Let the Data Speak

Sidney MacDonald Baker, MD

OUTLINE

INTRODUCTION

The importance of carefully eliciting and interpreting all possible information about a patient was discussed extensively in Chapter 140, Autism Spectrum Disorders. The autism spectrum is a medical landscape where there are more symptoms per patient than in other chronic illnesses. The collection, review, and analysis of such symptom data provide a rich resource for utilizing such data to understand their implications for the individual, the diagnostic category, and all individuals with chronic illness. The data discussed in this chapter are from Morgan, the patient described in Chapter 140. His mom had done a masterful job of completing a questionnaire's 500-symptom checklist, noting 24 strengths, 75 past symptoms, and 119 current symptoms. Of the past symptoms, 32 (43%) carry implications, as do 65 (54%) of his current symptoms. The breakdown of these indicators for Morgan is as follows:

Number	Code	Implication
24	NMI	Neuromuscular irritability
14	LIT	Loss of immune tolerance
5	LITs	Loss of sensory tolerance[a]
3	Y	Yeast issues
9	Dig	Digestive problems
8	FL	Abnormal microbiome
2	ANS	Dysautonomia

[a]The immune and sensory system join in noticing, remembering, and responding to environmental stimuli. As such, they are functions that are joined in the word "sensitive" that describes individuals in the autism spectrum more so than in other conditions.

These data offered options for therapeutic trials of *Saccharomyces boulardii*, other antifungals, Earth Dragon, and then *Hymenolepis diminuta cysticercoids* that led to his transformation from a child lost on the autism spectrum to one who performed at a very high scholarly and social level. What follows is an evaluation of a system for patients/parents and physicians to develop a comprehensive symptom portrait that captures individuality, reveals implications for actionable options, and offers a low-cost means for clinicians and parents to share a document conveying the meaning of symptoms from the dual perspective of etiology and therapeutic options. Access to an anonymous online interface for recording and reporting symptoms allows patients/parents and physicians to prepare for a thrifty but comprehensive process of prioritizing symptom-based treatment options that may be overlooked when diagnostic labels and laboratory data crowd therapeutic guidance.

GATHERING *ALL* THE DATA

My greeting Morgan with a swing test matches the placement of his strengths at the top of the patient's symptom checklist, making the point that nature's strong impulse toward healing is engaged when strengths are acknowledged and included in the treatment plan. Such treatment plans might include applied behavioral analysis; cognitive-behavioral therapy; developmental individual-difference relationship-based model (DIR)/floor time; discrete trial training; Early Start Denver model therapy; Lego-based therapy; occupational therapy; pivotal response training; a picture-exchange communication system; social scripts, social stories, and comic strip conversations; speech and language; sensory integration; music; and hyperbaric oxygen, where the question of "what are you good at?" may be overlooked. Morgan had a long list of strengths, and the attention called to them by their place in his questionnaire and in the moment of my exchange with him on the swing helped open a conversation with his mom that encouraged her inclusion of play and planned activities in which his strengths were engaged and honored. Our plans for patients of all ages and diagnostic classifications benefit if we embed this principle. I remind parents that when there may come a choice between a child's engagement in a favorite sport versus a therapy session, it is helpful to remember the value to all of us doing something that we are good at.

I created the tables shown in Tables 137.1 and 137.2 in Morgan's record by pasting his mom's symptom checklist from a Microsoft Word document into Excel, where I placed the codes, such as NMI, next to symptoms for which such an assignment was appropriate. The table listing his strengths is presented in Chapter 140. Tables 137.1 and 137.2, sorted by severity for past and present symptoms, show the codes I assigned to denote an implication if such could be recognized

Table 137.1 and 137.2's inventory of Morgan's "codable" symptoms, including those symptoms for which an implication cannot be assigned, provide an overview, the details of which are accessible and offer a picture of him that stands in contrast to the overview presented by his diagnostic label of autism spectrum disorder. The assignment of implications has been an exercise I have done manually in each

TABLE 137.1 Past Symptoms

Code	Symptom	Mild	Moderate	Severe	Occasional	Frequent	Always
NMI	Difficulty falling asleep			x			x
NMI	Insomnia			x			x
NMI	Sleeps less than normal			x			x
NMI	Colic			x			x
	Pica (eating nonedibles)			x			x
	Abnormal food cravings			x			x
	Behavior purposeless			x			x
	Aloof, indifferent, remote			x			x
	No purpose to play			x			x
	Uninterested in live pet			x			x
	Erratic			x			x
	Unable to predict actions			x			x
NMI	Hyperactive			x			x
NMI	Constant movement			x			x
NMI	Climbs to high places			x			x
	Spends time w/ pointless task			x			x
NMI	Toe walking			x			x
LITs	Licking			x			x
	Likes spinning objects			x			x
LITs	Sensitive to loud noise			x			x
LITs	Sounds seem painful			x			x
LITs	Bothered by bright lights			x			x
	Unaware of danger			x			x
	Repetitive play/objects			x			x
LITs	Hates wearing shoes			x			x
	Runs away		x				x
LITs	Covers ears with sounds		x				x
LITs	Insensitive to pain		x				x
	Uses adult's hand for activity						x
	Asks using "you" not "I"						x
	Answers by repeating question						x
	Receptive language poor						x
	Headaches			x		x	
NMI	Awakens screaming/crying		x			x	
	Cold sores on lips, face		x			x	
NMI	Teeth grinding		x			x	
	Poor appetite		X			x	
	Sits for long time staring		x			x	
	Poor sharing		x			x	
	Destructive		x			x	
NMI	Jumps when pleased		x			x	
NMI	Whirls self like a top		x			x	
NMI	Shrieks		x			x	
NMI	Flaps hands		x			x	
NMI	Likes to spin things		x			x	
NMI	Visual stims		x			x	
	Apathy		x			x	
	Blank look		x			x	
	Depression		x			x	
	Detached		x			x	
	Disinterested		x			x	
NMI	Anguish		x			x	
	Discontented		x			x	
NMI	Inconsolable crying		x			x	
NMI	Unhappy		x			x	
	Likes certain sounds		x			x	
	Conjunctivitis		x			x	
Y	Eye crusting		x			x	

TABLE 137.1 Past Symptoms—cont'd

Code	Symptom	Mild	Moderate	Severe	Occasional	Frequent	Always
Y	Lid margin redness		x			x	
	Likes fans		x			x	
	Likes flickering lights		x			x	
	Looks out of corner of eye		x			x	
	Unaware of people's feelings		x			x	
	Likes head burrowed		x			x	
	Likes head under blanket		x			x	
LITs	Very insensitive to pain		x			x	
	Muscle tone low trunk		x			x	
	Lost language @ 12–24 months		x			x	
	Occasional words when excited		x				
	Speech apraxia		x				
Y	Diaper rash	x			x		
NMI	Falls gets hurt running climbing	x			x		
	Stares at own hands	x			x		
	No answers to simple questions						

LITs, Loss of sensory tolerance; *NMI,* neuromuscular irritability; *Y,* yeast issues.

patient's Excel spreadsheet over the past 40 years of my practice. Doing so gave me a feel for the patient, similar to how chefs get a feel of the meal as it passes through their hands in the kitchen. I took a sample of 20,000 symptoms from the questionnaires of many patients, and from that body of data, I reconciled variations in my coding assignments that occurred over the years. Coding the implication of symptoms was facilitated by the use of a system in which the body system, function, and location are used as a basis for establishing the literal meaning of the words we use to name symptoms. Using symptom, function, and location from the conventional medical lexicon expanded to include designations made in the course of patients' narrative, the system scheme grew to include 50 systems, 50 functions, and hundreds of locations, the latter ranging from anatomic to geographic.[1] Table 137.3 provides three examples of NMI symptoms in which the English-language vernacular "uptight" gives a glimpse of a unifying feature that is not found in the commonalities of body system, function, or location.

From those normalized data, I was able to conclude the remarkably small number of implications to be found in a diverse population of patients of all ages and diagnoses. The small number of implications came from letting the data talk and in no way was a list that I had created at the beginning of this project except that I had, in the course of the project, created a mini-checklist for neuromuscular irritability as a teaching tool for patients to understand the functional medicine style of thinking when it comes to the clues to unmet needs for magnesium. Table 137.4 provides the magnesium checklist used for data acquisition with general medical patients.[2]

Table 137.5 shows Morgan's list of past NMI symptoms, and Table 137.6 shows his current symptoms.

As it happens, Morgan has an exceptionally large group of such symptoms. Clinicians may protest that the questionnaire and its harvest are overkill. Parents, on the other hand, benefit from having the details of a story that has so intensely occupied their time, emotions, and curiosity be heard and having sense made of it. The data on which we drive the decision to prescribe magnesium "to bowel tolerance" is soft. I should note that our colleague Derrick Lonsdale, MD, makes the point that unmet needs for vitamin B_1 have a symptom list that overlaps with this one, which reminds us that the data we are gathering and using to drive simple clinical decisions about interventions are essentially free of risk, with good odds for benefit, at low cost, in a setting where the stakes are very high. On the other hand, we have here a situation in which the only accurate way to assess magnesium status is a pair of 24-hour urine measurements with an intramuscular dose of magnesium in each buttock that could easily be wasted into wet pants, bed, or diapers. There is a good chance that all children on the autism spectrum and most individuals with chronic illness have unmet needs for magnesium. Why go to the trouble of asking all these questions if a clinical trial of magnesium to bowel tolerance may do the job? Respect! Respect for the sacred, respectful conversation. Respect for the data; the patient/parent who has harvested it with worry, attention, and love; and our own integrity—threatened as it is by the demands of complex patients and a tight appointment schedule.

TABLE 137.3 "Uptight"

	System	Function	Where
Constipation	Digestive	Decrease	Stool
Anxiety	Emotion	Abnormal	Fear
Calf cramps	Neuromuscular	Increase	Calf

TABLE 137.4 Magnesium Deficiency Symptoms by System

Skeletal Muscle

Muscle cramps, including backache, neck pain, tension headache, temporomandibular joint dysfunction
Muscle twitches
Muscle tension
Muscle soreness
Chest tightness or a peculiar "I can't seem to take a deep breath" or "I have to think about my breathing" that is often interpreted as hysterical. In children, this symptom is often seen as sighing.

Other Muscles

Constipation
Anal spasms—such as awaken people at night
Urinary spasm
Difficulty swallowing or "lump in throat," "globus hystericus"
Difficulty with adjusting to oncoming bright headlights because of spasm of the muscles that fine-tune pupillary diameter
Cold hands and feet due to vasospasm
Loud noise sensitivity due to abnormal tension on the stapedius muscle
Endometriosis due to "constipation" or reverse peristalsis of fallopian tubes
Menstrual cramps
Asthma/wheezing from constriction of bronchial muscles

Central Nervous System

Insomnia
Anxiety
Hyperactivity and restlessness, constant movement
Panic attacks
Agoraphobia
Irritability

Peripheral Nervous System

Numbness
Tingling
Other abnormal sensations, including "zips," "zaps," vibratory and other peculiar sensations

Cardiovascular

Mitral valve prolapse
Palpitations
Arrhythmias
Vasospastic angina
Hypertension

Other

Salt craving
Carbohydrate craving
Carbohydrate intolerance
Kidney stones

For four decades my parents and patients have filled out my questionnaire as a Word document, from which I move the symptoms checklist to Excel, where I tag the symptoms that guide decisions. I move it back to the patient's Word document, where the effort taken to record the data is rewarded in three ways:

- Patients who have previously had doctors ignore records are relieved to see them taken seriously.
- Patients understand that symptoms drive decisions in sometimes very specific ways.
- At a subsequent follow-up visit, patients are less likely to have simply forgotten the very symptoms that had driven treatment decisions.
- The idea and practice that the patient, not the disease, is the target of treatment are honored while crossing the solid bridge between the details of the narrative and a solution aimed at the individual.

Unmet needs for magnesium are rampant in our culture and displayed in all sorts of symptoms of being uptight—chronic stress; dietary sugars; and the agricultural use of nitrogen, phosphorus, and potassium fertilizers that lack the magnesium needed to meet the demands of animals and, needless to say, humans, such as patients stressed by chronic illness.

QUESTIONNAIRE INTERPRETATION

If a patient will bring the questionnaire input to a simple interface on an anonymous website where the data are examined and understood from the same perspective that I have described, then a simple report can be shared with the clinician who made the referral to the website. Done in this way, the process creates a shared responsibility in which the input helps awaken the patient to the value of the narrative and rewards the patient with simple information about steps to be taken in collaboration with the referring clinician. Instead of poring over a long questionnaire and writing up a plan based on its most conspicuous options, the clinician's job of interpreting the implications of the patient's symptoms is simplified by the tailored documentation of the part of the patient's plan that that is based on symptoms and leaves room for interpretation and explanation of laboratory results.

Such a website is pending. You will be able to help the website grow to be a collaborative endeavor in which users may offer pearls and the string that joins them in ways that reflect a practice of medicine in which not the disease but the patient is the target of treatment and the symptoms of the patient provide the most sensitive data that captures the patient's individuality.

NMI Guidance Example

NMI is an abbreviation for neuromuscular irritability.
Neuromuscular means nerves, brain, and/or muscles.
Irritability means an increase in function triggered at a low threshold.

Short Guidance Report

You (patient or parent) report the following symptoms of NMI, or you have been linked here through constipation and/or reference to magnesium.

(NMI symptoms in Tables 137.5 and 137.6.)

PROBLEM: Over the past centuries, people living in modern societies have suffered from changes in soil, food, and stress, giving rise to unmet needs for magnesium.

ANSWER: Supplemental magnesium is safe and convenient. Dietary change is difficult but necessary. Stress reduction requires taking its measure and tailoring to individual sensitivity.

OPTIONS

a. Laboratory testing is only of value if done in a way that is inconvenient but may be critical for some individuals; however, it is not well suited to children.
b. Avoidance of sugar
c. Supplementation with magnesium

EXAMPLES: A boy in his late teens goes away to college and starts to live on pizza, beer, and ice cream. Although a good student, he starts having severe anxiety to the point of panic attacks. He develops an irregular heartbeat called paroxysmal tachycardia. He is constipated, his sleep is poor, and he awakens with leg cramps. Over the winter

TABLE 137.5 Morgan's List of Past NMI Symptoms

Symptom	Mild	Moderate	Severe	Occasional	Frequent	Always
Falls or gets hurt when running, climbing	x			x		
Awakens screaming/crying		x			x	
Teeth grinding		x			x	
Jumps when pleased		x			x	
Whirls self like a top		x			x	
Shrieks		x			x	
Flaps hands		x			x	
Likes to spin things		x			x	
Visual stims		x			x	
Anguish		x			x

Anxious		x			x	
Holds bizarre posture		x			x	
Scripting		x			x	
Fearful of unusual events		x		x		

[a]Note that the symptom of a craving for salt gets a place in the list because it is a soft sign for unmet needs for magnesium, which is the first clinical takeaway from this group of symptoms.

holiday, his family doctor prescribes a tranquilizer. A second opinion from a doctor who is a neighbor and functional medicine practitioner suggests that he take magnesium citrate capsules 150 mg every evening and morning, increasing daily until he reaches bowel tolerance. Within a week, he reaches a daily dose of 4 to 6 capsules in the evening and 2 to 3 in the morning. His symptoms clear, and he agrees to modify his diet.

For further guidance on this subject, click here: Magnesium EXPANDED GUIDANCE.

Expanded Guidance Report

It tells us something that if we Google "magnesium deficiency", we do not come up with the name of even one "condition" or "disease."

Hypomagnesemia is mentioned, but that just means low blood magnesium.

My friend and colleague Leo Galland, MD, awakened my interest in 1980 after he had met Mildred Seelig, author of *Magnesium Deficiency in the Pathogenesis of Disease*.[3] It says a lot that a medical book would be reprinted in its original text 32 years later. A lot of things in medicine had changed, but not the basics of magnesium, including the indifference of most medical professionals while all sorts of drugs have come along to treat symptoms that would respond promptly to a supplement of magnesium.

Most people have little need for nutritional supplements if they consume a good diet. Vitamins A and D are exceptions, and magnesium is noteworthy for the prevalence of unmet needs for magnesium. There is, moreover, a wide range of effective magnesium doses. A few people have very large needs. They are "magnesium wasters," about whom I published "Magnesium Deficiency in Primary Care and Preventive Medicine: Symptom Profiles in Relation to Magnesium Loading Studies."[4] Let me briefly cover the laboratory test that helps discover such individuals for whom certain symptoms may be clues to their special needs.

The checklist in Table 137.4 helped me alert my patients' attention to the diverse symptoms that indicate an unmet need for magnesium. Such symptoms scatter in questionnaires and checklists of specialists who naturally group symptoms focused in their areas of interest. Here they are grouped to illustrate how the notion of "uptight" is expressed in different ways. Magnesium wasters are distinctive in having low blood pressure, fewer digestive symptoms, and fewer symptoms of inflammation, but more emotional symptoms.

Testing for Magnesium Status

The laboratory test that accurately measures a person's magnesium status is a 24-hour urinary loading test, which takes 2 days before and during which diet and supplements are unchanged. After the first 24 hours, when every drop of urine is collected, a second 24-hour collection is started after injecting 200 mg of elemental magnesium, as the sulfate. It is painful, and thus it is best to add a local anesthetic and give it slowly, deep in the upper outer buttocks, giving half of the 5-cc volume in each cheek (2 mL of 50% MgSO4 plus 0.5 mL of lidocaine). A second 24 hours' worth of urine is then collected, and calculations assess the percentage of the injected magnesium dose that was retained.

- Normal retention is up to 10%.
- Borderline retention is 10% to 20%.
- More than 20% retention is consistent with magnesium deficiency.
- Retention of 50% or more indicates marked deficiency.
- Wasters excrete 15% or more of the injected dose.

Now I tend to use this test only when symptoms suggest that a person may be a magnesium waster or if supplementing magnesium to a dose that is just short of producing frequent or loose bowel movements—what I call bowel tolerance—does not alleviate the symptoms that suggested unmet needs for magnesium.

Beyond that consideration, the magnesium story is quite simple: The benefit is high, the risk is zero, the odds are good, the cost is minimal, and the stakes are quite high given the importance of magnesium in more than 300 places in the body's chemistry.

NMI symptoms predict a positive response to meeting an unmet need for magnesium. Most, but not all, people with unmet needs for magnesium have at least a few of these symptoms, which overlap with those that brought the patient to this insight. Some of the symptoms have a higher value than others in that prediction, and the more symptoms a patient has, the greater becomes the chance of relief with magnesium supplementation.

How Do We Develop Unmet Needs for Magnesium?

Imagine your five-hundredth great-great-great-grandmother. She was a hunter-gatherer heading down to a river to fill her calabash with water for her migrating family. On the way, she encounters a beast and flees, with the beast in pursuit. Good fortune and strong legs bring her to a tree she can climb. There, she hangs on for dear life until the beast finally gets bored and leaves. Descending from the tree, she empties her bladder before heading back to the river. Her urine is rich in magnesium. It had shifted from inside her muscle cells into the bloodstream and into her bladder during her previous running, climbing, and hanging on. That shift was an essential component of her stress response.

Grandma returns to her campsite and replenishes her magnesium losses with a good meal of vegetation and a side order of beast. In other words, stress of the kind Grandma experienced is associated with a natural loss of magnesium, which must then be replenished by eating. Encounters with beasts in Grandma's time were infrequent. The muscular demands for magnesium's shifts for daily activities were modest. Her diet was adequate and free of sugar.

Compare her situation with those of us who live the modern way:

1. Since the 1950s, the soil of the major agricultural areas where our food is grown has been fertilized with nitrogen, potassium, and phosphorus but not with magnesium.
2. The magnesium content of the harvests has fallen, affecting consumers while not impairing the hardiness of the plants.
3. Since the 1950s, the diet of those living in modern industrialized countries has become sugarier and starchier.
4. Finally, the stresses in modern life are more like having a constant beastly presence than rare encounters with beastly attacks.

The combined effects of low magnesium intake and high stress-related magnesium losses have caused a failure to meet the needs of a very substantial proportion of the population.

Uptight

Our language aptly summarizes the way our bodies respond to danger. The theme of the checklist's NMI selections is captured by the word *uptight*: It applies equally to muscles and emotions. That response produces a tendency toward magnesium loss that is not replenished when the diet is low in magnesium. The resulting nervous and/or muscular contraction tension is associated with further magnesium shifts and losses. A vicious cycle, right? The more you become deficient in magnesium, the more you tend toward nervousness and/or muscular tension, which, in turn, tends to cause magnesium losses. Magnesium wasters simply cannot hang on to their magnesium and require especially large doses of magnesium given intravenously to correct their problem.

The Patient Is the Best Laboratory

For research, no test substitutes for magnesium-loading testing. The studies that I published revealing the distinctive symptom profile of magnesium wasters could not have been done without many magnesium-loading tests. On the other hand, the symptoms of magnesium deficit are so common and easy to spot that a trial of magnesium supplementation turns out to be a practical first—and often final—step in documenting magnesium problems. Given orally, magnesium is safe, except for individuals who have poor kidney function. The symptom of a magnesium overdose is diarrhea, so with the escalation of magnesium supplementation, loose bowel movements will reliably indicate an excess well before any other mischief could be produced. Taking magnesium "to bowel tolerance" and observing the effect on symptoms of neuromuscular irritability is the best test for unmet needs for magnesium.

To Bowel Tolerance

To replenish magnesium, start with a teaspoon of CALM—in water—magnesium or one capsule of 150 mg of magnesium citrate in the evening. These doses would be safe for children and adults, but for children who do not swallow capsules and for toddlers, CALM alone would do just fine. A daily increase in dosage by adding a teaspoon of CALM and 1 capsule of magnesium citrate (in a child or adult) will, in a matter of a week or two, produce more frequent and loose bowel movements. The idea is to increase up to the point short of risking a bowel accident. For an adult, this is not rocket science. For children and those with impaired sensory function, this trial requires precision and vigilance to avoid the humiliation of a bowel accident. The dose of magnesium that reliably results in two easy bowel movements daily is valuable knowledge. Knowing the limit of the magnesium dose will be useful if constipation is provoked by interventions, such as activated charcoal and antifungal medication, described in Section 4 and presented in detail in this chapter.

The Pebble in Your Shoe

Establishing a dose of magnesium at bowel tolerance first provides a way of dealing with constipation if it is already a problem. Then it gives a baseline for dealing with constipation should it arise. Most of all, it lets us see improvement in NMI symptoms and allows us to expect the alleviation of other, less noticeable problems that are solved by meeting magnesium needs. Magnesium is a cofactor in dozens of steps in every aspect of body chemistry. Many of these steps are relatively silent compared with those related to tension in the nerves and muscles. Keep in mind therefore that as important as magnesium is in correcting "uptight" symptoms, those symptoms are not the only target of magnesium supplementation. Removing a pebble from your shoe is not just for your foot but also for the journey.

Hirschsprung's Disease

Hirschsprung's disease is a good example of worst-case scenario thinking that must find its proper place in the minds of doctors and parents. Caused by an inborn lack of certain nerve cells in the lower bowel, the resulting intractable constipation calls for management that may overlap with treatments for "ordinary constipation" but demands other specific approaches. These approaches include the need for location and biopsy of the suspected gap in nerve connections. Surgery may also be required. Mild forms of Hirschsprung's may go undetected for years and complicate the lives of individuals whose constipation does not yield to the measures discussed here.

NMI EXPANDED GUIDANCE SUMMARY

1. The target of treatment in chronic illness is the individual, not the disease.
2. Treatment involves addressing unmet special needs to receive, avoid, or be rid of things, which—if addressed—will favor nature's buoyant impulse toward healing.
3. Before a particular intervention becomes a treatment, it is a test to see if it produces a benefit for the individual in question.
4. In many ways, such a test can be the best (or even the exclusive) way of finding what will work for a given individual.
5. Magnesium is a good example of a commonly effective therapeutic agent for children and adults with every sort of chronic illness. When it relieves symptoms of neuromuscular irritability, including constipation, it will likely benefit many areas of biochemistry where it is an important helper.
6. A person may have other symptoms of neuromuscular irritability but no constipation. A trial of magnesium to bowel tolerance is still a good idea because it is the best means of judging the benefits of magnesium and preparing for the constipation that may come with a Herx reaction.

Mycotoxin Exposure: Assessment and Treatment

Matt Pratt-Hyatt, PhD

OUTLINE

INTRODUCTION

Over the past several decades, there has been increased research into the role that mycotoxins from mold have in human health. Mycotoxins bind the ribosome, resulting in an inhibition of protein synthesis. They also inhibit the growth of rapidly proliferating cells, such as bone marrow and the gastrointestinal epithelium.[1] Other organs affected include eyes, ears, nasal cavities, nails, skin, respiratory tracts, liver, and kidneys.[2,3] The most common routes of exposure to mycotoxins are ingestion through contaminated food, inhalation of mycotoxins or fungi spores, or skin contact.[4]

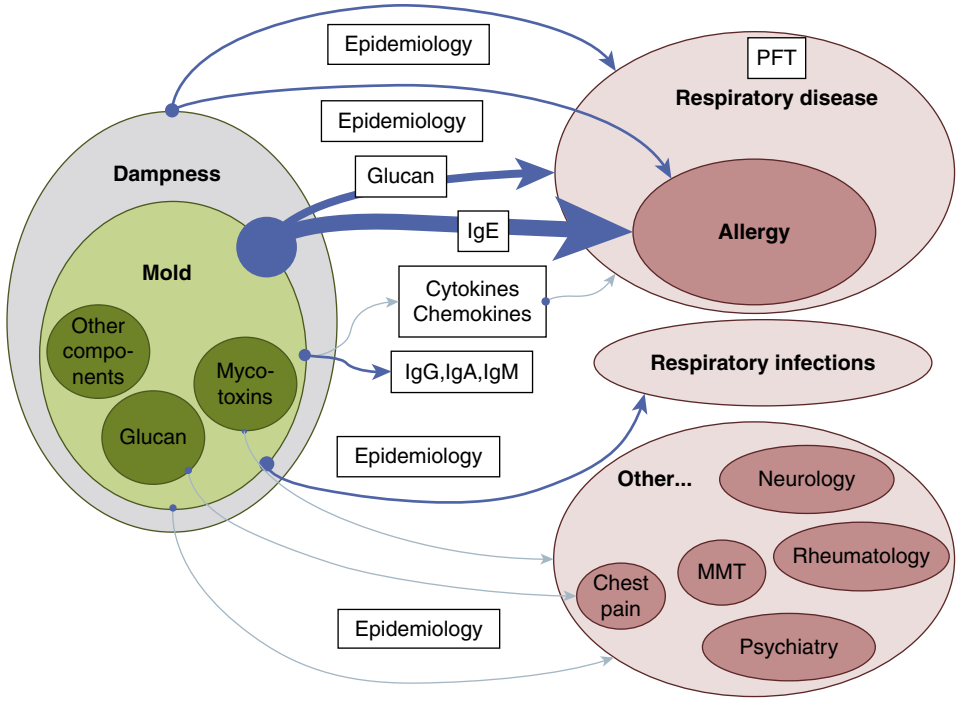
Common symptoms of mycotoxin exposure include cough, irritation of the eyes and skin, joint pain, headaches, and fatigue.[2,5,6] A particularly good example is how research has shown that mold and damp-building exposure are major factors in the asthma epidemic. Studies have shown that dampness or mold in houses causes 21% of asthma in the United States as well as a 30% to 50% increase in asthma and asthma-related health problems.[7] Mold toxicity should be considered in all patients with any chronic respiratory condition, especially those of adult onset (Fig. 138.1). Symptoms such as dyspnea, wheeze, cough, respiratory infections, bronchitis, allergic rhinitis, eczema, vocal cord dysfunction, and upper respiratory tract symptoms should also be included. Once individuals have become sensitized, they become much more reactive to even low to modest exposure. In addition, exposure to mold and dampness increases the risk of allergy to other allergens, such as house dust mites and pollen, and causes epigenetic modulation that upregulates many inflammatory genes.[8]

Mycotoxins are low-molecular-weight molecules and secondary metabolites produced by fungi that evoke a toxic response even in low concentrations.[9,10] There are more than 400 known mycotoxins, of which several are known to affect human health. The molecular masses of these mycotoxins are mostly between 200 and 800 kDa in size.[11] Mycotoxins are also very heat-resistant, being able to withstand temperatures up to 160ºC.[12]

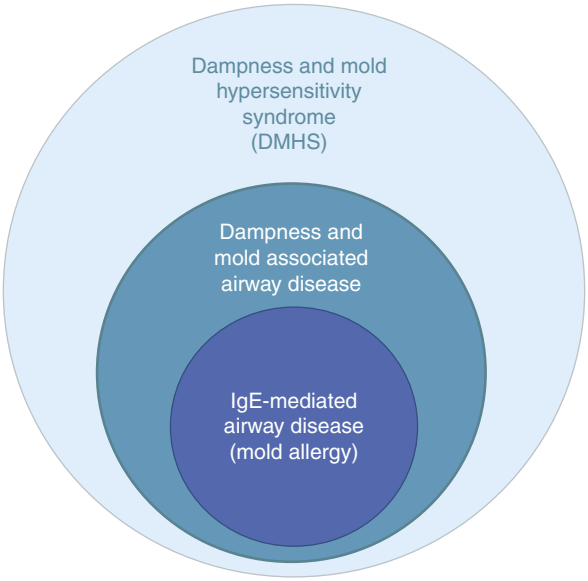
Most mycotoxins are produced by filamentous fungi, which are ubiquitous because of their ability to grow on many different materials and under many different conditions.[13] These fungi use dead matter for energy and are able to produce spores in a variety of different conditions.[14] Many different mycotoxins are produced from species of the genera *Aspergillus, Fusarium, Penicillium,* and *Stachybotrys.* It is common for one species of fungi to produce different mycotoxins, as well as one mycotoxin to be produced by multiple species of fungi (Table 138.1). Mycotoxins can induce disease through several different pathways, which include immunosuppression, cytotoxicity, and DNA damage. Interestingly, many of the clinical effects of mold exposure are very similar to those found with volatile organic compound (VOC) exposure.

Through their mycotoxin metabolites, pathogenic fungi can reduce the efficacy of the immune system. This is accomplished by suppressing multiple different components of the immune system. Mycotoxin metabolites can suppress T- and B-lymphocyte activity, inhibit immunoglobulin production, and reduce antibody production. Some species of fungi release mycotoxins that can interfere with which genes are activated. Some also release polysaccharides that can result in the induction of neutrophil apoptosis. All these processes result in the body's inability to fight off the fungi as well as other infections.[15–17]

Fungi can produce cytotoxicity in human cells through their metabolites, which causes reduced cellular viability.[18] Much of this toxicity in cells comes from the mycotoxins' ability to bind to the 60-S subunit of the ribosome and to the enzyme peptidyl transferase. These interactions inhibit cellular protein biosynthesis, which eventually results in cellular death.[19,20] However, some of these characteristics of mycotoxins are being used for some beneficial purposes. Some species of mycotoxins are being studied for their antitumor capabilities. Cell lines from colon cancer, breast cancer, lung cancer, and prostate cancer have been proven to be sensitive to these mycotoxins.[21]



A



B

Fig. 138.1 A and B, Estimates of evidence for a causal relationship between dampness/mold exposure and disease. The relationship between dampness and mold and respiratory disease is mainly clinical and epidemiological, and besides immunoglobulin E (IgE) as a biomarker of allergy, other biomarkers of exposure or specific to mold-induced disease are beginning to be recognized only now. This explains that visible mold or dampness is frequently assessed as an environmental factor, and in fact, correlation with clinical health effects is frequently higher than when specific exposure markers have been used in distinct settings. *PFT,* Pulmonary function testing; *MMT,* mixed-mold mycotoxicosis. (From Daschner A. An evolutionary-based framework for analyzing mold and dampness-associated symptoms in DMHS. *Front Immunol.* 2017;7:672. PubMed PMID: 28119688.)

Studies have shown that many different types of mycotoxins can be carcinogenic, which seems to stem from three possible factors. First is their ability to cause oxidative stress in cells, and second is their ability to cause DNA adducts.[22] Mycotoxins in cells cause reactive oxygen species (ROS) to increase. These ROS molecules lead to breaks in DNA molecules. However, a more common cause of DNA damage seems to be the mycotoxins' ability to covalently bind to DNA. Reports show that mycotoxins cause adducts on the N-7 position of guanine and the N-3 position of adenine. These adducts can interfere with DNA synthesis and can cause an incorrect substitution of a nucleotide or cause

TABLE 138.1 Mycotoxins Produced by Fungi

Species	Aflatoxin	Gliotoxin	Ochratoxin	Sterigmatocystin	Zearalenone	Roridin E	Verrucarin A	Enniatin B	Mycophenolic Acid	Citrinin
Acremonium sp.				Present						Present
Alternaria		Present

Scopulariopsis				Present						Present
Stachybotrys				Present		Present	Present			Present
Stachybotrys chartarum				Present						
Trichoderma viride		Present		Present						
Ulocaldium										
Verticillium				Present						Present

a deletion to occur.[23] The third possible cause of DNA damage from mycotoxins is inhibition of DNA topoisomerase I and II enzymes. These enzymes are required to untangle DNA during replication, and inhibition of these enzymes could lead to the accumulation of DNA breaks.[24]

MOLD SPECIES

Of the 400 known mycotoxins, there are 10 to 15 that have so far been linked to human disease. These are produced by about 350 different fungi species; however, some species are more prevalent than others.[25] Some of the most common mycotoxin-producing genera are *Aspergillus, Fusarium, Penicillium,* and *Stachybotrys.*[26]

Aspergillus

Aspergillus is the most prevalent mold genus in the environment. The two most common *Aspergillus* mycotoxins are aflatoxin and ochratoxin, and their main target is the liver.[27,28] *Aspergillus* species are commonly associated with indoor air problems.[29] The most common route of transmission for *Aspergillus* is inhalation.[30] Because *Aspergillus* spores are smaller than most other species, 2 to 10 µm, they can reach the lower airways. This can lead to fungal colonization, which results in prolonged mycotoxin exposure and allergic responses. This can lead to allergic fungal rhinosinusitis and asthma.[31]

These toxins have also been found in all major cereal crops, including peanuts, corn, cotton, millet, rice, sorghum, sunflower seeds, wheat, and a variety of spices. They are also found in eggs, milk, and meat from animals fed contaminated grains. This has caused billions of dollars in damage to crops and livestock.[32] There are multiple species of *Aspergillus* that can produce toxic metabolites (see Table 138.1). Some of the more common *Aspergillus* species that can induce diseases are *A. flavus, A. niger, A. fumigatus,* and *A. versicolor.*[33]

A. flavus is one of the more common fungal contaminants in agriculture. It has caused the loss of millions of dollars in crop damage and animal infection. The leading route of exposure to this species is the consumption of contaminated food, such as peanuts, milk, corn, rice, and coffee.[34,35] *A. flavus* infections can lead to cutaneous aspergillosis, keratitis, granulomatous sinusitis, and osteomyelitis.[36]

A. niger is one of the most common mold species because of its ability to grow on many different types of substances, such as food, soil, and indoor material. *A. niger* invades tissues that have been rendered susceptible by bacterial infections or physical injury. It can colonize the ear, nose, or throat, causing chronic infections. Patients who are immune compromised could develop pulmonary aspergillosis, which is characterized by chronic productive cough.[37]

A. fumigatus is the most common mold associated with pulmonary infections. *A. fumigatus* is also able to produce polypeptide allergen molecules that can cause asthma and rhinitis symptoms.[38] *A. fumigatus* mycotoxin products (see Table 138.1) cause immune suppression during hyphal growth in favorable conditions. Recent studies have linked these immune-compromising abilities to other opportunistic infections that occur in patients exposed to this mold.[39]

A. versicolor is commonly found in damp indoor environments and on food products.[40] This mold produces more than 20 allergens that can irritate the nose, eyes, and throat.[41] *A. versicolor* is one of the more invasive species of aspergillosis.[42] This fungus has also been reported to be a major cause of onychomycosis (a fungal infection of the nails).[43]

Fusarium

Fusarium fungi grow best in temperate climate conditions.[44] *Fusarium* is present in both indoor as well as outdoor environments.[45] It also grows worldwide on many different types of grains, including corn and wheat.[46] Most trichothecene mycotoxins are produced from *Fusarium* species. The fungi can infiltrate the body through breaks in the skin or through inhalation. One other source of exposure is ingestion through contaminated foods. *Fusarium* infections are more likely with individuals who are immune compromised. These infections can lead to pneumonia, thrombophlebitis, and sinusitis.[47] Two of the most common species of *Fusarium* are *F. verticilliodes* and *F. solani.*

F. verticilliodes commonly contaminates grains, maize, and rice.[48] *F. verticilliodes* infections are more common in immune-compromised individuals than in healthy individuals. *F. verticilliodes* infections have also been reported in patients who have undergone a major organ transplant. Infections with this fungus have been reported to cause neutropenia, keratomycosis, necrotic lesions on the skin, and fever.[49]

F. solani is one of the most virulent of all of the *Fusarium* species.[50] In patients who are immune compromised, *F. solani* can cause arthritis, cutaneous infections, subcutaneous infections, and sinusitis.[51] Some strains of *F. solani* have been reported to produce a biofilm on soft contact lenses. *F. solani* is also resistant to many antifungal agents but has been shown to be sensitive to amphotericin B and natamycin.

