeneration is 50% for people who have a relative with macular degeneration versus 12% for people who do not, a fourfold higher risk. Although genomic family scans of 364 families have revealed a region of chromosome 10 as possibly containing an association with ARMD,[10] diversity in phenotype and the late onset of disease complicate the feasibility of linkage studies. Interestingly, a higher birth weight and a lower ratio of head circumference to birth weight are associated with significantly higher risk.[11]

Reducing and Preventing Atherosclerosis

Although atherosclerosis is now a well-accepted risk factor for macular degeneration, this association was unconfirmed until 1995.[12] In the confirmation study, 104 subjects with macular degeneration and 1324 subjects without macular degeneration were evaluated for atherosclerosis via ultrasonographic determination of the intimal-medial thickness, assessed for the presence of atherosclerotic plaque in the carotid arteries, and measured for the ankle/arm systolic blood pressure ratio (an indicator of peripheral atherosclerosis). The results indicated that in subjects younger than 85 years, plaques in the carotid bifurcation were associated with a 4.7-times-higher prevalence of macular degeneration. Lower-extremity atherosclerosis was associated with a 2.5-times-greater risk. These results indicated that measures designed to reduce the risk of atherosclerosis are of great significance in the prevention and treatment of macular degeneration (see Chapter 149 for a comprehensive program for prevention and reversal).

Diet

A diet rich in fruits and vegetables is associated with a lower risk for ARMD. This protection is the result of a greater intake of antioxidant vitamins and minerals.[13–15] However, various food components, such as flavonoids and the non–provitamin A carotenes lutein, zeaxanthin, and lycopene, may be more significant in protecting against ARMD than traditional nutritional antioxidants (e.g., vitamins C and E, zinc, and selenium). The macula, especially its central portion, the fovea, owes its yellow color to its high concentration of lutein and zeaxanthin. These yellow carotenoids function in preventing oxidative damage to the area of the retina responsible for fine vision and have a central role in protecting against the development of macular degeneration.[16,17]

The carotene lycopene, a component of tomatoes and other red fruits and vegetables, is also protective. In one study, individuals with lycopene content in the lowest quintile were twice as likely to have ARMD.[15] In addition, moderate wine consumption is associated with a decreased risk of ARMD.[18] Red wine contains anthocyanins, which are powerful antioxidants and likely responsible for the protective effect. It is important to note that beer consumption increased the accumulation of drusen and the risk of exudative macular disease and therefore should be avoided.[19]

Similar to atherosclerosis, the type of dietary fat appears to play a role in ARMD. A cohort study of 261 individuals with early or intermediate stages of ARMD revealed a twofold increased risk of progression with a high intake of animal fats and processed baked goods. In contrast, increased intake of fish and nuts was associated with a lower risk of ARMD progression.[20] The intake of long-chain omega-3 fatty acids reduces the incidence of ARMD and was shown to be inversely associated with the 12-year progression to ARMD.[21–23]

Nutritional Supplements

In addition to recommending a diet high in antioxidants, supplementation with nutritional antioxidants (e.g., vitamin C, selenium, beta-carotene, and vitamin E) is certainly important in the treatment and prevention of macular degeneration. The Age-Related Eye Disease Study (AREDS) research group confirmed that a combination of these nutrients will likely produce better results than any single nutrient alone.[24] The specific daily amounts of antioxidants and zinc used by the study researchers were 500 mg of vitamin C, 400 IU of vitamin E, 15 mg of beta-carotene (often labeled as equivalent to 25,000 IU of vitamin A), 80 mg of zinc as zinc oxide, and 2 mg of copper as cupric oxide. It was further shown that a deficiency in any one of these antioxidants alone does not account for the impaired antioxidant status in ARMD. Instead, the lower antioxidant status reflects decreases in a combination of nutrients.[10] The Age-Related Eye Disease Study 2 assessed the value of substituting lutein/zeaxanthin in the AREDS formulation and found that participants taking lutein/zeaxanthin had a slightly lower progression rate to late ARMD than participants not taking lutein/zeaxanthin.[25] In fact, the totality of evidence on beneficial and adverse effects suggests that lutein/zeaxanthin could be more appropriate than beta-carotene in the AREDS-type supplements. A 2017 Cochrane review assessed the effects of antioxidant vitamin or mineral supplementation on the progression of ARMD in people with AMD.[26] The authors included 19 randomized controlled trials (RCTs) conducted in the United States, Europe, China, and Australia. Compared with placebo or no intervention, it was concluded that individuals with ARMD may experience some delay in progression of the disease with the use of antioxidant vitamin or mineral supplementation (alone or in combination).

In addition to the AREDS research, several studies using various commercially available broad-based antioxidant formulas have shown promising results. For example, a 1.5-year study demonstrated that the

progression of dry ARMD could be halted (but not reversed) with a broad-spectrum 14-component antioxidant capsule (Ocuguard).[27] A retrospective study of a nutritional supplement called ICAPS Plus (which contains beta-carotene, vitamins C and E, zinc, copper, manganese, selenium, and riboflavin) compared 38 patients who used the preparation regularly with 37 patients who used only one bottle and who served as controls.[28] Of the treated patients, 15 showed improvement in their vision by one line or more on a vision acuity chart, compared with only 6 in the control group. In addition, 3 of the 38 in the treatment group lost one line or more of vision, compared with 13 in the control group. In a second prospective blinded clinical trial reported in the same review, vision and contrast sensitivity were evaluated. After 6 months, visual acuity was the same or better in 36 of 61 controls compared with 168 of 192 treated patients.

In a randomized, double-blind, placebo-controlled trial, 5442 female health care professionals 40 years of age and older, with preexisting cardiovascular disease or three or more cardiovascular disease risk factors, randomly received a combination of folic acid (2.5 mg/day), pyridoxine hydrochloride (50 mg/day), and cyanocobalamin (1 mg/day) or placebo.[29] After an average of 7.3 years of treatment and follow-up, there were 55 cases of ARMD in the combination treatment group and 82 in the placebo group. For visually significant ARMD, there were 26 cases in the combination treatment group and 44 in the placebo group. These results indicate a 34% and 41% reduced relative risk, respectively.

Xanthophylls (Lutein, Zeaxanthin)

Several studies have confirmed the benefit of supplementing the diet with xanthophylls (e.g., lutein, zeaxanthin). A meta-analysis of 20 RCTs involving 938 patients with ARMD and 826 healthy subjects revealed a dose–response relationship between supplementation with lutein, zeaxanthin, and meso-zeaxanthin and improved macular pigment optical density (MPOD) both in patients with ARMD and healthy subjects.[30] A 12-month double-blind study, the Lutein Antioxidant Supplementation Trial, sought to determine whether nutritional supplementation with lutein or lutein together with antioxidants, vitamins, and minerals improved visual function and symptoms in atrophic ARMD.[31] Patients receiving lutein (10 mg) alone or in combination with a broad-spectrum vitamin and mineral supplement showed improvements in mean eye macular pigment optical density, Snellen-equivalent visual acuity, and contrast sensitivity. Patients who received the placebo, however, showed no significant changes in any of the measured findings.

A prospective randomized interventional study evaluated if the addition of epilutein would augment MPOD in 40 patients with ARMD.[32] Subjects were divided into two groups. Group 1 received daily oral administration of 8 mg epilutein in combination with 2 mg lutein, whereas group 2 received 10 mg of lutein for 2 months. In patients with early-stage ARMD, the administration of lutein in combination with epilutein was associated with an increase MPOD compared with the administration of lutein alone.