Penicillium

Penicillium is a blue-green mold found on fruits, vegetables, and indoor environments. Many different types of citrus fruits can become contaminated with *Penicillium,* but it can also contaminate seeds and grains. Factors leading to a contamination of *Penicillium* in the home, work, or school environment include inadequate heating and ventilation, water leaks, and low sunlight.[52] Indoor environments where *Penicillium* can be found include wallpaper, carpet, furniture, and fiberglass insulation. Exposure to *Penicillium* can lead to breathing difficulties such as wheezing, persistent cough, and asthma.[53] Besides the mycotoxins that are produced by *Penicillium,* there are several other allergens produced that affect human health. These include alkaline and vacuolar serine proteases, which are referred to as group 13 and group 18 allergens, respectively.[54]

Stachybotrys

Stachybotrys is a greenish-black mold. This mold can grow on materials with a high cellulose and low nitrogen content, such as gypsum board, paper, fiberboard, and ceiling tiles. The humidity requirements for *Stachybotrys* are higher than those for other fungi, around 93%, whereas other fungi grow at approximately 75%, and it often occurs in the presence of other fungi.[6,55] Toxicity caused by *Stachybotrys* is mostly through the toxins and other compounds produced and less so from particle penetration from the spores. *Stachybotrys* spores are between 10 and 60 µm, which is too large to reach the alveoli.[56] Toxin production is dependent on nutrient levels, pH, temperature, and moisture. *Stachybotrys* spores are produced when there is high moisture content, and they become airborne when they dry out and are disturbed or when they are attached to dust particles.[57] In addition to mycotoxins, *Stachybotrys* produces nine phenylspirodrimanes, which inhibit complement activation; spirolactams and spriolactones, which are anticomplement components; cyclosporine, which is a potent immunosuppressor; as well as endothelin receptors antagonists.[58–60]

COMMON MYCOTOXINS

As previously mentioned, there are more than 400 known mycotoxins naturally produced by fungi in nature.[12] These toxins have been observed since the Middle Ages and were recognized to come from fungi in the 17th century.[61] The most common mycotoxins that can cause diseases in humans are aflatoxin, ochratoxin, gliotoxin, sterigmatocystin, and citrinin. Mycotoxins are produced by multiple species

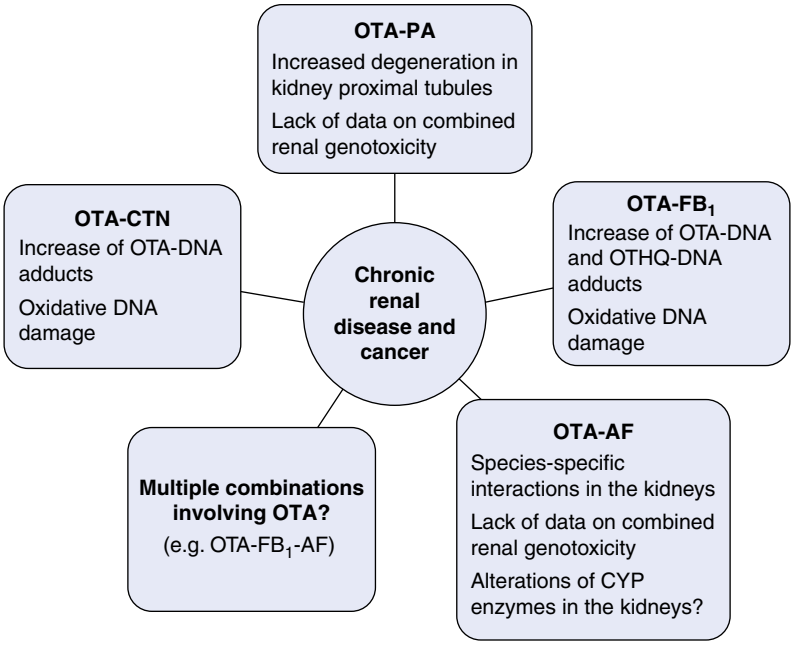

Fig. 138.2 Interactions of mycotoxin combinations involving ochratoxin A (OTA) and their possible role in the development of chronic renal diseases and cancer after chronic exposure to subtoxic concentrations of mycotoxin mixtures. (From Klaric MS, Rasic D, Peraica M. Deleterious effects of mycotoxin combinations involving ochratoxin A. *Toxins (Basel).* 2013;5[11]:196587. PubMed PMID: 24189375.)

of fungi depending on environmental conditions (see Table 138.1). The following summary discusses some of the more common mycotoxins and what organs they target.

Aflatoxin

Aflatoxin is produced by the fungi *Aspergillus* and is one of the most potent hepatocarcinogenic substances known.[62] The production of aflatoxin is dependent on the fungi's access to O_2, CO_2, zinc, and copper.[63] There are four major aflatoxins, called B_1, B_2, G_1, and G_2, of which B_1 is the most toxic.[64] Aflatoxin has been shown to be both toxic and carcinogenic to the human population, and the diseases caused by aflatoxin exposure are labeled aflatoxicoses. The liver is the primary target for aflatoxin. Aflatoxin is activated in the liver by the cytochrome P450s and is then capable of forming adducts to both DNA and proteins.[65] These DNA adducts may result in the activation of oncogenes, inhibition of DNA synthesis, disruption of DNA replication, and improper cellular division, leading to polypoidal cells.[66]

Aflatoxin is removed through the glutathione S-transferase system. This system can conjugate activated aflatoxin with reduced glutathione. This leads to aflatoxin becoming more water soluble, which assists in its excretion. It is theorized that variations in levels of P450s, glutathione transferase, and transporters can account for the variation in the response patients have to aflatoxin exposure.[67]

Ochratoxin

Ochratoxin is produced by species of *Penicillium* and *Aspergillus.* There are three forms of ochratoxin; however, only the A form exerts hazardous effects on humans. Ochratoxin is a common mycotoxin associated with indoor air problems; however, it is also known to contaminate many different types of food, such as cereals, meat, coffee, fruits, wine, and beer.[68,69] Ochratoxin can be distributed to many different tissues throughout the body, but its main targets are the liver and kidney. Ochratoxin is both nephrotoxic and carcinogenic to the kidney (Fig. 138.2).[70] Two of the most important mechanisms involved in ochratoxin toxicity include competition with phenylalanine in the phenylalanyl-tRNA synthase-catalyzed reaction, inhibiting protein synthesis, and induction of oxidative stress by lipid peroxidation.[71,72] Ochratoxin also has immunosuppressive effects. Exposure leads to the inhibition of T-helper-cell function and inhibition of antibody synthesis.[73] Crucial immune organs have also been shown to decrease in size from exposure, such as the thymus, bursa of Fabricius (in birds), the spleen, and lymph nodes.[74] This can lead to the overgrowth of intestinal pathogens such as *Candida* or *Clostridia*.[75]

Gliotoxin

Gliotoxin is produced by species of the fungi *Aspergillus, Penicillium,* and *Alternaria.* Gliotoxin exposure can be the result of contaminated food as well as from water damage. Gliotoxin is secreted by newly established hyphae, and its role is to inhibit the immune system of the host. Gliotoxin suppresses the phagocytic defenses, which is done by interfering with PtdIns (3,4,5) P_3 production. This impairs the macrophages' abilities to recognize, take up, and destroy invading pathogens.[76,77] Another way that gliotoxin promotes immunosuppression is by interfering with the activation of transcription factors that are involved in T-cell activation.[16] Gliotoxin's effects can lead to infections of *Aspergillus,* known as aspergillosis, which typically reside in the pulmonary system, the ears, the eyes, or the nails.

METHODS OF ASSESSMENT

For the past two decades, one of the greatest difficulties involving patients who may have been exposed to mycotoxins was determining whether the patient was exposed. For many years, researchers have been measuring mycotoxins in crops as well as in animals. The agricultural market needed a quick and inexpensive method to determine whether food was contaminated with mycotoxins and if it was fit for consumption. These methods have been attempted to be transferred to the analysis of human exposure; however, there are two barriers that

have prevented an easy transition. The first barrier has been the small quantity of mycotoxin in human samples, often in the parts per trillion (ppt), which can also be labeled ng/L. The U.S. Food and Drug Administration (FDA) action level for aflatoxin in food is 20 ppb (20 μg/L), which is a factor 100 times higher than seen in human samples.[78,79] Sample ranges for many mycotoxins in humans are normally in the range of 60 to 2000 ng/L (.06–2 μg/L).[79] The second barrier for transferring methods used in agriculture to human samples is matrix effects (MEs). MEs are compounds in the sample matrix that are not related to the analyte being measured but can cause a result to be either higher or lower than the actual amount. These MEs can influence any type of test, and protocols must be performed to separate the analyte of interest from these interferences.[80] There are two types of testing used to ascertain whether a patient has been exposed to mycotoxins, enzyme-linked immunosorbent assay (ELISA) and liquid chromatography–mass spectrometry (LC-MS/MS).

ELISA

ELISA has been used for analytical testing since the early 1970s.[81] ELISA can use multiple types of samples, such as (but not limited to) saliva, serum, and urine. It is used to detect the presence of antibodies or antigens in a sample. This technique normally uses 96-well plates, which are analyzed by a spectrometer. Antibodies are produced that can have direct degrees of selectivity to an antigen. The selection of an antibody will determine the specificity for an ELISA test. Most ELISA tests for mycotoxin use the competitive direct ELISA model. There are several steps involved in this model:

1. The primary antibody, which is specific to the analyte that is being measured, is incubated with the sample. During this step, the analyte that is being tested binds with the primary antibody. Any free antibody that is not bound at this step will bind with the antigen that is bound to the wells in step 2.
2. The antibody–antigen complex produced in step 1 is added to 96-well plates. These plates are coated with the same antigen (analyte) being testing. Free antibody that was not bound in step 1 will bind to the antigen coated to the wells. More antigen in the patient sample will lead to less antibody being bound to the plates.
3. After incubation, the plates are washed, which removes the antibodies that have been complexed to the patient's antigens.
4. The next step is to incubate a secondary antibody, which binds to the primary antibody. This secondary antibody has some type of label or enzyme covalently bound, which will cause a color change in the well. There are now three layers bound to the plate. The first layer is the antigen that is bound to the plate, the second layer is the primary antibody, and the third layer is the secondary antibody.
5. The final step is that a substrate is added that interacts with the label bound to the secondary antibody. The plate is then read in a spectrometer, which then gives a readout on the concentration. The result is inverse to the concentration. The more the well changes color, the lower the amount of analyte the patient has in his or her sample.

The benefit of ELISA tests is that it does not take expensive equipment to run the test, which means that the test can be done for a lower cost. An additional benefit is that many different analytes can be measured if specific antibodies can be developed. There are also several drawbacks to ELISA testing. First, there are more opportunities for interferences to influence the results, causing results to be either higher or lower than what is truly in the sample. Second, it is harder to monitor multiple analytes because each analyte requires its own well. Third, the dynamic range for ELISA tests is inherently limited, which causes the test to be more qualitative and less quantitative. This prevents the practitioner from receiving truly quantitative results.

Liquid Chromatography-MS/MS

The introduction of LC-MS/MS has allowed the quantitative measure of many different chemicals. These measurements can be done on compounds either individually or simultaneously if the compounds have similar molecular characteristics. A mass spectrometer is a device that measures the molecular mass of compounds. Many different fields have used this technology, and two of the most common are drug testing and chemical exposure testing, which both need the sensitivity and selectiveness that LC-MS/MS provides.[82] Over the past 10 years, LC-MS/MS has become the gold standard for the measurement of mycotoxins.[83] There are three parts involved in preparation and analysis with LC-MS/MS: extraction of the samples before injection, separation on a column, and fragmentation in the mass spectrometric detector.

Proper sample preparation is a critical step for accurate measurement of most molecules using LC-MS/MS. There are three methods used by laboratory professionals to separate the mycotoxin analytes away from the contaminates that can interfere with the analysis. These methods include liquid-liquid extraction (LLE); solid-liquid extraction (SLE); salting-out liquid-liquid extraction (SALLE); the quick, easy, cheap, effective, rugged, and safe (QuEChERS) method; and the dispersive liquid-liquid micro-extraction method (DLLME). Each of these methods has different benefits; however, the goal of each is to separate the analytes of interest away from matrix interferences and to concentrate the sample.[83]

After the samples are prepped, they must be injected into the LC-MS/MS. The samples are then transported through a separation column by a combination of solvent and water. There are multiple solvents that a laboratory can use, and the ratio of solvent to aqueous can also vary between preparation techniques. Common solvents include acetonitrile, methanol, chloroform, hexane, and ethyl acetate. The columns, which are labeled ultra-performance liquid chromatography (UPLC) columns, can also vary between protocols. Most protocols use C18 reverse-phase columns, which consists of strands of 18 carbon molecules packed into a column, usually between 100 to 150 mm in length. However, there are many different varieties of columns, which vary in their dimensions as well as the packing material. These differences in packing material can alter how quickly the sample will transverse through the column and then enter the mass spectrometer.[84]

Once the analytes enter the mass spectrometer, they are processed in two stages. In the first stage, molecules are ionized by electrospray ionization (ESI).[85] The instrument determines the mass-to-charge (m/z) spectra of the parent ions, which yields the mass of the molecule being analyzed. These molecules are then fragmented in a process called collision-induced dissociation (CID). In CID, an energized molecule collides with a buffer gas, which causes the molecule's bonds to break into predictable patterns. These patterns can be interpreted like a molecular fingerprint.[86] When molecules are fragmented with LC-MS/MS, they give a repeatable pattern, which can be used to properly identify molecules (Fig. 138.3). With this ability to have great specificity in distinguishing between different molecules, mass spectrometry provides both laboratory professionals and health care practitioners great assurance that their data are correct.

TREATMENT

Avoidance and Remediation

Mycotoxin and fungi exposure can lead to many different symptoms, including fatigue, headaches, difficulty breathing, rashes, gastrointestinal issues, joint pain, decreased libido, and more. As previously mentioned, these mycotoxins can come from water-damaged buildings or

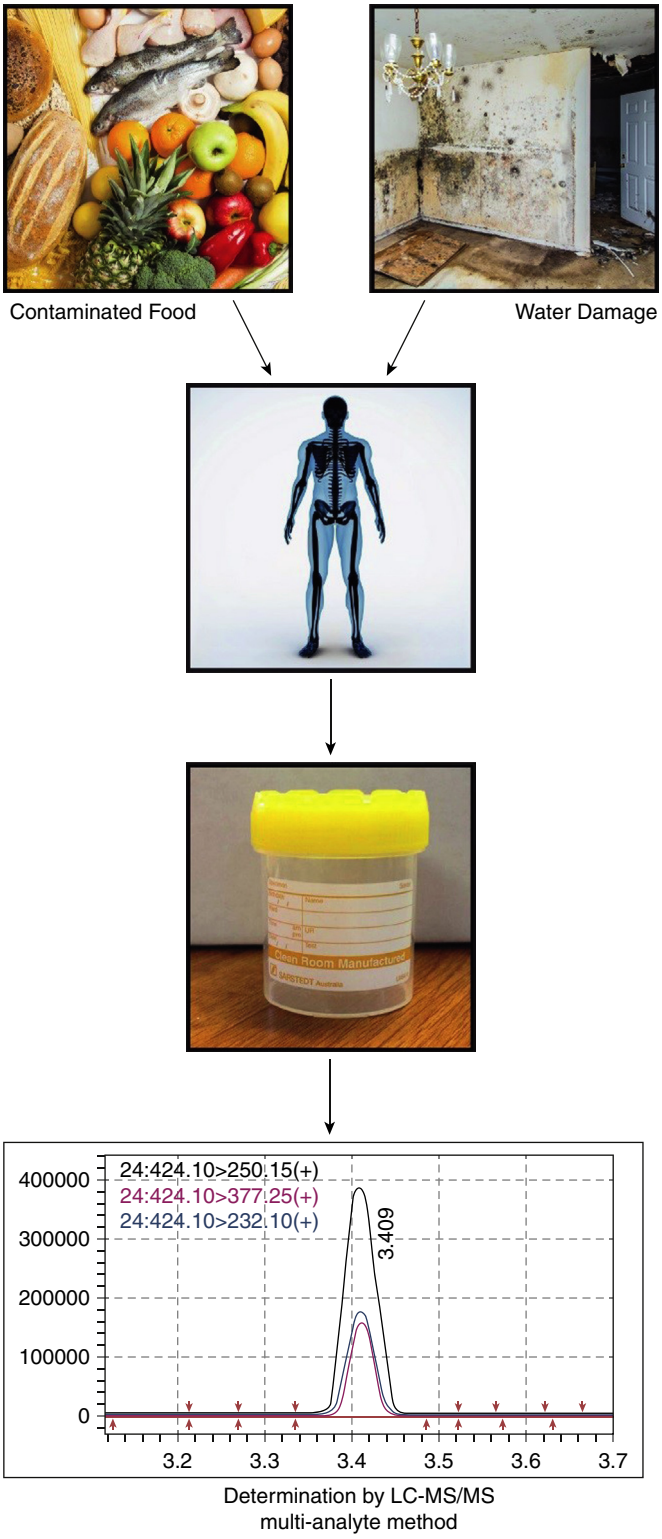

Fig. 138.3 When molecules are fragmented in liquid chromatography with mass spectrometry (LC-MS/MS), they give a repeatable pattern that can be used to properly identify molecules.

from food contamination. The most important element for treatment is the avoidance of further exposure to water-damaged environments as well as contaminated foods. Using a licensed company to inspect and remediate the area is recommended. Remediation of contaminated areas is difficult because heat, ultraviolet (UV) light, bleach, ammonia, and ozone do not completely remove mold from contaminated areas.[87] Air spore counts are frequently done; however, they are usually done over a short period of time and often result in false-negative results. Another problem is that killing the mold does not eliminate the risk because mycotoxins will remain in the environment.

Mycotoxin Excretion and Detoxification

Patients exposed to mycotoxins from mold may have two different conditions to treat. The first is the mycotoxin exposure, which can cause problems in many different tissues mentioned previously, and second is a possible infection and colonization of the fungi. To detoxify the mycotoxins, it is recommended to use a combination of glutathione, sauna, sequestering/binding agents, and antioxidants. Patients may also need to treat fungal infections and colonization.

Detoxification of many mycotoxins is dependent on the endogenous molecule glutathione (GSH). For example, deoxynivalenol (DON) is a mycotoxin produced by certain *Fusarium* species that frequently infect corn, wheat, oats, barley, and rice, which can be detoxified when glutathione-S-transferase forms a conjugant with GSH and DON (Fig. 138.4). GSH is a tripeptide, which is made of glycine, cysteine, and glutamate. Mycotoxin toxicity is intensified in patients with glutathione transferase mutations (GSTP1 and GSTM).[88] GSH can be introduced in several ways, including treating with GSH precursors such as N-acetyl cysteine and whey protein or with an oral liposomal, transdermal, intravenous, nebulized, or intranasal form of GSH. It is recommended to use GSH with sequestering agents because treatment with GSH has been shown to increase the mobilization of mycotoxins in the bloodstream.[89]

Sauna therapy has been used for centuries for the removal of toxins from the body. Some of the most commonly used saunas are dry-heat radiant saunas and far-infrared saunas. Both have been shown to be equally as good at removing toxins from the body. Infrared saunas have the advantage of inducing sweating at lower body temperatures. Sweating is important because many mycotoxins are lipophilic and can bind to lipid proteins, which will allow the mycotoxins to persist in the body for extended periods of time.[90] The use of sauna has two benefits pertaining to detoxification of mycotoxins. First, it breaks the bonds between mycotoxins and lipids in the body, increasing the circulation of mycotoxins; and second, it provides a second excretion route because several mycotoxins have been found in human sweat.[91] One study of 28 individuals who had been exposed to mycotoxins included a regimen of sauna, exercise, and physical therapy. In this study, all 28 individuals experienced significant improvement.[92]

Because both GSH treatment and sauna therapy increase the number of mycotoxins in the bloodstream, it is important to use sequestering agents in the treatment of mycotoxins. Many of these agents have shown efficacy in lowering mycotoxin levels. The most common sequestering agents used are activated charcoal, cholestyramine, clay, and chlorophyll. Activated charcoal has been used for about two decades in the treatment of mycotoxins. Multiple studies have validated the use of activated charcoal because of its high affinity for many different types of mycotoxins.[93–95] Cholestyramine (CSM) is an anion exchange resin that works as a bile-acid–sequestering agent. Multiple studies have demonstrated that CSM treatment leads to a reduction of ochratoxin levels in the plasma and urine and increases the fecal excretion. CSM has also been shown to be safely tolerated in children.[96,97]

Antioxidants

One additional component of treatment that is necessary is the addition of antioxidant support. Mycotoxins exposure induces oxidative stress and cell as cellular DNA damage; however, antioxidants have been shown to decrease these effects. Patients treated with vitamins A,

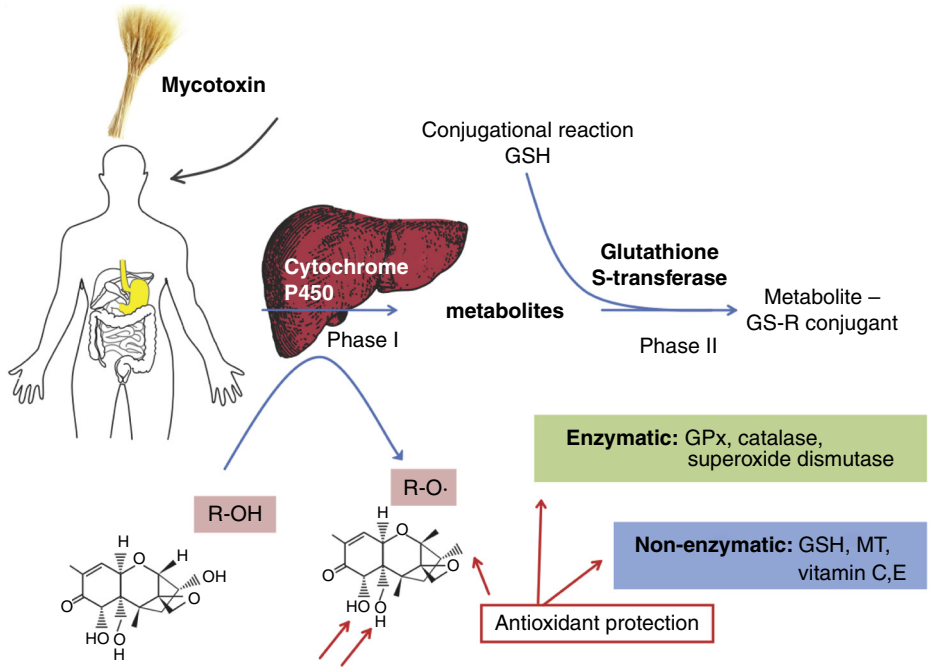

Fig. 138.4 Scheme of the possible manner of deoxynivalenol detoxification. The first—and perhaps the most important—pathway used for the detoxifying of deoxynivalenol (DON) is cytochrome P450, which serves to catalyze the oxidation of organic substances. This pathway, however, can cause free hydroxyl groups of DON to be cleaved, producing DON-radical, which can be more dangerous. The DON-radical can be scavenged by enzymatic (glutathione peroxidase [GPx], catalase, superoxide dismutase) or nonenzymatic (reduced glutathione [GSH], metallothionein [MT], and vitamins) processes. Nevertheless, cytochrome P450 can be followed by Phase II, in which glutathione-S-transferase can form a conjugant with GSH and DON, which results in detoxification of the xenobiotic. (From Sobrova P, Adam V, Vasatkova A, Beklova M, Zeman L, Kizek R. Deoxynivalenol and its toxicity. *Interdisc. Toxicol.* 2010;3[3]:94–99. PubMed PMID: 21217881.)

C, and E were shown to have better outcomes.[98] Another antioxidant that has been shown to cause significant hepatoprotective activity is curcumin. In a rat study, rats that were exposed to aflatoxin B1 and treated with curcumin had significantly lower serum enzyme markers and higher levels of reduced glutathione, catalase, and glutathione peroxidase.[99]

Fungal Treatment

Patients who have high levels of mycotoxins in their bodies may also be suffering from fungal infections and colonization. This is usually caused by direct exposure to elevated levels of mold spores. Fungal infections can occur in many different parts of the body. The most common areas of infection are the sinus cavities, lungs, and intestine. One Mayo Clinic study found fungal growth in 96% of patients with chronic sinusitis. The types of mold found included *Aspergillus, Penicillium, Alternaria, Cladosporium, Fusarium,* and *Cryptococcus.* All of these molds are known to produce mycotoxins and cause significant diseases.[100,101] One study demonstrated that antifungal drug therapies were useful in combating microbial pathogens detected by gas chromatography–mass spectrometry.[102] Another recent study compared organic acid results from patients who had positive results on an LC-MS/MS mycotoxin with control subjects. This study demonstrated that certain markers are more elevated in patients who have been exposed to mycotoxins.[103] The two categories of markers that were most pronounced were fungal markers and mitochondrial markers (Fig. 138.5). The two fungal markers that were significant were 5-hydroxymethyl-2-furioc and Furan-2,5-dicarboxylic, which are both fungal metabolites.[104,105] These data indicate that certain organic acid tests that measure these markers may be helpful in diagnosing fungal infections.

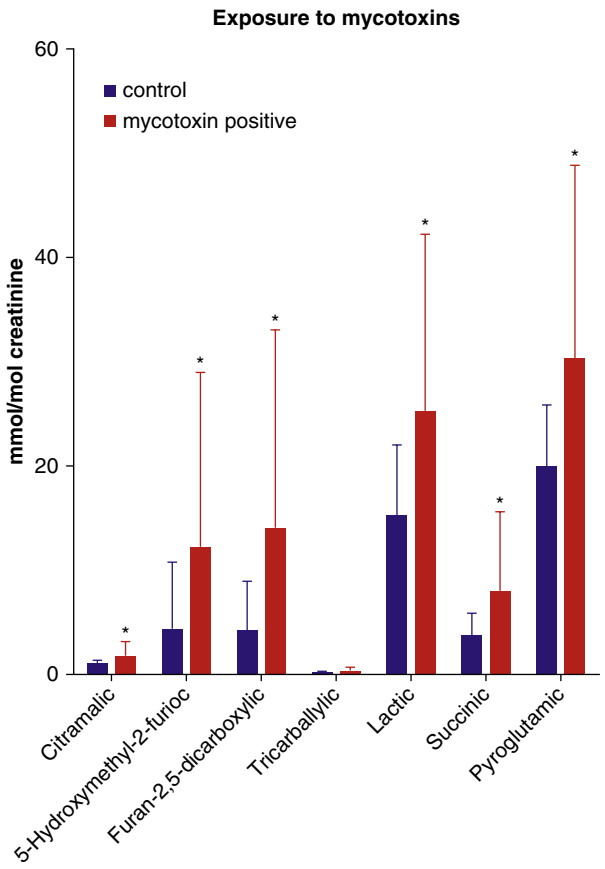

Fig. 138.5 Exposure to mycotoxins.

Treatment for fungal infections may involve several steps. The first step should be the avoidance of elevated spore counts and particulates through proper remediation and air filters. Second, antifungal medications have been shown to be efficacious. Multiple studies have used amphotericin B for the treatment of fungal infections.[106–108] Other antifungals that have been used include ketoconazole, fluconazole, and itraconazole. For intestinal fungal infections, nystatin or liposomal nystatin may be a good alternative.[109,110]

CONCLUSION

Mycotoxin and fungal exposure can lead to many chronic illnesses, including fatigue, headaches, rashes, pulmonary infections, and even cancer. Mycotoxin exposure may also lead to many other coinfections because of the mycotoxins' abilities to impair immune system function. Because the concentrations of mycotoxin metabolites in human patients are quite low, testing has moved away from ELISA to the more sophisticated and sensitive LC-MS/MS technology. Treatment plans for patients exposed to mycotoxins that have been the most efficacious have been multifactorial, including binders, sauna, glutathione, antioxidants, and sometimes antifungal therapies. Treatment plans can take anywhere from a few months to a year to have sufficient removal of the toxins. However, most patients show significant improvements after removal of the mycotoxins.

Sports Nutrition

Ralph Esposito, ND, LAc, Jade Teta, ND, and *Keoni Teta, ND*

OUTLINE

Becoming leaner, faster, and stronger, and performing better for longer, all while staying healthy, is the hope of every athlete from the weekend warrior to the elite professional. Sports nutrition is about fueling and enhancing performance, recovering from stress, improving skills quickly, and maintaining optimal body composition for the sport. In this chapter, we will cover the pertinent issues involved in sports nutrition, including supplementation for performance, fitness, muscle maintenance, weight loss, and fat loss.

NUTRITION AND PERFORMANCE

Performance Nutrition and Fat Loss

Before we begin the discussion of sports nutrition, it is useful to cover the topic of body composition. Participating and excelling in sports has much to do with achieving and maintaining an ideal body composition. Athletes seek to optimize the correct ratio of muscle tissue to fat weight that allows the best performance advantage in their sport. More times than not, simply participating in the sport improves body composition. However, when it does not, athletes may, at times, seek to increase muscle mass or decrease their fat weight, or even their overall weight. In addition, the average recreational sport enthusiast, who is not engaged in the competitive side of athletics, will often adopt the eating habits of the elite athletes in the sport they participate in. This practice can be a point of confusion and can lead to undesirable effects.

The "glycogen paradigm" is a way of thinking about sports performance that seeks to maximize muscle sugar storage. Some sports nutritionists believe this effort to enhance muscle sugar storage is the best way to increase training intensity, accelerate recovery, and improve performance. This glycogen dogma has resulted in confusion for athletes and exercise enthusiasts regarding optimal exercise for improving body composition. Health practitioners have known for some time that maximizing glycogen storage increases the performance of endurance athletes. In a 1991 study, Wagenmakers et al.[1] showed this effect conclusively. However, this study also showed a direct negative association between glycogen storage and fat burning. Other studies have shown that exercise done in a glycogen-depleted state may have benefits for increasing fat loss.[2–4]

This information has consequences for athletes and weekend warriors. At times, fat loss is the key aim of an athlete. When this fat loss is the goal, it may be important to tweak the glycogen-centered philosophy of maximizing performance to an approach that instead focuses on fat loss. Health practitioners working with athletes and the general population would be wise to remember the positive association of glycogen with performance and the negative association with fat loss.

Ketogenic Diet and Athletic Performance

Currently, low-carb diets are the latest trendy diets in the weight loss circles. The one that appears to have the most evidence supporting its use for fat loss as well as some disease states is the Ketogenic diet. This diet is best categorized as a high-fat, moderate-protein, and very low-carb meal plan, resulting in significant increase in blood ketone levels, sometimes upwards of 4 mmol/L[5]. Some athletes have implemented the diet to help with athletic performance and weight loss. Although some evidence has been found that the Ketogenic diet can induce

favorable changes in body composition as well as blood lipid/lipoprotein and glucose levels,[6] there is mixed support for its use in improving athletic performance.

Daily carbohydrate intake, and to some extent the protein intake, have to be monitored closely so that the body can keto-adapt, typically requiring carbohydrate intake to less than 50 grams daily. By keto-adapting, ketones become the body's main fuel source over glucose. Once the body keto-adapts or goes into nutritional ketosis, it is forced to start burning fat from the diet and/or from the fat stored in the body via beta-oxidation. High protein intake may make it difficult to put the body into nutritional ketosis, which is due to the gluconeogenic effect of excess protein but also due to the increased supply of oxaloacetate (OAA) from dietary protein, where OAA is the key limiting substrate for the Krebs cycle. Conversely, insufficient protein while in ketosis may affect long-term athletic performance. Furthermore, a keto diet can easily become hypercaloric given the high caloric density of high-fat, low-carbohydrate foods, thus affecting caloric balance and weight loss. This balancing act of hitting the right macronutrient ratio needs to be individualized and carefully monitored; otherwise, it may mean the difference between weight loss and improved performance or fat gain and fatigue.

The paucity of studies on the ketogenic diet in terms of ergogenic effects seem to have mixed results, which may explain the limited research. However, some of the research on ketogenic diet and improving athletic performance is intriguing. From a biochemical standpoint, it seems to make sense, at least for endurance athletes, that a more efficient fuel source would be fat instead of carbohydrates. For years, the thought has been that carbohydrate loading for endurance athletes enhances performance. Indeed, some studies support this approach.[7] However, some of the research on the ketogenic diet contradicts this notion. Thus far, studies of competitive athletes seem to show that this diet does not adversely affect aerobic endurance[8,9] and explosive strength[10] and may help with body composition.[11–13] However, as yet, there is no consensus on their efficacy in improving performance, and some studies show negative effects of very low-carb diets in athletes.[14]

Intermittent Fasting

Another intriguing trend that is becoming more prevalent for losing weight, improving health, and enhancing athletic performance among both athletes and the general public is intermittent fasting (IF). Some fitness enthusiasts think IF is a useful tool for losing excess fat weight while simultaneously helping preserve lean body mass.[15,16] Short-duration IF of 8 to 48 hours enhances fat burning without causing the rebound weight-gain effects of long-term energy restriction (e.g., the "eat less, exercise more" dogma). Because IF is voluntary as opposed to involuntary fasting (i.e., as in famines, starvation, and long-term dieting), the stress of short-term fasting seems to have significant benefit for the athlete and average person who needs to lose excess weight, the main one being improved compliance. Also, IF and the ketogenic diet seem to potentiate one another in regard to ease of implementation and keto-adapting.[17]

IF is one way for the average person to lower elevated insulin levels quickly, thus enabling fat burning.[18,19] The less insulin in the body, the better one is able to burn fat. Just adding more time without eating between meals over time will help improve insulin sensitivity. Also, high insulin levels tend to cause the kidneys to retain sodium, and thus result in water retention. Becoming more insulin sensitive helps the body shed excess water, which is one of the first signs that a person is less resistant to insulin and that fat burning is beginning to happen.

There are many myths about IF that are not borne out in the research, because many of the studies are done on complete fasting (some with individuals who were even foregoing water) and long-term caloric restriction. IF is very different physiologically from starvation or long-term energy deficient states. Some of the more common misconceptions are the following:

- IF causes muscle loss.
- IF causes fatigue, irritability, and low energy.
- IF causes athletic performance to suffer.

Although it may be true that fasting more than 24 hours can cause athletic performance to be compromised in some individuals, and much longer fasts (longer than 72 hours) can cause muscle loss and poor mood, IF for less than 24 hours typically will not have such results and may even improve performance, depending on the sport. In addition, the notion that short-term fasting causes muscle loss or fat gain, or low energy, poor moods, and compromised focus simply is, as of yet, unfounded. In fact, the opposite may be true.[20]

From an ancient ancestral perspective, our species endured numerous periods of feast and famine. If they had not adapted to that forced intermittent fasting, our species, as we know it, would not have survived. Those experiences primed our ancient ancestors and us to preserve our muscle mass and brain function during times of food scarcity so that we would have the energy level and focus to find food. This process occurs because the body has an alternative fuel source like ketones, which result from burning fat. Keto-adaptation (nutritional ketosis) helps preserve muscle mass, energy levels, and brain function so that food can be pursued and found.[21] If the famine continues too long, then starvation ketosis sets in, and muscle mass, energy levels, and eventually focus suffer.