In a study using a comprehensive formula, 27 patients with nonadvanced ARMD and visual acuity at or equal to 0.2 logarithm of the minimum angle of resolution were enrolled and randomly divided into two age-similar groups.[33] Fifteen patients added an oral supplement containing vitamin C (180 mg), vitamin E (30 mg), zinc (22.5 mg), copper (1 mg), lutein (10 mg), zeaxanthin (1 mg), and astaxanthin (4 mg) daily for 12 months, whereas 12 patients had no dietary supplementation during the same period. Based on multifocal electroretinogram response-amplitude densities and visual acuity assessments, the results clearly indicate that early-stage ARMD can respond positively to supplementation with carotenoids and antioxidants.

See Chapter 57 for more information on lutein, zeaxanthin, and astaxanthin.

Zinc

Zinc plays an essential role in the metabolism of the retina, and the elderly are at high risk for zinc deficiency. In addition to the studies with a combination of nutrients, a 2-year prospective, randomized, double-blind, placebo-controlled trial involving 151 subjects with dry ARMD demonstrated that the group taking 200 mg/day of zinc sulfate (approximately 80 mg of elemental zinc) had significantly less visual loss than the placebo group.[34] This initial report was one of the key prompts of the AREDS group to further evaluate whether antioxidant or zinc supplements delay age-related macular degeneration.

In another study using a zinc-monocysteine (ZMC) supplement, 40 subjects with ARMD were randomized to receive either ZMC 25 mg or placebo twice daily for 6 months.[35] At the end of the study, the ZMC group showed improved visual acuity and contrast sensitivity. Macular light-flash recovery time shortened in the ZMC group at 3 months by 2.1 to 3.6 s and at 6 months by 7.2 to 7.4 s. No improvement occurred in the placebo group. ZMC was well tolerated, with a gastrointestinal irritation rate of less than 2%.

It should be noted that a double-blind study in 112 patients with wet ARMD failed to show any benefit with zinc supplementation.[36]

Flavonoid-Rich Extracts

Flavonoid-rich extracts of bilberry *(Vaccinium myrtillus), Ginkgo biloba,* or grape seed *(Vitis vinifera)* offer significant benefits in the prevention and treatment of ARMD. In addition to possessing excellent antioxidant activity, all three extracts have been shown to exert positive effects on retinal blood flow and function. Clinical studies in humans have demonstrated that all three are also capable of halting the progressive visual loss of dry ARMD and possibly even improving visual function.[37–40] Of the three extracts, bilberry extracts standardized to contain 25% anthocyanidins appear to be the most beneficial. Studies of animals with visible light-induced retinal degeneration demonstrate that bilberry anthocyanin extracts at appropriate dosages significantly inhibited retinal dysfunction; increased the levels of superoxide dismutase, glutathione peroxidase, and catalase; suppressed lipid peroxidation and proinflammatory cytokines; and attenuated the changes caused by light to certain apoptotic proteins.[41] The anthocyanosides of *V. myrtillus* have a strong affinity for the retinal pigmented epithelium that constitutes the optical or functional portion of the retina, reinforcing the collagen structures of the retina and preventing free-radical damage. Extracts of anthocyanins from blueberries inhibit the induction and progression of ARMD through antioxidant mechanisms (e.g., decreasing levels of malondialdehyde and increasing the levels of superoxide dismutase, catalase, and glutathione peroxidase) as well as decreasing the levels of vascular-endothelial cell-growth factor in human retinal epithelial cells.[42] In addition, proanthocyanidins of Japanese horse chestnut seed shells *(Aesculus turbinata)* also inhibit oxidative stress and apoptosis, resulting in a protective effect on the retina from diseases such as ARMD.[43] Because the retinal pigmented epithelium is the portion of the eye affected in ARMD, anthocyanosides appear to be ideal therapeutic agents for the disorder.

G. biloba extract with a 24% ginkgo flavoglycoside content is perhaps a better choice if the patient is also showing signs of cerebrovascular insufficiency, and grape seed extract may be the most useful in the patient with significant photophobia or poor night vision.

Omega-3 Polyunsaturated Fatty Acids

Numerous epidemiological studies have demonstrated that omega-3 polyunsaturated fatty acids (PUFAs) are associated with a decreased

risk of ARMD. Omega-3 PUFAs have structural, functional, and neuroprotective roles and may favor the retinal accumulation of lutein and zeaxanthin and thus increase MPOD. A double-blind, placebo-controlled, prospective randomized clinical trial performed in 120 patients examined the associations of MPOD with plasma omega-3 PUFAs in subjects with a family history of ARMD.[44] The subjects included in the study were aged 40 to 70, had at least one parent treated for ARMD, had no major eye conditions, and had no use of supplements containing lutein or zeaxanthin the preceding year. After multivariate adjustment, high MPOD was significantly associated with higher plasma levels of omega-3 docosapentanoic acid. However, a Cochrane review found that omega-3 long-chain PUFA supplementation in people with ARMD for periods up to 5 years does not reduce the risk of progression to advanced ARMD or the development of moderate to severe visual loss.[45]

Exercise

Although exercise may not play a role in reversing or directly preventing ARMD, patients with visual impairment should consider strength and balance training to minimize the risk of falling.[21]

THERAPEUTIC APPROACH

As with most diseases, prevention or treatment of ARMD at an early stage is most effective. The treatment of the wet form is laser photocoagulation soon after diagnosis. Because free-radical damage and a lack of blood and oxygen supply to the macula appear to be the primary causes of macular degeneration, the consumption of antioxidant supplements and promotion of retinal blood flow are the keys to effective treatment.

The use of nutritional supplementation in ARMD has undergone extensive cost–benefit analysis. Compared with no therapy, antioxidant therapy yielded a cost-effectiveness ratio of $21,387 per quality-adjusted life-year (i.e., it lowered medical costs by $21,387 per quality-adjusted life-year gained) and lowered the percentage of patients with ARMD who developed visual impairment in the better-seeing eye from 7.0% to 5.6%.[46]

Diet

Foods to avoid in ARMD:

- Fried and grilled foods and other sources of free radicals
- Animal fat
- Processed baked goods
- Beer

Foods to add to the diet of a patient with ARMD:

- Yellow vegetables, green vegetables, tomato products (carotenes)
- Flavonoid-rich berries (blueberries, blackberries, cherries, etc.)
- Fresh fruits and vegetables, nuts, and fish
- Moderate wine consumption (advisable in those without contraindications to alcoholic beverages)

Supplements

- Vitamin C: 500 to 1000 mg/day
- Vitamin E (mixed tocopherols): 200 to 400 IU/day
- Selenium: 200 to 400 mcg/day
- Folic acid: 800 mcg/day
- Pyridoxine hydrochloride: 50 mg/day
- Vitamin B_{12}: 800 mcg/day
- Lutein: 10 to 15 mg/day
- Zeaxanthin: 1 to 2 mg/day
- Astaxanthin: 4 to 6 mg/day

Botanical Medicines

One of the following extracts may be selected:

- *G. biloba* extract (24% ginkgo heterosides): 120 to 240 mg/day
- *V. myrtillus* (bilberry) extract (25% anthocyanidin content): 120 to 240 mg/day
- Grape seed extract (95% procyanidolic content): 150 to 300 mg/day

Exercise

Balance training and strength exercises are recommended, especially for patients who are visually impaired.

Menopause

Tori Hudson, ND,* and *Joseph Katzinger, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Last spontaneous menstrual period occurred 12 months prior.
- Average age at onset is 51 years.
- Symptoms can but do not necessarily include hot flashes, night sweats, palpitations, headaches, insomnia, mood swings, anxiety, vaginal dryness, urinary incontinence, rheumatism, fatigue, hair thinning, skin dryness, acne, facial hair, low libido, bladder infections, vaginal infections, nausea, mild cognitive changes, and irregular bleeding with perimenopause.