The benefits of IF over conventional weight loss recommendations are that it seems to increase compliance,[22] improve health,[23] and possibly improve performance[24] and mental focus.[25] Much more study is needed, but thus far, IF seems to have many health benefits over long-term energy restriction for fat loss and may improve athletes' performance if done intermittently for short periods of time while ensuring the unique needs of the athlete are met.

Diet Concerns for Athletes

Nutrition for exercise performance involves fueling the body for performance. This process requires optimal energy resources to make up for caloric expenditure during exercise. Athletic activities can use significant resources. High-intensity daily exercise can burn from 600 to 1200 calories/day.[26–28] Elite athletes, such as professional cyclists, can burn as many as 12,000 calories/day, necessitating a large compensatory calorie intake. Caloric needs this high can be extremely difficult to obtain through "real" food alone.[26–31] This difficulty makes supplementation of functional foods and supplements necessary for athletes undergoing heavy training.

Health care providers advising athletes on nutrition must take many factors into account. In addition to the caloric issues just described, there are several other issues. Many athletes undergoing the intense stress of training can experience loss of appetite, especially after intense exercise.[32] Athletes are often also under the constraints of tight schedules of competition and travel requirements, which can prevent or interrupt scheduled meals. Given the already tight training schedules, athletes can quickly become overwhelmed by food considerations. Another potential problem may be lack of variety in the diet, which can lead to lack of enjoyment in eating and loss of appetite.

To address these issues, athletes engaged in heavy training should work to ensure muscle is not lost and weight is maintained, which means eating calorie-dense meals and snacks that are convenient for an athlete's lifestyle. Although real and whole foods should be emphasized, the use of protein bars, meal-replacement shakes, electrolyte beverages, and nutritional vitamin and mineral supplements will often be needed. Ideally, athletes involved in intense training should eat

between four and six meals per day and should eat in consistently timed intervals. Meal and snack timing around training is also an important consideration to replenish energy and aid recovery.[32] Athletes should understand that without calorie balance, many supportive training aids will not provide much advantage. Maintaining caloric needs is the foundation on which all other ergogenic aids should be built.

Macronutrient Ratios

In addition to the caloric considerations of athletes, balancing the protein, fat, and carbohydrate ratio is also important. Recreationally active individuals are usually advised to consume from 45% to 55% carbohydrates, 10% to 15% protein, and 25% to 35% fat.[26–28] The macronutrient needs of athletes can far exceed these numbers. Carbohydrate requirements for athletes can increase up to 10% to replenish and maximize liver and muscle glycogen storage.[27,28] These carbohydrates should come from low-glycemic-index sources that do not cause rapid fluctuations in blood glucose. Because higher levels of complex, low-glycemic carbohydrates can be hard to consume, fruit juices, energy bars, and other convenience foods may be considered.

Research related to carbohydrate intake in athletes shows that athletes may reach what is called a "carbohydrate tipping point."[27] This point is a level of carbohydrate beyond which there ceases to be a performance advantage. Research suggests the body can burn 1 to 1.1 g of carbohydrate per minute, amounting to roughly 60 g of carbohydrate per hour of exercise.[27] Harger-Domitrovich et al.[33] showed approximately 50 g of carbohydrate for a 165-lb individual was the optimal intake of carbohydrates for athletes. This intake amounts to 0.27 g of carbohydrate needed per pound of body weight each hour during exercise.

It is also interesting to note that not all carbohydrates are created equal. Research suggests that sugars composed mainly of glucose (maltose, maltodextrin, and other polysaccharides) are burned at a higher rate in comparison with nonglucose sugar (fructose, galactose, etc.). The combination of these sugars seems to be most advantageous.[27] Evaluating carbohydrate sources on the relative ratios of these sugars may be wise. The glucose/fructose ratio of close to 1:1 seems optimal.

Protein

Protein is an essential nutrient for all humans but especially so for athletes. Recent research on protein intake has shown that athletes require two times or more of the reference daily intake.[27,34–39] It is now recommended that athletes involved in very high-volume training catabolize between 0.7 and 0.9 g of protein per pound of body weight per day. This amounts to between 115 and 150 g of protein per day for a 165-lb athlete. Lean proteins sources such as chicken breast, fish, and lean meats provide approximately 25 g of protein per 3-oz serving; therefore athletes benefit most from consuming approximately 5 to 7 oz of these lean protein sources per day. This amount would be the equivalent of about five to seven 3-oz servings of chicken, fish, or other lean protein per day, with the assumption of fats and carbohydrates to be negligible in lean protein sources. Protein considerations are especially important for endurance athletes, who are more susceptible to protein malnutrition due to the catabolic hormonal environment created by their sport.[39–41]

Like carbohydrates, not all protein is the same. The amino acid content of protein sources varies and has direct bearing on quality. Different types of protein can be described as fast proteins or slow proteins.[42,43] Slow proteins are digested more evenly and take longer to process. Fast proteins are digested more rapidly and allow amino acids to be quickly available to the body. The typical fast- and slow-protein sources are whey and casein, respectively. Health care providers working with athletes may want to look at slow proteins as good meal options, whereas fast protein may be great options to aid performance and recovery by timing them for intake before and after exercise. The best sources of protein are low fat and have a high biological value with optimal amino acid ratios. These sources include skinless chicken, lean beef, fish, egg whites, skim milk, lean pork, and the supplemental milk proteins casein and whey.

The International Society of Sports Nutrition published its position on protein intake in 2017, highlighting the following points[44,45]:

1. Highly active individuals should consume between 1.4 and 2 g of protein per kilogram of body weight.
2. Higher protein intakes (2.3–3.1 g/kg/day) may be needed to maintain lean body mass in resistance-trained athletes following a hypocaloric regime.
3. Concern that protein intake within this range is unhealthy is unfounded.
4. Attempts should be made to get protein from whole foods, but supplemental protein is a safe and viable method of protein intake.
5. Timing protein intake before and after exercise may have benefits, including enhanced recovery and development of muscle mass.
6. Certain amino acids, such as leucine, a branched chain amino acid (BCAA), have been shown to be beneficial for increasing the rate of protein synthesis, decreasing protein breakdown, and increasing recovery from exercise.[46]

Exercising individuals require more protein than their sedentary counterparts require.

Fat

Fat intake for athletes involves several important considerations and depends on an athlete's goals and training state. In general, athletes' fat recommendations should be at or slightly greater than those for their nonathlete sedentary counterparts.[27,34] High-volume athletic training has been shown to lower testosterone concentrations, and decreasing fat intake can exacerbate this effect.[47–49] Most research suggests athletes should keep their dietary fat intake at around 30% of total calories. However, ultraendurance athletes, in particular, may go much higher than this. Athletes undergoing very intense training regimes have been shown to safely tolerate and benefit from diets containing as much as 50% of total calories from fat.[50] As mentioned previously, weight loss is occasionally a concern for athletes. In those cases, a lower-fat diet may be advisable, with research suggesting a diet of 0.25 to 0.5 g of fat per pound per day.[51] Fat quality is also a concern. The polyunsaturated fatty acid ratio of ω-6/ω-3 may be a concern in immune system function and inflammatory responses. Saturated fat intake may also be associated with more optimal testosterone responses.[49] Given these considerations of fat and the emerging understanding of the different function of fats, it is wise for athletes to consume a wide range of dietary fats, with a special focus on balancing the ω-3/ω-6 ratio.

Improving Athletic Performance with Nutrition

International Society of Sports Nutrition position stand: nutrient timing 2010

Prolonged exercise (>60–90 min) of moderate-to high-intensity exercise will deplete the internal stores of energy, & prudent timing of nutrient delivery can help offset these changes.

During intense exercise, regular consumption (10–15 fl oz.) of a carbohydrate/electrolyte solution delivering 6%–8% CHO (6–8 g CHO/100 ml fluid) should be consumed every 15–20 minutes to sustain blood glucose levels.

Glucose, fructose, sucrose, and other high-glycemic CHO sources are easily digested, but fructose consumption should be minimized as it is absorbed at a slower rate and increases the likelihood of gastrointestinal problems.

Continued

Improving Athletic Performance with Nutrition—cont'd

The addition of PRO (0.15–0.25 g PRO/kg/day) to CHO at all time points, especially post-exercise, is well tolerated and may promote greater restoration of muscle glycogen when carbohydrate intakes are suboptimal.

Ingestion of 6–20 gms of essential amino acids and 30–40 gms of high-glycemic CHO within 3 hours after an exercise bout and immediately before exercise has been shown to significantly stimulate muscle PRO synthesis.

Daily post-exercise ingestion of a CHO plus PRO supplement promotes greater increases in strength and improvements in lean tissue and body fat percentage during regular resistance training.

Milk PRO sources (e.g., whey and casein) exhibit different kinetic digestion patterns and may subsequently differ in their support of training adaptations.

Addition of creatine monohydrate to a CHO plus PRO supplement in conjunction with regular resistance training facilitates greater improvements in strength and body composition as compared with when no creatine is consumed.

Dietary focus should center on adequate availability and delivery of CHO and PRO. Including small amounts of fat does not appear to be harmful and may help to control glycemic responses during exercise.

Irrespective of timing, regular ingestion of snacks or meals providing both CHO and PRO (3:1 CHO: PRO ratio) helps to promote recovery and replenishment of muscle glycogen when lesser amounts of CHO are consumed.

CHO, Carbohydrate; *PRO*, Protein.

Performance, Recovery, and Nutrient Timing

Athletes and those working with them can benefit greatly from understanding how to time meals for performance and recovery. When it comes to performance nutrition, it is useful to think about first maximizing storage capacity (i.e., filling the liver and muscle glycogen stores) and fueling exercise (i.e., having nutrients more recently consumed to fuel exercise).[26–28,46] Complex carbohydrates take about 4 to 6 hours to be digested, absorbed, and then stored in the liver and muscle as glycogen.[26–28,46,52] Recommendations regarding carbohydrate loading for training and competition should take that time into account. Morning training sessions or competition will benefit from nighttime loading strategies, whereas afternoon competition and training sessions will benefit from morning loading strategies. A light carbohydrate and protein shake roughly 45 minutes (30–60 minutes) before activity has been shown to improve performance toward the end of high-intensity activity. The inclusion of protein also serves to spare muscle tissue by decreasing the need for the body to cannibalize its own muscle tissue.[53,54]

Although exercise sessions of less than an hour require no special nutritional or hydration strategies, exercise sessions lasting longer do. Strategies that manage pre-, post-, and within-workout nutritional requirements can dramatically aid performance and recovery. This is where electrolyte solutions and sports drinks consumed before and during exercise have an important role to play. These beverages can help prevent low blood sugar, optimize hydration, replace lost minerals, and reduce the immune suppression that occurs after intense long-duration exercise.[55,56] A carbohydrate beverage of 6% to 8% with an equal mixture of glucose and fructose taken every 20 minutes during exercise is advised.[27,54,57] In addition, adding protein to carbohydrate intake may result in higher rates of glycogen storage after exercise.[32,55,57,58] Research suggests consumption of approximately 20 g of a rich source of essential amino acids (e.g., whey protein) combined with 40 g of a good glucose source (e.g., grape juice) taken 40 minutes before exercise may be useful and within 3 hours after exercise may improve performance and aid recovery. The addition of a small amount of fat may also be helpful in stabilizing blood glucose levels.[57]

After exercise, there is a unique opportunity to fuel the body for recovery. During this "recovery phase," nutritional strategies should be instituted as soon as possible and at least within the first 30 minutes after the cessation of exercise. A mixed carbohydrate–protein beverage containing close to a 3:1 ratio of carbohydrate to protein within 3 hours after exercise appears to provide greater recovery benefits than do lesser amounts of carbohydrate.[32,55,57–59] Upon completion of this postworkout "snack," another more carbohydrate-heavy postworkout meal should be eaten again within 90 minutes.

Most athletes will taper their training by one third to one half 2 to 5 days before their events. During that time, it may be beneficial to consume 200 to 300 extra grams of carbohydrates daily. This technique has been shown to maximize glycogen storage before the event and improve performance.[57]

Water

Easily the most beneficial ergogenic aid is water. Working to prevent dehydration during exercise is one of the most useful endeavors for improving exercise performance. Intense exercise can result in significant loss of water through sweat. When this fluid is not replaced, athletic performance will suffer. A loss of 2% water through sweat can impair the ability to compete, and a loss of 4% can result in the inability of the body to cool itself during exercise.[56] Athletes can lose 1 to 2 L in sweat through exercise per hour. Unfortunately, athletes cannot rely on thirst perception to regulate fluid balance.[56] There are several objective ways for athletes to measure fluid loss.[56] One way to ensure adequate hydration recovery is for athletes to weigh themselves before and after exercise and drink 3 cups of liquids per pound of weight lost through exercise. During heavy exercise, athletes should consume 1 to 2 L of water or glucose and/or electrolyte beverage per hour.[56,60]

Vitamins and Minerals

It is now recommended by most medical organizations that a low-dose multivitamin be consumed daily to assure optimal vitamin and mineral status.[27,61] Few, if any, vitamins and minerals have been shown conclusively in research to have any performance benefit. However, the nutritional status of an athlete can affect quality of performance, training, and recovery.[27,61–64] When considering vitamin and mineral supplementation for athletes, health care practitioners should view their recommendations in the context of nutrient adequacy. Athletes may be more susceptible to vitamin and mineral inadequacies, given the previously mentioned issues on nutrition and potential caloric deficits. Although there may be no direct benefits to performance, many vitamins and minerals aid recovery and support.[27,61–64]

Vitamin C and zinc in particular have good research suggesting immune enhancement during intense training periods.[27] Vitamins C and E, along with other antioxidant nutrients, may also protect athletes from excessive oxidative damage, which could also lead to immune suppression.[27]

Mineral deficiencies are particularly problematic for athletes. Restoring any mineral deficiencies can aid performance.[27] Certain minerals may also provide benefit for optimizing performance. Calcium is one mineral that can aid athletes. Although there is no evidence that calcium supplementation improves performance, at supplement levels of approximately 1000 mg per day, calcium has been shown to assist athletes susceptible to osteoporosis as well as improve body composition.[65,66] Phosphorus supplementation may have ergogenic effects when supplemented as sodium phosphate but not in other forms (calcium phosphate, potassium phosphate, etc.).[67] Levels of supplementation for phosphate are 4000 mg/day (1 g tribasic

dodecahydrate sodium phosphate 4 times/day) for 3 days for endurance improvement. Sodium intake has benefit for training in the heat and reduces the risk of hyponatremia.[48] With most minerals, as with vitamins, the real benefit to athletes comes when identified deficiencies are corrected. Restoring vitamin and mineral status to optimal levels can aid exercise performance.[7,41-44]

Along these lines, vitamin D is a special consideration. Vitamin D deficiency is now epidemic, and athletes have the same rates of deficiency as the rest of the public have.[68,69] In one study of elite female gymnasts, 77% were found to have vitamin D levels lower than 35 ng/mL, and a full third had levels lower than 10 ng/mL (which is defined as a clinical deficiency).[69] In a group of athletes susceptible to prolonged and constant bone stress (i.e., long-distance runners), this finding was especially troubling and underscores the need for athletes to ensure adequate vitamin D status.

Although vitamin D supplementation in individuals with sufficient vitamin D does not appear to increase performance, vitamin D therapy delivered to deficient athletes may improve performance.[69,70] Vitamin D is known for its role in bone metabolism. However, the fact that skeletal muscle has vitamin D receptors is not commonly known. As far back as the 1930s, there have been numerous reports of the beneficial effects of ultraviolet therapy on athletic performance.[71,72] In addition, some studies suggest the season of training makes a difference. One of these studies showed that training in the summer months creates greater gains than the same volume of training in autumn or winter does, despite the same stimulus.[72]

In both older and younger individuals, adequate vitamin D status affects neuromuscular function and may have a specific relationship to the maintenance of the fast-twitch type 2 muscle fibers.[68,71,73,74] In a study on teenage athletes, vitamin D deficiency lowered muscle power and force.[75] Vitamin D levels are also related to myalgia, fatigue, and reduced motivation to exercise. Studies in older adults showed that levels of vitamin D were correlated with the propensity to fall.[76] A meta-analysis of vitamin D levels showed a 20% reduction in the risk of falling among people with higher levels.[77] This reduction was likely due to vitamin D's ability to improve reaction speed, balance, and neuromuscular performance. Much of this effect may be explained by the ability of vitamin D to help maintain and even build type 2 muscle fibers.

Athletes should be tested for vitamin D levels with a serum 25-hydroxy vitamin D laboratory test with a target between 50 and 100 ng/mL. If they are found to be insufficient, a combination of supplementation and sun exposure is advisable. For quick restoration of adequate vitamin D levels, 50,000 International Units (IUs) of vitamin D per week for 12 weeks has been shown to allay symptoms of vitamin D deficiency. Maintenance doses of between 1000 and 10,000 IU/day, depending on sun exposure and living latitude, should also be considered to prevent subclinical and clinical deficiencies.

ASSESSMENT

Serum Nutrient Testing

Nutrient deficiencies can affect many aspects of physical performance, recovery, and immune function. Athletes, because of the imposed increases in metabolism, can be at an increased risk for nutrient deficiencies. Serum testing is a reliable and useful tool for diagnosis of severe nutrient deficiencies but may be inadequate for certain vitamins and minerals.[78] Therefore those working with athletes will find it useful to have more functional tools for assessment of metabolic and nutritional needs.

Testing blood for nutritional levels can be misleading. Serum nutrient concentrations are closely regulated by the body and can fluctuate based on recent intake. Furthermore, some vitamins and minerals are almost entirely found intracellularly. As stated by Lord and Bralley in their textbook *Laboratory Evaluations for Integrative and Functional Medicine*, "For various reasons specific to each vitamin, it is possible for an individual to have normal serum levels of a vitamin while exhibiting signs of insufficiency for that vitamin owing to a lack of adequate intracellular concentration to meet the metabolic demands of the cells."[78] Given these factors, serum may not always be the best means of determining nutritional status for all nutrients. A range of laboratory analyses that can provide more functional assessments of nutrition status are now available.[78] The ones that may be most beneficial are adrenal hormone profiles (cortisol and dehydroepiandrosterone [DHEA]), organic acid testing, and intracellular nutrient analysis.

Adrenal Hormone Testing

Analyzing the adrenal hormones cortisol and DHEA can give insight into training status and into whether an athlete may be overtraining or overreaching.[79–81] Salivary cortisol and DHEA levels provide an indication of catabolic versus anabolic balance in the body as well as neuroendocrine adaptation to stress. The optimal ratio of salivary cortisol to DHEA is approximately 5:1 to 6:1, which indicates an appropriate state of stress adaptation. The closer this ratio is to 1:1, the less likely it is for the individual to be able to adapt to daily stressors.[82] The test is simple and noninvasive, involving salivary collection at four time points during the day (morning, noon, evening, and night). Depending on the laboratory, the cortisol and DHEA test may also provide markers of immune function, such as immunoglobulin-A. All these measures are important for athletes looking to compete at high levels for prolonged periods.

The body goes through four stages in response to stress. Stage 1 occurs in response to acute stress and involves elevations in cortisol with no changes in DHEA. Stage 2 involves continued stress and is marked by a sustained cortisol peak with a matching elevation of DHEA. At stage 3, when stress continues and becomes chronic, cortisol levels drop, whereas DHEA stays high. Finally, both cortisol and DHEA fall, a stage often referred to as adrenal exhaustion or stage 4.

Testing athletes for levels of adrenal hormones gives important guidance concerning nutritional therapy and supplementation. Cortisol is a highly catabolic agent, and increased cortisol levels with normal to low DHEA indicate excessive stress and potential muscle wasting.[78] This status necessitates increased protein and amino acid intake, especially increased glutamine.[83] High cortisol levels also give an indication of increased need for other nutrients that are easily depleted through increased metabolic activity (e.g., magnesium, zinc, and vitamin B_6).[78] Cortisol-suppressing supplements, such as phosphatidylserine, may also be indicated,[84] as is the potential for DHEA supplementation and/or immune support.[85] Changes in adrenal hormones may occur long before clinical symptoms appear and can be used to monitor training status and recovery.

Organic Acid Testing

Organic acid testing is a useful analysis that looks at metabolic by-products in urine.[78] The test does not measure actual vitamins and minerals or their absolute values but assesses them indirectly by measuring excreted metabolic by-products. Although the test is not diagnostic, it can be used to analyze the metabolic consequences of insufficient nutrient intake. It can also offer insights into toxic exposures, digestive health, amino acid need, and neuroendocrine function.

Fats, proteins, and carbohydrates become carboxylic acids before they are completely burned to carbon dioxide. These acids, formed by the body's metabolic processes, are usually low or nonexistent in urine. When perturbations occur in metabolism due to inefficient enzymes as a result of genetic polymorphisms and/or lack of a vitamin or mineral cofactor, the metabolic by-products can build up in the cell, be

released into the blood, and then begin to show up in the urine. The organic acids that appear can then be traced back to known biochemical pathways, indicating a particular nutrient need.

Given the fact that almost all nutrients become ergogenic when there is a deficiency or increased need, organic acid testing may be useful in understanding which nutrients may be indicated for a particular athlete and whether the supplements they are currently taking are actually doing the job. Using organic acid testing may provide health care practitioners working with athletes a way to pinpoint potential nutrient issues and bolster key metabolic pathways.

Intracellular Nutrient Analysis

Because many nutrients, like magnesium, are not well measured in serum, another useful functional analysis for athletes is intracellular nutrient analysis.[78] This testing involves drawing blood, isolating white blood cells, and growing them in a nutrient-rich medium. Individual nutrient concentrations are then manipulated one by one while measuring cell growth rates. Cellular growth from an athlete with insufficient levels of a nutrient will be slower than from an athlete with sufficient levels.[86] This analysis allows tailored nutrient supplementation to optimize intracellular levels of all nutrients.

Amino Acid Testing

Due to the high turnover of amino acids required in the participation and recovery from intense exercise, amino acid analysis can be useful for athletes.[78,87] When testing athletes for amino acids, it may be useful to measure plasma levels, urine levels, and organic acids. Plasma levels give the best indication of protein utilization and are the most scientifically validated. However, urinary amino acids may give greater insight into protein breakdown from factors interfering with amino acid utilization (i.e., micronutrient deficiency or toxic exposures). These two measures, along with the ability to map biochemical pathways through organic acid testing, can provide an athlete with in-depth information about protein utilization, breakdown, and metabolic needs.

CRITICAL EVALUATION OF ERGOGENIC AIDS

It is important for the health care practitioner to be aware of the large gap that often exists between supplement marketing and research. Given that nutritional supplements are not regulated to the same degree as pharmaceuticals, and little financial incentive exists to research natural compounds, it is important to look for valid and objective resources on nutritional supplements. When evaluating whether a nutraceutical might be useful, it is important to keep several things in mind.[27]

A good first question to ask is, "Does the basic science make sense?" Natural health practitioners need to be good students of biochemistry and physiology. Knowing the compound and its involvement in biochemical pathways is a necessary first step. If the mechanism of action "makes sense" from a biochemical perspective, the supplemental aid may have merit. A good example here is the use of the nutrient L-carnitine. Understanding the biochemistry of this nutrient as key in delivering fat to the mitochondria to be burned for energy allows consideration that it may have fat loss and performance benefits.

The next question must be, "Is it feasible to deliver the nutrient in a form that can actually be absorbed and utilized by the body?" Although a nutrient may seem like a perfect candidate for performance enhancement properties, if it cannot be delivered to the body in a safe, feasible, and usable form, it will not have much use. In the case of L-carnitine, several issues warrant consideration. First, L-carnitine is not well absorbed; therefore understanding the different delivery forms is essential. The next obvious question, "Would L-carnitine bound to tartrate, fumarate, or another molecule be most feasible for delivery?" Also, in the case of amino acids like carnitine, there are two forms, L-carnitine and D-carnitine. L-carnitine is active in the body, whereas D-carnitine is not and can actually block the action of L-carnitine. Confidence would therefore be less on studies using the racemic mixture of this nutrient versus those using pure L-carnitine.

Another important consideration is, "Does any good research exist on the substance?" Health care practitioners should further consider other aspects: Are the studies in vitro or in vivo studies? Were they animal or human studies? Was the sample size big enough? Was the study designed appropriately? Was it well controlled? Human clinical trials with a large sample size that are double-blinded and placebo-controlled are obviously the gold standard and should be weighted heavier. However, these types of studies often do not exist for sports performance supplements, accounting for much of the skepticism regarding sports performance aids. Moreover, these types of studies are cost-prohibitive, especially when considering the diminutive financial gain, if any at all, of doing natural compound studies because there is essentially no patent protection. Much of this skepticism is warranted, although discounting a supplement purely on the basis of lack of these types of trials is probably not wise.

Some final considerations would be whether or not the product is safe, legal, and appropriate. In 2006 the 109th Congress passed the Dietary Supplement and Nonprescription Drug Consumer Act. This law requires supplement companies to disclose all complaints about their products and make them available to the public. For supplement issues that are more serious in nature, the companies must notify the U.S. Food and Drug Administration within a 2-week time frame. There are also consumer organizations that help police the industry. These organizations independently test supplement products against claims of efficacy and issues with contamination, and such groups can be useful resources to those advising supplement use. Finally, there are always completely safe products that may present issues in certain populations. All these considerations should be evaluated when using nutritional supplementation.

GENERAL HEALTH CONCERNS FOR ATHLETES

The American Medical Association has suggested Americans use supplemental vitamins to maintain health; these recommendations seem especially prudent in the athletic world. Although there is no performance benefit to the use of multiple vitamins and minerals, as discussed previously, athletes can be susceptible to deficiencies and/or require more support in areas due to increased vulnerability to stress or injuries encountered during sports. Glucosamine can aid in the healing of damaged cartilage and reduce joint pain.[69] Supplements such as zinc, glutamine, vitamin C, lipoic acid, selenium, and other nutrients may support immune function and antioxidant capacity.[26,27,46,88–90] Amino acids are especially useful. Creatine, whey protein, BCAAs, and L-carnitine tartrate have all been shown to help athletes through the stress of intense training periods.[26,27,46] Finally, ω-3 fats can help balance inflammatory and anti-inflammatory reactions in the body.

NUTRITIONAL SUPPLEMENTS

Obviously, a full treatment of all the nutraceuticals purported to have beneficial effects in exercise and body composition could fill an entire book. We selected the compounds discussed here that demonstrated the most research supporting their use as ergogenic aids. We attempted to avoid looking at compounds that have strong theoretical support for their use but have not yet been studied. We gave special consideration to compounds that have been studied in humans and have been

evaluated under double-blinded and placebo-controlled conditions. Newer compounds that did not meet these criteria may not be covered. In certain cases, we included compounds that are novel in their reported use as ergogenic substances.

Arginine

Arginine has several potential benefits for athletes, including increasing human growth hormone production, blood flow, mitochondrial biogenesis, fat loss, and muscle gain. Many of these effects are related to nitric oxide, for which arginine is a precursor. However, several of these benefits are relatively new discoveries regarding arginine supplementation. Animal studies and human studies show arginine might have particular benefit in improving exercise capacity and body composition.

Arginine may play a role in endurance performance. A 2010 study showed that a proprietary arginine supplement given to elderly male cyclists was able to positively affect performance. The arginine supplement significantly increased the anaerobic threshold within 1 week of beginning supplementation, with the effect lasting throughout the 3-week study.[91] No change in maximal oxygen consumption (VO_2max) among the cyclists was found in this particular study. However, in another study, this time on younger cyclists, oxygen kinetics were sped up in relation to L-arginine supplementation.[92] Another study in 2010 showed arginine's potential role in illness associated with reduced cardiovascular capacity.[93] In this analysis, arginine supplementation improved exercise capacity in heart transplantation patients, resulting in furthering the distance walked and delaying the ventilatory threshold by 1.2 minutes.

In addition to endurance benefits, arginine may also have a role to play in strength training. An April 2010 study showed increased growth hormone and insulin-like growth factor 1 release in response to heavy resistance training.[94] This newer study lends credibility to older reports.

Research on rats, pigs, and humans showed arginine to be a potential antiobesity aid through several unique mechanisms.[95] Supplemental arginine appears to have activity that increases glucose and long-chain fatty acid oxidation while at the same time suppressing gluconeogenesis and lipogenesis. In rats, L-arginine was shown to increase muscle mass by 12% and increase glucose metabolism by 14% without affecting insulin. Most interestingly, arginine was shown to coax white adipose tissue to become brown adipose tissue and, as a result, significantly elevated the metabolic rate. Arginine appears to act partly via its conversion to nitric oxide. It may act via cyclic guanosine monophosphate and cyclic adenosine monophosphate dependent mechanisms. It was found to increase mitochondrial biogenesis, upregulate GLUT-4 receptors, and improve muscle mass.

A 21-day randomized and double-blind, placebo-controlled study of arginine in obese men was conducted in 2006 by Lucotti et al.[96] Thirty-three obese males were put on a low-calorie diet (1000 kcal/day) and an exercise program (45 minutes of exercise twice per day for 5 days/week). They were then randomized to receive 8.3 g per day of arginine or placebo. As expected, the lifestyle intervention resulted in weight loss, waist circumference reduction, lowered fasting glucose, and reduced insulin in both groups. However, the arginine group had statistically better responses in most measures in comparison with the placebo group ($P < 0.0001$). Most interestingly, the arginine group was able to maintain their muscle mass, whereas the placebo group had significant reduction in lean body mass. Forty-three percent of the weight lost in the placebo group was fat in comparison with a full 100% for the arginine group.

Although earlier research shows the athletic performance benefits of L-arginine, more recent analyses suggest the ergogenic benefit is nonexistent to minimal at best. Using various doses of arginine, from 0.04 g/kg, 0.75 g/kg[97] to absolute amounts of 6 g,[98,99] with various forms, including arginine alpha-ketoglutarate to pure L-arginine, creates a situation that makes it difficult to construct a valid comparative analysis. However, among these various studies, arginine showed no change in performance outcomes[97] or only very slight improvements.[99]

Not to be ignored, many of the studies testing the efficacy of L-arginine on athletic performance are studying individuals under unique circumstances, all with significant effect on performance. The variables among these studies are inconsistent with variation in supplement duration, combination of arginine with other agents,[100] varying exercise protocols from aerobic endurance, high-intensity to combative sports,[99] and the fitness level of the athlete (healthy men to highly trained athletes).[97,98] Furthermore, their use of small sample sizes questions the power of the studies. However, this research is what the literature provides, which then requires a thorough analysis of the research as a whole, which must then be applied through the lens of the patient.

Dosage

The appropriate dose of arginine based on the animal and human studies appears to be 80 mg/kg body weight per day, or 3 g three times daily for a 155-lb adult. Results of the National Health and Nutrition Examination Survey indicated arginine intake in the United States averages about 4.4 g per day, with 25% of the population receiving suboptimal levels.[95]

Other Considerations

Both animal and human studies suggest there are no safety concerns related to arginine supplementation when it is taken in appropriate doses and in an appropriate form. There is a theoretical concern that increased arginine supplementation will alter the arginine/lysine ratio and possibly increase herpes virus activity. Arginine is also known to increase the inducible form of nitric oxide synthase, resulting in potential negative cytokine activity and immune consequences. This result is a special concern for those suffering from autoimmunity.

Biochemically, an intricate relationship exists between citrulline and arginine in the synthesis of nitric oxide, as citrulline acts as a precursor to arginine. Several studies have shown citrulline supplementation at doses up to 6 g daily to improve arginine levels and NO levels in the blood superior to arginine alone.[101–103] Although this can simply be attributed to citrulline being a precursor, thus increasing usable substrate, additional research further suggests arginine is catabolized via first-pass metabolism in the gut and liver by arginase. Citrulline does not undergo this process and further acts as an allosteric inhibitor of arginase, resulting in increased peripheral circulation of arginine, thus increasing available arginine as a substrate for NOS.[103]

Beta-Alanine

Beta-alanine is a precursor, along with histidine, of carnosine and is found in high concentration in skeletal muscle. It is widely assumed carnosine has performance benefits due to its ability to resist pH changes in muscle. In one study, oral intake of β-alanine for 4 weeks was shown to increase carnosine levels.[104] Another study showed supplementation with β-alanine for 10 weeks significantly elevated carnosine levels at weeks 4 and 10.[105] Subjects taking β-alanine have been shown to complete a greater number of repetitions during resistance exercise,[81-82] resist fatigue,[105–107] generate greater force with the legs,[108] and even improve body composition.[109] The intention and goals are to determine whether and how β-alanine use translates to actual benefits in athletes and their performance. The aforementioned improvements are assumed to convert into improved performance, which has been confirmed by several studies.[110–112] In athletes, most benefits have been

identified with improvements in intense, short-duration exercises of 0.5 to 10 minutes,[112] such as sprinting and jumping ability.[111] Although the benefits of β-alanine are much more pronounced in untrained athletes, benefits were still evident in trained athletes, which can be explained by improved exercise adaptation in highly trained athletes. However, the enhancements in trained athletes may be worthwhile if used in an applied setting, such as competition, where even a slight advantage may have profound results.[112]

Dosage

Typical doses in studies range between 400 and 800 mg given multiple times throughout the day to achieve between 4 and 8 g. Doses above 800 mg at any given time may cause transient paresthesias. β-alanine appears to have a low toxic profile and is generally considered a safe nutraceutical.

Other Considerations

β-alanine and sodium bicarbonate together, over β-alanine alone,[113–115] have shown synergism in improving performance in highly trained athletes. Gains were most impressive after chronic use for 7 days, with the mechanism theorized to be due to the improved muscular alkalosis.[116]

Beta-Hydroxy Beta-Methylbutyrate

Beta-hydroxy beta-methylbutyrate (HMB) is derived from the BCAA leucine, a known activator of mTORc1 (mechanistic target of rapamycin).[117] HMB use at levels from 1 to 3 g per day while undergoing weight training may increase strength results and have positive effects on lean muscle gains.[38,118,119] The largest and most beneficial responses come from studies on untrained athletes. Older individuals may also enjoy benefits from supplementation. Volkovich et al., in 2001, showed 3 g of HMB daily over 8 weeks given to elderly men and women led to significantly greater loss in fat in comparison with a placebo group.[120] Muscle mass gains usually ranged from 1 to 2.2 lb over 3 to 6 weeks of training for those taking HMB versus placebo.[27]

Until recently, performance benefits in athletes or well-trained individuals were not as convincing as results in untrained subjects. However, the literature has shown significant benefits in young trained and untrained individuals. One quality study by Knitter et al., in 2000, showed HMB might protect against muscle damage from exercise.[121] Well-trained runners were supplemented with 3 g per day over 6 weeks. In comparison with placebo, HMB-supplemented runners had lower markers of muscle damage evident by lower lactate dehydrogenase and creatine phosphokinase. Additional studies in younger trained subjects, showed supplementation of 3 g of HMB improved peak power and 1 rep-max (1RM) leg press,[122] along with increased strength in bench press, squat, and deadlift, vertical jump power, and improved lean body mass.[123,124]

Strikingly, HMB also shows promise as an ergogenic aid via its effect on the endocrine system. Studies in young, resistance-trained men taking HMG along with a resistance training protocol exhibited significant increases in growth hormone (GH), insulin-like growth factor 1 (IGF-1), and attenuation of elevated cortisol.[123–125]

The mechanism is not completely understood. However, it is suspected to induce mTORc1, inhibit the ubiquitin proteasome pathway thus reducing muscle degradation, stimulate mitochondrial biogenesis,[126] and induce synthesis of skeletal muscle satellite cells,[117,127,128] with the result of increased muscle hypertrophy and muscle recovery.

Dosage

The dose of HMB shown to be effective is 1 to 3 g per day.

Other Considerations

HMB supplementation along with creatine may behave in a synergistic fashion.[129] HMB is generally considered safe to use.

Branched Chain Amino Acids

BCAAs are perhaps the most beneficial aspect of increased protein intake. They have been shown to increase protein synthesis, decrease protein breakdown, and speed recovery from exercise.[130–132] Research suggests they may have some acute performance enhancement effects and play a key role in body composition.[133–135]

BCAAs include leucine, isoleucine, and valine. The body cannot synthesize these amino acids, making their dietary intake essential. BCAAs are necessary for production of other amino acids, most notably alanine and glutamine, two of the most important amino acids used in gluconeogenesis. Low-calorie diets and stress can greatly increase the need of amino acid precursors for gluconeogenesis. Because BCAA are mainly metabolized by the muscle in comparison with other amino acids, which are metabolized by the liver,[136] a large pool of BCAAs through dietary intake spares muscle protein breakdown and likely promotes muscle protein synthesis.[137–139]

BCAA supplementation has shown some effect on exercise performance, perceived exertion, and recovery. Matsumoto et al.[135] had subjects drink either a BCAA beverage or a placebo 6 days before performing high-intensity cycling until exhaustion. The trial was a double-blind, crossover, placebo-controlled study with a 1-week washout period between exercise sessions. BCAA increased plasma levels of leucine, isoleucine, and valine during the exercise test. The contribution of fat burned during the exercise session was significantly greater for BCAA in comparison with placebo, as was the oxygen uptake and lactate thresholds at equivalent work levels. VO_2max was also greater in the BCAA supplementation. Taken together, these results suggest BCAA supplementation may improve endurance exercise performance.

Another study by Greer et al.[132] looked at BCAA for endurance exercise improvement. This study did not show an acute performance advantage for BCAA during exercise but did show reduced damage. BCAA supplementation was significantly better than consumption of either a carbohydrate beverage or placebo at reducing markers of muscle damage. An earlier study by the same group showed comparable findings.[134]

One of the limiting factors for athletes is recovery. There are impressive findings on enhanced recovery from exercise using BCAA in response to high-intensity weight lifting and resistance training,[131] with reductions in muscle damage evaluated via creatine kinase, lactate dehydrogenase, myoglobin, delayed-onset muscle soreness, and muscle function alteration.[136] Preexercise supplementation of BCAAs in young trained athletes reduced exercise-induced muscle damage, attenuate the loss of strength and power after exercise,[140] and reduce overall perception of muscle soreness.[140,141] It is suspected that in addition to being a fuel source for myocytes, BCAA may induce mitochondrial biogenesis and scavenge ROS via upregulation of peroxisome proliferator-activated receptor-γ coactivator 1α.[142]

One of the more intriguing aspects of BCAA supplementation may be its role in optimizing body composition. Low-calorie diets and aerobic exercise are both known to reduce lean muscle tissue. BCAA supplementation attenuates this response and helps maintain muscle mass.[133] In addition, BCAAs, specifically leucine, have unique actions as metabolic signaling molecules that may be able to increase energy expenditure,[143] suppress appetite,[144] and lower insulin.[145] Although all these relatively new mechanisms have been shown only in mice, one small pilot human study including BCAA supplementation suggested that the same mechanisms may be at play in humans.[146] Fifty-nine

healthy subjects participated in the study and were divided into a placebo group (fiber) and then given either a high-concentration (12 g per day) or low-concentration (6 g per day) BCAA supplement. Subjects were supplemented for 14 days and were encouraged not to modify either eating behavior or exercise habits.

Degree of weight loss was directly correlated with dose of BCAA given, with the largest weight loss being achieved in those who received the 12 g per day dose. Given the short time of the study, statistical significance was not achieved. The authors noted, "Design of this pilot study has more effects than can be analyzed satisfactorily with available sample sizes. An analysis with "best possible" outcome did show that significance would have been possible with maximum weight loss difference from one group to another." Based on this study, it is not yet possible to make a determination as to BCAA supplementation in weight loss. However, given the new understanding of BCAA signaling, the promising results in animals, and the interesting, although not statistically significant, findings of this study, further evaluation certainly seems warranted.

Dosage

Most research suggests a dose of between 6 and 12 g per day of BCAA.

Other Considerations

Given that the dosages of BCAA are so high, it may be impractical to recommend this supplement in capsule form. BCAA powders are widely available and may provide convenience. Mixing BCAA powder in a small amount of high-glucose fruit juice, such as grape juice, may help increase compliance by masking the bitter taste and increasing absorption and utilization.

Caffeine

Perhaps the most well-known performance-enhancing aid is caffeine. The consensus of studies shows caffeine has value in endurance exercise performance, anaerobic exercise outcomes, exercise recovery, and weight loss.[147–149] In the body, caffeine absorption occurs rapidly and is then metabolized in the liver into theophylline, theobromine, and paraxanthine. Caffeine is lipid soluble, giving it quick access to the brain and other tissues. Caffeine is detectable in blood within 15 minutes of intake, reaching peak levels at 1 hour. Caffeine is cleared from the system in 1 to 12 hours, depending on the individual's activity of CYP1A2.

Caffeine exerts strong influence on the nervous system, affecting both the central nervous system and peripheral nervous system, and several review studies suggest this is the most beneficial action of caffeine related to performance enhancement.[147–149] It acts to increase mental focus and fine motor skills. Beta-endorphin concentrations also rise with caffeine consumption, possibly resulting in decreased pain perception during intense activity.[147] Also, the nervous system activation plays a strong role in sports, requiring bursts of speed and intensity.

Caffeine spares muscle glycogen and shifts metabolism toward the increased use of fat from both subcutaneous and intramuscular compartments.[149–151] Given that fat oxidation is a key component of endurance sports, caffeine can improve outcomes in long-distance events. It also has an interesting effect when dosed along with carbohydrate.[152] A carbohydrate electrolyte beverage (6% glucose) spiked with caffeine (5 mg/kg of body weight) was able to bolster endurance performance by 9%.[151]

In high-intensity exercise, caffeine raises catecholamine production, increasing both lipolysis and glycogenolysis.[147–149] This effect, along with increased activation of the central nervous system, may be the mechanism responsible for better performance in high-intensity endeavors. In 2006 Schneiker et al.[153] compared 6 mg/kg of body weight caffeine ingestion with placebo in amateur male athletes. In this study, either caffeine or placebo was taken 60 minutes before two 36-minute exercise sessions consisting of multiple short sprints separated by 2 minutes of recovery. Caffeine intake increased sprint performance 8.5% and 7.6% over placebo in the first and second bouts, respectively. Caffeine also increased power output in comparison with placebo. Additional studies confirm these ergogenic effects of caffeine in high-intensity and resistance training activities. When comparing caffeine intake and placebo, caffeine showed significant improvements in total weight lifted in comparison with placebo. Interestingly, the same study compared coffee with decaffeinated coffee with added caffeine and found both the coffee and decaffeinated plus caffeine improved power output, thus suggesting the benefits of coffee may be due to the caffeine content.[154] Two well-designed meta-analyses both concluded caffeine to be a beneficial ergogenic aid in improving anaerobic performance, peak power output, and total power output.[155,156] Furthermore, it appears to be most effective in exercises lasting 45 seconds to 8 minutes.[143]

This same combination, carbohydrate and caffeine, may also play a role in recovery from activity. In a study comparing a carbohydrate recovery beverage alone with one spiked with caffeine, glycogen synthesis was increased by 66% in the carbohydrate-plus-caffeine group.[157] This may be mostly due to caffeine's ability to increase the absorption of glucose from the digestive tract into the bloodstream.

Caffeine's activity as a fat-loss aid comes from its epinephrine-inducing effects. Studies as far back as 1990 showed as little as 100 mg of caffeine, the equivalent of a cup of coffee, could increase thermogenesis even in habitual coffee drinkers.[158] Other studies on caffeine showed increased fat oxidation, with one older study showing a 30% greater blood free fatty acid level 2 hours after workout in comparison with placebo.[147–150]

Although the mechanism by which caffeine exerts its benefits is unclear, it is suspected to be due to several factors, including improved catecholamine response to the stress of exercise, improved contractility by reduced intramuscular potassium accumulation,[159] a decreased perception of pain, and increased alertness and arousal.[147]

Dosage

Caffeine intake appears to be physiologically somewhat different from coffee intake. Although the research on pure supplemental caffeine consumption is fairly clear on performance benefits, effects of coffee consumption are less clear. Caffeine consumption shows effects when taken from 15 to 60 minutes before exercise at a dose of 6 mg/kg of body weight. For a 160-lb individual, this amount is the equivalent of about 430 mg of caffeine. An 8-oz cup of coffee has about 150 mg of caffeine on the high end. This amounts to close to 3 cups of drip coffee as the dose for a 160-lb individual.[147–149]

Other Considerations

Concerns about coffee intake and risk of dehydration are unfounded. No good evidence suggests caffeine intake leads to an increased risk of dehydration. Users of caffeine will develop some tolerance. Nonhabitual users experience slightly better benefits from coffee intake in comparison with regular users. Coffee intake can also have a negative effect on digestive function.[147–149] High amounts of caffeine intake can cause negative symptoms, including heart palpitations, insomnia, anxiety, and tachycardia. Coffee intake and caffeine intake can be especially problematic for individuals who are genetically known as "slow metabolizers" of caffeine (CYP1A2*1C). As such, the therapeutic window for enhancing athletic performance may be enhanced in comparison with a "fast metabolizer" of caffeine.

Creatine Monohydrate

The International Society of Sports Nutrition has called creatine "the most effective nutritional supplement available to athletes to increase high-intensity exercise capacity and muscle mass during training."[27] All the performance-enhancing benefits are hypothesized to come down to two factors: increasing the amount of energy available to mitochondria in the form of adenosine triphosphate and increasing cellular hydration.

Creatine has been under investigation for more than 60 years. It is highly concentrated in muscle tissue, with all but 4% to 5% of body creatine residing in the muscle. Most of the creatine in the body is in a phosphorylated form called phosphocreatine. The major function of this supplement is to provide a rapid source of energy by maintaining adenosine triphosphate (ATP) availability.

Although creatine can be made in the body, it requires significant resources, including the amino acids arginine and glycine, magnesium, S-adenosylmethionine, vitamin B_{12}, and folate, among others. Creatine is also present in the food supply and is especially rich in animal protein. The highest concentrations are found in lean cuts of red meat, game meat, and fish, including salmon and tuna. Two pounds of lean red meat contains close to 5 g of creatine. Cooking food may have a negative effect on the availability of creatine.

Creatine Monohydrate (CM)
(The Most Effective Supplement for Enhancing Athletic Performance)

International Society of Sports Nutrition position stand on CM 2010

1. The most effective ergogenic nutritional supplement currently available to athletes in terms of high-intensity exercise capacity (HIEC) and lean body mass during training.
2. It is not only safe, but possibly beneficial in regard to preventing injury and/or management of select medical conditions when taken w/in recommended guidelines.
3. There is no compelling scientific evidence that the short- or long-term use has any detrimental effects on otherwise healthy individuals.
4. If proper precautions and supervision are provided, supplementation in young athletes is acceptable and may provide a nutritional alternative to potentially dangerous anabolic drugs.
5. CM is the most extensively studied and clinically effective form of creatine for use in nutritional supplements in terms of muscle uptake and ability to HIEC.
6. The addition of carbohydrate or carbohydrate and protein to a creatine supplement appears to t muscular retention of creatine, although the effect on performance measures may not be greater than using creatine monohydrate alone.
7. The quickest method of t muscle creatine stores appears to be to consume ~0.3 grams/kg/d of CM for at least 3 days followed by 3–5 g/d thereafter to maintain elevated stores. Ingesting smaller amounts of CM (e.g., 2–3 g/d) will T muscle creatine stores over a 3–4 wk period, however, the performance effects of this method of supplementation are less supported.
8. CM has been reported to have a number of potentially beneficial uses in several clinical populations.

(From Kerksick CM, Arent S, Schoenfeld BJ, et al. International society of sports nutrition position stand: nutrient timing. *J Int Soc Sports Nutr.* 2017;14:33. https://doi.org/10.1186/s12970-017-0189-4.)

Phosphocreatine can supply ATP for the energy required for quick bursts of activity lasting around 10 seconds. Once these high-energy phosphates are depleted, the body relies more heavily on anaerobic metabolism. Supplementation of creatine is thought to "supersaturate muscle" and allow for greater performance of short, explosive exercise.

Another benefit of creatine that may be key is cellular hydration. Creatine storage in the muscle is thought to set up a hyperhydration muscle cellular environment, which then improves the thermoregulatory response of the cell, allowing for improved adaptation to heat stress, thus better helping the cell respond to the stressors of exercise.[148,160,161] Research has shown hydrated muscle tissue may be better able to both synthesize new muscle tissue and resist protein breakdown.[26–28,162]

Studies on weight training and high-intensity interval exercise showed creatine as a reliable and beneficial training aid. Rawson et al.[163] in an April 2011 study showed that, in comparison with placebo, a low-dose creatine supplement (approximately 2 g daily) taken for 6 weeks significantly enhances the ability of muscle to resist fatigue.[117] Kerksick et al.[164] showed 4 weeks of creatine supplementation significantly improved both strength and lean body mass when loaded at 20 g per day for 5 days followed by 5 g per day. In another study on creatine, 23 young males were divided into a creatine group and a placebo group.[165] The creatine dose was given 5 g four times daily for 6 days. Both before and 7 days after supplementation, participants did 30 seconds of maximal sprinting on a bicycle ergometer. This regimen was repeated five times with 2 minutes rest in between. The creatine group enjoyed greater power output and less fatigue in comparison with the placebo group. Researchers found 7.6% increased power in the creatine group from the first to the second test, whereas the placebo group saw no improvement. Compounded lower body movements are key exercises in athletic training and performance. Creatine supplementation was shown to significantly improve maximal weight lifted in squats and leg presses by 8% and 3%, respectively.[166]

The ergogenic benefits of creatine are very impressive, with several large meta-analyses suggesting creatine as a significant athletic performance aid, especially in exercises requiring athletes to perform more series of sets or sprints. By increasing gains in athletic training such as increased strength, muscle mass, and endurance, supplementation with creatine allows athletes to achieve the most benefit out of their training, thus resulting in improved real-life athletic performance.[167]

In addition to improving performance, creatine may also increase recovery from intense exercise and increase lean body mass.[144–146,168] Lean body mass gains can be significantly greater with creatine than with controls while weight training. A review by Krieder et al.[168,169] determined creatine supplementation could generate a 2- to 5-lb greater muscle gain over 4 to 12 weeks of training in comparison with nonsupplementation. Recovery is often overlooked in athletes, with the mentality that more is better; however, overtraining is very common and certainly is a detriment to overall performance. The muscle-sparing and enhanced-recovery effects of creatine are evident in several studies that found anti-inflammatory effects of creatine supplementation, with reductions in prostaglandin E2 (PGE2), tumor necrosis factor alpha (TNF-alpha), lactate dehydrogenase (LDH), creatine kinase (CK), and C-reactive protein (CRP),[170,171] and additionally with sparing muscle glycogen.[172] Those studies strongly suggest that creatine establishes a biochemical environment allowing athletes to tolerated increased exercise volume and intensity.

Dosage

Creatine monohydrate is the most-studied form of creatine. Dosage of creatine is usually prescribed in two ways: a loading dose "fast dose" or a maintenance dose "slow dose." Creatine loading, or "fast dosing," is the most-studied protocol and reliably saturates muscle creatine stores. This dose entails 0.3 mg/kg of body weight daily taken in divided doses every 2 to 4 hours over 3 to 5 days. This dose essentially amounts typically to 20 to 30 g of creatine monohydrate daily for a 160- and 220-lb individual, respectively. Thereafter, the maintenance dose is used and consists of 3 to 5 g of creatine daily. Dosing the maintenance dose from the beginning, or "slow dosing," involves consuming 2 to 5 g per day over 3 to 4 weeks. Consuming creatine with a small amount of

glucose-rich juice, such as grape juice, can improve muscle saturation but has not been shown to increase performance benefits.[27,162]

Other Considerations

Creatine has now been studied extensively in several reviews, and long-term studies on safety have shown it to be safe in adults and adolescents. The only potential drawback to creatine use may be in those predisposed to fat gain.[162,173–175] There also may be implications for testosterone metabolism with creatine, because one study showed increased testosterone-to-dihydrotestosterone conversion with creatine intake.[176]

Green Tea Extract

Tea catechins from green tea have been consumed in Asian countries for centuries. Habitual green tea consumption has been shown to be correlated with lower body weights and less body fat.[177] Studies have shown extracts of catechins from green tea can increase oxidation of fat both at rest[126] and while exercising.[178]

Dulloo et al.[179] showed green tea intake elevated 24-hour resting energy expenditure with increased fatty acid oxidation in comparison with an equal amount of caffeine taken alone. A 90-day clinical trial combining green tea extract (GTE) with a low-calorie diet resulted in significantly greater weight loss in comparison with weight loss in a nontreatment group (30 vs. 11 lbs).[177] Interestingly, the activity of GTE may have particular use against abdominal fat.[180]

Ichnose et al.[181] conducted a double-blind, placebo-controlled trial of GTE intake over a 10-week period. Exercise testing was done before and after the 10-week supplementation. Subjects received either a placebo or GTE (573 mg total of green tea catechins). Both the placebo and GTE contained equal caffeine content. In addition to the supplement, both groups exercised by cycling at 60% VO_2max 60 min/day, 3 days/week. At the conclusion of 10 weeks, no changes in performance parameters were noted between groups. However, there was a statistically significant increase in fat utilization for the GTE group but no such change in the placebo group. The pre-exercise use of GTE was tested in a small human trial and showed induction of GLUT-4 receptors and improved fat oxidation. This finding further supports the use of GTE in improving body composition.[182] Animal studies have shown GTE to improve endurance and reduce fatigue,[183,184] and one human trial showed significant improvement in power and endurance in nontrained healthy males.[185]

Dosage

GTE dosage is usually 300 to 500 mg of a standardized extract daily.

Other Considerations

GTE can cause nausea in susceptible populations. It is also frequently combined with caffeine.

Quercetin

Quercetin is a bioflavonoid present in a variety of foods, including black and green tea, capers, apples, onions (giving them their yellow color), grapes, citrus fruit, tomato, broccoli, leafy green vegetables, and a number of berries. Davis et al.[186] conducted a small double-blind, placebo-controlled crossover trial on quercetin's effect on endurance capacity. Baseline VO_2max and time to exhaustion were determined for 12 participants before 7 days of supplementation with either quercetin (500 mg twice daily) or placebo. On follow-up testing, the quercetin group saw statistically significant increases in time to fatigue (13.2%) and VO_2max (3.9%) in comparison with placebo. Similar but more modest results were seen by Nieman et al.[187] in untrained subjects. Dumke et al.[188] showed no effect of quercetin on trained subjects.

Quercetin's performance-enhancing effects are often attributed to its being a polyphenol and a potent antioxidant. Given that in nature quercetin is present among other polyphenols, the benefits of polyphenols on exercise performance cannot be ignored. Although quercetin, among the many polyphenols, appears to be the most predominant ergogenic polyphenol, polyphenols as a whole appear to moderately improve athletic performance.[189] Although the goal is to be as precise as possible in deciphering which polyphenol and which dose produces beneficial outcomes, there is something to say about the synergism of multiple polyphenols that mimics their occurrence in nature. The synergism of multiple polyphenols is evident in the research showing benefit overall from polyphenol intake up to 688 mg daily, which is certainly feasible through diet.[189]

Dosage

The dosage of quercetin based on the previously mentioned studies is 1000 mg per day in divided doses.

Rhodiola

Rhodiola rosea is widely regarded as an "adaptogen." Adaptogens are defined as substances that aid the physiology in adaptation to stress, increasing function when it may be low and lowering it when it may be high. Anecdotal, animal, and some human research has hinted that *Rhodiola* may have ergogenic properties.[190–193] Several studies on *Rhodiola* suggest it may have benefit for performance, but the consensus leans more toward increased ability to adapt and recover.[191–193]

A well-designed study on *Rhodiola* was completed by Parisi et al.,[194] in which 14 competitively active males between the ages of 20 and 35 were given supplements of 170 mg of *Rhodiola rosea* extract daily for 4 weeks. All subjects completed VO_2max testing before supplementation. At the conclusion of 4 weeks, 30 minutes of cycling at 75% of VO_2max was completed. The subjects then had a 2-week washout period when no supplementation was taken. This process was followed by 4 more weeks of supplementation of placebo. At that point, the testing was repeated.

In this study on *Rhodiola* and placebo supplementation, participants' blood was drawn before testing, during supplementation, and after testing. Their rating of exertion was also monitored via the Borg exertion scale. There were no differences in any performance parameters, including perceived exertion. Both lactate and creatine kinase levels were reduced postexercise in the *Rhodiola* group. The *Rhodiola* group also showed increased levels of total antioxidants in comparison with placebo.

Dosage

Typical dose ranges are between 100 and 600 mg per day of *R. rosea* extract standardized to 3% rosavin + 1% salidroside. *Rhodiola* appears to have very low occurrences of side effects, and clinical evidence suggests it has a low toxicity.

Sodium Bicarbonate

Due to the fast accumulation of protons (hydrogen [H^+]) and carbon dioxide (CO_2) during high-intensity anaerobic activity, buffering capacity in muscle and blood is essential. The chief buffering compound is the bicarbonate ion (HCO_3^-). HCO_3^- buffers by the following reaction:

$H^+ + HCO_3^- \longleftrightarrow H_2CO_3 \longleftrightarrow H_2O + CO_2$. The CO_2 can then be offloaded in the lungs.

Sodium bicarbonate provides a reservoir of HCO_3^-, theoretically giving greater capacity to resist fatigue-induced pH changes at the muscle cell. Several studies have shown supplemental sodium bicarbonate can stabilize pH changes for exercise lasting from 60 seconds to several minutes and improve performance.[195–198] This finding explains the significant benefits seen with the use of sodium bicarbonate in high-intensity short duration exercises such as sprinting.[199] An additional study assessed the benefits of sodium bicarbonate on a basketball

simulation protocol, resulting in significant improvements in sprint time and muscle fatigue attenuation.[200] Benefits in endurance racing were also seen in athletes, with improvements in maximum running speed, muscle fatigue, and increased time to exhaustion.[201,202]

Dosage

Sodium bicarbonate can be taken in a performance dose before exercise or a loading dose several days before an event. The pre-exercise dose is 0.3 g/kg body weight of sodium bicarbonate taken in water between 60 and 90 minutes before an exercise bout. The loading dose of bicarbonate is taken over a 5-day period and consists of 5 g taken twice a day for 5 days.

Other Considerations

No safety issues appear to arise with sodium bicarbonate intake aside from digestive upset at higher doses. However, because the average person consumes excessive amounts of sodium, this intervention should be accompanied by recommendations to decrease other sources. The primarily source is salt, but because sodium is the cation for several chemical food additives, all prepared foods must be considered.

Spirulina

The consumption of the well-known algae *Spirulina* has been a practice among athletes from diverse cultures such as India, China, and Cuba.[203] *Spirulina* is considered a member of the "blue-green algae family" along with another popular algae, *Chlorella*. *Spirulina* differs from *Chlorella* because it does not have a cell wall, rendering it more digestible. Little research has been reported on this compound except the anecdotal reports of use and benefit from athletes in the countries mentioned and some positive outcomes in mice.[204] Although there is very little supportive evidence for its use, we include it here in this chapter as a novel compound that shows some promise.

A 2006 study by Lu et al.[203] followed up on anecdotal reports from athletes and positive outcomes in animals that *Spirulina* may aid in decreasing oxidative stress from exercise. Sixteen student volunteers were divided into two groups. One group added approximately 7 g *Spirulina* to their regular diet, whereas the control group was given the same amount of soy protein. The supplementation lasted for 3 weeks. Blood was collected before and after supplementation in both groups. Both groups also participated in a treadmill run to exhaustion the day before and day after supplementation. After 3 weeks, the *Spirulina* group saw positive changes in blood chemistry, such as reductions in malondialdehyde, and increases in superoxide dismutase (SOD) and lactate, as well as significant improvement in treadmill running time to exhaustion (713 vs. 765 seconds).[203] No significant change was seen in the soy group. These findings suggest that *Spirulina* can reduce oxidative damage induced by exercise while still improving performance.

A 2010 study by Kalafati et al.[205] looked at *Spirulina* supplementation in a small double-blind, placebo-controlled and counterbalanced trial. Each subject received 6 g *Spirulina* or placebo for 4 weeks and then underwent exercise testing. The exercise challenge involved a moderate-intensity run at 70% to 75% of VO_2max for 120 minutes followed by a 95% of VO_2max run until exhaustion. *Spirulina* supplementation decreased carbohydrate oxidation by 10.3% while improving fat burning by 10.9% during the 2-hour run. Time to fatigue was also significantly improved in the *Spirulina* group. Similar to the findings by Lu et al. and others,[206] these performance enhancements were also complemented by multiple positive changes in exercise antioxidant status, such as increased glutathione and reduced lipid peroxidation, even up to 24 hours after exercise.

Although exercise is a physical activity, a mental endurance and focus is essential in athletic performance. Spirulina may affect the physical and mental aspect of training; one study showed 3 g daily of *Spirulina* significantly improved mathematical-based mental fatigue acutely and after 8 weeks, and improved short-term endurance exercise.[207]

Dosage

Spirulina dose, based on these limited studies, appears to be 6 to 7 g per day.

Other Considerations

Quality of algae in products is a concern, because these compounds can easily accumulate heavy metals present in the environment. Clean sources of *Spirulina* should be sought.

Whey Protein

Whey protein is one of the most popular meal replacements and protein sources for athletes. The protein present in whey mimics many of the proteins present in human breast milk. Whey is very rich in essential amino acids and has an exceptionally high biological value of 104. It is a rich source of sulfur-containing amino acids (methionine and cysteine), is high in glutamine, and contains large amounts of the BCAAs leucine, isoleucine, and valine. The large amount of BCAA present in whey protein may be one of its key benefits (see section on "Branched Chain Amino Acids").[208]

Whey moves through the stomach rapidly and is absorbed quickly. For this reason, it has been designated as a "fast protein." Casein, on the other hand, transits the stomach slowly and is referred to as a "slow protein."[209] The different speed of absorption between whey and casein protein fractions can be harnessed when used in muscle-building protocols as described in the "Protein" section.

No studies exist comparing the effects of different protein sources on nitrogen balance, body composition, or performance in trained athletes. However, whey has been shown to promote growth and enhance nitrogen balance in experimental animals and burn victims.[210,211]

Whey protein has one of the highest concentrations of cysteine, the rate-limiting molecule in the de novo synthesis of glutathione.[212] Any supplement that can aid the body's endogenous production of key antioxidants like glutathione may play a role in lessening damage and speeding recovery from exercise. Although free-radical generation during exercise has been shown to be a normal consequence,[213] and training, in and of itself, increases antioxidant systems in the body, supplementation can further aid endogenous antioxidant systems. Although this supplement may help with recovery,[214,215] it has not been shown to directly enhance performance.[216]

Glutathione levels are reduced during exercise.[217,218] Ultraendurance events, such as marathons and triathlons, can increase oxidized glutathione levels by 189%.[219] Because whey protein provides factors that increase glutathione production, a higher intake could play a role in protecting against damage during exercise and recovery after exercise.[220]

Another benefit of whey protein may be its ability to bolster the content of other important amino acids. Whey enhances body levels of cysteine, taurine, glutamine, and BCAAs, among others.[159] This enhancement could have consequences in several areas, including immune function.[221,222] Nothing interrupts training more than illness.

Whey protein also has merit as a fat loss and muscle-building aid. Twenty grams of whey protein taken 20 minutes before exercise increased the number of calories burned after exercise by 100 compared with no supplementation.[223] This increase may make it a useful preworkout meal compared with carbohydrate, which may slow fat loss.[1] More recent studies suggest that the benefit of whey protein in inducing muscle protein synthesis may relate more to the dose rather than the timing.[224] Young resistance-trained males were given 20 g and 40 g of whey protein after training, when the latter group have greater muscle protein synthesis. The exercise stimulus cannot be ignored because these participants trained 3 days a week with total-body exercises, which may increase the demand of amino acids given more muscle groups are exercised. This finding then suggests that perhaps more strenuous and complete total-body exercises may require more protein.[224] With improvements in muscle mass, subsequent increases in basal metabolic rate and improved body composition are expected and confirmed in both male and female athlete and nonathletes.[225–228]

Whey protein also shows a powerful ability to regulate hunger and binge eating for weight control. Pal et al.[229] carried out a randomized crossover study on 22 males given equivalent gram doses of four liquid protein meals. The four protein meals were whey, tuna, turkey, and egg albumin. Four hours after the liquid protein meals, participants were given access to an all-you-can-eat buffet-style meal. The whey protein group had much greater satiety response and consumed significantly less food than any other group reported, showing whey protein as having a potential role in appetite regulation. A similar study by Akhavan et al.[230] showed whey protein taken before an all-you-can-eat pizza meal significantly lowered food intake, postmeal glucose, and insulin levels in response to the meal.

Dosage

As discussed in this section as well as in the sections on protein and meal timing, whey protein can provide benefit when timed appropriately with exercise. Consuming whey protein postworkout may be one of the most beneficial things an athlete can do to maximize lean body mass. Whey protein is low glycemic but insulinogenic at the same time.[222,229] Immediately after a workout until about 2 hours after the workout, the body is uniquely sensitized to insulin. This sensitization may create a unique opportunity for muscle growth without fat gain, especially in a postworkout setting.[222]

The addition of a small amount of carbohydrate may be more beneficial in terms of muscle gain. In studies analyzing postworkout intake of protein alone, carbohydrate alone, or a combination of both, protein and carbohydrate together generated the greatest insulin response.[178,180,181,231] This combination enhances muscle glycogen synthesis and storage and has benefit for athletes in terms of recovery.[178,180] Adding fat to the mix is not beneficial and may blunt this response.[232,233]

Combining whey protein with creatine may have synergistic benefit as well. Men supplementing their diets with a combination of whey protein and creatine together (1.2 g/kg per day of whey with 0.1 g/kg per day creatine) enjoyed greater improvements in strength and muscle mass in comparison with placebo.[234]

Other Considerations

Although many individuals are dairy intolerant, whey protein seems to be handled well by most people, probably because pure whey protein has low levels of lactose and is easily digested. However, people with known dairy sensitivities or allergies should be cautious with their intake of whey.

Bovine serum albumin (BSA) protein in whey has been suggested as a potential cause or possible contributing factor to insulin-dependent diabetes mellitus.[235,236]Anti-BSA antibodies have been found in people with insulin-dependent diabetes mellitus. Proteins on the β-cells of the pancreas may "mimic" the BSA proteins in whey, causing immune reactivity against both the whey protein and the β-cells.[235] Theoretically, this is "protein mimicry" at work and an ongoing debate that has not yet been resolved. Although the research is inconclusive,[237] it should not be completely ruled out as a possible environmental etiology.

Magnesium

From the basic understanding of biochemistry and physiology, the role of magnesium in nerve conduction, skeletal muscle contraction, and cardiovascular physiology is often overlooked as involving an essential mineral. In fact, most Americans are deficient in magnesium; approximately 60% receive less than the recommended 330 to 350 mg per day for men and 255 to 265 mg per day for women. Although we may not see an epidemic of magnesium deficiency, we are seeing a significant increase in chronic inflammatory diseases, which has been connected with subclinical magnesium deficiency.[238–240] Increased levels of inflammatory markers such as CRP, IL-1, fibrinogen, and VCAM-1 are correlated with magnesium deficiency,[238] raise concerns that perhaps magnesium-deficient athletes, given the metabolic stress brought on by rigorous training, may further be affected by inflammation potentially impairing performance and recovery.

Studies assessing magnesium intake in athletes confirms that athletes are not unique, and they too are deficient due to inadequate consumption of dietary magnesium similar to that of the general population,[241–243] with some studies showing consumption as low as 75% of the RDA.[244] Athletes cannot be assumed to be immune to the adverse effects of magnesium deficiency. Athletes with adequate magnesium intake were associated with improved endogenous antioxidants, such as catalase and glutathione.[245]

This finding would lead to the assumption that magnesium is an ergogenic aid. Many of the studies done on athletes assessed

magnesium status via a dietary intake, whereas others showed differences in magnesium status via erythrocyte or plasma magnesium concentrations. Surprisingly, several studies did not show improved performance from magnesium supplementation. However, one study assessing male volleyball athletes did show a small but significant improvement in plyometric countermovement exercise.[246] An additional study in elderly women suggests magnesium supplementation may improve age-related decline in physical performance as evident in functional movements, such as chair-stand time and walking speed.[247]

Taking a holistic, functional approach and given the common deficiency of magnesium among various populations, it would be prudent for athletes to consume at minimum the 400 to 500 mg of magnesium daily, preferably in more bioavailable forms such as citrate and glycinate. Although the literature does not strongly correlate magnesium with athletic performance, supplementation would provide optimal neurological, muscular, and cardiovascular function.

Dosage

Based on the RDA, a minimum of 400 to 500 mg of magnesium supplementation daily would at minimum provide the necessary requirements for muscle function. Loose stools may occur in bolus doses, which may require slow titration up to 500 mg or bowel tolerance.

Cold Water Immersion

Much anecdotal evidence exists asserting cold water immersion (CWI), a form of hydrotherapy or cryotherapy, as helping with recovery. Athletes from high school to the professional level have been using it for years to help with delayed-onset muscle soreness (DOMS) and fatigue. If recovery time can be shortened, then athletic performance can at least be maintained or improved, allowing athletes improved competitive performance and more time to train. This practice can allow for enhanced training loads, resulting in improved muscle function. Currently, the research tends to suggest there may be some benefit[248–250] to using CWI, with improvements in jump performance[250] and improved ability to complete more work subsequent to training sessions.[249] However, blood biochemistries showed no significant variations after cold water immersions.[250] A meta-analysis published in *The Journal of Strength and Conditional Research* by Higgins et al. in general showed benefits from CWI in terms of neuromuscular recovery and the perception of fatigue but not necessarily perception of muscle soreness.[251]

The most benefit from CWI in reducing muscle soreness was noticed at durations of 11 to 15 minutes at 11ºC to 15ºC.[252] Interestingly, this time and temperature range resulted in reduced muscle soreness up to 24 hours postexercise and in some after 24 hours. Some of the acute benefit may be attributed to the analgesic effect of cold on the pain-spasm cycle,[253] but the prolonged benefit may be attributed to the reduction and slowing of the inflammatory response.[254] However, more study is needed in this area to flesh out the details of the mechanics behind CWI.

Considering that CWI tends to be a safe and cost-efficient way of possibly improving performance, an athlete, trainer, or coach looking for a competitive edge may benefit from putting it to use. Caution must be taken with longer emersions and lower temperatures, when CWI may excessively depress sensory and motor neurons, possibly leading to temporary nerve damage.[255] CWI should not be used before exercise or activity, because it reduces nerve conduction velocity, thus affecting the neuromuscular response.[255]

Dosage

Optimal cold immersion appears to be 11 to 15 minutes at 11ºC to 15ºC.

Ribose

The amount of ATP stored in the muscle available for immediate use is limited, and once used, must be resynthesized in the muscle. Ribose, a naturally occurring pentose sugar, is attached to the adenine that is necessary to produce adenosine. Some studies show benefit of ribose supporting and replenishing ATP levels,[256] and although this makes sense biochemically, realistically it has not translated into improved athletic performance. Studies assessing the by-product of adenine nucleotide after ribose ingestion showed no significant changes.[257] There is no convincing evidence suggesting ribose is a limiting factor in muscle ATP synthesis, nor does it improve athletic performance.[257–260]

The literature suggests ribose supplementation may be most beneficial for the elderly population, in comparison with younger individuals. Ribose has a rejuvenating effect on the heart, as it improves well-being and quality of life. As part of the aging process, the ability of mitochondria to synthesize ATP may become less efficient, thus affecting skeletal and cardiac muscle function. Therefore ribose supplementation in older athletes may provide an ergogenic effect in terms of workout recovery and endurance.[261–263]

Although the safety profile of ribose is excellent, it needs much more study before classifying it as an ergogenic aid.

Stress Management

Michael T. Murray, ND

OUTLINE

INTRODUCTION

Stress is defined as any disturbance (e.g., heat or cold, chemical toxin, microorganisms, physical trauma, strong emotional reaction) that can trigger the "stress response." How an individual handles stress plays a major role in determining his or her level of health. Comprehensive stress management involves a truly holistic approach designed to counteract the everyday stresses of life. Most often, the stress response is so mild, it goes entirely unnoticed. However, if stress is extreme, unusual, or long lasting, the stress response can be overwhelming and quite harmful to virtually any body system.