The baseline evaluation of the menopausal woman should consist of the following assessments:

- Detailed personal medical history, including an understanding of the chief complaint, review of other systems, medical history, past and present medications, family history, dietary habits and history, exercise habits and history, social history, and occupation
- General physical examination
- Breast examination
- Pelvic examination
- Laboratory tests to consider: complete blood count, blood chemistry panel, lipid panel with subfractions, thyroid function panel, follicle-stimulating hormone (FSH), homocysteine, C-reactive protein, and estrogen metabolites
- Screening mammography
- Bone density testing
- Cervical cytology (Pap smear or liquid-based technologies)
- Electrocardiogram
- Colonoscopy

Some of these tests are routinely performed either initially or on a yearly basis. The indications and frequency for other tests are determined by individual health history, disease risks, current health problems, and family history.

INTRODUCTION

Menopause denotes the cessation of menstruation in a woman, which usually occurs when she reaches the age of 51 years. Twelve months without a spontaneous period is the commonly accepted rule for diagnosing menopause. The time before menopause is referred to as the *menopausal transition,* whereas the time after menopause is referred to as *postmenopausal.* Per the 2012 Staging of Reproductive Aging Workshop (STRAW) classifications, *perimenopause* includes the menopausal transition as well as the first year following the final menstrual period.[1] During the perimenopausal period, women ovulate irregularly, infrequently, or not at all; therefore, they begin to experience changes in the menstrual cycle with or without other symptoms.

With the prolongation of life expectancy, the menopausal and postmenopausal periods are becoming more significant in a woman's life. In fact, today's average woman can expect to live at least one-third or more of her life in the postmenopausal stage.

In 2015, nearly 50% of the women in the United States were postmenopausal, and by 2025, the number of postmenopausal women globally will reach 1.1 billion. Between 1990 and 2020, the menopausal population in the country will double. This dramatic rise in the number of menopausal women is changing the way health care providers work with women and changing medicine itself. At no other time in history have so many individuals been dealing with the same set of health issues. Now more than ever, clinicians have options for the management of menopause.

Current conventional medical treatment of menopause primarily involves short-term (1–4 years) hormonal therapy (HT) for the primary indication of moderate to severe vasomotor symptoms, using estrogen with or without a progestogen. The obvious question is, "Is hormone replacement therapy necessary?" The goal of this chapter is to answer this question and offer an approach to perimenopause and menopause that provides many different options.

GENERAL CONSIDERATIONS

The goals of an integrative medicine approach to menopause are to provide relief from common menopausal symptoms and to prevent and/or treat osteoporosis, cardiovascular disease, and other diseases of aging while minimizing the risks of breast cancer, coronary heart disease (CHD), venous thromboembolism, strokes, and gallbladder disease. The evaluation process reveals a woman's perimenopausal/menopausal symptoms, other acute and chronic health problems, health habits, mental/emotional stressors, and risks for future diseases.

One of the most complicated and difficult health care decisions that menopausal women face today is whether to use HT. Women look to their health care providers for definitive answers to these questions. Practitioners are faced with an even greater challenge: evaluating the benefits and risks of conventional hormone therapy (cHT) and natural hormone therapy (nHT) for an individual patient.

In the year 2000, the peak of HT usage, some 46 million prescriptions for conjugated estrogen (Premarin) were written in the United States. An additional 22.3 million prescriptions were written for the same preparation with medroxyprogesterone (Prempro). Almost one in three women given a prescription for cHT never has it filled. Of those who do start cHT, the majority discontinue its use shortly after starting therapy. And after the initial results of the Women's Health Initiative (WHI) were published, most women opted to discontinue or avoid starting HT—in 1999, 13.5% of women age 45 to 64 were taking HT (23.2% of 57-year-old women), but this declined dramatically to 2.7% in the year 2010.[2] Reasons given for discontinuing the drug include uterine bleeding; side effects, including mood changes, breast tenderness, bloating, and weight gain; a fear of breast cancer; and not understanding or believing in the need for its long-term use. Lack of compliance can also be attributed to inadequate education of many healthcare practitioners regarding the needs of menopausal women, both gynecological and nongynecological. Many practitioners also have a limited understanding of the many therapeutic options for menopausal symptoms and of the more global issues of menopause. In addition, holistic menopause practitioners who use both cHT and nHT hold that compliance improves with the use of nHT and that many side effects disappear or improve when patients switch from cHT to nHT.

Sadly, many menopausal women have a limited understanding of the long-term health risks associated with this change in hormone status, and very few women believe that they are well informed about the benefits and risks of cHT or nHT. Each woman wants to know whether HT is right for her—how she may benefit, how long she will have to take the drug to receive those benefits, and what the short-term side effects and potential long-term negative effects are.

Scientific evidence regarding the use of postmenopausal HT comes in many shapes: observational studies, large-scale randomized trials, small clinical trials, biological plausibility, in vitro studies, and animal studies. Other factors involved in the hormone conundrum are theoretical questions, areas of scientific uncertainty, popular consumer opinions and fears, and history. Definitive evidence for the benefits and risks of HT has been clarified by the two Heart and Estrogen/Progestin Replacement Studies (HERS I and HERS II), the Women's Health Initiative (WHI), and the Early versus Late Intervention Trial with Estradiol (ELITE). Another large-scale trial conducted in 14 countries, the Women's International Study of Long Duration Oestrogen after Menopause (WISDOM), was discontinued in November 2004 for scientific and practical reasons. Because WISDOM was to be completed after the publication of WHI results, "there were no safety concerns for the 5700 women enrolled in the study. However, the trial was not expected to provide substantial evidence that would have an impact on clinical practice decisions in the next 10 years."[3]

The North American Menopause Society (NAMS) has a very comprehensive position statement, last updated in 2017.[4,5] In summary, this document says that although there are many benefits (with regard to vasomotor symptoms, urogenital atrophy, urinary health, osteoporosis, and reduction in the onset of type 2 diabetes mellitus), there are also slight statistical risks for some women (of stroke, venous thromboembolism, dementia, and coronary heart disease). What has emerged from this position statement, as well as others, is that *the timing of HT initiation may be very important,* the so-called "hormone-timing" or "timing" hypothesis. Specifically, younger women (those <59) may have a very favorable risk–benefit profile with HT use, including a potential reduction in mortality and cardiovascular risk, whereas women aged 60+ may see an increase in risk. Thus the NAMS current position concludes, "For women aged younger than 60 years or who are within 10 years of menopause onset and have no contraindications, the benefit-risk ratio appears favorable for treatment of bothersome VMS (vasomotor symptoms) and for those at elevated risk of bone loss or fracture. Longer duration may be more favorable for ET (estrogen therapy) than for EPT (estrogen-progestogen therapy), based on the WHI RCTs." Indeed, the ELITE trial found that oral estradiol therapy was associated with less progression of subclinical atherosclerosis (determined by carotid artery intima-media thickness) than placebo *when initiated within 6 years after menopause,* but not when initiated 10 or more years after.[6]

The bottom line is that women and their health care practitioners are faced with trying to make the best decisions possible on the basis of what we do know, what we do not know, and what we are still uncertain about.

Benefits

Symptoms

The decline of endogenous estrogen leads to multiple tissue and organ changes and problems. In addition to the reproductive and urinary tracts, estrogen-sensitive tissues include the skin, bone, vascular lining, the teeth and gums, the eyes, the brain, and the central nervous system.

Some 50% to 80% of women in the United States report menopause-related hot flashes, night sweats, vaginal dryness, insomnia, mood swings, and depression. During the first 5 to 10 years of menopause, vulvovaginal symptoms begin to appear. Later, as the other mucous membranes of the urogenital tract become affected, rates of incontinence and infection rise. Vasomotor symptoms persisted an average of 7.4 years in the Study of Women's Health Across the Nation and have subsequently been found to be associated with cardiovascular, bone, and cognitive risks.[7–9]

There is strong evidence from randomized clinical trials that estrogen therapy is very effective in controlling vasomotor and genitourinary symptoms. Vaginal estrogen is as efficacious as oral or transdermal estrogen for genitourinary symptoms and may be an advantageous method because of the local delivery and effect, and even at a low dose (e.g., 7.5 ug vaginal ring), it appears to be effective for managing symptoms of vulvovaginal atrophy.[10] Lower doses of HT (oral conjugated equine estrogens [CEE] 0.3 mg; oral 17b-estradiol ≤0.5 mg; or estradiol patch 0.025 mg) may take 6 to 8 weeks to provide symptom relief but may also lower the incidence of adverse effects, such as breast tenderness or unscheduled vaginal bleeding.[5]

Sex steroids also affect sleep, libido, cognitive function, motor coordination, and pain sensitivity. Data are mixed regarding the role of menopause in depression and mood swings; however, depression and mood disorders appear to be more common or at least exacerbated in perimenopause or early menopause compared with the reproductive period, and HT benefits many women. Although a 2017 systematic review found no benefit of bioidentical hormone therapy for

menopausal-related depression, longer exposure to exogenous estrogen does appear to have a protective effect, and it may be that estradiol (either as bioidentical or conventional) has an antidepressant effect in perimenopausal but not postmenopausal depressed women, although this is not clearly established.[11–13]

The NAMS and its advisory panel published a post-WHI report and recommendations on postmenopausal HT. One of its basic recommendations is that the treatment of menopausal symptoms (especially vasomotor and urogenital) remains the primary indication for HT or estrogen replacement therapy (ERT). The NAMS 2017 position paper also cites the U.S. Food and Drug Administration (FDA) approval of HT for premature hypoestrogenism as well as for genitourinary symptoms.

Osteoporosis

Estrogen is known to inhibit the age-related bone loss that occurs in most menopausal women, and both observational and controlled trials are in agreement about the benefit of HT for the prevention and treatment of osteoporosis. Observational studies have indicated that the use of estrogen reduces the risk of vertebral fracture by approximately 50% and the risk of hip fracture by 25% to 30%.[14] A systematic review and meta-analysis of randomized controlled trials published in 2016 found that the overall relative risk of HT was 0.74 for total fractures, 0.72 for hip fractures, and 0.63 for vertebral fractures. Again, the benefit was more apparent among women younger than 60, and there was a greater decrease in fracture risk with estradiol compared with conjugated equine estrogens.[15] Estrogen had been considered the therapeutic agent of choice for both the prevention and treatment of postmenopausal osteoporosis in women for many years—until the WHI results, which shifted the perception of benefit versus risk. Estrogen has been the most studied agent for prevention and has been shown to decrease bone resorption, prevent osteoporosis, and reduce fractures. Nevertheless, the FDA has removed estrogen from the list of agents approved as effective in treating women who already have osteoporosis (although in 2013 it approved Duavee, a combination of conjugated estrogens with bazedoxifene, for use in postmenopausal women with an intact uterus for the prevention of osteoporosis and for the treatment of moderate to severe vasomotor symptoms).[16] The decision to remove estrogen from the approved list had nothing to do with any new discovery of a decrease in effectiveness for this indication; rather, it arose as an issue of fairness in new standards that have been applied to approving other drugs for osteoporosis treatment, such as the bisphosphonates (risedronate and alendronate). These agents have involved prospective fracture reduction studies on women with low bone mass and/or fracture and were not associated with the same perception of adverse effects demonstrated in the WHI.[17]

That being said, the WHI was a large clinical trial in which 16,608 postmenopausal women 50 to 79 years of age were studied at 40 U.S. clinical centers.[18] The regimen used was continuous combined estrogen–progestogen therapy (CCEPT) (e.g., Prempro). Women in the CCEPT group experienced lower rates of hip fracture (10 per 10,000 person-years vs. 15 per 10,000 person-years in the placebo group, a 34% lower relative risk) and vertebral fracture (9 events per 10,000 women annually vs. 15 events per 10,000 women annually for placebo, also a 34% lower relative risk). Statistically significant fracture reductions were also seen in other osteoporotic fractures (23%) and total fractures (24%).

The different estrogen agents approved for the prevention of osteoporosis and their antiresorptive effects are as follows (with dose-dependent benefits):

- Oral micronized estradiol, 1.0 mg/day
- Conjugated equine estrogens (CEE), 0.625 mg/day
- Ethinyl estradiol, 5 mcg/day
- Transdermal estradiol, 50 mcg/day
- Esterified estrogen, 0.3 mg/day

It is important to keep in mind that some women derive benefits from these doses, some will need higher doses, and others will have adequate bone protection with lower doses. Dual-energy x-ray absorptiometry (DEXA) scans provide the most reliable objective information on the status of bone mineral density.

Colorectal Cancer

Accumulated observational studies suggested that the use of ERT reduced the risk for colorectal cancer as well as the risk of dying from colon cancer.[19] Although not all study findings are consistent, some studies have shown that the risk of developing fatal colon cancer was reduced by 33%[20]; others show as little as an 8% reduction in risk.[21] In the WHI intervention phase, women who received combined estrogen and progestin versus placebo were 38% less likely to develop colorectal cancer; however, further analysis of the WHI data, postintervention data, and analysis of the HERS trial found no strong evidence of a protective effect of CEE alone or CEE and medroxyprogesterone acetate (MPA) on the risk of colorectal cancer.[22]

Risks

Endometrial Cancer

Unopposed estrogen administration is associated with an increase in the risk of endometrial cancer by a factor of 2.3, although this greatly increases to 9.5 among women using unopposed estrogen for more than 10 years, and the risk remains elevated at least 5 years after cessation of estrogen. Vaginal estrogen does not substantially lower this risk.[23] This results in an excess of 46 cases per 10,000 women for women who use unopposed estrogen for at least 10 years.[24] Adding a proved dose and delivery method of a progestogen (progestins or progesterone), which opposes the effects of estrogen on the endometrium, reduces the risk to a minimum and is essential in preventing endometrial hyperplasia and endometrial cancer.

Support for the use of natural hormones, particularly oral micronized progesterone (OMP), came in the form of the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial and its study of the effects of HT on endometrial histology in postmenopausal women.[25] This trial confirmed that daily CEE, 0.625 mg, enhanced the development of endometrial hyperplasia and that combining CEE with cyclic or continuous MPA protected the endometrium from hyperplastic changes. What was new was that the trial also concluded that cyclic OMP (200 mg daily for 12 days per month) also protected the endometrium from the hyperplastic changes associated with estrogen-only therapy. Thus the PEPI was the first clinical trial proving that OMP was as appropriate as MPA for use in the protection of the endometrium. Compounded OMP was already available, but the product Prometrium came on to the market as a result of that study. Unfortunately, data from the E3N (a large French cohort study) suggest that 100 mg OMP used continuously or 200 mg used sequentially may not be adequate; an overall hazard ratio of 1.80 for endometrial cancer was associated with its use (but other progesterone derivatives were not associated with an elevated risk). This increase in risk with OMP compared with other progesterone derivatives was also observed in the European Prospective Investigation into Cancer and Nutrition (a cohort of over 115,000 postmenopausal women), which found an overall hazard ratio of 1.53 with OMP use, compared with 0.84 with other progesterone derivatives. Although other trials have not observed this increased risk with OMP, and a 2016 international panel of experts approved this dosing, this issue needs further evaluation.[23,26–28]