Before one can discuss methods for helping patients deal effectively with stress, it is important to understand the stress response. Ultimately, the success of any stress management program depends on its ability to improve an individual's immediate and long-term responses to stress.

THE GENERAL ADAPTATION SYNDROME

The stress response is actually part of a larger response known as the *general adaptation syndrome*, a term coined by the pioneering stress researcher Hans Selye. To fully understand how to combat stress, one must understand the general adaptation syndrome. The syndrome is composed of three phases: alarm, resistance, and exhaustion.[1] These phases are largely controlled and regulated by the adrenal glands.

The initial response to stress is the alarm reaction, which is often referred to as the fight-or-flight response. The fight-or-flight response is triggered by activation of the sympathetic nervous system and, ultimately, the hypothalamic–pituitary–adrenal (HPA) axis, which causes the adrenals to secrete adrenaline and other stress-related hormones.

The fight-or-flight response is designed to counteract danger by mobilizing the body's resources for immediate physical activity. As a result, the heart rate and force of contraction of the heart increase to provide blood to areas necessary for response to the stressful situation. Blood is shunted away from the skin and internal organs, except the heart and lungs, whereas the amount of blood supplying required oxygen and glucose to the muscles and brain is increased. The rate of breathing rises to supply necessary oxygen to the heart, brain, and exercising muscle. Sweat production increases to eliminate toxic compounds produced by the body and to lower body temperature. Production of digestive secretions is severely reduced because digestive activity is not critical for counteracting stress. Blood sugar levels rise dramatically as the liver converts stored glycogen into glucose for release into the bloodstream.

Although the alarm phase is usually short-lived, the next phase—the resistance reaction—allows the body to continue fighting a stressor long after the effects of the fight-or-flight response have worn off. Other hormones, such as cortisol and other corticosteroids secreted by the adrenal cortex, are largely responsible for the resistance reaction. For example, these hormones stimulate the conversion of protein to energy so that the body has a large supply of energy long after glucose stores are depleted, and they promote the retention of sodium to keep blood pressure elevated.

As well as providing the necessary energy and circulatory changes required to deal effectively with stress, the resistance reaction provides the changes required to meet emotional crises, perform strenuous tasks, and fight infection. The effects of adrenal cortex hormones are quite necessary when the body is faced with danger, but prolongation of the resistance reaction or continued stress increases the risk of significant disease (including diabetes, high blood pressure, and cancer) and results in the final stage of the general adaptation syndrome, exhaustion.

Exhaustion may manifest as a partial or total collapse of a body function or specific organ. Two of the major causes of exhaustion are loss of potassium ions and depletion of adrenal glucocorticoid hormones, such as cortisone. Loss of potassium results in cellular dysfunction and, if severe, cell death. Depletion of adrenal glucocorticoid stores diminishes glucose control, leading to hypoglycemia.

Another cause of exhaustion is weakening of the organs. Prolonged stress places a tremendous load on many organ systems, especially the heart, blood vessels, adrenals, and immune system, and is associated with many common diseases, as listed in Box 140.1.

STRESS: A HEALTHY VIEW

Hans Selye is considered the father of modern stress research. Having spent many years studying this subject, Selye developed valuable

BOX 140.1 Diseases Strongly Linked to Stress

- Angina
- Asthma
- Autoimmune disease
- Cancer
- Cardiovascular disease
- Common cold
- Depression
- Diabetes (adult onset—type 2)
- Headaches
- Hypertension
- Immune suppression
- Irritable bowel syndrome
- Menstrual irregularities
- Premenstrual tension syndrome
- Rheumatoid arthritis
- Ulcerative colitis
- Ulcers

Data from Benson H. The relaxation response. New York: William Morrow, 1975.

insights into the role of stress in disease. According to Selye, stress in itself should not be viewed in a negative context. It is not the stressor that determines the response; instead, it is the individual's internal reaction that triggers the response. This internal reaction is highly individualized. What one person may experience as stress, the next person may view entirely differently. Selye perhaps summarized his view best in the following passage from his book *The Stress of Life*[2]:

> *No one can live without experiencing some degree of stress all the time. You may think that only serious disease or intensive physical or mental injury can cause stress. This is false. Crossing a busy intersection, exposure to a draft, or even sheer joy is enough to activate the body's stress mechanisms to some extent. Stress is not even necessarily bad for you; it is also the spice of life, for any emotion, any activity causes stress. But, of course, your system must be prepared to take it. The same stress which makes one person sick can be an invigorating experience for another.*

The key statement Selye made may be "your system must be prepared to take it." A significant body of knowledge has been accumulated delineating methodologies for helping patients develop healthful, rather than disease-facilitating, responses to both short- and long-term stress.

DIAGNOSTIC CONSIDERATIONS

Evaluating the effect of stress on a patient's health status requires a complete clinical assessment (e.g., review of systems, medical history, physical examination, sleep history, etc.). Many people who are "stressed out" may not be able to identify exactly what is causing them to feel stressed. Typical presenting symptoms are insomnia, depression, fatigue, headache, upset stomach, digestive disturbances, and irritability.

One useful tool to assess the role that stress may play is the Social Readjustment Rating Scale developed by Holmes and Rahe[3] (Table 140.1). The scale was originally designed to predict the risk of a serious disease due to stress. Various life-changing events are numerically rated according to their potential to cause disease. Notice that even events commonly viewed as positive, such as an outstanding personal achievement, carry stress.

TABLE 140.1 The Social Readjustment Rating Scale

Rank	Life Event	Mean Value
1	Death of spouse	100
2	Divorce	73
3	Marital separation	65
4	Jail term	63
5	Death of a close family member	63
6	Personal injury or illness	53
7	Marriage	50
8	Fired at work	47
9	Marital reconciliation	45
10	Retirement	45
11	Change in health of family member	44
12	Pregnancy	40
13	Sex difficulties	39
14	Gain of a new family member	39
15	Business adjustment	39
16	Change in financial state	38
17	Death of a close friend	37
18	Change to different line of work	36
19	Change in number of arguments with spouse	35
20	Large mortgage	31
21	Foreclosure of mortgage or loan	30
22	Change in responsibilities at work	29
23	Son or daughter leaving home	29
24	Trouble with in-laws	29
25	Outstanding personal achievement	28
26	Spouse begins or stops work	26
27	Beginning or end of school	26
28	Change in living conditions	25
29	Revision of personal habits	24
30	Trouble with boss	23
31	Change in work hours or conditions	20
32	Change in residence	20
33	Change in schools	20
34	Change in recreation	19
35	Change in church activities	19
36	Change in social activities	18
37	Small mortgage	17
38	Change in sleeping habits	16
39	Change in number of family get-togethers	15
40	Change in eating habits	15
41	Vacation	13
42	Christmas	12
43	Minor violations of the law	11

Data from Holmes TH, Rahe RH. The social readjustment rating scale. *J Psychosom Res* 1967;11:213–218.

If a person is under a great deal of immediate stress or has endured a fair amount of stress for a few months or longer, it is appropriate to assess adrenal dysfunction more accurately with laboratory methods.

The standard interpretation of the Social Readjustment Rating Scale is that a total of 200 or more units in 1 year is considered to

BOX 140.2 Negative Coping Patterns

- Dependence on chemicals: legal and illicit drugs, alcohol, smoking
- Overeating
- Too much television
- Emotional outbursts
- Feelings of helplessness
- Overspending
- Excessive behavior

be predictive of a high likelihood of experiencing a serious disease. However, rather than using the scale solely to predict the likelihood of serious disease, the clinician can use the scale to evaluate a patient's level of stressor exposure because everyone reacts differently to stressful events.

Laboratory assessment generally involves evaluating aspects of the HPA axis. The gold standard for diagnosing dysfunction of the HPA axis is the combined dexamethasone/corticotropin-releasing hormone test. This test is often used in research studies to monitor the clinical course of depression. More popular in the clinical setting are assessment tools based on salivary cortisol levels.[4,5] Salivary hormone levels are reproducible, comparable to plasma levels, and easy to assess.

One straightforward test that is a reasonably good predictor of HPA dysregulation is the cortisol-awakening response. Salivary levels generally show a sharp rise upon awakening and during the first hour after waking. Generally, an initially hyperactive HPA response results in elevated cortisol levels, whereas more chronic stress, insomnia, or depression may blunt this effect.[6,7]

Another popular test is measuring salivary cortisol levels at awakening and in the evening, usually along with dehydroepiandrosterone (DHEA). The classic pattern associated with chronic stress is elevated cortisol combined with reduced DHEA, indicating a shift toward glucocorticoid production and away from sex hormone steroid production. This pattern is often associated with anxiety and depression. Adrenal exhaustion is characterized by low cortisol and low DHEA. Adrenal exhaustion is a common side effect of continual high stress as well as steroid drugs, such as prednisone, which are used in the treatment of allergic or inflammatory diseases.

THERAPEUTIC APPROACH

Whether currently aware of it or not, the patient has developed a pattern for coping with stress. Unfortunately, most people have found patterns and methods that ultimately do not support good health. Negative coping patterns must be identified and replaced with positive ways of coping. The clinician should try to identify any negative or destructive coping patterns, listed in Box 140.2, that the patient may have developed and try to replace those patterns with more positive measures for dealing with stress.

Stress management can be substantially improved by assisting the patient in the following six equally important areas:

- Techniques to calm the mind, promote parasympathetic tone, and promote a positive mental attitude
- Lifestyle factors
- Exercise
- A healthful diet designed to nourish the body and support physiological processes
- Dietary and botanical supplements designed to support the body as a whole, but especially the adrenal glands
- Supervised stress management program

BOX 140.3 The Stress Response

- The heart rate and force of contraction of the heart increase to provide blood to areas necessary for response to the stressful situation.
- Blood is shunted away from the skin and internal organs, except the heart and lungs, whereas the amount of blood supplying required oxygen and glucose to the muscles and brain is increased.
- The rate of breathing rises to supply necessary oxygen to the heart, brain, and exercising muscle.
- Sweat production increases to eliminate toxic compounds produced by the body and to lower body temperature.
- Production of digestive secretions is severely reduced because digestive activity is not critical to counteracting stress.
- Blood sugar levels are raised dramatically as the liver dumps stored glucose into the bloodstream.

BOX 140.4 The Relaxation Response

- The heart rate is reduced, the heart beats more effectively, and blood pressure is reduced.
- Blood is shunted toward internal organs, especially those organs involved in digestion.
- The rate of breathing decreases as oxygen demand is reduced during periods of rest.
- Sweat production diminishes because a person who is calm and relaxed does not experience nervous perspiration.
- Production of digestive secretions is increased, greatly improving digestion.
- Blood sugar levels are maintained in the normal physiological range.

Calming the Mind and Body

Learning to calm the mind and body is extremely important in relieving stress. Among the easiest methods for the patient to learn are relaxation exercises. The goal of relaxation techniques is to produce a physiological response known as a relaxation response—a response that is exactly opposite to the stress response that reflects activation of the parasympathetic nervous system. Although an individual may relax by simply sleeping, watching television, or reading a book, relaxation techniques are designed specifically to produce the relaxation response.

The term *relaxation response* was coined by Harvard professor and cardiologist Herbert Benson in the early 1970s to describe a physiological response that is just the opposite of the stress response.[1] With the stress response (Box 140.3), the sympathetic nervous system dominates. With the relaxation response (Box 140.4), the parasympathetic nervous system dominates. The parasympathetic nervous system controls bodily functions such as digestion, breathing, and heart rate during periods of rest, relaxation, visualization, meditation, and sleep. Although the sympathetic nervous system is designed to protect against immediate danger, the parasympathetic system is designed for repair, maintenance, and restoration of the body.

The relaxation response can be achieved through a variety of techniques. The methodology should be determined by patient interest because all techniques have the same physiological effect—a state of deep relaxation. The most popular techniques are meditation, prayer, progressive relaxation, self-hypnosis, and biofeedback. To produce the desired long-term health benefits, the patient should use the relaxation technique for at least 5 to 10 minutes each day.

Breathing

Producing deep relaxation with any technique requires learning how to breathe. One of the most powerful methods of producing less stress and more energy in the body is by breathing with the diaphragm.

BOX 140.5 Instructions to Help Patients Learn Diaphragmatic Breathing

1. Find a comfortable and quiet place to lie down or sit.
2. Place your feet slightly apart. Place one hand on your abdomen near your navel. Place the other hand on your chest.
3. You will be inhaling through your nose and exhaling through your mouth.
4. Concentrate on your breathing. Note which hand is rising and falling with each breath.
5. Gently exhale most of the air in your lungs.
6. Inhale while slowly counting to four. As you inhale, slightly extend your abdomen, causing it to rise about 1 inch. Make sure that you are not moving your chest or shoulders.
7. As you breathe in, imagine the warmed air flowing in. Imagine this warmth flowing to all parts of your body.
8. Pause for 1 second, then slowly exhale to a count of four. As you exhale, your abdomen should move inward.
9. As the air flows out, imagine all your tension and stress leaving your body.
10. Repeat the process until a sense of deep relaxation is achieved.

Diaphragm breathing activates the relaxation centers in the brain and the parasympathetic nervous system. Box 140.5 lists a 10-step technique for teaching diaphragmatic breathing.

Progressive Relaxation

One of the most popular techniques for producing the relaxation response is progressive relaxation. The technique is based on a very simple procedure of comparing tension with relaxation. Many people are not aware of the sensation of relaxation. In progressive relaxation, an individual is taught what it feels like to relax by comparing relaxation with muscle tension.

The basic technique is to have the patient contract a muscle forcefully for a period of 1 to 2 seconds and then give way to a feeling of relaxation in that muscle. The procedure systematically goes through all the muscles of the body, progressively producing a deep state of relaxation. The procedure begins with contracting the muscles of the face and neck, then the upper arms and chest, followed by the lower arms and hands. The process is repeated progressively down the body, from the abdomen through the buttocks, the thighs, and calves to the feet. This whole process is repeated two or three times. This technique is often used in the treatment of anxiety and insomnia.

Progressive relaxation, deep-breathing exercises, or some other stress reduction technique is an important component of a comprehensive stress management program.

Lifestyle Factors

A patient's lifestyle is a major determinant of his or her stress levels. The two primary areas of concern (other than addressing negative coping patterns) are time management and relationship issues.

One of the biggest stressors for most people is time. They simply do not feel they have enough of it. Box 140.6 provides tips on time management for patients.

Another major cause of stress for many people is interpersonal relationships. Interpersonal relationships can be divided into three major categories: marital, family, and job related. The quality of any relationship ultimately comes down to the quality of the communication. Learning to communicate effectively goes a very long way in reducing the stress and occasional (or frequent) conflicts of interpersonal relationships. Box 140.7 lists seven tips for effective communication, regardless of the type of interpersonal relationship.

BOX 140.6 Patient Tips for Improved Time Management

- Set priorities. Realize that you can only accomplish so much in a day. Decide what is important, and limit your efforts to that goal. Organize your day. There are always interruptions and unplanned demands on your time, but create a definite plan for the day on the basis of your priorities. Avoid the pitfall of always letting the "immediate demands" control your life.
- Delegate authority. Delegate as much authority and work as you can. You cannot do everything yourself. Learn to train and depend on others.
- Tackle tough jobs first. Handle the most important tasks first, when your energy levels are high. Leave the busy work or running around for later in the day.
- Minimize meeting time. Schedule meetings to bump up against the lunch hour or quitting time; that way, they cannot last forever.
- Avoid putting things off. Work done under the pressure of an unreasonable deadline often has to be redone. That creates more stress than if it had been done right the first time. Plan ahead.
- Do not be a perfectionist. You can never really achieve perfection anyway. Do your best in a reasonable amount of time, then move on to other important tasks. If you find time, you can always come back later and polish the task some more.

BOX 140.7 Keys to Assist Patients in Improving Communication

- The first key to successful communication is the most important: learn to be a good listener. Allow the person you are communicating with to really share his or her feelings and thoughts uninterrupted. Empathize with the person; put yourself in his or her shoes. If you first seek to understand, you will find yourself being better understood.
- Be an active listener. This means that you must be truly interested in what the other person is communicating. Listen to what he or she is saying instead of thinking about your response. Ask questions to gain more information or clarify what he or she is telling you. Good questions open lines of communication.
- Be a reflective listener. Restate or reflect back to the other person your interpretation of what he or she is telling you. This simple technique shows the other person that you are both listening to and understanding what he or she is saying. Restating what you think is being said may cause some short-term conflict in some situations, but it is certainly worth the risk.
- Wait to speak until the person you want to communicate with is listening. If the person is not ready to listen, your message will not be heard no matter how well you communicate.
- Do not try to talk over somebody. If you find yourself being interrupted, relax; do not try to out-talk the other person. If you are courteous and allow him or her to speak, eventually (unless extremely rude), he or she will respond likewise. If that does not happen, point out that the other person is interrupting the communication process. You can do this only if you have been a good listener. Double standards in relationships seldom work.
- Help the other person become an active listener. This can be done by asking whether he or she has understood what you were communicating. Ask him or her to tell you what he or she heard. If the other person does not seem to be understanding what you are saying, keep trying until he or she does.
- Do not be afraid of long silences. Human communication involves much more than human words. A great deal can be communicated during silences; unfortunately, in many situations, silence can make us feel uncomfortable. Relax. Some people need silence to collect their thoughts and feel safe in communicating. The important thing to remember during silences is that you must remain an active listener.

Exercise

The immediate effect of exercise is stress on the body. However, with a regular exercise program, the body adapts, and exercise becomes an effective stress reduction technique. With regular exercise, the body becomes stronger, functions more efficiently, and has greater endurance. Exercise is a vital component of a comprehensive stress management program and overall good health.

People who exercise regularly are much less likely to experience fatigue and depression. Tension, depression, feelings of inadequacy, and worries diminish greatly with regular exercise. Exercise alone has been demonstrated to have a tremendous effect in terms of improving mood and the ability to handle stressful life situations in both adults of all ages and adolescents as well. Exercise positively affects mood and reduces stress through physiological and biochemical mechanisms, including endorphins, mitochondria, mammalian target of rapamycin, neurotransmitters and the hypothalamic–pituitary–adrenal axis, and even the microbiome.[8,9]

Dietary Guidelines

An individual with stress or anxiety must support the biochemistry of the body by following some important dietary guidelines. Specifically, the patient must do the following:

- Eliminate or restrict the intake of caffeine.
- Eliminate or restrict the intake of alcohol.
- Eliminate refined carbohydrates from the diet.
- Eat a diverse range of whole foods.
- Increase the potassium-to-sodium (K/Na) ratio.
- Eat regular planned meals in a relaxed environment.
- Control food allergies.

According to Selye,[2] whether or not stress is harmful is based on the strength of the system. From a purely physiological perspective, it can be strongly argued that the delivery of high-quality nutrition to the cells of the body is the critical factor in determining the strength of the system.

When the eating habits of Americans are examined as a whole, it is little wonder that so many people have stress, anxiety, and fatigue. Most Americans are not providing their bodies with the high-quality nutrition they need. Instead of eating foods rich in vital nutrients, most Americans focus on refined foods high in calories, sugar, fat, and cholesterol.

Caffeine

The average American consumes 150 to 225 mg of caffeine daily, or roughly the amount of caffeine in two cups of coffee. Although most people can handle this amount, some people are more sensitive to the effects of caffeine than other people, owing to decreased activity of Phase I detoxification enzymes. Even small amounts of caffeine can affect sensitive people, whereas those with normal sensitivity respond to large amounts. Excessive caffeine consumption can produce "caffeinism characterized by symptoms of depression, nervousness, irritability, recurrent headache, heart palpitations, and insomnia." People prone to feeling stress and anxiety tend to be especially sensitive to caffeine.[10,11]

Alcohol

Alcohol produces chemical stress on the body. It also increases adrenal hormone output and interferes with both normal brain chemistry and normal sleep cycles. Although many people believe that alcohol has a calming effect, a study of 90 healthy male volunteers given either a placebo or alcohol demonstrated significant increases in anxiety scores after consumption of alcohol.[10,11]

Refined Carbohydrates and Glycemic Volatility

One of the consequences of the stress response is abdominal fat cell growth and loss of muscle mass, a scenario that obviously leads to insulin resistance and obesity. It is a complex set of events orchestrated by cortisol released as a result of the stress response that is ultimately responsible for the fact that stress promotes weight gain. Cortisol is also a contributing factor in a high degree of glycemic volatility. Rapidly fluctuating blood sugar levels are generally related to some degree of insulin resistance and made worse by more-than-moderate consumption of foods with a high glycemic impact. Refined carbohydrates (e.g., sugar and white flour) are known to contribute to problems in blood sugar control, especially hypoglycemia, as well as glycemic volatility. The association between hypoglycemia and impaired mental function is well known. Numerous studies have shown a high percentage of hypoglycemia in depressed patients.[12,13] Because depression is one of the most common causes of anxiety, this finding provides a link between hypoglycemia and feelings of stress. Simply eliminating refined carbohydrates from the diet is occasionally all that is needed for effective therapy in patients who have depression or anxiety due to hypoglycemia.

Potassium-to-Sodium Ratio

One of the key dietary recommendations to support the adrenal glands is to ensure adequate potassium levels within the body. This can best be done by consuming foods rich in potassium and avoiding foods high in sodium. Most Americans have a dietary K/Na ratio of less than 1:2. In contrast, most researchers recommend a dietary K/Na ratio higher than 5:1 for health. However, even this recommendation may not be optimal. A natural diet rich in fruits and vegetables can produce a K/Na ratio higher than 50:1 because most fruits and vegetables have a K/Na ratio of more than 100:1.

Meal Planning

Mealtimes should be spent in a relaxed environment. As noted previously, digestion is a process largely controlled by the parasympathetic nervous system. Eating in a rushed manner or in a noisy or hurried environment is not conducive to good digestion or good health.

Food Allergies

People with symptoms of anxiety or chronic fatigue must be concerned about food allergies. As far back as 1930, pioneering allergist Albert Rowe began noticing that anxiety and fatigue were key features of food allergies.[14] Originally, Rowe described a syndrome known as "allergic toxemia" to describe a syndrome that included the symptoms anxiety, fatigue, muscle and joint aches, drowsiness, difficulty concentrating, and depression. Around the 1950s, this syndrome began to be referred to as the "allergic tension-fatigue syndrome." Due to the popularity of chronic fatigue syndrome, many physicians and other people are forgetting that food allergies can lead to anxiety as well as chronic fatigue.

NUTRITIONAL AND BOTANICAL SUPPORT

Nutritional and botanical support for the individual experiencing signs and symptoms of stress largely involves supporting the adrenal glands. Long-term stress and corticosteroids cause the adrenal glands to shrink and become dysfunctional, aggravating the stress symptoms of anxiety, depression, and chronic fatigue.

An abnormal adrenal response, either deficient or excessive hormone release, significantly alters an individual's response to stress. Often, the adrenals become "exhausted" as a result of constant demands put on them. An individual with adrenal exhaustion usually experiences chronic fatigue and may complain of feeling "stressed out" or chronically anxious. He or she typically has reduced resistance to allergies and infection.

Nutritional Supplements

The nutrients especially important for supporting adrenal function are vitamin C, vitamin B_6, zinc, magnesium, and pantothenic acid. All of these nutrients play a critical role in the health of the adrenal gland as well as the manufacture of adrenal hormones. During stress, the levels of these nutrients in the adrenals decrease substantially.

For example, during chemical, emotional, psychological, or physiological stress, the urinary excretion of vitamin C is increased. Examples of chemical stressors are cigarette smoke, pollutants, and allergens. Extra vitamin C in the form of supplementation and a higher intake of vitamin C–rich foods is often recommended to keep the immune system working properly during times of stress.

Equally important during high periods of stress or in individuals needing adrenal support is pantothenic acid (vitamin B_5). Pantothenic acid deficiency results in adrenal atrophy, characterized by fatigue, headache, sleep disturbances, nausea, and abdominal discomfort. Pantothenic acid is found in whole grains, legumes, cauliflower, broccoli, salmon, liver, sweet potatoes, and tomatoes. In patients who have chronic stress or a history of corticosteroid (prednisone) use, the typical level of supplementation is 100 to 500 mg/day.

The appropriate daily dose of vitamin B_6 is 50 to 100 mg; of zinc, 20 to 30 mg; and of magnesium, 250 to 500 mg.

Gamma-aminobutyric Acid

Gamma-aminobutyric acid (GABA) is a major neurotransmitter that is abundantly and widely distributed throughout the central nervous system. Low levels or decreased GABA function in the brain are associated with several psychiatric and neurological disorders, but most primarily anxiety, depression, insomnia, and epilepsy. Currently, many popular antianxiety drugs—the sedative-hypnotics—interact primarily with GABA receptors. These drugs include the benzodiazepine drugs like alprazolam (Alprazolam, Xanax) and diazepam (Valium), as well as drugs like flurazepam (Dalmane), quazepam (Doral), temazepam (Restoril), triazolam (Halcion), zolpidem tartrate (Ambien), and baclofen (Kemstro and Lioresal).

Clinical studies with PharmaGABA, a naturally manufactured supplement via a fermentation process that uses *Lactobacillus hilgardii,* have shown it to produce significant antistress effects.[15,16] Specifically, PharmaGABA has been shown to produce relaxation, as evidenced by changes in brain-wave patterns, pupil diameter, and heart rate, as well as reduce markers of stress, including salivary cortisol and chromogranin A levels. These effects are thought to be the result of activation of the parasympathetic nervous system rather than PharmaGABA crossing the blood–brain barrier. The typical dosage is 100 to 200 mg up to three times daily. As a general guideline, it is recommended to take no more than 1000 mg within a 4-hour period and no more than 3000 mg within a 24-hour period.

Botanical Medicines

Several botanical medicines support adrenal function. Most notable are the ginsengs—Chinese ginseng (*Panax ginseng*) and Siberian ginseng (*Eleutherococcus senticosus*)—rhodiola (*Rhodiola rosea*), and ashwagandha (*Withania somnifera*). All of these plants exert beneficial effects on adrenal function, enhance resistance to stress, and are often referred to as "adaptogens." These plants have historically been used as follows:

- To restore vitality in debilitated and feeble individuals
- To increase feelings of energy
- To improve mental and physical performance
- To prevent the negative effects of stress and enhance the body's response to stress

Both Siberian and Chinese ginsengs possess this kind of equilibrating, tonic, antistress action, and so the term *adaptogen* is quite appropriate in describing their general effects.

The ginsengs have been shown to enhance the ability to cope with various stressors, both physical and mental.[17–19] Presumably, this antistress action is mediated by mechanisms that control the adrenal glands. Ginseng delays the onset and reduces the severity of the alarm-phase response of the general adaptation syndrome.

People taking either of the ginsengs typically report an increased sense of well-being. Clinical studies have confirmed that both Siberian and Chinese ginsengs significantly reduce feelings of stress and anxiety. For example, in one double-blind clinical study, nurses who switched from day to night duty rated themselves for competence, mood, and general well-being and were given a test for mental and physical performance along with blood cell counts and blood chemistry evaluation.[20] The group who were given *P. ginseng* demonstrated higher scores in competence, mood parameters, and mental and physical performance compared with those receiving placebos. The nurses taking the ginseng felt more alert yet more tranquil, and were able to perform better than the nurses who were not taking the ginseng.

In addition to these human studies, several animal studies have shown the ginsengs to exert significant antianxiety effects. In several of these studies, the stress-relieving effects were comparable to those of diazepam (Valium); however, diazepam causes behavior changes, sedative effects, and impaired motor activity, but ginseng has none of these negative effects.[21]

On the basis of the clinical and animal studies, ginseng appears to offer significant benefit to people experiencing stress and anxiety. *P. ginseng* is generally regarded as being more potent than *E. senticosus. P. ginseng* is probably better for the patient who has experienced a great deal of stress, is recovering from a long-standing illness, or has taken corticosteroids, such as prednisone, for a long time. For the patient who is under mild to moderate stress and is experiencing less obvious impairment of adrenal function, *E. senticosus* may be the better choice.

Another useful botanical medicine to support stress management is *R. rosea* (artic root), a popular plant in traditional medical systems in Eastern Europe and Asia, where it has traditionally been recommended to help combat fatigue and restore energy. Modern research has confirmed these effects and its qualities as an adaptogen. However, the adaptogenic actions of *R. rosea* are different from those of Chinese and Siberian ginsengs, which act primarily on the HPA axis. *R. rosea* seems to exert its adaptogenic effects by working on neurotransmitters and endorphins. *R. rosea* appears to offer an advantage over other adaptogens in circumstances of acute stress because it produces a greater feeling of relaxation and antianxiety effects. A single dose of *Rhodiola* extract before acute stressful events has been shown to prevent stress-induced disruptions in function and performance, but like the ginsengs, *R. rosea* has also shown positive results with long-term use.[22–25] In one randomized, placebo-controlled trial of 60 patients with stress-related fatigue, *Rhodiola* was found to have an antifatigue effect that increased mental performance, particularly the ability to concentrate, as well as decreased the cortisol response to awakening stress.[26]

On the basis of the results of clinical trials with a standardized *R. rosea* extract, the therapeutic dose varies according to the rosavin content. For a dosage target of 3.6 to 7.2 mg of rosavin, the daily dose would be 360 to 600 mg for an extract standardized for 1% rosavin, 180 to 300 mg for 2% rosavin, and 100 to 200 mg for 3.6% rosavin. When *R. rosea* is used as an adaptogen, long-term administration is normally begun several weeks before a period of expected increased physiological, chemical, or biological strain and continued throughout the duration of the challenging event or activity. When *R. rosea* is used as a single dose for acute

stress (e.g., for an examination or athletic competition), the suggested dose is three times the dose used for long-term supplementation. No side effects have been reported in the clinical trials, but at higher doses, some individuals might experience greater irritability and insomnia.

Lastly, clinical studies with extracts of roots and leaves from *Withania somnifera* (ashwagandha) have shown considerable antistress and adaptogenic effects.[27] In one human double-blinded study, chronically stressed subjects taking a proprietary extract (Sensoril) had significant reductions in a modified Hamilton anxiety scale, serum cortisol, C-reactive protein, pulse rate, and blood pressure and significant increases of serum DHEA-S and hemoglobin compared with the placebo group. In addition, there were dose-dependent responses in lowering fasting blood glucose and improving the serum lipid levels. Dosage was 125 to 250 mg one to two times daily.[28] In another double-blind study, 50 healthy male/female athletic adults were given a proprietary extract (KSM-66) at a dosage of 300 mg twice daily or a placebo for 12 weeks. Not only were quality-of-life scores significantly improved, but the ashwagandha extract also increased VO_{2max} compared with placebo at 12 weeks (5.67 and 1.86, respectively).[29]

Stress Management Programs

Supervised stress management programs are thought to offer greater compliance and better results than unsupervised, patient-directed programs. In one study, stress management experts evaluated six widely used occupational stress management interventions (relaxation, physical fitness, cognitive restructuring, meditation, assertiveness training, and stress inoculation) on the basis of 10 practicality criteria and 7 effectiveness objectives. They found that relaxation was the most practical intervention and that meditation and stress inoculation were the least practical. Physical fitness was chosen to be the most effective intervention, and both meditation and assertiveness training were rated overall as the least effective. What these results imply is that although relaxation training may be the most practical intervention, physical exercise was the most effective intervention.[30]

Meditation was shown to be the least practical and least effective method in this evaluation, but when it is part of a supervised program, it can be very effective. In one trial of 103 adults, 59% and 61% of the meditation and control groups, respectively, completed the study.[31] The intervention program consisted of an 8-week group stress reduction program in which subjects learned, practiced, and applied "mindfulness meditation" to daily life situations. Those in the control group received educational materials and were encouraged to use community resources for stress management. Compared with the control group, intervention subjects reported significant decreases from baseline in effect of daily hassles (24%), psychological distress, (44%), and medical symptoms (46%) that were maintained at the 3-month follow-up.

SECTION 6

Diseases

A big challenge in writing *A Textbook of Natural Medicine* is how to address the concept of disease. Although some disease names correlate well with the pathophysiology and are real entities—a good example is trichomoniasis, which is the result of a successful invasion by a pathological organism—most diseases are simply convenient names for grouped patterns of abnormal physiology. Focusing on the disease name implies it is a real entity separate from the natural body. This focus can obfuscate an understanding of what is actually happening with the patient's physiology. A prime example is type 2 diabetes. Although loss of proper blood sugar control is the common denominator, the actual abnormal physiology could be due to a number of different underlying mechanisms, such as cellular insulin insensitivity, loss of pancreatic production of insulin, or hypercortisolemia, because there are multiple separate substantive dysfunctions—all with very different optimal interventions—that result in loss of blood sugar control. Treating the disease by forcing a lowering of blood sugar may appear effective in the short term, but because the foundational underlying causes have not been addressed, the patient suffers progressively worse sequelae. The failure to address these factors is a key reason why (at the time of this publication) diabetes and its complications account for an astounding 20% of healthcare spending in the United States.

Nonetheless, because most clinicians and patients still have a disease diagnosis and treatment perspective, we address disease—but always in the context of the physiological abnormalities that are the actual causes of the patient's ill health and symptoms.

This section is both a therapeutic handbook and a study of the origins and causes of disease. Each disease is thoroughly discussed, with particular emphasis on the biochemistry of the altered physiology leading to the symptomatology and pathology. We also discuss, as appropriate, the aspects of genetics and lifestyle leading to the disorder. Finally, we present a comprehensive therapeutic regimen using the most natural and least invasive therapies available.

Although we believe this to be the most effective way to present the material, we are extremely concerned that it could continue to promote the disease orientation of the current dominant medical system. We can only offer the following suggestion: Always treat the patient, not the disease!

All recommendations made here should be considered in the context of the whole patient. Our purpose is to help our patients to become well, not to simply alleviate symptoms and allow the true cause(s) of their disease to continue unabated. We therefore recommend that readers carefully study Sections I and IV before reading this section and that treatment providers should always consider the psychological and spiritual reasons people may have for being sick.

Organization

In general, each chapter is divided into the following five parts:

- Diagnostic summary—brief list of the key diagnostic elements
- General considerations—discussion of the underlying pathology and altered physiology
- Therapeutic considerations—discussion of the correctable nutrient deficiencies, possible toxin causes, and various natural therapies that may be used to treat the underlying pathophysiology
- Therapeutic approach—a concise therapeutic regimen
- References—thorough documentation through peer-reviewed scientific research of the discussion to aid those who seek further study of our treatment rationale

The section is arranged alphabetically by disease name. Please also use the Index to look for diseases because some are addressed in other disease chapters or within a grouping, and occasionally disease-naming conventions change. For example, depression is discussed in the chapter "Affective Disorders."

To aid us in the further development of this textbook, we welcome comments. In particular, we are greatly interested in well-documented successes, **and failures**, of the use of these procedures. We would also appreciate recommendations for therapeutic and diagnostic approaches not included here that have documented success.

141

Acne Vulgaris and Acne Conglobata

Michael Traub, ND, DHANP, FABNO

OUTLINE

DIAGNOSTIC SUMMARY

- Open comedones—dilated follicles with central dark, horny plugs (blackheads)
- Closed comedones—small follicular papules with (red papules) or without (whiteheads) inflammatory changes
- Superficial pustules—collections of pus at follicular opening
- Nodules—tender collections of pus deep in dermis
- Cysts—from nodules that fail to discharge contents to the surface
- Large, deep pustules—from nodules that break down adjacent tissue, leading to scars

GENERAL CONSIDERATIONS

Acne vulgaris is characterized as a pilosebaceous disease with comedones, papules, and pustules, whereas cystic acne is a more severe form, with cyst formation and subsequent scarring. Acne lesions occur predominantly on the face and, to a lesser extent, on the back, chest, and shoulders. It is more common in males, and onset is typically at puberty (somewhat later for the cystic form).

Etiology

Acne is the most common of all skin problems. A key factor is genetics. It is inherited in an autosomal-dominant pattern with incomplete penetrance. If both parents had acne, three of four children will have acne. If one parent had acne, then one of four of the children will have acne.[1]

The onset of acne vulgaris usually reflects an increase in pilosebaceous gland size and sebum secretion due to androgenic stimulation. In puberty, changes in the lipid profile of sebum (dys-seborrhea), stress, irritation, dietary composition, and cosmetics can lead to inflammation. Epidermal dysbiosis leads to disruption in the skin barrier. The severity and progression are determined by a complex interaction among hormones, keratinization, sebum, and bacteria.