Venous Thromboembolism

Venous thromboembolism (VTE) is an almost expected complication of the postmenopausal use of exogenous hormones. Observational studies have demonstrated that in postmenopausal women who use ERT, the risk of VTE is increased by a factor of 2 to 3.5. These observations are consistent with the data found in HERS I (discussed later). The investigators reported that the risk of thromboembolic events was increased by a factor of 2.7 in the women receiving the estrogen-progestin therapy.[20] HERS II showed that the relative risk (RR) of VTE increased 108% (RR 2.08), and the absolute risk was 0.59% in the HT group compared with 0.29% in the placebo group (59 events vs. 28 events annually per 10,000 women, respectively).[29]

The WHI reported similar results. The relative risk was 2.11 in the HT group, a 111% increased risk. The absolute risk was 34 events in the HT group compared with 16 events in the placebo group per 10,000 women.[20] Owing to the uncommon presence of idiopathic venous thromboembolism in women above 50 years of age, the absolute risk associated with postmenopausal HT is pretty small. For women who are already at risk for thromboembolism or who are older, the absolute risks of HT will be higher. For example, women in the CEE and MPA arm of the WHI aged 50 to 59 had a 2.27 relative risk for VTE, whereas it was 4.28 among those age 60 to 69 and 7.46 among women age 70 to 79.[30] Although no randomized trials have confirmed it, observational studies and clinical findings strongly suggest that the increase in risk with oral ERT may be avoided with transdermal therapy, as found in the Estrogen Thromboembolism Risk (ESTHER) case-control study and two recent nested case-control studies.[31,32]

Coronary Heart Disease

For the past 30 years, practitioners have been advising menopausal women that HT reduces the risk of coronary heart disease (CHD). More than 40 observational studies in the past three decades have suggested that this risk is 35% to 50% lower among women who take estrogen than in women who do not.[33,34] These observational data have been reinforced by additional research demonstrating some of the impact of estrogen on individual factors known to be associated with CHD, thereby also establishing a biologically plausible mechanism for the association of HT and reduced CHD. Randomized trials have shown that estrogen therapy reduces plasma levels of low-density-lipoprotein cholesterol (LDL-C) by 10% to 14% and raises plasma levels of high-density-lipoprotein cholesterol (HDL-C) by 7% to 8%.[20,35] Estrogen has also been shown to reduce Lp(a) lipoprotein, inhibit oxidation of LDL-C, improve endothelial vascular function, reduce fibrinogen, and reduce thickening in the arterial walls.

However, estrogen may have detrimental effects on cardiovascular risk markers, such as by raising triglyceride levels, increasing clotting, and raising levels of C-reactive protein. These detrimental effects of estrogen may override the beneficial effects of estrogen on cardiovascular function and may explain the surprising results of randomized, placebo-controlled trials indicating that HT did not reduce the overall rate of CHD. In HERS II and the WHI, it actually increased the rate of CHD. These new data from randomized trials, compared with the 30 years of observational data and the biologically plausible mechanisms, have rendered recommendations to postmenopausal women about HT more complex and challenging. Both patients and practitioners have questions with no clear-cut answers, and concerns about the benefits and risks of HT are more difficult to sort out.

Heart disease is the leading cause of morbidity and mortality in women, and an understanding of the current state of the evidence and the potential for the cardioprotective effects of HT, as well as the negative cardiovascular effects of HT, is of vital importance to women's health. In this discussion, however, one must not forget the potential cardioprotective effects of nutrition, exercise, stress management, and select nutrients such as niacin, magnesium, and fish oils.

The basic problem with HT and CHD is that the later randomized trials of estrogen among women with preexisting CHD have not confirmed the 40 observational studies of the last 30 years. The first large-scale randomized, double-blind, placebo-controlled trial of HT (a combination of CEEs [Premarin] and CEEs with medroxyprogesterone acetate [Provera]) for the secondary prevention of CHD was HERS I.[20] In a total of 2763 women with established CHD studied at 20 clinical centers throughout the United States, the death rates from coronary causes and nonfatal myocardial infarctions in the hormone group and the placebo group were similar. Perhaps more worrisome was the 50% increase in the risk of CHD events (thromboembolism) during the first year in the women receiving HT. The HERS I data prompted a barrage of questions, as follows:

- Are the HERS data simply wrong?
- Does one clinical trial outweigh the vast array of observational studies?
- Is the pattern of early risk real, and if so, what caused it?
- Is the early risk related to some other factor present in a subgroup of women but not others?
- Were the results related to the hormone regimen used?
- Would the results be different with a natural estradiol and/or a natural progesterone?
- Did the MPA counteract the potential beneficial effects of estrogen?
- Do these HERS I results for secondary prevention have implications for questioning HT's role in primary prevention?

A brief attempt at some answers was made after HERS I: The early risk for increased CHD events in the hormone-treated group has been a pattern seen in subsequent studies—the Puget Sound Group Health Cooperative of Seattle,[36] the Nurses' Health Study,[37] and the early data from WHI.[38] An early risk for blood clots in the legs and lungs, heart attack, and stroke appears to be a real phenomenon in postmenopausal women who begin HT. Two hypotheses to explain this finding are that estrogen has a prothrombotic effect and a proinflammatory effect on the vascular endothelium.

There indeed may be some subgroup of women with a predisposition for the prothrombotic and/or proinflammatory effects of estrogen—for example, women with hyperinsulinemia, hypertension, elevated homocysteine levels, increased C-reactive protein and Lp(a) lipoprotein levels, obesity, and/or elevated LDL-C. Interestingly, in the HERS I trial, differences were observed between hormone-treated women who also took lipid-lowering therapy (statins) and hormone-treated women who did not. The rate of CHD events after 1 year was much lower in the HT-plus-statin group than in those who did not use statins. The same was true for the risk of venous thromboembolic events.

Another controlled trial attempted to address the question of whether estrogen inhibits atherosclerosis. In the placebo-controlled Estrogen Replacement and Atherosclerosis (ERA) trial, neither estrogen alone nor estrogen plus the progestin[39] affected the progression of coronary atherosclerosis. Plasma levels of LDL-C were reduced by 9.4% in the unopposed estrogen group and by 16.5% in the estrogen-plus-MPA group. Both groups had significant increases in HDL-C (18.8% and 14.2%, respectively) compared with the placebo group. The two estrogen groups had a rise in triglyceride levels (6.1% and 10.1%, respectively), but these changes were not significantly different from the levels in the placebo group. The ERA trial provided the first anatomical end point (angiographically determined effects on coronary arteries) in women who had known CAD. The ERA trial supported the overall null effect found by the HERS I trial and also showed that the MPA did not cancel out the beneficial effects of estrogen, as

was suspected in the HERS I trial. These data and other study results indicate that HT does not have a significant impact on the progression of atherosclerosis in women with established heart disease.

Preliminary data from the Papworth Hormone-Replacement Therapy Atherosclerosis Study (PHASE), a small clinical trial in 225 postmenopausal women with angiographically proved CAD, showed no cardiovascular benefits of HT and also possibly a slight increase in the rates of cardiovascular events during the first 2 years of HT.[40] This trial evaluated transdermal natural estradiol alone or with norethindrone, a different progestin.

An interim analysis of the WHI data also suggested that there had been a slight increase in the number of heart attacks, strokes, and thromboembolic events during the first 1 or 2 years in postmenopausal women undergoing HT.[41]

One clinical trial looked at estrogen use in postmenopausal women without clinical coronary disease. The Estrogen in the Prevention of Atherosclerosis Trial (EPAT) was designed to determine whether unopposed natural estradiol reduces the progression of subclinical atherosclerosis.[42] Postmenopausal women with high cholesterol levels but no preexisting cardiovascular disease, diabetes, or smoking history received either oral micronized natural estradiol or placebo and also lipid-lowering medication if serum LDL-C exceeded 160 mg/dL. The women were monitored for 2 years. The investigators evaluated the rate of change in carotid artery intimal-medial thickness. Women in the placebo group had an expected progression in the thickening of the carotid arteries over the 2 years. The women taking estradiol had a small amount of regression of the thickness of the carotid arteries. In women not receiving lipid-lowering therapy, the placebo group had a greater progression, and the estradiol group had no progression of intimal-medial thickness—a dramatic difference. Curiously, in the women who received lipid-lowering drugs, there was no difference in the rate of progression between the women receiving estrogen and those receiving placebo.