The lesions begin in the upper portion of the follicular canal, with hyperkeratinization being the first microscopical change. This leads to blockage of the canal, resulting in dilation and thinning. Eventually, a comedone is formed. The formation of open or closed comedones appears to be related to the degree of keratinization and the level of blockage of the duct.

Despite a large amount of purulent exudate in pustular and cystic lesions, the only bacteria commonly cultured are normal skin species. *Propionibacterium acnes* proliferates in the pilosebaceous unit and releases lipases that hydrolyze sebum triglycerides into free fatty-acid lipoperoxides, activating expression of protease-activated receptors (PARs), tumor necrosis factor-alpha, and toll-like receptors and the production of interferon-gamma, interleukins 1, 8, and 12, and matrix metalloproteinases by keratinocytes, thus promoting an inflammatory cascade and hyperkeratinization of the pilosebaceous unit.[2]

Acne-like lesions can occur in response to various compounds: corticosteroids, halogens, isonicotinic acid, diphenylhydantoin, lithium carbonate, anabolic steroids (e.g., testosterone), and immunotherapeutic agents. Exposure to various industrial pollutants can also cause acne: machine oils, coal tar derivatives, and chlorinated hydrocarbons.

Cosmetics, pomades, overwashing, and repetitive rubbing can produce acne as well.

Chloracne is an acneiform eruption of blackheads, cysts, and nodules associated with exposure to halogenated aromatic compounds, including the dioxins. Most cases of chloracne have resulted from agricultural occupational exposures. However, nonoccupational chloracne has occurred from contaminated industrial wastes and contaminated food products and can accumulate in the human and animal food chains. The primary clinical manifestations of chloracne are noninflammatory comedones and straw-colored cysts that appear on the face (particularly the cheeks), neck, trunk, extremities, genitalia, and/or axilla.[3] The presence of chloracne is considered to be a clinical sign of dioxin exposure.

Endocrinological Aspects

Acne is an androgen-dependent condition, and androgen excess, either systemic or local, is associated with more severe forms of the disease. Androgens control sebaceous gland secretion and exacerbate the development of abnormal keratinizing follicular epithelium. Endocrine disorders producing excess androgens are important etiological factors: idiopathic adrenal androgen excess, partial defect in 21-hydroxylase, and polycystic ovary syndrome. Free testosterone, dehydroepiandrosterone, dehydroepiandrosterone sulfate, and low sex-hormone-binding globulin levels have all been implicated.[4–6] The skin of patients with acne shows greater activity of 5-α-reductase, the enzyme that converts testosterone to a more potent androgen, dihydrotestosterone.[7,8] This increased activity is independent of systemic levels of androgens and may explain the poor correlation between systemic levels of androgens and the severity of acne lesions. Receptors for growth hormone and insulin-like growth factor-1 (IGF-1) are present on the sebaceous gland, and these hormones also stimulate sebum production. Conditions of growth-hormone excess (e.g., acromegaly) are associated with increased sebum production and acne. Insulin at high levels can interact with IGF-1 receptors. IGF-1 promotes the expression of enzymes responsible for androgen biosynthesis and conversion. Elevated cortisol due to chronic stress thickens sebum. The stress of acne compounds this problem.

THERAPEUTIC CONSIDERATIONS

Effective treatment of acne is a significant clinical challenge. Success with natural treatments can be obtained only by the rigorous, comprehensive application of dietary, nutritional, and botanical interventions.

Guidelines for the management of acne were published in 2016 by the American Academy of Dermatology.[9] Referring to these guidelines may be instructive in making alternative natural medicine recommendations.

Diet

Although historically there was controversy regarding diet in the etiology of acne, there is now clear evidence of causality. In Western societies, acne vulgaris is a nearly universal skin disease afflicting 79% to 95% of the adolescent population. Among men and women older than 25 years, 40% to 54% have some degree of facial acne, and clinical facial acne persists into middle age in 12% of women and 3% of men. In contrast, epidemiological evidence suggests that acne incidence rates are considerably lower in non-Western societies. For example, researchers found no cases of acne among the Kitavan Islanders of Papua New Guinea and the Ache hunter-gatherers of Paraguay.[10]

The exact diet for acne sufferers to follow has not been evaluated, but foods high in iodine should be eliminated and milk consumption limited.[11] Milk contains estrogens, progesterone, and androgens, as well as glucocorticoids and IGF-1.[12] Trans-fatty acids and saturated fats should also be eliminated because they can increase sebaceous secretions and increase inflammation (Fig. 141.1). The composition of the diet should be in the range of 45% protein, 35% carbohydrate, and 20% fat because such a composition produces substantially less 5-α-reduction of testosterone and enhanced cytochrome P450 hydroxylation of estradiol, both therapeutic goals.[13] A high-carbohydrate diet (10% protein, 70% carbohydrate, and 20% fat) has the opposite effect. A diet that encourages a high insulin response chronically can promote acne by resulting in elevated levels of IGF-1.[14,15]

Sugar, Insulin, and Chromium

Many dermatologists have reported that insulin is effective in the treatment of acne, suggesting that impaired cutaneous glucose tolerance, insulin insensitivity, or both may contribute to acne lesions.[16,17] In these studies, insulin was either given systemically (5–10 units two to three times a week) or injected directly into the lesions.

One study comparing the results of oral glucose tolerance tests in acne patients showed no differences from controls. However, repetitive skin biopsies revealed that the skin glucose tolerance was significantly impaired in patients with acne.[18] One researcher coined the term *skin diabetes* to describe the disorder of acne.[17] Considering the known immunosuppressive effects of sugar (see Chapter 136), all simple carbohydrates should be strictly eliminated.

High-chromium yeast is known to improve glucose tolerance and enhance insulin sensitivity[19] and has been reported in an uncontrolled study to induce rapid improvement in patients with acne.[20]

A review of the role of diet and acne published in 2014 reaffirmed that the contribution of diet in acne is not a myth.[21] Moderate to severe acne is closely associated with the following:

1. Family history of acne in first-degree relatives
2. Obesity
3. High consumption of milk, particularly skim milk, cheese, and yogurt
4. Consumption of sweets/cakes, chocolate
5. Low consumption of fish
6. Limited intake of fruits and vegetables[22]

The higher content of omega-3 fatty acids in Kitavan and Ache' societies may have also played a role in the absence of acne. Omega-3 contributes to maintaining the stratum corneum permeability barrier, maturation and differentiation of the stratum corneum, formation and secretion of lamellar bodies, and inhibition of proinflammatory eicosanoids. A 2014 study showed for the first time that omega-3 fatty acids and gamma-linolenic acid could be used as adjuvant treatments for patients with acne.[23]

NUTRIENTS

Vitamin A

Many studies have demonstrated that retinols, including oral vitamin A, reduce sebum production and the hyperkeratosis of sebaceous follicles. Retinol has been shown to be effective in treating acne when used at high and potentially toxic dosages (i.e., 300,000–400,000 IU/day for 5–6 months).[24]

Although dosages of vitamin A below 300,000 IU/day for a few months rarely cause toxic symptoms,[25] early recognition is

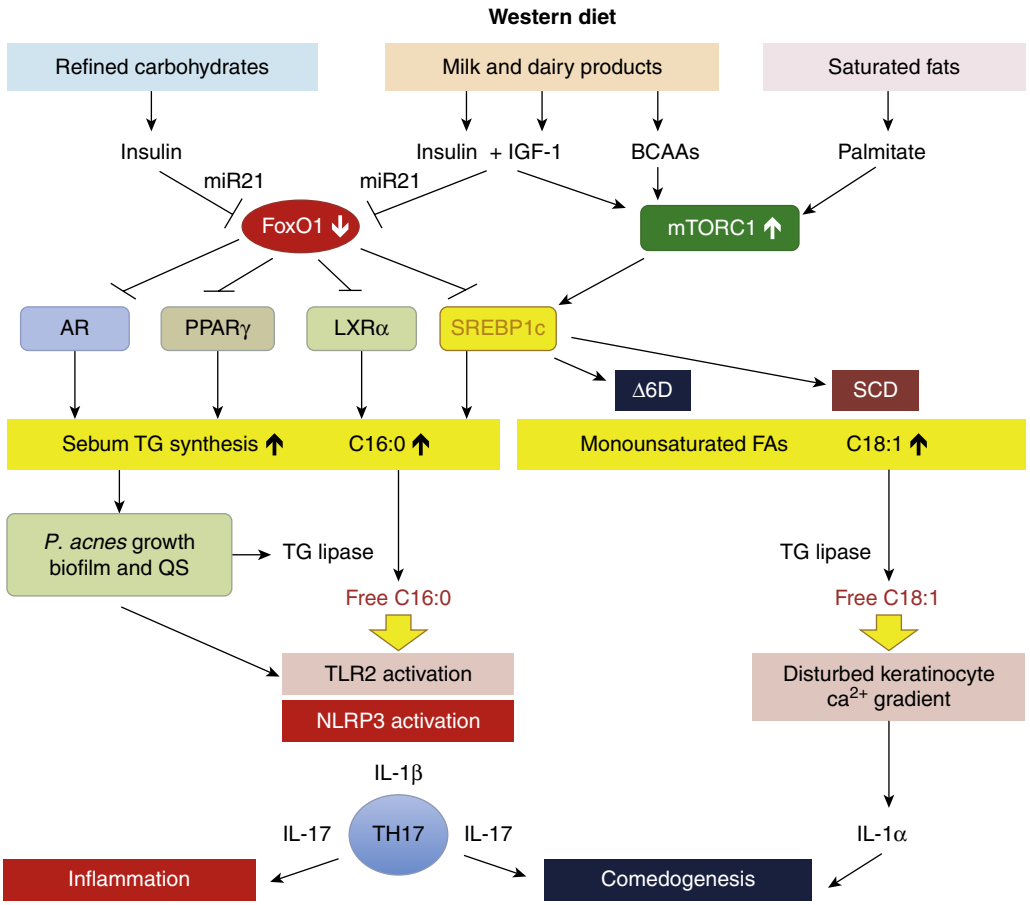

Fig. 141.1 Acne vulgaris, a Western diet–induced sebofollicular inflammasomopathy. *AR,* androgen receptor; *BCAAs,* branched-chain amino acids; *C16:0,* palmitic acid; *C18:1,* oleic acid; *FoxO1,* forkhead box class O1; *IGF-1,* insulin-like growth factor 1; *IL-17,* interleukin-17; *IL-1α,* interleukin-1α*IL-1β,* interleukin-1β; *LXRα,* liver X receptor-α; *miR21,* microRNA-21; *mTORC1,* mechanistic target of rapamycin complex 1; *NLRP3,* Nod-like receptor family, pyrin domain containing 3 inflammasome; *P. acnes, Propionibacterium acnes; PPARγ,* peroxisome proliferator-activated receptor-γ; *QS,* quorum sensing; *SCD,* stearoyl-CoA desaturase; *SREBP1c,* sterol response element-binding protein 1c; *TG,* triglyceride; *Th17,* Th17 T-cell; *TLR2,* toll-like receptor 2; *Δ6D,* Δ6-desaturase. (Michael Traub, ND, DHANP, FABNO & Lavelle Brown, MBS, CMPE, SHRM-SCP).

important. Cheilitis (chapped lips) and xerosis (dry skin) generally occur in most patients on high-dose vitamin A, particularly in dry weather.

The first significant toxic symptom is usually headache, followed by fatigue, emotional lability, and muscle and joint pain. Laboratory tests appear unreliable for monitoring toxicity because serum vitamin A levels correlate poorly with toxicity, and serum glutamate oxaloacetate transaminase and serum glutamate pyruvate transaminase are elevated only in symptomatic patients. Of far greater concern is the teratogenicity of massive dosages of vitamin A. Women of childbearing age must use effective birth control during treatment and for at least 1 month after discontinuation.

Contraception counseling is mandatory, and two negative pregnancy test results are required before the initiation of vitamin A therapy in women of childbearing potential. The baseline laboratory examination should also include cholesterol and triglyceride assessment, hepatic transaminase levels, and a complete blood count. Pregnancy tests and laboratory examinations should be repeated monthly during treatment.

In the author's experience, vitamin A 150,000 IU daily in an emulsified form has proven to be a reliable and safe means of bringing acne under control.

Zinc

Zinc is involved in local hormone activation, retinol-binding protein formation, wound healing, immune system activity, and tissue regeneration.

Zinc supplementation in the treatment of acne has been the subject of much controversy and many double-blind studies. Inconsistent results may be due to the differing absorbability of the various zinc salts used. For example, studies using effervescent zinc sulfate show efficacies similar to those of tetracycline, with fewer side effects from chronic use,[26] whereas those using plain zinc sulfate have shown less beneficial results.[27] The majority of patients required 12 weeks of supplementation before good results were demonstrated, although some showed dramatic improvement immediately.

In another study, 66 patients with inflammatory acne were given zinc gluconate (30 mg elemental zinc) or placebo for 2 months.[28] On

the basis of the number and severity of lesions, an "inflammatory score" was attributed to each patient. In the placebo group, the inflammatory score dropped from 58 to 47 in the 2-month period, whereas in the treatment group, the score dropped from 49 to 27. Physicians rated 24 of 32 patients in the zinc group as responders compared with only 8 of 34 in the placebo group.

At least two additional double-blind studies with zinc gluconate provide additional support,[29,30] but unfortunately, there have been no studies to date using better-absorbed forms of zinc, such as zinc picolinate, citrate, acetate, or monomethionine.

The importance of zinc to normal skin function is well recognized, especially considering the zinc-deficient syndrome acrodermatitis enteropathica. Zinc is essential for retinol-binding protein and thus for normal serum retinol levels.[31] Although low levels of zinc increase 5-α-reduction of testosterone, high concentrations significantly inhibit this reaction.[32] Serum zinc levels are lower in 13- and 14-year-old males than in any other age group.[33]

Vitamin E and Selenium

Serum vitamin A levels in rats on vitamin E–deficient diets remain low regardless of the amount of oral or intravenous vitamin A supplementation given. Serum levels return to normal after vitamin E is restored to the diet. Vitamin E has been shown to regulate retinol levels in humans.

Male patients with acne have significantly decreased levels of erythrocyte glutathione peroxidase, which normalizes with vitamin E and selenium treatment. Acne in both men and women improves with this treatment,[34] likely due to inhibition of lipid peroxide formation, suggesting that the use of other free-radical quenchers may be beneficial.

Pyridoxine

Women with premenstrual aggravation of acne often respond to vitamin B_6 supplementation, reflecting its role in the normal metabolism of steroid hormones.[35] In rats, a vitamin B_6 deficiency appears to cause an increased uptake of and sensitivity to testosterone.[36] However, this observation has never been replicated.

Vitamins A and D

Interleukin-17 is induced by *P. acnes* and expressed in acne lesions. Vitamins A and D inhibit the genetic expression of *P. acnes*–induced Th17 differentiation.[37,38]

TOPICAL TREATMENTS

Various topical gels, ointments, and creams containing natural products are available to treat acne. The goal of these preparations is the same as that of benzoyl peroxide (i.e., to reduce both the bacterial level and inflammation). Although there are many choices, the most popular formulas are those with tea tree oil, azelaic acid, vitamin C, or nicotinamide.

Tea Tree Oil

Melaleuca alternifolia, or "tea tree," is a small tree native to only one area of the world: the northeast coastal region of New South Wales, Australia. The leaves, the portions of the plant that are used medicinally, are the source of a valuable therapeutic oil.

Tea tree oil possesses significant antiseptic properties and is regarded by many as the ideal skin disinfectant. This claim is supported by its efficacy against a wide range of organisms (including 27 of 32 strains of *P. acnes*)[39] and its good penetration and lack of irritation to the skin (although cases of allergic reaction have been reported). The therapeutic uses of tea tree oil are based largely on its antiseptic and antifungal properties.

In a study conducted at the Royal Prince Hospital in New South Wales, a 5% tea tree oil solution demonstrated similar beneficial effects as 5% benzoyl peroxide in acne, but with substantially fewer side effects.[40] However, this 5% tea tree oil solution is probably not strong enough for moderate to severe acne. Stronger solutions (up to 15%) should provide even better results. Numerous studies have shown that tea tree oil is extremely safe for use as a topical antiseptic, but because it can occasionally produce contact dermatitis, a trial dose on a small area should be attempted first to ensure tolerability.

Azelaic Acid

This naturally occurring nine-carbon dicarboxylic acid has exerted much pharmacological activity, including antibiotic activity against *P. acnes.* Clinical studies with 20% azelaic acid cream have shown it to produce results equal to those achieved with benzoyl peroxide, tretinoin, and oral tetracycline.[41] It has been shown to be effective in all forms of acne. To achieve benefits, azelaic acid must be applied to affected areas twice daily for a period of at least 4 weeks. Treatment should be continued for at least 6 months to maintain the benefits produced after the first month.

One review article found a topical cream containing 20% azelaic acid to be as effective as 5% benzoyl peroxide, 4% hydroquinone cream, 0.05% tretinoin, 2% erythromycin, and 0.5 to 1 g/day of oral tetracycline in ameliorating comedonal, papulopustular, and nodulocystic acne but less effective than oral isotretinoin at a dose of 0.5 to 1 mg/kg per day in reducing cystic acne. The authors suggested that the few side effects of topical azelaic acid and lack of overt systemic toxicity made it a better choice for chronic use than other agents. The lower incidence of allergic sensitization, exogenous ochronosis, and residual hypopigmentation offers a clear advantage over conventional drugs.[42]

Vitamin C

Sodium L-ascorbyl-2-phosphate 5% lotion is a stable vitamin C derivative and highly effective antioxidant that has demonstrated statistically significant improvement of acne compared with vehicle in all the parameters measured.[43]

Nicotinamide

Topical nicotinamide inhibits the release of lysosomal enzymes, vasoactive amines, and the activity of *P. acnes* lipase. It is well tolerated, does not induce bacterial resistance, and has shown superior efficacy compared with 1% clindamycin gel for moderate inflammatory acne.[44]

Proprietary Topical Therapy

A randomized, investigator-blinded, split-face 10-day study of an over-the-counter (OTC) botanical spot treatment gel containing 2% salicylic acid, *Rheum palmatum, Portulaca oleracea, Scutellaria baicalensis, Chrysanthemum indicum, Phellodendron amurense, Sanguisorba officinalis,* and *Sapindus mukorossi* conducted in 2017 of 25 patients with mild to moderate acne found that after only five applications (over 36 hours), a dramatic reduction of visible acne, both inflammatory and noninflammatory lesions, was achieved.[45]

New Natural Agents

In 2018 a Korean group of researchers reported their review of new natural products for the topical treatment of acne.[46] Green tea has been found to improve acne by modulating intracellular targets and decreasing *P. acnes.* Lupeol, a constituent of *Solanum melongena,* and cannabdiol demonstrated sebum-reducing, anti-inflammatory, and antimicrobial activities. *Lactobacillus* fermented *Chamaecyparis obtusa* (a species of cypress) showed superiority compared with tea tree oil in a double-blind, randomized, controlled, split-face study. Mangostin, the main component

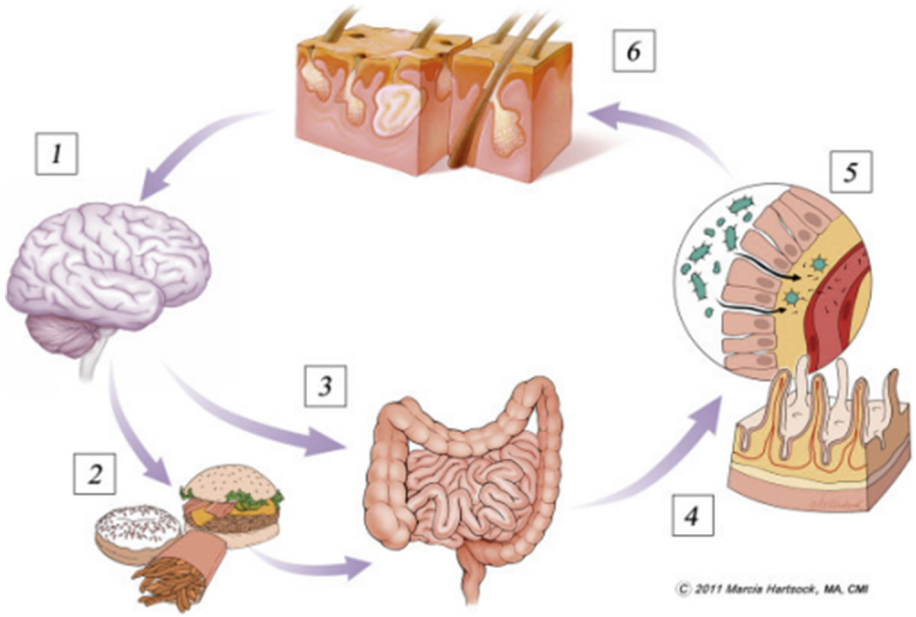

Fig. 141.2 Potential pathways of the gut–brain–skin axis in acne vulgaris. *(1)* Psychological distress alone or in combination with *(2)* high-fat diet and processed comfort foods devoid of fiber cause alterations to *(3)* gut motility and microbiota profile *(4)*. Loss of normal microbial biofilm *(Bifidobacterium in particular)* causes intestinal permeability, and endotoxins gain systemic access *(5)*. Burden of inflammation and oxidative stress is increased, substance P is elevated, and insulin sensitivity is decreased due to endotoxemia *(6)*. In those genetically susceptible to acne vulgaris, this cascade increases the likelihood of excess sebum production, exacerbations in acne, and additional psychological distress. Both probiotics and antimicrobials may play a role in cutting off this cycle at the gut level. (From Bowe WP, Logan AC. Acne vulgaris, probiotics and the gut-brain-skin axis—back to the future? *Gut Pathol.* 2011;3[1]:1. PubMed PMID: 21281494.)

of *Gacinia mangostana,* demonstrated improvement in acne severity score and inflammatory lesion counts when applied in a nanoparticle formulation.

PROCEDURAL TREATMENTS

There is a growing interest in the nonmedical treatment of acne. Traditional acne procedures include comedone extraction, intralesional injections, epidermal exfoliation (cryotherapy, peels, microdermabrasion). More recent procedures include the use of various types of lights and lasers. Blue light may be anti-inflammatory, reducing the cytokine-induced production of IL-1 alpha in keratinocytes.[47]

OTHER CONSIDERATIONS

Psychological support may be necessary because depression is a common occurrence in patients with acne, appearing twofold to threefold more often compared with the general population.[48] In 1948 Sulzberger and Zaidens stated, "There is no single disease which causes more psychic trauma and more maladjustment between parents and children, more general insecurity and feelings of inferiority, and greater sums of psychic assessment than does acne vulgaris."[49]

Acne has always been associated with emotional stress, but it is possible that the emotional stress also plays a role in the disease progression. In the 1940s dermatologists John H. Stokes and Donald M. Pillsbury first proposed a gastrointestinal mechanism for the overlap between depression, anxiety, and skin conditions such as acne.[50] The doctors hypothesized that emotional states might alter the normal intestinal microflora, increase intestinal permeability, and contribute to systemic inflammation. They also noted that as many as 40% of those with acne have hypochlorhydria and hypothesized that less than adequate stomach acid would set the stage for migration of bacteria from the colon toward the distal portions of the small intestine, as well as an alteration of normal intestinal microflora. The remedies these authors discussed to cut off the stress-induced cycle included administration of *Lactobacillus acidophilus* cultures long before they were known as probiotics. Many aspects of this gut–brain–skin unifying theory proposed by Stokes and Pillsbury have been validated (Fig. 141.2). The ability of the gut microflora and oral probiotics to influence systemic inflammation, oxidative stress, glycemic control, tissue lipid content, and even mood itself may have important implications in acne.[51] Probiotic supplementation is often indicated, especially given the common use of oral antibiotics to treat acne.

A trial of 45 females randomized to one of three arms of acne treatment with and without probiotic supplementation found that at 8- and 12-week follow-up, the arm with a probiotic (containing *L. acidophilus, Lactobacillus bulgaricus,* and *Bifidobacterium bifidum*) and minocycline had a significant decrease in total lesion count versus the groups with the probiotic ($p < 0.001$) or minocycline ($p < 0.01$) alone.[52]

Another randomized, double-blind, controlled trial of 20 adults with acne given *Lactobacillus rhamnosus* or placebo for 12 weeks found a 32% reduction ($p < 0.001$) in acne in the probiotic group compared with placebo.[53]

The relationship between hypochlorhydria and acne was investigated in a large study of 13,000 adolescents with acne. An increased prevalence of halitosis, gastroesophageal reflux, bloating, and constipation was observed. Hypochlorhydria is a recognized risk factor in small intestine bacterial overgrowth (SIBO). SIBO has been detected on hydrogen breath testing in 5% of patients on long term proton-pump inhibitor therapy.[54]

THERAPEUTIC APPROACH

Acne is a multifactorial disease requiring an integrated therapeutic approach to avoid toxicity and adverse effects during treatment. Patients should be checked for treatable causes and underlying hormonal abnormalities before specific therapies are initiated.

The most effective acne medication is isotretinoin, a derivative of vitamin A. It is approved only for severe and recalcitrant nodulocystic acne. Concern over the safety and of this drug is widespread. Specifically, reports of intracranial hypertension, depression, and suicidal ideation with isotretinoin use have prompted an examination of its serious and life-threatening potential risk. A warning is attached to its product label for signs of depression and suicidal ideation, and a U.S. Food and Drug Administration–mandated registry exists for all individuals prescribing, dispensing, or taking isotretinoin. This registry aims to further decrease the risk of pregnancy and other potentially dangerous adverse effects during a course of isotretinoin therapy.

Diet

Eliminate all refined and concentrated carbohydrates and limit saturated fats and high-carbohydrate foods. Avoid foods containing trans fatty acids and iodine.

Supplements

- Vitamin A: 150,000 IU/day for 3 months (please note cautions described earlier)
- Vitamin E: 400 IU/day
- Vitamin C: 1000 mg/day
- Zinc: 30 to 45 mg/day (picolinate form may be best)
- Selenium: 200 mcg/day
- Chromium: 200 to 400 mcg daily or brewer's yeast 1 tablespoon twice a day
- Probiotic: 5 to 10 billion live bacteria a day

Physical Medicine

- Sun or ultraviolet lamp
- Fruit acid peels
- Light therapy (blue and red light), intense pulsed light, laser, photodynamic therapy, fractionated light (for acne scars)

Topical Treatments

- Tea tree oil (5%–15%) preparations
- Azelaic acid (20%) preparations
- Nicotinamide gel (4%)
- Thorough daily cleansing with mild cleanser
- Expression of comedones with comedo extractor

Affective Disorders

Peter B. Bongiorno, ND, MSAc, LAc

OUTLINE

INTRODUCTION

Affective disorders are characterized by a disturbance in a person's emotional state. Although the rubric "mood disorders" refers specifically to depression and bipolarity, affective disorders are broken down into three main types: depression, anxiety, and bipolar disorders.

The burden of affective disorders is profound throughout the world but far outpaced by the burden in Westernized countries. For example, Nigeria has a 0.1% anxiety rate, and New Zealand has a rate of 6.2%. The overall global average prevalence of anxiety disorders rests around 7.3%.[1] In comparison, the U.S. population has prevalence of around 18% to 20%. Furthermore, the United States trumps the world when it comes to low mood, too: the global population of depression in 2015 is approximately 4.4%, but 7% of Americans are depressed.[2,3]

According to 2016 data from the Centers for Disease Control, mood disorders are on the rise, with suicide rates increasing in almost all age groups and states. Since the year 2000, the number of women who have died from suicide has nearly doubled from 6000 to almost 12,000.[4] This increase is despite the fact that diagnoses and prescription medications for mood are at an all-time high. The number of people taking antidepressants increased by 65% between 1999 and 2014.[5] In that same time period, the annual rate of suicide increased from 10.5 to 13 people out of 100,000—a 24% increase, which was the highest in almost three decades.[6] About 16% to 20% of the population take antidepressant or antianxiety drugs.[7]

There isn't much greater parity when it comes to the total spectrum of bipolar disorder, as the United States has a 4.4% lifetime rate, much higher than the 2.4% worldwide average.[8]

DIAGNOSIS

Depression

Characterized by periods of low mood, sadness and anhedonia, depression is broadly grouped into:

- Major depression: Characterized by persistent sad feelings that leave a person unable to functional normally. This is also known as unipolar depression.
- Dysthymia: A persistent chronic form of mild depression that typically allows a person to function at some level, but he or she generally feels somewhat sad and often will still lose interest in activities that would typically be pleasurable.
- Seasonal affective disorder: Low mood or sad feelings that occur during a certain time of year. Typically, this time is during the fall into wintertime, when the hours of daylight decreases.

Anxiety

Anxiety disorders are characterized by extreme nervousness and feelings of fear. Anxiety disorders are further grouped into these types:

- Generalized anxiety disorder, which has symptoms that include 6 or more months of exaggerated fears, worry, and general emotional tension.
- Obsessive compulsive disorder, which is type of anxiety where a person has repetitive images, ideas, and bodily feelings (called obsessions) that drive the person to display behaviors and actions in response (these are the compulsions).
- Panic disorder, which is a type of anxiety in which intense and often sudden anxiety results in a person being overwhelmed by these feelings and unable to function normally.
- Posttraumatic stress disorder, which is anxiety that follows a trauma or major stressor, when a person often has repeated thoughts of an event or subsequent disturbing anxiety that can be triggered by something that reminds the person of the originating event.
- Social anxiety, which involves an anxiety with a main feature in which a person's worry, often regarding other people's judgment or evaluation, leaves him or her unable to function in a social situation.

Bipolar Disorder

Bipolar disorder can include feelings of mania (excessive elation and positivity) and/or feelings of low mood and depression. The types of bipolar disorders are:

- Bipolar I, characterized by manic symptoms that either last 7 days or are so severe the person require some type of hospitalization or restraint for the patient's safety or the safety of others. Depressive episodes are periods of depression that last 2 weeks and may interchange with the symptoms of mania.
- Bipolar II, featuring symptoms of depression along with hypomania, which is a subtler form of mania that usually does not require restraint or hospitalization.
- Cyclothymia, a milder form of bipolar disorder, in which there may be 2-year cyclical occurrences of elevated mood and euphoria (hypomanic symptoms) and depressive symptomology.

Stress → Prefrontal Cortex Activity → Amygdala Activation → HPA Activation → Inflammation

Fig. 142.1 Result of Stress.

CAUSAL CONSIDERATIONS

Stress and Hypothalamic-Pituitary-Adrenal Axis Dysfunction

Although stress is universally recognized as a major player in affective disorder, the definition of stress varies wildly among physicians. Furthermore, there is little agreement on the best ways to handle stress. Hungarian endocrinologist Hans Selye first used the term "stress" when he defined it as a "non-specific strain on the body caused by irregularities in normal body functions. This stress resulted in the release of hormones."[9] Stressors can take many different forms: changes in environmental milieu, weather, social structure, and interpersonal interaction. The stress response can also be initiated as a result of feeling preyed on by onset of new illness, from exposure to toxins, and even by food sensitivity.

Stress results in prefrontal cortex activity sending signals to the amygdala, the fear center of the limbic system. The amygdala plays a key role in emotional processing and will modify activation of the hypothalamic pituitary adrenal (HPA) axis, increasing levels of corticotropin-releasing hormone (CRH); will upregulate inflammation and the cytokine cascade; and will reset downstream glucocorticoid sensitivity.[10] See Fig. 142.1.

Raised levels of CRH are known to have neurotoxic effects.[11] As the final common pathway in the stress response, CRH is released to the hypothalamus and feeds directly to the anterior pituitary and initiates adrenocorticotropin release (ACTH). ACTH travels through the bloodstream and initiates adrenal cortex release of cortisol.[12] CRH and ACTH production is augmented when the hypothalamic paraventricular neurons are chronically activated. Oxytocin counters this effect. Although cortisol will negatively feed back through the action of mineralocorticoid and glucocorticoid receptors to exert negative feedback on the hippocampus, the pituitary, and the hypothalamus,[13] chronic stress encourages glucocorticoid resistance and allows the stress response to continue.

According to McEwen, during a stressor the CNS and the body communicate in a bidirectional fashion via the endocrine, immune, and autonomic systems.[14] In the short term, these responses are beneficial because they serve to promote physiological and psychological survival. In the midterm, regulatory processes, behaviors, and physiology are challenged, but functioning remains relatively normal. In the long term, consistent experience of stress, fear, and/or trauma, and the body's attempts at homeostasis will contribute to the chronic negative effects of chronic stress and behavioral changes that encourage unhealthy lifestyles and illness[15] and support the varied mechanisms of anxiety and mood disorders. Bruce McEwen's research team created the new term "allostatic load" to recognize the parallel healthful and noxious results of the stress response. Although allostatic load works to dynamically rebalance, it can, at the same time, damage tissues, deplete reserves, and encourage development of affective disorders, cardiovascular disease, cancer, and other illnesses.

One notable type of stress is social stress that induces physiological effects that block healing. For example, animals exposed to long-term social subordination will present with altered HPA set points, ineffective hippocampal survival, glucocorticoid resistance, cognitive changes, withdrawal behavior, and lowered immune status in the effort to produce coping mechanisms to the stressor.[16,17] All these precipitate and maintain affective disorders.

This animal research has been duplicated in humans. For example, a San Francisco Federal Reserve study noted that the highest rates of suicide occur among nonaffluent people who live in affluent areas. This study strongly correlated a sense of low worth and utility when individuals' relative income is less than those around them.[18] When social stress creates low self-esteem, affective disorders thrive. Patients under social stress may need significantly more support to help regain mental health.

Disordered Sleep

Adequate sleep is critical for repair, healing, and detoxification. During sleep, inflammation is balanced, mitochondria are recycled and created, neurons regenerate, the hormonal system resets, and the digestive tract cleans and repairs. Without proper sleep, balancing mood is near impossible due to deficiencies and imbalances in all these processes. Poor sleep predicts worse outcomes in depression, anxiety, and bipolar disorder.[19]

Clinicians often find it challenging to ascertain whether sleep disturbances are a precursor to or a sequelae of mood disorder. Sleep is bidirectionally related to mood disturbance, as poor sleep will raise the stress response. Increased stress response will contribute to poor sleep. Research shows us that sleep challenges occur in bipolar stages and will exert a negative effect on disease course, life quality, and treatment outcomes.[20] The clinician should identify and treat any insomnia, REM-sleep concerns, and sleep apnea.

Typical underlying causes for sleep problems include excessive stimulants; psychological stress; high levels of stress hormones (such as cortisol and norepinephrine); disrupted circadian rhythms; low levels of serotonin or melatonin; imbalances in estrogens and progesterone, which affect neurotransmitter production; dyglycemias; and digestive upheaval.

Sunlight, Spending Time in Nature, and Light Therapy

The benefits of light exposure are threefold: to maintain healthy levels of serotonin, support circadian rhythm, and to increase levels of vitamin D in the body.

Vitamin D is produced through exposure to ultraviolet B rays, which transform skin 7-dehydrocholesterol into vitamin D_3. One report suggests a 12-minute exposure of 50% of body skin to noontime sun on a clear day is equivalent to oral intake of 3000 IU of vitamin D_3.[21] Supplemental vitamin D is discussed in a subsequent section of this chapter. Interestingly, a study over a 2.3-year period of 198 patients with multiple sclerosis found that sunlight exposure, and not vitamin D levels, are best correlated with mood and fatigue symptoms.[22] Although ultraviolet B's ability to make vitamin D may be important, sunlight's infrared wavelengths may play a separate and distinct role in mood. Animal research shows the amount of time until an animal will "give up" and become depressed after continuous stress is increased significantly after 4 weeks' exposure to infrared irradiation, suggesting that application of infrared irradiation has an antidepressant effect.[23]

Humans are animals designed to spend time in nature. Natural areas like forests are shown to have calming and balancing effects on the body. The Japanese practice of forest bathing, called *shinrin yoku,* lowers adrenaline levels and improves natural killer cell activity.[24] Studies of postsurgical patients show that those given exposure to a window with a nature view had a better mood, shorter hospital stays, and fewer complications.[25] Patients exposed to houseplants show lowered blood pressures, less pain, and less fatigue and anxiety than individuals in the rooms without plants.[26]

Also known as bright light therapy exposure, phototherapy has been shown to block the negative mood effects of acute tryptophan depletion.[27] Phototherapy, or light-box therapy, is most often used in seasonal affective disorder. Typical light-box therapy involves using a 10,000-lux, full-spectrum white light for at least 30 minutes every morning. Light boxes with smaller power do not seem to provide the same benefit as the 10,000-lux devices. Meta-analysis of light therapy studies showed that enough high-quality studies to confirm benefit are lacking. Nevertheless, in my clinical experience, I see clearly beneficial changes in mood.