On the basis of data from these randomized clinical trials conducted before HERS II and WHI, HT did not appear to reduce the risk of cardiovascular events in postmenopausal women who already had CHD. Then along came the world-shifting news in July 2002, when the results of HERS II and the WHI were published less than a week apart.

HERS II investigated the effects of 0.625 mg of CEE plus 2.5 mg of MPA on the prevention of CHD in older U.S. women (average age 71 years) with preexisting CHD.[29] This study, a continuation of HERS I, was intended to determine whether a trend toward prevention of heart disease would appear if the study were continued longer. Once again, though, the results were not positive for women with heart disease. In HERS II there were no significant decreases in the rates of primary CHD events (or strokes or clots) among women assigned to the HT treatment group who had already had CHD before starting the HT regimen (RR, 1% decreased risk and absolute risk of 3.66% for HT vs. 3.68% for placebo). The investigators concluded that "postmenopausal hormone replacement therapy should not be used to reduce the risk of CHD events in women who already have CHD."[29]

A few days later, the results of the landmark WHI study were published.[18] The WHI investigated the effect of the most common HT regimen in the United States (0.625 mg Premarin plus 2.5 mg Provera, or Prempro) on the incidence of heart disease, breast and colorectal cancers, and fractures in postmenopausal women. The cardiovascular research was intended to investigate the effect of this HT regimen on the prevention of CHD in healthy postmenopausal U.S. women (aged 50–79 years) who do not have CHD. After a mean of 5.2 years of follow-up, the trial was stopped earlier than planned for the women using combined HT (mostly owing to harm from breast cancer incidence). In the WHI, there was a significantly higher risk of CHD annually per 10,000 women: a 29% increase in the relative risk and 37 more events in the HT group compared with 30 events in the placebo group. These findings, showing that estrogen plus progestin does not confer benefit in preventing CHD among women with a uterus, concurs with the HERS findings among women with clinical CHD as well as those of the ERA trial and others. The WHI results extend the findings of the earlier trials to include a wider range of women.

More recent analyses also suggest that the "timing hypothesis" may play a central role in determining risk and currently is the best explanation for the relationship between cardiovascular risk and HT. As mentioned previously, initial data from the WHI suggested an increase in CHD risk, but the WHI was a somewhat older population (mean age 63). Women aged 50 to 59 in the WHI receiving CEE appear to have had a protective benefit on CHD, as well as a 30% statistically significant reduction in overall mortality.[43] A 13-year follow-up of the WHI and a meta-analysis of trials (including the WHI) came to the same conclusion: When given to women near menopause, HT appears to have a cardioprotective effect, whereas it may increase the risk when given to women 60 years or older.[44,45] This timing hypothesis was also supported by data from the ELITE trial, which found oral estradiol to be associated with less progression of coronary atherosclerosis (measured by CIMT) when initiated within 6 years of menopause but not when given 10 years or more after menopause.[6]

Stroke

In the WHI, there was no excess risk of stroke in the estrogen-plus-progestin group in the first year, but such a risk did appear in the second year, and it persisted.[46] The mechanism does not seem to be related to an increase in blood pressure. The WHI findings were consistent but more dramatic than those of the HERS, which reported a nonsignificant 23% increase in the treatment group.[29] The WHI results were also more extreme than those of the Women's Estrogen for Stroke Trial (WEST) of estradiol (without progestin) in women with a history of a prior stroke. Overall, the WEST trial found no effect of estrogen on recurrent strokes but some rise in rates in the first 6 months.[47] Some might criticize the WHI statistics because they include older women. However, there was no indication that excess strokes were more likely to occur in older women, in women with prior stroke, through differences in race/ethnicity, or in women with high blood pressure. It is apparent that estrogen plus a progestin increases the risk of stroke in women who have been judged to be healthy. The estrogen-only arm of the WHI showed a slight increase in stroke for women in the youngest age group at study entry.[48] The ERT arm was quite different from the HT arm. A 2015 Cochrane review of 19 randomized controlled trials found that although there was an increase in stroke risk with HT therapy, this appeared to be limited to women who started treatment 10 or more years after menopause.[49]

One of the most recent studies on estrogen leads us to the most provocative question: Do different kinds of estrogens have different effects? In this study, the risk of VTE was compared among those who used esterified estrogen, conjugated equine estrogen, and no estrogen at all.[50] The findings concluded that CEE but not esterified estrogen was associated with venous thrombotic risk. Transdermal estrogen may also have an advantage on stroke risk compared with oral ET.[51]

Gallstones

The risk of gallstones or cholecystectomy appears to be raised by a factor of 2 to 3 in postmenopausal women who are taking ERT. This finding has been reported by several large observational studies. In HERS I, the women taking estrogen plus progestin were at a 38% higher risk of gallbladder disease than women who were taking a placebo.[20] HERS II found similar results, reporting a higher incidence of biliary tract

surgery, with a 48% increased relative risk for those in the HT group and an absolute risk of 191 versus 129 events annually per 10,000 women.[52] A 2017 Cochrane review that was heavily weighted by the WHI and HERS trials found that the absolute risk for gallbladder disease after 5.6 years of HT use increased from 27 per 1000 with placebo to between 38 and 60 per 1000 with HT.[53] It has been suggested by observational trials but not proven by randomized trials that transdermal estrogen may help to reduce this increase in risk.[54]

Areas of Uncertainty

Breast cancer. For many women, fears about breast cancer and a higher risk of breast cancer from HT dominate the decision-making process about menopause management. Clinicians must be educated about this topic and must be prepared to summarize the results of relevant research in order to counsel each woman about the benefits and risks in her particular situation.

It is true that there are unanswered questions about the long-term safety of HT, especially regarding the risk of breast cancer. What is often forgotten is that the clinical trial data on ERT span the last 100 years. No other pharmacological agent has been as thoroughly studied as estrogen. A half-century of research preceded the early 1940s, when HT became commercially available. Even though patient fears are high and alternative practitioners are particularly suspicious and skeptical about its safety, no data clearly and consistently demonstrate a higher risk of breast cancer associated with HT. Nevertheless, many patients and practitioners continue to be certain that taking HT will cause breast cancer.

Close to 60 observational studies of the association between HT and breast cancer have been published during the past 25 years, and no definitive answer exists because of inconsistency in the results of those studies. One analysis (before the WHI) of the evidence in those studies found that more than half of them reported either no difference in risk or a decrease in the risk of breast cancer with ERT/HT use.[55] The remainder of the studies reported only slight rises in breast cancer risk. Another group of researchers attempted to reanalyze more than 90% of the published data on breast cancer and HT use.[56] They reported that postmenopausal women who had ever used HT had a small but statistically significant increase in the risk for breast cancer compared with women who had never used HT. In women who were currently using HT or had recently used it, the relative risk rose by a factor of 1.02 to 1.04 for each year of use. After HT had been discontinued for 5 years, no significant excess risk remained. Also, breast cancers diagnosed in women who had used HT tended to be less advanced and were more localized.