Once again, modern research documents the efficacy of foundational naturopathic concepts of health and healing through sun and nature exposure.

Exercise

Known since Hippocrates' time to elevate mood, exercise can help regenerate and protect the brain areas needed for stable temperament and optimal cognition. Movement and exercise assist the brain glial cells to produce brain-derived neurotrophic factor (BDNF), which is responsible for the regeneration and repair of the CNS. Exercise has also been identified to increase hippocampal volume.[28]

Low levels of exercise have been linked to lowered life quality, poor physical function, and mood symptoms.[29] The literature regarding the effect of exercise as an intervention for major depression and bipolar disorder has shown comparable effect sizes.[30] Exercise has been shown to reduce anxiety, counter depression, and improve negative mood, while simultaneously improving self-esteem and even memory.[31] Other research also suggests the efficacy of exercise-augmentation strategies added to cognitive behavioral therapy (CBT) for anxiety disorders.[32]

Often, mood disorders like bipolar and depression present with a strong lack of motivation and interest. These symptoms can make implementing an exercise schedule a challenge. As such, for some patients, it may be best to proffer an exercise protocol that is gentle and does not cause discomfort, especially if patients have concomitant fibromyalgia and chronic fatigue. For fitness, the American College of Sports Medicine recommends 5 days a week of moderate to vigorous exercise for 30 minutes—but clinicians may want to start the patients with mood disorder on a lighter schedule if their energy is not vital or they are new to exercise.[33]

Although not as common, excess exercise may also result in damaging changes to mental health. Some patients become excessively dependent on physical activity and exercise, where excess activity can

cause both disturbances in mood and worsened physical health.[34] Extremely heavy or exhaustive exercise can promote exercise-induced mitochondrial dysfunction, a condition where mitochondria suffer due to nutrient deficiencies, excess reactive oxygen species, and metabolic toxicity, which contribute to neurodegeneration.[35] Heavy exercise may also lead to adrenal fatigue, recognized as an Addison's disease type of overtraining syndrome.[36] In this situation, the adrenal glands cannot competently produce sufficient hormone levels, and the body and mind suffer.

Blood Sugar Dysregulation

Balanced blood sugar is key for mood regulation, whereas dysglycemia (recurrent episodes of either too many lows or highs) will contribute to affective disorders. Research on patients with diabetes suggests good blood sugar control supports healthy mood and good judgment.[37] Hypoglycemia-prone patients are known to be at greater risk for depression. Dysglycemia has been shown to contribute to smaller hippocampal and cortical volumes in bipolar disorder.[38] A study from Johns Hopkins evaluated lung injury patients in an intensive care unit and noticed that subjects who had low blood sugar of under 60 nanograms (normal is 80 to 100 ng) were at a 360% increase risk of depression 3 months later.[39] Associations between anxiety and insulin resistance have been established.

Converse to hypoglycemia, hyperglycemia also contributes to mood disorders. Studies of patients with diabetes are clear that high-blood–sugar episodes will deteriorate mood, instigate cognitive difficultly, and most notably increase sadness and anxiety.[40] People with hyperglycemia or high insulin are also predisposed to depression. A study of young adults in their late 20s and early 30s showed that when blood sugar or insulin was too high, the chances of becoming depressed was 150% to 200% as high.[41] Higher rates of bipolar disorder exist among patients with diabetes as well.[42]

Balancing blood sugar requires quality sleep, lower stress response, and healthy eating. The tenets of blood sugar control include balanced protein intake, healthy fat intake, and consuming healthy carbohydrates while minimizing simple carbohydrates and sugary foods. Small frequent meals can be very helpful for many patients to abate fluctuations that lead to mood changes as noted in the next section. One supplement that can help is chromium, which will be discussed in the mineral section later in this chapter.

Maldigestion

Healthy digestion is critical for mood management. In 1999 Michael Gershon's book, *The Second Brain,* set forth a "new" perspective (almost a century earlier, naturopathic pioneer Otis Carroll, ND, asserted that disease begins in the bowels) regarding the digestive system, seeing it not just as a means for nutrient absorption and elimination but also as a neuroendocrine organ[43] that partners in a bidirectional relationship with the CNS. Evidence shows that bowel disorders are correlated with disruptions in mood. In fact, almost two thirds of patients with anxiety and depression are described to have intestinal function disturbance, such as irritable bowel syndrome (IBS).[44] Almost one third of patients with major depression are thought to have constipation, and patients with IBS are more prone to both anxiety disorders as well as depression than are individuals who do not have IBS.[45] Looking at 136 patients with bipolar disorder versus matched controls, investigators found a strong association between mood and gut symptoms. Interestingly, their study also showed that patients with bipolar disorder with minimal mood symptoms typically do not have more gastrointestinal symptoms versus control subjects.[46] There are also case reports of anxiety and panic attacks in patients before diagnosis of pancreatic cancer.[47] Although the reason is unclear, I have seen very direct clinical associations between pancreatic inflammation, high levels of amylase and lipase, and anxiety and mood disorders.

This bidirectional relationship is in part due to the vitality and composition of the microbiota of the digestive tract, where, researchers suggest, estimates of these bacteria outnumber human cells by an order of 10. The dynamics of the microbiome ultimately affect synthesis of neurotransmitters and metabolites. The microbiome regulates vagus nerve activation and also modulates immunological consequences. Emerging studies in both animals and human subjects suggest perturbations in the microbiome are also key factors in altered gut health. Animal studies have shown alterations create changes in production of BDNF in the hippocampus and amygdala as well as behavioral changes.[48] Furthermore, stress will alter the microbiome, and the microbiome will alter function of the HPA axis, leading to reregulation of the stress response.[49] Evidence suggests that microbiome alterations from antibiotics may also predispose individuals to bipolar disorder, and patients diagnosed with bipolar disorder with more severe symptomology seem to have altered microbiomes that differ from those of healthy controls.[50]

Inflammation

Inflammatory markers such as CRP and IL-6 are typically raised in situations of anxiety,[51] depression,[52] and bipolar disorder.[53] The majority of the body's immune system is housed in digestive tract, where it resides as mucosa-associated lymphoid tissue and gut-associated lymphoid tissue. Stress and poor digestion lead to inflammatory activation. Food sensitivities and food allergens can also trigger inflammation in the body. High-glycemic foods also trigger release of excess insulin. Increased chronic levels of insulin leads to insulin resistance, which is also shown to drive inflammation.[54]

As discussed earlier, imbalances in the microbiome will also upregulate inflammatory cytokines and interleukins. A digestive tract full of *Candida albicans* (yeast), and all the toxins associated with it, may also contribute to mood disorder. Presence of yeast will alter the ability to absorb nutrients and push hypersensitivity reactions of toxin by-products, which translates to inflammation in the body.[55] Inflammation will greatly contribute to depression, anxiety, and poor mental function.

Chronic inflammation in the digestive tract can lead to gut permeability, which is often referred to as "leaky gut." The concept suggests that other structure and repair mechanisms of the digestive tract are compromised over time. With an inflammatory fire partially driven by an imbalance in microbiota, tight junctions deteriorate. When these structures break down, luminal materials gain greater access to the bloodstream. These leaked particles travel through the hepatic portal system and spur upregulation of hepatic Kupffer cells, which can trigger brain inflammation via microglia activation. Inflammation in the brain will result in activation of the HPA axis, lowered serotonin, higher anxiety, and higher glucocorticoid resistance. Over time, higher cortisol levels contribute to brain degeneration and poor mood. The likelihood of this cascade of events is far greater than if the intestines are intact.[56] See Fig. 142.2.[57]

Leaky gut has been a term all but mocked in conventional care circles until relatively recently, where reviews of the literature show connections not only between leaky gut and more direct inflammatory issues like autoimmunity[58] but also with cardiovascular

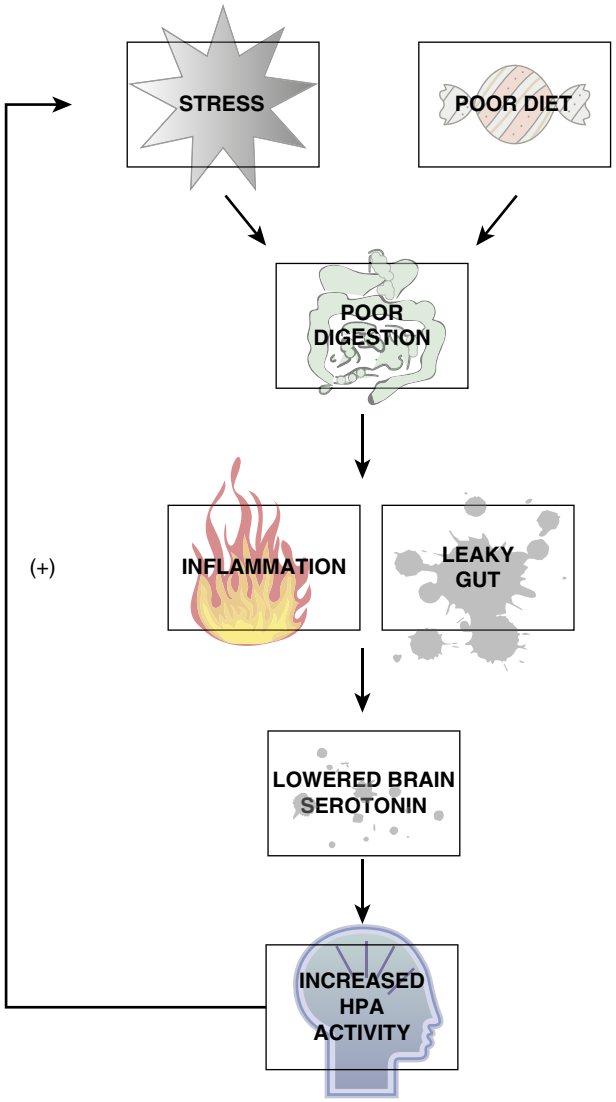

Fig. 142.2 Stress and Diet.

disease,[59] kidney disease,[60] and psychiatric concerns.[61] Out of the purview of this chapter, but covered in Chapter 19 Intestinal Permeability, practitioners should consider that a patient with affective disorder may greatly benefit by testing and treatment of gut permeability.

Hormonal Imbalances

The endocrine system plays a strong role in the signaling and function of the nervous system and inflammatory response. Undoubtedly, it is a contributor to mood disorders.

Thyroid Hormones

Thyroid hormones affect virtually every cell body, and imbalances will contribute to affective disorder. Most notably, hyperthyroidism can contribute to overt feelings of anxiety and mania in bipolar disorder, and low levels will contribute to low mood and depression.[62,63] Regarding the hypothalamic-pituitary-thyroid axis (HPT), high-stress states and allostatic load will also alter the thyroid axis, whereby high levels of ACTH affect levels of thyroid-releasing factor and thyroid-stimulating hormone (TSH). Repeated and chronic stress can lower serum levels of tetraiodothyronine (T4).[64] Glucocorticoid levels will also influence the de-iodinase enzyme that peripherally converts T4 to the three times more active triiodothyronine (T3).[65] T3 augmentation has been shown valuable in treating patients with depression that is resistant to selective serotonin-reuptake inhibitor (SSRI) treatment.[66]

Cortisol

Cortisol is the major glucocorticoid for mediating the stress response. Imbalances in HPA axis function and adrenal production, as seen in treatment-resistant depression, are evidenced by higher cortisol-to-dehydroepiandrosterone (DHEA) ratios.[67] Cortisol and stress catalyze activation of tryptophan oxygenase, resulting in the delivery of less tryptophan to the brain. In addition, cortisol downregulates serotonin receptors in the brain, making them less sensitive to the serotonin that is available. In studies on depression and cortisol levels, particularly the awakening response (CAR), depression itself has also been associated with both increased and lowered or blunted (nonsignificant, nominal change in) CAR. In my experience, cortisol levels throughout the day will be more often dysregulated in patients with affective disorders. This dysregulation can manifest as high levels of cortisol, low levels of cortisol, or varying levels throughout the day, including low early morning and afternoon levels and high nighttime and early morning levels. Assessing cortisol levels via saliva or urine testing can help the practitioner determine an individual patient's adrenal profile.

Dehydroepiandrosterone sulfate

Considered a "neurosteroid," DHEA and dehydroepiandrosterone sulfate (DHEAs) are molecules produced by the adrenal gland. Low DHEA levels are related to symptoms and severity of depression and anxiety.[68] DHEA may protect against the adverse effects of stress, especially with regard to the brain atrophy caused by chronically high levels of cortisol. Like exercise, DHEA can increase neuronal growth in the hippocampus and will protect new nervous tissue from being destroyed by stress hormones. Higher levels are likely present in bipolar disorder.[69] Generally, supplementation when low is helpful. A 2014 literature review looked at 22 studies, finding DHEA supplementation is helpful for depressive symptoms overall.[70] One case in the literature suggested 150 to 200 mg per day of DHEA may have contributed to acute mania onset in a patient with a history of these episodes.[71]

Testosterone

DHEA metabolizes into testosterone. High levels of testosterone are associated aggression, impulsivity, compulsiveness, and paranoia. Testosterone increases monoamine oxidase (MAO) and decreases catechol-o-methyl transferase (COMT), an enzyme responsible for breakdown of both neurotransmitters and estrogens. Low testosterone levels can contribute to fatigue, depression, flat mood, and mood swings, as well as sleep disorders; high levels can also contribute to depression.[72] SSRIs are known to lower levels of testosterone and negatively affect libido. Testosterone administration in 15 females reported reductions in unconscious fears in a placebo-controlled, double-blind crossover trial,[73] suggesting that low levels may participate in difficulty conquering anxiety. Concerning bipolar disorder, testosterone levels are notably lower for male patients in comparison with controls, whereas women with bipolar disorder had significantly

higher testosterone levels versus female controls.[74] Again, assessing individual profiles to help balance levels in each patient is important for optimal care.

Estrogen

As a prime mood-enhancing hormone, estrogen is important to both male and female brain function. The highest density of estrogen receptors are in the amygdala, hippocampus, hypothalamus, and dorsal raphe, where most of the brain serotonin is produced. Estrogens (primarily estradiol) will affect brain estrogen receptor activation, which affects all neurotransmitter levels, with a preference for supporting serotonin and dopamine levels. Estrogen also lowers levels of MAO.[75] Conversely, low estrogen levels increase activation of MAO activity, which will lower levels of neurotransmitters and can contribute to affective disorders. However, research regarding replacement of estrogens as a monotherapy to help mood are equivocal or found it to be even possibly detrimental to cognition.[76] A number of studies and case reports reveal mood benefits, especially in depression. Studies also show estrogen therapy may augment antidepressants' efficacy in treatment-resistant cases.[77] It seems that in the right patient, testing levels and considering natural hormone-replacement therapy might be valuable.

Progesterone

Acting more yin to estrogen's yang, progesterone is generally a more calming hormone that can work by limiting estrogen's ability to support serotonin. Allopregnanolone is a metabolite of progesterone that also affects gamma amino-butyric acid (GABA) activity to drive progesterone's calming effect. HPA axis activation resulting in higher levels of cortisol will lower production of progesterone. A double-blind, placebo-controlled trial of 17 patients documented a clear anxiolytic and lowered irritability effect of progesterone vaginal suppositories (200 mg twice a day) without changes in blood levels of the hormone.[78] Progesterone is also a valuable sleep ally that does not change undisturbed sleep but can restore normal sleep when sleep is disturbed.[79]

Oxytocin

Oxytocin is a hormone that also acts as a neurotransmitter. It is best associated with feelings of love, meaningful touch, cuddling, and combating anxiety. People with higher comfort levels in social situations and who trust are able to release appropriate amounts of oxytocin, whereas people who have social anxiety disorder often have dysregulated oxytocin.

Oxytocin reduces amygdala hyperactivity and blocks the perception of a threatening environment. High levels of oxytocin are consistent with bonding experiences, regular community interaction, and consistent social engagement. Known to be low in people with depression and anxiety,[80] oxytocin may be a reasonable trait marker for bipolar disorder as well.[81] Intranasal administration is shown to enhance social abilities in children with autism[82] and has shown antidepressant properties in rats. No clinical trials for depressed humans have been published as of this writing.[83]

Oxytocin may be one of the reasons pets improve mood; it is released by petting a dog.[84] More oxytocin-raising suggestions are given in the nutrigenomics section of this chapter.

Melatonin

Melatonin is hormone that acts as a powerful antioxidant and is involved with detoxification and immune function. Melatonin facilitates sleep by lowering body temperature and inducing drowsiness. Deficient or delayed melatonin levels may contribute to depression[85,86] and anxiety.[87] Delayed bedtime will encourage the stress response and suppress melatonin. Studies showing supportive effects for melatonin supplementation as a monotherapy for affective disorders, including bipolar, are lacking.[88] Time-released melatonin has shown benefit to support sleep and reduce fatigue in depressed patients.[89] Although melatonin itself has not been shown as successful in alleviating mood disorders on its own, supplemental melatonin has been shown to help improve sleep quality and quantity in depressed patients[90] and will likely help a patient with mood disorder ultimately heal by improving sleep.

Lifestyle Factors: Smoking, Alcohol, and Caffeine

A health-promoting lifestyle and diet are important in the treatment of depression. Particularly important are the cessation of smoking, excessive alcohol consumption, and caffeine.

Smoking

Smoking upregulates cortisol levels, leading to HPA axis and adrenal dysregulation, a feature of affective disorders. Cigarette smoking also leads to a relative vitamin C deficiency. Vitamin C is concentrated in adrenal glands, so adrenal function is likely compromised, which can contribute to depression.[91] Early life smoking neurodevelopmentally encourages anxiety and other mood disorders later due to increases in inflammation, oxidative stress, and mitochondrial dysfunction.[92] Individuals with bipolar disorder are up to 300% more likely to smoke and are far less likely to initiate or maintain smoking cessation.[93]

Alcohol

Alcohol is a potent nervous system depressant that also wreaks havoc with blood sugar regulation, leading to cravings and hypoglycemic episodes (see section on blood sugar imbalances). Interestingly, alcohol seems to stabilize GABA, which may be why alcohol has a temporary calming effect.[94] Chronic alcohol ingestion also leads to multiple vitamin and mineral deficiencies. Patients with alcoholism often have a deficiency in the delta-6 desaturase enzyme, which is responsible for the conversion of linoleic acid to the omega-6 fatty acid gamma-linolenic acid, a precursor to prostaglandin E1 (PGE1). PGE1 helps maintain neurotransmitter levels in the brain to support positive mood and a calm sense. Alcohol may also temporarily stimulate production of PGE1 and help lift mood.[95] If delta-6 desaturase is impaired for any reason, mood can decline—usually more toward depression. Excess sugar intake, high insulin levels, coffee, and trans-fatty acids can all lower inhibit 6 desaturase activity.

Caffeine

Caffeine is the most frequently consumed psychoactive drug in the world. Found in coffee, green tea, and black tea, caffeine may be beneficial or antagonistic to mood disorders. According to a meta-analysis of 11 studies with more than 300,000 people, a range of caffeine intake between 68 mg per day and 509 mg per day (approximately ¾ cup to 6 cups of coffee a day) reduces depression, whereas more can promote depression and suicidal thoughts.[96] In most cases, anxious patients are aggravated by caffeine, although in practice I recognize a subset of anxious patients who can actually benefit from caffeine intake, likely due to it raising low levels of dopamine. Caffeine acts on the neurotransmitter system by antagonizing adenosine receptors, which initiates a cascade that increases glutamate, cortisol, dopamine, and epinephrine. Generally, for anyone who has suspected depleted adrenal function, as evidenced by

low cortisol or DHEA, or for a person with high levels of epinephrine or dopamine, coffee is not recommended—especially if she or he is not sleeping well.

Digital Screen and Social Media Exposure

Although electronics are an important part of our everyday lives, exposure to these large and small screens may be playing a role in the increased levels of affective disorders in our society. Functional MRI studies have shown that short-term use of television may have a relaxing effect on brain insular cortex and amygdala regions,[97] whereas moderate or severe depression level was associated with higher amounts of time spent on TV watching and use of computers for more than 6 hours a day[98] (although this seems like a lot of time, it is not really much considering the millions of students and working people who spend the majority of their time looking at a computer screen—as I do). An analysis of more than 30 years of U.S. national data of 30,000 adults corroborates this, showing that spending time watching television may contribute to viewers' happiness in the short-term moment, but unhappy people watch far more TV than happy people do.[99]

Regarding social media, an online survey of 1730 U.S. adults ages 19 to 32 suggested those who classified themselves as "wired" and "connected" (versus "diffuse dabblers," "concentrated dabblers," and "unplugged") greatly increased the likelihood of anxiety and depression symptoms. Smartphone addiction is correlated with depression.[100] Dependence on media may likely create changes in the dopamine-reward system similar to the changes opioids and other drugs of addiction may cause, as loss of devices such as a smartphone may create feelings of panic, anxiety, or withdrawal. Younger adults seem to be more affected by media and smartphone addiction in terms of anxiety and depression. Besides being causative, use of devices may encourage an underlying trait. For example, someone with social phobia might avoid in-person contact by using the phone, and/or someone with OCD traits may manifest by using his or her phone to check things repeatedly.[101]

It should also be noted that, when used wisely, computers and media can aid those with anxiety and depression. Research shows the effectiveness of Internet-based CBT (ICBT) in treating and controlling psychiatric illnesses, including depression, GAD and social anxiety, panic disorders, phobias, addiction and substance-use disorders, adjustment disorder, bipolar disorder, and OCD, and ICBT may be quite cost effective for many patients.[102]

Environmental Toxicity

Toxic metals (lead, mercury, cadmium, arsenic, nickel, and aluminum) as well as solvents (e.g., cleaning materials, formaldehyde, toluene, and benzene), pesticides, herbicides, and mold toxins all have an affinity for nervous tissue. The oxidative stress from these neurotoxins can substantially contribute to mitochondrial dysfunction (see next section). As a result, various psychological and neurological symptoms can occur, including anxiety and depression as well as headaches, extremity tingling, and abnormal nerve function. For example, social and emotional challenges in children correlate with pre- and postnatal exposure to lead.[103] Methylmercury exposure will produce mitochondrial dysfunctions via oxidative stress and downregulation of tryptophan hydroxylase, the enzyme needed to produce proper amounts of serotonin.[104] Surveys of residents of eight European cities revealed dampness and mold is associated 30% increased depression.[105]

(For a comprehensive discussion of the large body of research on neurotoxins and mood disorders, see Crinnion and Pizzorno, *Environmental Medicine*, Elsevier 2018.)

Mitochondrial Dysfunction

Mitochondria are the considered "the powerhouse of the cell" and are absolutely vital to mental health. These organelles create ATP molecules from glucose molecules needed for maintenance of the sodium and potassium pumps that keep the electrical gradient that is responsible for neuronal depolarization. Mitochondrial dysfunction is responsible for low ATP stores that lead to lack of ATP, which leads to generation of reactive oxygen species, neuroinflammation, and eventual neurodegeneration via apoptosis.[106] Mitochondrial dysfunction is increasingly recognized for its association with neuropsychiatric abnormalities such as dementia, major depression, and bipolar disorder.[107] ATP production is greatly decreased, and mitochondrial DNA deletions are increased in major depression.[108,109] Mitochondrial dysfunction may be most salient when considering natural treatments for bipolar disorder,[110] which seems more correlated with mitochondrial dysfunction than the other affective disorders.

Mitochondria are damaged by poor sleep, insufficient or excessive exercise, excess stress, toxins (heavy metals, solvents, herbicides, and mold), drugs, chronic hyperglycemia, dysinsulinemia, inflammation, and poor nutrition. In a way, this damage encompasses all we discuss in this chapter.

Work on sleep, exercise, and stress balance and removing toxic load is needed for mitochondrial healing. Supplemental strategies include consumption of B vitamins to help Krebs cycle function and fish oil to support mitochondrial dynamics.[111] Foods and supplements that support Phase I and II liver detoxification can help when there's a strong toxicity picture. In addition, direct mitochondrial supports may include carnitine, CoQ10, lipoic acid, glutathione, and nicotinamide. I often prescribe *N*-acetyl cysteine (NAC), because it encourages oxidative phosphorylation, mitochondrial membrane integrity, and homeostasis of the mitochondrial milieu. Selenium deficiency and poor antioxidant status will contribute to mitochondrial dysfunction and should be considered.[112] These supplements are only a partial list, because there are many other evidenced-based supplements I might use, depending on the particulars of a patient's case. I will also recommend hypericum for mitochondria-related depression to help improve mood and promote neuronal mitochondria regeneration.[113]

THERAPEUTIC CONSIDERATIONS

Nowhere more than in the field of mental health is it paramount that the health care practitioner understand the wide breadth and range of factors that can result in an affective disorder. This chapter touches on topics covered throughout the rest of this book. The keen mental health practitioner knows mental health challenges can be symptoms of both psychological and physiological imbalance and should view mood symptoms as an opportunity and a necessity to check in on the multiple body systems and physiology along with a patient's psychological concerns. This section will review those major factors to help best treat the patient.

Conventional Medications

With the number of filled prescriptions for affective disorders soaring, patients are often overmedicated, using pharmaceutical compounds that do not address the underlying causes, and in

many cases create a situation that can inhibit true healing. When used judiciously, however, pharmaceuticals may help patients avoid hurting themselves or someone else in severe and urgent care cases when other, more natural recommendations are not practical.

Meta-analysis has shown that for depression, drugs do not work any better than placebo in mild to moderate cases,[114] the primary reason for millions of prescriptions. Even more startling, these drugs carry with them an increased likelihood of many other problems, with side effects that impair quality of life. For example, antidepressants show a 32% increased risk for all-cause mortality, including a 45% increased risk of stroke[115] in postmenopausal women. A comprehensive review of all the available (published and unpublished) controlled clinical trials of antidepressants in children and adolescents led the U.S. Food and Drug Administration (FDA) to issue a public warning in October 2004 about an increased risk of suicidal thoughts or attempts in children and adolescents treated with SSRI antidepressant medications.

Drugs for anxiety clearly do help relieve symptoms but at a cost. Efficacy of antianxiety medications such as benzodiazepines is high in the short term, but these medications, like their depression counterparts, are fraught with side effects. According to a report in the 2010 *Canadian Journal of Psychiatry,* people who use antianxiety medication have a 36% increased mortality risk.[116] In addition, the long-term efficacy of antianxiety medication has not been shown.[117] Addiction to antianxiety medications is also another problem, as drug-induced changes in brain function will lead to the need for progressively increasing dosages, withdrawal, and increased treatment disability.[118] To sum up, antianxiety medications can help a person feel better in the short term but pose the clear dangers of addiction, withdrawal problems, and increased risk of death.

Medications for bipolar disorder can be lifesaving and allow some patients with this condition who would otherwise be bound to homes or institutions in years past to lead normal lives. These medications unfortunately are also fraught with side effects, including extrapyramidal effects, changes in brain volume, hyperlipidemias, thyroid dysfunction, and kidney burden; via toxicity, they undermine mitochondrial health, which is a key to long-term neurological and emotional well-being (as with mitochondrial function discussed in this chapter). Despite the steady state of psychotic prevalence, antipsychotic medicine use has tripled from 1995 through 2008, with 50% of these medications provided for dubious diagnoses and "off label" use.[119] Especially alarming is the increased use of these medications in children and the elderly.[120]

Given this information, the clinician needs to be prudent and evaluate each patient to help decide the necessity for medication. If there is possible harm to self or others, or if patients cannot function well enough to take care of themselves or their dependents, then medication may be appropriate to help stabilize mood symptoms. Use of such medications during pregnancy and while breastfeeding should be decided on a case-by-case basis. See Fig. 142.3.[121]

Stabilizing mood is a key in naturopathic and integrative care to provide the patient the opportunity to work on the underlying causes such as lifestyle, toxic load, diet, and supplement needs. When a patient presents with affective disorder, the first order of business is safety. Although natural care is powerful and effective, sometimes the dedicated change in lifestyle needed to heal is not possible due to the mental health symptoms. When a person is incapacitated due to mental illness, these changes may not be possible. In this case a drug may be the best lifesaving option if it can create a fast "switch" that affords the patient the ability to start to take care of herself or himself. Once a patient is feeling better with medication, he or she can start working on the underlying factors to heal. As this process takes place, at the right time the practitioner can then slowly help wean the patient off medications. If the patient is not in an urgent care situation and is willing to work with natural care, then clinicians would be prudent to avoid medications entirely.

CHOOSING NATURAL OR CONVENTIONAL THERAPIES

If risk of hurting self or others → use conventional therapies first and natural as an adjunct

If patient cannot take care of self or family → use conventional therapies first and natural as an adjunct

If the above criteria is not met and patient is willing → use natural therapies first

Pregnancy and breast feeding → needs case-by-case evaluation

If patient is on medications → start by working with natural therapies and begin to slowly taper medications after natural treatments begin to take an effect

Fig. 142.3 Choosing Natural and/or Conventional Medicines.

Counseling

A main cause of both stress and disordered sleep is amygdala overactivation. As the fear center of the brain, the amygdala expresses high levels of CRH receptors in chronically stressed individuals, making it more reactive in times of stress. Stress-induced changes in the amygdala are a likely critical step in the pathophysiology of the development of chronic anxiety states. As noted elsewhere in this chapter, chronic stress also encourages maladaptive responses that result in affective disorders.[122]

Cognitive Behavioral Therapy

Therapeutic counseling is of enormous value to help process stress properly. Although many counseling techniques are useful for affective disorders, the one with the best support in the medical literature is CBT. CBT is shown to be especially effective and enduring for depression and anxiety[123] and may be of value for bipolar disorder.[124] Oftentimes, in conventional care, patients taking drugs for mood disorder tend to stay on them for the rest of their lives. That tendency is proven not to be the case with CBT, because the patient is taught new skills with which to deal with depression, and these skills are shown to be at least as enduring in effect as keeping patients on medication.[125] CBT works to help a patient recognize his or her negative automatic thoughts and change these to more empowering, positive thoughts and beliefs.

Mind Body Work

Mindfulness Based Cognitive Therapy (MBCT) is a form of cognitive therapy combined with mindful meditation. Using MBCT, bipolar disorder patients saw improvements in cognitive functioning and emotional regulation, as well as reduction in symptoms of anxiety,

depression, and manic episodes.[126] Studies dating back to the early 1900s have shown that meditation training programs can effectively reduce symptoms of anxiety and panic and help maintain these reductions in patients with generalized anxiety disorder, panic disorder, or panic disorder with agoraphobia.[127]

Yoga and Meditation

Yoga and meditation can both help lower stress hormones and return the body to parasympathetic mode. Numerous studies point to yoga's ability to modulate HPA axis function to effectively reduce depression, anxiety, and stress.[128] Yoga's ability to lower cortisol, modulate hormones, and regulate the activity of both the parasympathetic and sympathetic nervous systems may underlie some of the benefits it offers for both anxiety and stress. Physiologically, yoga has been shown to lower cortisol and decrease inflammatory markers such as C-reactive protein (CRP).

Massage Therapy

Massage therapy can also balance HPA axis dysregulation while helping balance neurotransmitters. A review of 37 randomized, controlled trials on massage found the benefits of massage even rivaled psychotherapy for depression and state anxiety (a temporary anxious change spurred by an outside situation).[129]

Diet

Healthy eating leads to better mental health. Increasingly, research is showing that wholesome, whole food intake helps prevent mood disorders and can help treat them too. Nutrient intake allows for the fundamental building blocks of neurotransmitters, membranes, and neuronal cells. Our food will help maintain neuroplasticity via influence on trophic factors, by creating inflammation balance, and by maintaining a healthful microbiome.

A landmark 5-year study in Spain looked at the lives and eating patterns of 10,000 people. Those people who followed a Mediterranean diet (MD) were 50% less likely to develop anxiety or depression. The study specifically found that intake of fruits, nuts, beans, and olive oil supported mood best.[130] Other studies regarding the MD have also shown that the endothelial linings of the subjects were much healthier, and rates of cardiovascular disease were lower with the MD. Furthermore, additional studies by the same group in Spain found that those people who ate in this healthy way also had higher levels of BDNF. BDNF has been shown to be low in individuals with depression[131] and anxiety.[132] The components of a Mediterranean Diet are listed in Table 142.1.

Mounting research also points to the beneficial effects of a healthy diet on neurotransmitter activity, the inflammasome, oxidative stress, mitochondrial dysfunction, and neurological pathology in patients with bipolar disorder.

Fermented foods contain probiotics, which cultivate many beneficial microorganisms and probiotic strains for gut and brain health. Many of these species and strains are not found in supplementation. A whole foods diet is also replete with nondigestible fiber that is prebiotic, or food for gut microorganisms. The practitioner can tell a patient that even short-term healthy fiber-full changes in diet can improve mood by influencing changes in microorganism species.[134]

Oftentimes, patients and practitioners alike will ask my opinion on the best diet. Although I think these questions are best answered by understanding each patient case and possible food sensitivities, if I do not know the individual or his or her history, I would recommend the Mediterranean diet. Although no one diet is completely perfect for every individual due to possible allergies and sensitivities, there is reason to believe the Mediterranean diet may far surpass the benefits of other choices for people with mood disorders.

TABLE 142.1 Components of a Mediterranean Diet[133]

1. High amounts of mono-unsaturated fats and low amounts of saturated fats
2. High intake of legumes
3. High fish intake
4. High intake of vegetables
5. High intake of fruits and nuts
6. High intake of whole grain cereals and breads
7. Moderate alcohol intake
8. Moderate intake of milk and dairy products
9. Low intake of meat and meat products

Insufficient Protein Intake

Protein breaks down into amino acids, which are used to make neurotransmitters. Inadequate protein intake will contribute to compromised neurotransmitter production. For example, tryptophan depletion studies have shown evidence of a clear decrease in available brain tryptophan as well as low levels of serotonin.[135] Repletion of amino acids to a diet low in protein has been shown in animal studies to correct learning disabilities and cognitive dysfunction.[136] Interestingly, low tryptophan intake, relative to other amino acids, may also contribute to low brain serotonin when other large neutral amino acids (phenylalanine, tyrosine, tryptophan, threonine, methionine, valine, isoleucine, leucine, and histidine) in the diet compete with tryptophan for transport across the blood–brain barrier. This is why therapeutic doses of amino acids are best taken away from other amino acids and protein sources.

Food Allergies/Sensitivities

Beyond eating healthy, specific food components can provoke the immune system toward proinflammatory pathways that will promote poor mood (see the section on Inflammation). Depression and fatigue have been linked to food allergies for more than 90 years. In 1930 Rowe coined the term "allergic toxemia" to describe a syndrome that included the symptoms of depression, fatigue, muscle and joint aches, drowsiness, difficulty in concentration, and nervousness.[137] Although the term is no longer used, today we know both adults and children dealing with food allergy will show impaired quality of life, a higher level of stress and anxiety, and increased incidence of many diseases.[138] For example, both celiac disease and gluten sensitivities may present with a wide variety of neurological and psychiatric comorbidities.[139] Patients with bipolar disorder show an increase of blood antigliadin deamidated antibodies (IgGs)[140] as well as antibodies to bovine milk caseins.[141] Although beyond the scope of this chapter, helping patients identify and treat food allergies and sensitivities will be of value when helping gut function and balancing immunological activity in most effectively treating affective disorders.