Later reports from observational studies are also inconsistent. The report from the National Cancer Institute's Breast Cancer Detection Demonstration Project was published in January 2000.[57] These findings showed that the risk associated with recent HT use (both current use and use within the previous 4 years) was twice that associated with ERT. However, the relative risk for recent use of ERT was not statistically significant, and the difference between risks with ERT and HT was not tested for statistical significance. Right after that report was published, another group of investigators published and reported higher risk estimates for sequential HT regimens for 5 years or more of use than for continuous combined HT, although the difference was not statistically significant.[58] In contrast to previous reports, this study found no difference in risk between current and past users.

At the end of 2000, the Nurses' Health Study published its estimates of breast cancer risk associated with HT in postmenopausal women.[59] The results were expressed as percentage increases in the cumulative risk of breast cancer and were frightening to many: The use of estrogen alone for 10 years was found to lead to a 23% increase by age 70 years, and the use of estrogen plus progestin for 10 years was found to lead to a 67% increase by age 70 years. It is important for clinicians to realize (1) that the result is not an actual mathematical conclusion but the conclusion of the model—the consequences of a small difference in risk at the beginning that then is magnified as the math is carried out into the future—and (2) that risk estimates represent a projection, not an actual measurement.

One of the most disturbing reviews was published in 1998. Colditz[60] summarized the evidence that endogenous estrogen and ERT not only increase the risk but are causally related to breast cancer. In his review of hormones and breast cancer, he included reports on cell proliferation and endogenous hormone levels as well as epidemiological studies of the relationship between the use of postmenopausal hormones and the risk of breast cancer. He found evidence of a causal relationship between female hormones and breast cancer based on consistency, dose–response pattern, biological plausibility, temporality, strength of association, and coherence. He stated that the magnitude of the increase in breast cancer risk per year of hormone use is comparable with that associated with delaying menopause by a year. The fact that women who menstruate longer have a higher risk of breast cancer also provides support for a biological mechanism for the relationship between the use of exogenous hormones and increased risk. Colditz concluded that existing evidence supports a causal relationship between the use of estrogens and progestins, levels of endogenous estrogens, and breast cancer incidence in postmenopausal women.

The WHI was the first randomized controlled trial confirming that conjugated equine estrogens combined with progestins do increase the incidence of breast cancer and the first to quantify the increase. The 26% higher risk of breast cancer occurred after about 4 years and translated to 8 more cases annually per 10,000 women.[18] This is consistent with other epidemiological data. The study was discontinued primarily because of the breast cancer incidence, which crossed the monitoring boundary for safety.

It is important to note that among women who received estrogen only (CEE) for a median of 5.9 years in the WHI, there was a decrease in invasive breast cancer incidence and breast cancer mortality over the median 11.8 years of follow-up.[61] Unopposed estrogen was also found not to increase breast cancer risk in the Caroline Breast Cancer Study.[62] Although estrogen should not be recommended as a preventative treatment for women without a uterus, they may be reassured regarding the effects of estrogen on breast cancer risk.

At the other end of the pendulum, investigations that have found no increased risk of breast cancer with HT or ERT use receive much less attention. The Iowa Women's Health Study is prospectively following a cohort of women who were selected in 1985.[63] After 6 years of monitoring, a statistically significant increase in the risk of breast cancer could not be detected in women who either had ever used or were currently using HT. Another report through 8 years of follow-up examined whether postmenopausal HT raised the risks for breast cancer and death from cancer in women with a family history of breast cancer.[64] There was no significant increase in the rate of breast cancer even in women who had a family history of breast cancer and had been using HT longer than 5 years. These results are consistent with those of other reports that there is no additional risk in using HT/ERT for women who have a first-degree relative with breast cancer.

The latest analysis from the Iowa Women's Health Study, an 11-year follow-up, showed an association between women who had ever used postmenopausal HT and the risk of breast cancers that were more localized and had a better prognosis.[65] The researchers did not find an increased risk of invasive ductal or lobular carcinoma in women who had used HT for either less than or more than 5 years. A slight increase in risk was observed in current users and users for less than

5 years; current users with more than 5 years of use had no increase in risk. These results are the opposite of those seen in the Nurses' Health Study—that women who use HT for more than 5 years have a higher risk.[66] Two other studies, the Carolina Breast Cancer Study[67] and analyses from the National Health and Nutrition Examination Survey (NHANES),[68] found no increase in risk with postmenopausal hormones. These later studies perpetuate the inconsistency in research on this issue that has been seen in the last 25 years. This pattern provides some logic to the point of view that if there is an increased risk of breast cancer associated with ERT/HT, the risk must be small, because by now, after so many years, we would have seen more consistency in the data, and the size of the risk estimates would be large rather than slight.

It is to be hoped that, in consultations with patients, clinicians can offer a balanced view, reassuring them that no studies find an increased risk of breast cancer with the short-term use of HT and that the conflicting, inconsistent results of more than 60 studies show that if there is an increased risk with long-term use, it is a small one. We can evaluate the benefits and risks for each patient and make our recommendations on a short-term basis, which can help each individual to make decisions that are not necessarily permanent. Research in this area of medicine is prolific, and if we keep up to date on the latest findings, we can inform our patients so that they can make informed, timely choices about their health care.

Cognitive function. Observational studies have suggested that there is a relationship between endogenous estrogen exposure and cognition.[69] A number of other observational reports have demonstrated that HT use may prevent or delay the onset or progression of Alzheimer's disease, but additional observational results have been conflicting.[70] A meta-analysis and systematic review was conducted in March of 2001 in which 29 studies were rated.[71] In women who were symptomatic from menopause, postmenopausal use of estrogen improved verbal memory, vigilance, reasoning, and motor speed. There were no consistent effects on visual recall, working memory, complex attention, mental tracking, mental status, or verbal functions. Estrogen did not appear to enhance asymptomatic women's performance consistently on formal cognitive testing. The meta-analysis did suggest that HT was associated with a lower risk of dementia, but the reviewers acknowledged that the studies analyzed had important methodology problems and that the information was inadequate to allow a proper assessment of the effects of various estrogen preparations or doses, progestin use, and duration of use.

Studies in animals and the laboratory suggest plausible mechanisms for the potential of estrogen and the prevention and/or treatment of Alzheimer's disease. Estrogen increases dendritic spine growth, axonal elongation, synapse formation, and neuronal survival. It also influences several neurotransmitters, including acetylcholine; modulates nerve growth factor; increases apolipoprotein E; enhances blood flow; serves as an antioxidant; and enhances the uptake and metabolism of glucose. All of these effects could possibly inhibit the neurotoxicity of beta-amyloid and the damaging effects of free radicals, moderate the inflammatory events involved in plaque formation in the brain, enhance cerebral blood flow, and facilitate neuronal repair after brain injury.

Results of randomized trials of ERT and Alzheimer's disease and the potential of estrogen for the treatment of this disorder have not been impressive in terms of benefits. In one study, estrogen replacement for 1 year did not slow disease progression or improve global, cognitive, or functional outcomes in women with mild to moderate Alzheimer's disease.[72] In another, participants at 10 of the 20 HERS centers were enrolled in the cognitive function substudy. The mean age of participants at the time of cognitive function testing was 71 ± 6 years. Among these older women with coronary artery disease (CAD), 4 years of treatment with conjugated equine estrogens plus progestins did not result in better cognitive function as measured on six different standardized tests.[73]

In a later prospective study of dementia, prior use of HT was associated with reduced risk of Alzheimer's disease, but the duration of use very specifically affected the benefit; there was no apparent benefit from the current use of HT unless the use exceeded 10 years.[74] More recent data suggest that the "timing hypothesis" may be relevant to cognitive function as well. For example, a 2017 Cochrane review found that women over 65 taking continuous combined HT showed an increase in the incidence of dementia (from 9 per 1000 to 11–30 per 1000).[53] However, the results from a subset of the Kronos Early Estrogen Prevention Study (KEEPS) data suggest no effect on cognitive function among recently postmenopausal women.[75] The timing hypothesis was not confirmed in a trial looking for just this effect, however. In a randomized trial with a duration of 57 months, no effect on cognitive function was observed, and no difference was observed when HT was initiated within 6 years of menopause or after 10+ years postmenopause.[76]

Ovarian cancer. Evidence concerning a possible positive association between HT use and ovarian cancer risk is less consistent and of lesser significance than that for endometrial and breast cancers. Most of the data show a weak positive association. A large prospective cohort (observational) U.S. study of 211,581 postmenopausal women treated for longer than 10 years with conventional HT found an association with an increased risk of ovarian cancer.[77] No distinction was made regarding the type or regimen of HT or whether a progestogen was added to the ERT. Participants had no history of cancer, hysterectomy, or ovarian surgery. The study, monitoring women from 1982 to 1996, showed that women who were using HT at study entry had higher death rates from ovarian cancer than women who had never used HT. The risk was slightly but not significantly higher among former estrogen users. Women who used HT at baseline and for 10 years or more had a relative risk of 2.20, and former users with at least 10 years of use had a relative risk of 1.59. The annual age-adjusted cancer death rates from ovarian cancer per 100,000 women were 64.4 for baseline HT users with 10 or more years of use, 38.3 for former users with 10 or more years of use, and 26.4 for women who had never used HT.

In this observational study, as in the Nurses' Health Study, the lack of information is almost more disturbing than the actual information. We have no data as to the type, dose, or combination of estrogen and progestogen used by the participants. As a result, many assumptions were made that influenced data analysis and the effect on relative risk. We know that the way in which hormones have been prescribed has changed from 1982 through 1996 and since then. In the early 1980s, most women were prescribed unopposed daily estrogen. During the 1980s, sequential estrogen plus progestogen therapy was introduced to eliminate the increased risk of endometrial cancer. Most women began to take 7 to 10 days of progestogen per month along with their estrogen. In the 1990s, common prescribing habits involved continuous and combined estrogen/progestogen regimens and lower doses of both hormones. Whether sequential or cyclic, progestogen is generally prescribed for at least 12 days per month. The number of different estrogens and progestogens has also significantly expanded and changed since the early 1980s and even in the last few years.

The investigators also reported on relative risk. Given the low incidence of ovarian cancer, even if there is a significant increase in relative risk, it may not have much of an impact on absolute risk. Although this study shows a doubling of the relative risk, the incidence of ovarian cancer mortality in postmenopausal women is extremely low, at 1.6%.

It is also interesting to remember that 7 years or more of oral contraceptive use in reproductive-age women actually lowers the incidence of ovarian cancer.

A large, prospective study reported a significant twofold-higher risk of ovarian cancer among long-term users of HT and ERT.[78] A total of 44,241 postmenopausal women were selected from the Breast Cancer Detection Demonstration Project (BCDDP); 329 women who experienced ovarian cancer were identified. Women who used estrogen-only replacement therapy, especially for more than 10 years, were at significantly higher risk of ovarian cancer, with a relative risk of 1.8; women who used estrogen only for 20 or more years had a relative risk of 3.2. The good news was that women who used short-term combination replacement therapy were not at increased risk.

In 2015 a meta-analysis of 52 epidemiological studies was published in the *Lancet.* An increase in risk was observed even among women using HT for less than 5 years, as well as among those taking estrogen only or estrogen and a progestogen. The absolute risk for women taking HT for about 5 years and starting around age 50 was 1 additional case per 1000 users and one additional ovarian cancer death per 1700 users.[79]

Focus on estrogen only. The WHI originally had three components: HT, a low-fat dietary modification, and supplementation with calcium and vitamin D. In addition, many of the women who did not qualify for the active treatments of the WHI became part of an observational group that was studied. Both arms of the placebo-controlled HT component (estrogen plus progestin [HT] and estrogen only [ERT]) were terminated before the planned ending date. The ERT arm of the WHI was halted on March 1, 2004, after 6.8 years of follow-up and less than a year before the planned closing date.[48] The ERT arm was quite different from the HT arm in that the risks in the ERT arm did not exceed the benefits. The study showed a slightly increased risk of stroke, a decreased risk of hip fracture, a lack of increase in the risk of breast cancer, and a possible reduction in breast cancer risk and no effect on the incidence of CHD.

The key clinically relevant issues from the WHI ERT study are as follows:

- CHD was reduced by almost half in the youngest age group (the most common age group of women who initiate ERT).
- The risk of stroke increased only slightly for women in the youngest study-entrance age group.
- The risk of VTE was increased in all three age groups, but the degree of risk increased with age at study entry.
- The risk of invasive breast cancer was reduced in all three age groups.
- The risk of colorectal cancer was decreased in the two younger groups, especially in women aged 50 to 59; it was increased in women aged 70 and older.
- The overall reduction in risk of fracture was most evident in younger women.
- ERT was associated with a lower death rate in the group that was the youngest at study entrance.
- The middle age group had about the same death rate in both the ERT and placebo groups, and there was a slightly higher death rate in the oldest age group.

What the WHI ERT study basically showed is that ERT, using CEE, is safe for most menopausal women who do not have a uterus. ERT reduced the risk of CHD in those women who started ERT near the age of menopause; it decreased the risk of fractures; it did not increase the risk of breast cancer; the risk of colorectal cancer was increased in women who started therapy at age 70 or older; and it was associated with a slight increase in the risk of stroke and VTE, but there was no increase in death rates.

It would appear that the use of ERT alone by women without a uterus is safer than using estrogen plus a progestin.

Natural hormones. It is important to understand that most of the research on hormone regimens is on CEEs and MPA. However, that is not exclusively the case, and certainly some of the cardiovascular research has equally implicated 17-beta-estradiol (bioidentical estradiol). Nonetheless, in the most damaging data to date, from HERS I and II and the WHI, the hormones used were the equine estrogens and progestin. So, what we definitely know to be negative effects are associated with those regimens, and we do not, in fact, know whether the data can be applied to other regimens. It would be naive to dismiss the data and not to admit the possibility that the results would be the same. When hormones are determined to be appropriate or even necessary, however, it would at the very least seem logical to use the hormones we know not to be those with adverse effects.

Natural compounded estrogens and natural compounded progesterone, as well as natural testosterone and dehydroepiandrosterone (DHEA), such as those used by compounding natural pharmacies and the natural progesterone creams sold over the counter, are distinct and different in several critical ways from CEEs, conjugated plant estrogens, synthetic estrogens, and synthetic progestins. Natural hormones are made from either beta-sitosterol extracted from the soybean or from diosgenin extracted from Mexican wild yam root. Those compounds are then made into the desired hormone and are biochemically identical to the hormone the body produces. By definition, a natural hormone is plant derived and bioidentical. The natural compounded estrogens are either estriol, estrone, or estradiol. Estriol is particularly unique because it has approximately one-fourth the potency of estradiol and estrone. Natural compounded estrogens are generally used in lower doses owing to the combined effect of the weaker estriol along with the estradiol and/or estrone. These natural estrogens are thought to be metabolized significantly differently by the body, have shorter half-lives, can be used in customized dosing regimens and potencies to fit each individual woman and clinical situation, and can be adjusted to be stronger or weaker in small units to taper someone off or onto hormones.

There is another distinction worth making; hormones may be bioidentical, that is, have the same molecular structure as endogenously produced hormones, and manufactured in standardized dosages by drug companies, for example, Vivelle (estradiol) and Prometrium (micronized progesterone). These are distinct from compounded bioidentical hormones, which also optimize dosages, currently do not have FDA approval, and are discouraged by most conventional organizations.[80]