Probiotics

In a number of studies using various animal models, supplemental probiotics have been shown to reverse the effects of stress. Although more studies are welcome, currently a few human clinical trials suggest that supplementation may promote stress resilience or

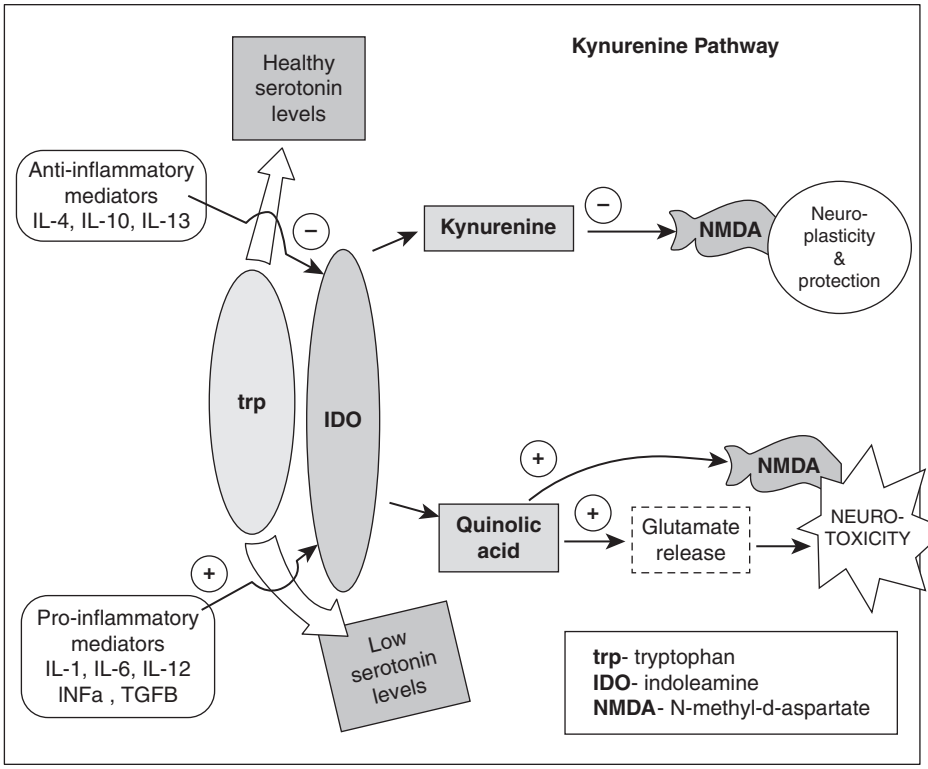

Fig. 142.4 The Inflammation and the Kynurenine Pathway.

reduce stress-induced physical symptoms and cognitive deficits in humans. Clinical evaluations of *Lactobacillus helveticus* R0052 and *Bifidobacterium longum* R0175 supplementation in rats and a double-blind, placebo-controlled, randomized human trial suggested lowered anxiety and alleviation of psychological distress in subjects after 30 days.[150] In what is probably the first study to look at probiotic supplementation effects on sad mood, a Leiden University evaluation studied 20 patients in a triple-blind study for 4 weeks. These patients were given *B. bifidum, B. lactis, L. acidophilus, L. brevis, L. casei, L. salivarius,* and *L. lactis.* In comparison with controls, the intervention showed a significantly reduced overall cognitive reactivity to sad mood, which was largely accounted for by reduced rumination and aggressive thoughts.[151] A meta-analysis of probiotic supplements for mood reviewed five randomized, controlled trials, with a total of about 280 patients during a 4- to 8-week duration. This analysis revealed that probiotics significantly decreased depression scale scores in depressed subjects. Interestingly, there was no effect in patients older than 65 years,[152] which may suggest there are more formidable digestive concerns that need to be addressed among the senior population.

Can probiotic supplements help bipolarity? A Johns Hopkins University School of Medicine study looked at 66 patients hospitalized for mania where patients were randomized after discharge to receive 24 weeks of adjunctive probiotics *L. rhamnosus* strain GG and *B. animalis*. This study found 24 rehospitalizations in the 33 individuals who received placebo and only 8 rehospitalizations in the 33 individuals who received the probiotics. Probiotic treatment also resulted in fewer days actually rehospitalized versus placebo.[153] Even more interesting and as a nice segue to the next section, this study showed us that the positive effects of the probiotic treatment on the prevention of rehospitalization was greater in individuals with elevated levels of systemic inflammation at baseline. This finding suggests to us that the probiotics may have a beneficial effect on lowering inflammation, a known factor in mood disorder.

Amino Acid Therapy

Amino acids are used by the body to synthesize neurotransmitters. Typically taken as supplements, the following amino acids are the most typical ones used to support mood.

Tryptophan and 5-Hydroxytryptophan

Tryptophan is the precursor to hydroxytryptophan (5-HTP), which converts to serotonin, which ultimately makes melatonin. Theoretically, individuals with mood disorders due to low serotonin may benefit by taking supplementation of these serotonin precursors. Despite the widespread use and anecdotal reports, relatively very few studies explored use of tryptophan and 5-HTP for mood disorders. A study of 25 healthy young volunteers showed positive affect scores after subjects consumed a high-tryptophan diet versus a low-tryptophan diet, including fewer depressive symptoms and decreased anxiety.[154] Some research suggests more benefit from tryptophan supplementation in patients with low expression of the 5-hydroxytryptamine transporter-linked promoter region (5-HTTLPR).[155]

5-HTP is the downstream metabolite of tryptophan. Although some published pilot research of small subject groups taking 5-HTP has been completed, clearly more study is needed. For patients with high levels of inflammation, 5-HTP may be a more suitable choice because tryptophan may convert more easily to quinolinic acid via the kynurenine pathway in these patients (see Fig. 142.4). Patients with bipolar disorder tend to shift to the hydroxykynurenine arm of the kynurenine pathway and probably should avoid tryptophan supplementation.[156] In addition, 5-HTP may also be more able to cross the blood–brain barrier; 5-HTP may be contraindicated in depressed patients with already low catecholamine levels and/or as a long-term monotherapy as 5-HTP is recognized to deplete catecholamines, which can participate in depression.[157,158]

One meta-analysis looking at all the depression studies evaluating tryptophan and 5-HTP found that few were well done. Out of 108

studies, only two studies with a total of 64 patients met sufficient quality criteria to be included. However, these studies did suggest 5-HTP and L-tryptophan are better than placebo at alleviating depression.[159]

Two small studies show tryptophan supplementation to be possibly as successful in the treatment of seasonal affective disorder as light therapy. The first study of 16 patients used 3 grams per day for 2 weeks as augmentation after light therapy alone was not sufficient to create a helpful effect. The second 13-patient study used light therapy or tryptophan and showed greater benefits when the supplement was used.[160] There is promising research using tryptophan and 5-HTP, but given the widespread use already, more high-quality research on a larger number of individuals is very welcome.[159]

Phenylalanine and Tyrosine

As tryptophan and 5-hydroxytryptophan are precursors for serotonin, L-phenylalanine and tyrosine are the precursors for neurotransmitters dopamine (DA) and norepinephrine (NE).[162] Phenylalanine is a precursor of brain phenylethylamine (PEA), an amino acid derivative that promotes overall energy and elevation of mood.[163] Phenylalanine also converts to tyrosine, which is in turn converted to dopamine, and subsequently norepinephrine and epinephrine, and is known to mildly stimulate the nervous system, which may have benefit in depression and attention issues.

PEA ← Phenylalanine → tyrosine→ dopamine → norepinephrine → epinephrine

Studies of both phenylalanine-and tyrosine-depleted patients paint a picture of them as less content and more apathetic.[164] However, few clinical studies have examined the effects of supplementing either of these two amino acids for depression. In 1990 a randomized, prospective, double-blind comparison of 65 outpatients with major depression were given oral L-tyrosine or imipramine. Although both treatments trended toward some improvement, imipramine showed greater improvement, with little difference between placebo and tyrosine. The only effect noted to achieve statistical significance was greater dry mouth with imipramine.[165] Researchers in 1978 administered DL-phenylalanine in doses from 75 to 200 mg per day for 20 depressed patients for 20 days. In this trial, 12 patients were able to be discharged without any further treatment due to positive response. Another 4 patients had mildly positive response, and two did not respond. L-phenylalinine is known to raise dopamine. The L version acts more as an analgesic, so if the patient is also suffering from fibromyalgia or other chronic pain, the D-L combination might be most suitable. Neither tyrosine nor phenylamine amino acids are suggested for patients with anxiety or bipolarity. One work suggests increased susceptibility to tardive dyskinesia in neuroleptic-prescribed patients with high blood levels of phenylalanine, so supplementing may be contraindicated in these patients until more is known (Table 142.2).[166]

Acetyl-L-Carnitine

Carnitine is an amino acid that has been shown to help mood, fatigue, and depression in patients with cancer and encephalopathies.[167,168] Acetyl-L-carnitine (ALC) is similar in structure to the neurotransmitter acetylcholine and acts as an acetylating agent and cholinergic neurotransmitter. ALC has also been shown to have epigenetic effects on receptor production in the hippocampus and prefrontal cortex to contribute to a rapid antidepressant effect.[169] MRI studies in geriatric depressed patients found imbalances in the prefrontal cortex were resolved using doses of ALC.[170] As the word "carnitine" comes from the Latin word "carne," which represents meat, it is not surprising that the highest concentrations of this amino acid comes in red meats. Although intraperitoneal administration of carnitine in rats has shown antianxiety benefits, there are no trials showing anxiety benefit in humans.[171]

Glycine

The simplest of the amino acids, glycine is a calming amino acid known to reduce neuronal excitement, optimize GABA levels, and bind to the locus coeruleus to decrease the release of norepinephrine. Two double-blind, placebo-controlled studies in 14 and 16 healthy patients exposed to loud sounds found that high doses of glycine (0.8 g/kg of body weight) calmed the brain's cortex and decreased reaction to the sound by lessening auditory-evoked potentials.[172]

Gamma Amino-Butyric Acid and Phenibut

Gamma amino-butyric acid (GABA) is a natural calming brain neurotransmitter that may act like a natural benzodiazepine. People who suffer with anxiety, insomnia, epilepsy, and other brain disorders often do not manufacture sufficient levels of GABA. Supplemental GABA creates a hypnotic effect by opening chloride channels to allow cell hyperpolarization, thereby inactivating the nerve cell to slow its firing. Also, evidence suggests decreased brain beta waves.[173] Contradicting studies question the ability of this supplement to cross the blood–brain barrier.[174] Very little research has been conducted to evaluate benefit for anxiety. A study of 40 patients with insomnia given 300 mg showed improved sleep latency and efficacy with preservation of slow-wave sleep and REM sleep, which is something sedative hypnotic drugs can impair. Mild abdominal discomfort (2 people), headache (1 person), and drowsiness (1 person) were reported.[175] Given the ability to calm the brain without drowsiness, GABA may be a good choice for anxiety but should be avoided in depression without anxious features. Phenibut is a form of GABA known as beta-phenyl-gamma-amino-butyric acid which acts on γ-aminobutyric acid (GABA) B and A, as well as D β-phenethylamine receptors, to create both anxiolytic and nootropic effects. Used as a prescription drug in Russia, it is available as a supplement in Western countries. Like its GABA counterpart, this supplement has had little in terms of evidenced-based research. I have seen clear anxiolytic properties as a monotherapy. However, for those committed to use and to prescribing only natural products, Phenibut is of concern.

No known toxicity is associated with GABA when used in recommended dosages. Phenibut has had limited research. Some case reports suggest that dependence, tolerance, and withdrawal symptoms are possible,[176] and it is my recommendation to use sparingly, monitor for these concerns, and ensure causes are addressed first.

Taurine

The amino acid–derivative taurine acts by supporting levels of glycine and GABA to help relax the brain and nervous system while keeping levels of toxic glutamate low. It has been shown to block the effects of excess acetylcholine that contributes to bipolar disorder.[177] Taurine is usually dosed about 500 mg up to three times daily.

N-Acetyl-Cysteine

N-Acetyl-cysteine (NAC) is a precursor of the master antioxidant glutathione, a needed molecule for the increase oxidative stress found in bipolar disorder. NAC has been shown to help reverse glutathione depletion, increase both CNS and peripheral glutathione levels, as well as upregulate production of neuronal stem cells. NAC can also promote mitochondrial integrity and the oxidative phosphorylation needed to produce ATP.

A study of 75 patients with bipolar depression in a double-blind study had patients take 1g of NAC twice a day along with standard medications for 20 weeks compared with medication only. The patients taking NAC showed significant improvements based on the Montgomery-Åsberg Depression Rating Scale. Discontinuation of

TABLE 142.2 Studies Using Both Natural Medicines and Antidepressants in Combination

Supplement	Drug	Condition	Study	Outcome	Side effects	Ref
5-HTP—300 mg/day	Clomipramine	Depression	Study of 26 patients	• 5-HTP plus drug patients enjoyed better mood, lower anxiety, and less uncomfortable physical symptoms	No signs of serotonin syndrome or other serious adverse events	
Curcumin (500–1000 mg/day)	Various antidepressants	Depression	12-week, double-blind, placebo-controlled trial, 65 participants	• Much better placebo in improving MADRS scores by 12 and 16 week • Better effect in men than women	None	274
Eicosapentaenoic acid (EPA) 2 g/day	Various antidepressants	Depression	20-patient, 4-week, parallel-group, double-blind study	• Reduction in HAM-D score in patients receiving E-EPA was 12.4 versus 1.6 in patients receiving placebo	None	275
Folic acid 200 mcg / day	Lithium carbonate	Bipolar	Folic acid or matched placebo in a group of 75 patients on lithium therapy	• Highest plasma folate concentrations showed a significant reduction in their affective morbidity	None	276
Folic acid or 5′-methyltetrahydrofolic acid 500 mcg/day	Various antidepressants	Trazodone	Cochrane review of 3 randomized trials of 247 patients	• Two studies showed improved HAM-D scores with folate • One study showed no benefit		277
Inositol	SSRIs	Treatment-resistant depression	Double-blind controlled 4-week trial of 27 patients SSRI plus placebo or SSRI plus inositol	• No benefit with inositol		278
Melatonin 5–10 mg	Various antidepressants	Depression	9 patients with treatment-resistant depression	• 36% decrease insomnia • Half of patients with 50% improvement—significantly lower levels of fatigue	None noted	279
S-adenosyl-methionine (SAMe) 200 mg/day intramuscularly	Imipramine	Depression	63 patients in an 8-week, double-blind study	• Decreased depressive symptoms versus imipramine monotherapy, helped faster onset of drug benefit	None noted	280
Saffron 30 mg/d	Fluoxetine	Depression and sexual side effects from medications	36 men, 4-week randomized double-blind placebo-controlled study	• Significantly greater improvement in erectile function and intercourse satisfaction • No change in orgasmic function, satisfaction, or desire	Same as placebo	281
Saffron 30 mg /d	Fluoxetine	Depression and sexual side effects from medications	38 women, 4-week randomized double-blind placebo-controlled study	• Improved sexual function, arousal, lubrication • No benefit in desire, satisfaction, or orgasm	Same as placebo	282
Tryptophan 2 g daily	Prozac	Depression	One 8-week randomized controlled trial of thirty patients with major depression	• Statistically significant decrease in HAM-D scores • Protective effect on slow-wave sleep	Mild daytime drowsiness reported in the tryptophan group	283
Zinc (25 mg/day)	SSRIs	Tricyclics in depressed patients	12-week, placebo-controlled, double-blind pilot study of versus placebo	• 40% reduction in HAM-D and BDI scores versus placebo treatment	None	284
Zinc (25 mg/day)	SSRIs	Depression	44 patients	• Mean score of Beck Depression Inventory reduced significantly compared with the placebo by end of 6th and end of 12th week	None reported	285

5-HTP, 5-hydroxytryptophan; *BDI, Beck's Depression Inventory*; *E-EPA*, ethyl eicosapentaenoic acid; *HAM-D,* Hamilton Depression Rating Scale; *MADRS,* Montgomery-Åsberg Depression Rating Scale; *SSRIs,* selective serotonin reuptake inhibitors.

the supplement at 24 weeks led to "a dramatic return" of symptoms.[178] A second trial of 149 gave patients already prescribed mood stabilizers 2 g per day NAC as adjunct maintenance treatment with a substantial decrease in symptoms during the 8-week open-label phase.[179]

S-Adenosyl-l-methionine

S-Adenosyl-l-methionine (SAMe) is a naturally occurring molecule derived from the amino acid methionine and adenine triphosphate (ATP). Described as early as 1952, it has a decades-long history of use for depression, especially in Europe. Even the American Psychiatric Association has acknowledged it "might be considered" as an alternative to pharmaceutical medications.[180] Known best as an antidepressant, SAMe serves in many biological reactions by transferring methyl groups to DNA, proteins, fats, and amino acid compounds and supporting production of the monoamine neurotransmitters dopamine, serotonin, and norepinephrine.[181] Via the function of the methionine pathway, deficiency of B vitamins can contribute to homocysteinemia, with subsequent decreases in SAMe. Hyperhomocysteinemia also leads to increased glutamate, a brain toxin linked to mood disorder.

SAMe has been found to be safe and effective in the treatment of mild and moderate depression. According to some accounts, SAMe has a faster onset of action than conventional antidepressants.[182] The most recent meta-analysis suggests promising effects, but evidence is still somewhat limited.[183,184] Anxiety studies have not been conducted, and a few case studies suggest SAMe may exacerbate or precipitate symptoms of mania in bipolar disorder.[185] Its best use may be especially for depression accompanied by low B-vitamin status and hyperhomocysteinemia or known genetic defects in the methionine pathway.

Essential Fatty Acids

The brain neuronal membranes contain a high proportion of omega-3 polyunsaturated fatty acids (PUFAs). Communities who consume high levels through fish are known to have fewer instances of anxiety and depressive illness. Mechanistically, fish oil helps normalizes the membranes of brain tissues and simultaneously supports and calms the adrenal system during anxious and stressful times.[186] Essential fatty acids (EFAs), obtained through both fish oil as well as some vegetable sources in smaller amounts, provide an array of pleiotropic activity, including anti-inflammatory effects, nerve growth factor production, improved glucose metabolism, and calming of the anterior cingulate and prefrontal cortex (areas that are known to be overactive in people with both depression and anxiety).[187,188]

There is conflicting evidence regarding the effective use of omega supplements as a monotherapy for depression. This conflicting evidence may be explained by the presence or absence of essential fat deficiency,[189] intake levels of competing omega-6 fatty acids, and status of the fatty acid desaturase enzyme. (See Nutrigenomics and Single Genetic Nucleotide Polymorphisms section.) For depression, omega supplementation makes sense (unless the patient is allergic) as a nutritive and neuroendocrine support and may be a necessary part of addressing underlying factors. Higher dietary levels of essential fatty acids (EFAs) are inversely associated with anxiety.[190] A meta-analysis reviewing 19 high-quality clinical trials (both placebo and nonplacebo controlled) spanning 2240 participants from 11 countries found significantly reduced anxiety symptoms with treatment of omega-3 PUFA dosage of 2000 mg or more per day compared with controls.[191] In a study of 100 bipolar I patients, either 1000 mg of omega-3 supplement or placebo was given daily for 3 months. Significant improvements were seen in the group with mania.[192]

Vitamin D

Deficiency of the "neurosteroid" vitamin D causes mood changes in several ways. Hypothalamic brain centers are responsive to the presence of vitamin D, where low levels will affect the function of the HPA axis.[193] Vitamin D affects nerve growth factor,[194] which is important for brain and neuronal repair and growth and helps production of serotonin, testosterone, and thyroid hormone.[195] A cross-sectional study of anxiety patients also found significantly lower levels of calcidiol (a vitamin D precursor) in men and women with depression as well as in age-matched patients with anxiety disorders. To be expected, bipolar patients may benefit from proper levels of vitamin D as well. A Dutch study's evaluation of 118 patients with bipolar disorder and 202 patients with schizophrenia or schizoaffective disorder revealed vitamin D deficiency was 4.7 times more common among outpatients with bipolar disorder, schizophrenia, or schizoaffective disorder than among the general population.[196]

A stringent meta-analysis of 15 randomized controlled studies clearly determined statistically significant improvements in depression using vitamin D supplementation greater than 800 IU per day, with an effect size comparable to medications.[197] Although trials are ongoing on vitamin D for bipolar patients, a recent 8-week open trial of 2000 IU did result in improved mood symptoms. Imaging also showed increases in anterior cingulate cortex GABA levels, which may imply a calming effect, too.

Whenever prescribing vitamin D, be sure to consider the status of vitamins A and K_2.

B Vitamins and Folate

B vitamins play an important role in neurotransmitter production, mitochondrial function, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide reduced (NADH) metabolism, prostaglandin formation, and homocysteine regulation, all of which affect mood. An association between B-vitamin deficiencies (especially vitamins B_6, B_{12}, and folate) with higher prevalence of anxiety and depressive symptoms has been described in several epidemiological reports.[198] An evaluation of 3500 adults revealed higher intakes of B_6, B_{12}, and folate, whether through foods or supplementation, were associated with a decreased likelihood of incident depression for up to 12 years of follow-up. For each 10 additional milligram of vitamin B_6 and 10 additional micrograms of vitamin B_{12}, researchers found a 2% decreased risk of depressive symptoms per year.[199]

Vitamin B_3 (niacinamide) increases availability of tryptophan as well as production of 5-HTP. Vitamin B_6 (pyridoxine) is a main cofactor for enzymes that convert L-tryptophan to serotonin. In females with known evidence of serum vitamin B_6 deficiency due to oral contraceptive use, supplementation with 40 mg per day of vitamin B_6 improved both anxiety and depression.[200] Vitamin B_{12} is a key player in the synthesis of serotonin.

Besides being an important factor in serotonin synthesis, folic acid is also needed to support dopamine, norepinephrine, and epinephrine.[201] Generally low folate status seems to be more associated with low mood and depression and but not as much with anxiety.[202] Folic acid has been well implicated in depressive disorders, and folic acid deficiency has been noted among people with depression; some estimates suggest up to 33% of depressed individuals are folate-deficient. Several studies regarding its role in the pathophysiology of depression show that patients with depression often have a functional folate deficiency, and the severity of such deficiency correlates with depression severity.[203] More about methylfolate is discussed in the Nutrigenomics and Genetic Predispositions section.

Inositol

Inositol is an abundant carbohydrate in the body and brain and modulates serotonin receptors and neurotransmitter uptake.[204,205] Low levels of inositol has been reported in the cerebrospinal fluid of

patients with depression. A meta-analysis of seven randomized, controlled trials suggests modest benefit for depression and especial usefulness in patients with premenstrual dysphoric disorder.[206] In one double-blind, controlled, randomized crossover study of 20 subjects with panic attacks, researchers had each participant take 18 grams per day followed by 1 month of fluvoxamine. In the first month, inositol reduced the number of panic attacks per week to 4.0, compared with 2.4 fewer attacks with fluvoxamine.[207]

Triacetyluridine

Uridine is a precursor molecule for ribonucleic acid (RNA). Triacetyluridine (TAU) is a more bioavailable form of this nutrient. Found in high levels in beer, it can be a support for neuronal synthesis. In vitro work shows TAU can inhibit neurotoxic effects by improving mitochondrial recovery. Clinical studies of 18 g per day for 6 weeks showed decreased depressive symptoms in bipolar patients while increasing brain pH.[208] Supplement dosages range from 25 mg up to the study dosage of 18 g per day.

Minerals

Chromium

As increased sugar intake is correlated with depression, the essential trace mineral chromium may be a useful means to balance blood sugar and the brain. Chromium's mechanism of action seems to be via modification of brain serotonin levels[209] as well as by increasing insulin insensitivity.[210] In a 6-month, randomized, double-blind, placebo-controlled trial, subjects received 1000 mcg chromium per day, 600 mcg chromium per day, or placebo. Fasting glucose was significantly reduced in both chromium groups compared with the placebo group; similarly, numerically but not significantly, greater reductions in binge frequency, weight, and symptoms of depression were observed in those treated with chromium versus placebo, although statistical power was limited in this pilot trial. Other research suggests chromium's best mood effect may be in patients with blood sugar regulation (like diabetes) who have concomitant disturbances in dopamine and serotonin function.[211]

Magnesium

Magnesium is a mineral cofactor involved in hundreds of biochemical reactions. Low magnesium intake occurs in almost 70% of the U.S. population.[212] Magnesium deficiency may be a key player in the pathophysiology of affective disorders, as the limbic system and HPA axis function are both sensitive to magnesium status. Lowered magnesium will allow easier damage to nervous tissue, increasing inflammation, as evidenced by increased levels of C- reactive protein.

Iron

Important for myelin-sheath formation, neurotransmitter creation, and energy metabolism, iron is a mineral needed for best mood. Iron deficiency anemia is associated with both depressive mood, anxiety,[213] and gastrointestinal symptoms such as bloating and dyspepsia.[214] Decreased dopamine levels will encourage low iron status, although norepinephrine and glutamate levels tend to increase available iron. Interestingly, levels of GABA are elevated in iron deficiencies, as an overall reduction in neurotransmission rates and brain activity occurs due to insufficient energy.[215]

Excess iron can also be problematic: neuronal damage can be caused by iron overload. Iron levels even in high normal ranges can increase depressive symptoms in young male adults, but not in females,[216] and hemochromatosis has been implicated in treatment-resistant bipolar disorder.[217]

Finally, in this world of heavy contamination of the environment with neurotoxins, the importance of iron for the heme backbone of the cytochromes for their detoxification is critical.

Zinc

Zinc is a mineral that supports hippocampal BDNF production[218] and is a pleiotropic cofactor in multiple reactions involved in energy metabolism and digestive health. Zinc is predominately found in glutamatergic neurons, typically acting as an inhibitory factor at the N-methyl-D-aspartate (NMDA) glutamate receptor.[219] Low zinc status may cause lower levels of GABA, increasing anxiety symptoms. Zinc levels are decreased by inflammation and stress.[220]

Meta-analyses demonstrate clear inverse association between depression severity and serum zinc levels.[221] Zinc supplementation alleviates anger and depression.[222] Patients with anxiety also reveal significantly higher plasma levels of copper and copper-to-zinc ratios as well as lowered absolute zinc levels compared with controls. In treated patients, zinc picolinate daily for 8 weeks restored that balance and improves symptoms.[223] Optimal zinc dosage is 15 to 30 mg per day. It should be taken with food due to the possibility of gastric upset. Top foods sources of zinc include beef, lamb, and turkey.

Lithium

Lithium is a mood-stabilizing mineral with antidepressant, antimanic, and oxytocin-supporting properties. Geographical areas with higher natural lithium concentrations in the drinking water are associated with lower mortality rates from suicide.[224] Most well known in the carbonate form, which is prescribed for patients with bipolar disorder, although now newer drugs are available.

The typical supplement form of lithium is lithium orotate, which is a salt of lithium and orotic acid. Lithium orotate may be the preferred form, because the orotate ion is known to traverse the blood–brain barrier more easily than the drug version, which uses the carbonate ion of lithium. As a result, the orotate form can be used in much lower doses with reasonable results and no side effects.[225] Lithium orotate has not been extensively studied. In one evaluation, alcoholic patients were prescribed 150 mg of lithium orotate (approximately 5 to 7 mg of elemental lithium a day) 4 to 5 times a week. Out of 42 patients, 10 of the patients had no alcoholic relapse for more than 3 and up to 10 years, and 13 patients remained without relapse for 1 to 3 years. The remaining 12 had relapses between 6 to 12 months.[226]

Lithium orotate is commonly dosed at 5 to 20 mg per day of elemental lithium with no toxicity. Its best use seems to be for anxiety and bipolar disorder with a strong manic component. At this time, it is not recommended for depression that does not have a strong anxiety component. There is a case study of lithium orotate overdose in an 18-year-old, with an estimated intake of more than 2000 mg of elemental lithium. This patient had normal vital signs but complained of nausea and vomiting, and she presented with a tremor, which resolved after 90 minutes of IV fluids.[227]

Botanical Medicines

Hypericum perforatum (St. John's Wort)

St. John's wort (SJW) is one of the most studied herbs of all time. The Latin name *Hypericum perforatum* means "above a ghost," and this botanical was originally gathered as a way to ward off evil spirits. Although often thought of as a "natural SSRI," SJW has pleiotropic effects all around the body and brain via multiple mechanisms. The overall benefits of this herb cannot be attributed to a single constituent.

SJW may affect neurotransmitters, acting as a mild monoamine oxidase inhibitor and having serotonin enhancement properties,[228,229] although some literature suggests this effect is too weak to have

therapeutic effect for depression.[230] *Hypericum* also inhibits acetylcholine breakdown,[231] balances norepinephrine and dopamine, and supports GABA production. Besides neurotransmitter actions, it has pleiotropic effects that may also encourages mitochondrial function and oligodendrocyte development.[232] It may have anti-inflammatory effects and nerve protective properties.[233]

As of this writing, the latest meta-analysis of SJW reviewed 27 clinical trials with a total of 3808 patients, which compared the use of St. John's wort with use of SSRI medications. Study durations varied from 4 to 12 weeks and showed St. John's wort has comparable efficacy and safety in comparison with SSRIs as well as a significantly lower patient discontinuation of the herb versus the drugs.[234]

Case reports link St. John's wort to mania, suggesting it may not be a good choice for bipolar disorder treatment.[235] Because hyperforin, one of the chief components of SJW, plays an important role in the induction of cytochrome P450 enzymes and P-glycoprotein transporter,[236] it can affect pharmacokinetics of various drugs and should be used cautiously with pharmaceuticals.

Curcumin

Inflammation is an underlying cause of mood disorder. Baseline levels of high-sensitivity CRP, TNF-α, and IL-6[237] are elevated in patients with major depression.[238] Curcumin, a plant polyphenol with anti-inflammatory, antioxidant, and neuroprotective properties, is considered the main active component of the spice turmeric.

Meta-analysis of six clinical trials showed significant clinical efficacy of curcumin in ameliorating depressive symptoms as well as significant antianxiety effects.[239] Putatively, curcumin may be of benefit for bipolarity due to its influence on known mechanisms of the disorder, including influence on proinflammatory cytokines, growth factors, inflammatory mediators, and antiapoptotic proteins.[240]

Cannabidiol Oil

Cannabidiol (CBD) oil is typically extracted from the hemp plant and is not psychoactive like the tetra hydro cannabinoid (THC) found in marijuana. With known anticonvulsive, anxiolytic, antipsychotic, and neuroprotective effects, this flavonoid does not directly bind with cannabinoid receptors, but it does inhibit degradation of the natural endocannabinoid anandamide.[241] It also affects the adenosine receptor function that controls wakefulness and the vanilloid receptors to regulate inflammation, and it may bind to serotonin receptors as well.[242]

CBD's best use might be for anxiety. CBD was first studied in patients taking marijuana, where it was shown to blunt the anxiety effects of THC.[243] In human trials, CBD has significantly reduced the social anxiety associated with a simulated public speaking tests in healthy subjects where it helped balance amygdala (fear center) and hippocampus (memory and emotion) areas of the limbic system. This effect was comparable to the anxiety medications ipsapirone and diazepam (Valium).[244] Given its mechanisms, it may be beneficial in bipolar disorder. As of this writing, a Brazilian clinical trial is recruiting to study CBD in bipolar patients.[245] More research is needed, but the available research is compelling, and I have seen very good clinical results with CBD.

Passiflora (Passionflower)

Passionflower has a long and rich folklore history of use as a calmative agent because it has anxiolytic properties and is considered an official plant medicine in many countries worldwide. Passionflower works for reducing anxiety in part by binding itself to benzodiazepine receptors in the brain. It has chrysin and other flavonoid-like compounds with confirmed antianxiety, anti-inflammatory activities.[246] A 2007 Cochrane review looked at two studies with a total of 198 participants, which found lack of difference in the efficacy between benzodiazepines and *passiflora*, improved job performance, and lower rate of drowsiness versus the drugs. Although the author concluded that there are too few studies to conclude efficacy for *passiflora*, it seems reasonable to try it given the long history of use for anxiety and minimal side effects.[247] I do not find *passiflora* to be as powerful an anxiolytic as a benzodiazepine might be, but with a full integrative natural medicine plan, it can help create a calming effect to avoid the need for more addictive pharmaceuticals.

Rhodiola rosea

Rhodiola was originally described in the Russian literature as a plant medicine useful to combat physical, biological, and chemical stressors. As an adaptogenic herb, studies show it acts as a neuroprotective, cardioprotective, antifatigue, antidepressive, anxiolytic, nootropic (cognitive enhancing) agent, with life-span–increasing effects and CNS-stimulating activity.[248] Rhodiola is typically standardized for 1% of the molecule rosavin. Longer-term studies of this adaptogen are needed, but what we know so far is that rhodiola is a great choice for patients who are depressed and/or anxious and feeling burnt out.

In an early study pitting an herb directly against an antidepressant, researchers compared 340 mg of a powdered extract of *R. rosea* standardized to a content of 3.7% rosavin, with sertraline HCl (Zoloft) or placebo for 12 weeks. Twenty patients were randomized to the *R. rosea* group, 19 to the sertraline group, and 18 to the placebo group. Interestingly, all treatments had similar findings: nonstatistical reductions in symptom assessments, with more patients suffering adverse reactions with sertraline (63.2%) in comparison with *R. rosea* (30.0%) or placebo (16.7%).[249] These results suggest sertraline had a slightly greater effect versus *R. rosea,* although the botanical medicine had significantly fewer side effects. Strikingly noted is that the benefits of neither the drug nor the herb differed much in comparison with placebo. Remember that meta-analysis has shown that in cases of mild to moderate depression, pharmaceuticals generally do not work any better than placebo,[250] which boasts a 25% to 30% effectiveness rate. This study is consistent with a greater body of research that shows minimal but measurable effects for botanicals in mild and moderate depression, and suggests that given the similar efficacy, ability to heal underlying causes, and lower side effects, these botanicals make a better choice.

Saffron

With serotonergic, anti-inflammatory, neuroendocrine, and neuroprotective properties, the traditional Persian medicine pharmacopeia has long understood the vibrant color and power of saffron. This spice is one of the world's most expensive and healthful. There are a number of clinical trials related to saffron for depression. In 2014 an Australian meta-analysis found large treatment effects, with similar effective rates compared with patient antidepressants.[251]

With a number of studies looking at saffron for depression, a 2018 meta-analysis reviewed 11 clinical studies for qualitative analysis, with 9 studies pooled for statistical analysis, and identified that saffron has a significant effect on the severity of depression.[252] Consistent with past analysis, it seems this herb has at least the same benefits as antidepressant drugs.

What interests many patients is that saffron has also been studied for helping alleviate the sexual side effects of antidepressant medications. Studies have separately looked at the effect on 36 men and 38 women. For the men, greater improvement was apparent in erectile dysfunction and intercourse satisfaction in 9 patients (60%) with saffron versus one patient (7%) in the placebo group who achieved normal erectile function.[253] The women enjoyed significant improvement in arousal, lubrication, and dyspareunia, although desire, satisfaction, and orgasm were not changed.[254] A separate meta-analysis has confirmed saffron's benefit on erectile dysfunction.[255]

Homeopathic Medicines

Studies evaluating homeopathic medicines for psychiatric illness are relatively scant but increasing. One systematic review of studies between 1982 and 2016 found two double-blind placebo-controlled trials looking at using homeopathics in depression. One study was of 91 patients, and another evaluated 133 subjects. Both suggested effects comparable to those of antidepressant medications.[256] A review looking at general practitioner offices found patients with affective disorders who chose to work with doctors prescribing homeopathy reported less use of psychotropic drugs, and they were marginally more likely to experience clinical improvement than patients managed with conventional care.[257] A larger review by the *Journal of Clinical Psychiatry* used very stringent criteria and accepted only 25 studies out of more than 1400 reviewed. Efficacy of homeopathic medicines was certified for fibromyalgia and chronic fatigue syndrome, but benefit was not seen for anxiety or stress. The authors concluded that "Studies in psychiatry are very limited, but results do not preclude the possibility of some benefit."[258] Please see Chapter 39 for more on homeopathy.

Nutrigenomics and Genetic Single Nucleotide Polymorphisms

Although the field of nutrigenomics is still in its infancy, it is progressing rapidly. It may be premature to make dogmatic recommendations regarding the presence of a particular genetic single nucleotide polymorphism (SNP). However, a few SNPs and gene associations are pertinent to affective disorders, and if it is possible to obtain this genetic information, these should be kept in mind and correlated with laboratory testing and clinical symptomology to create an overall holistic plan for the patient with mood disorder. Although this short list of some genetic polymorphisms with reasonable literature to suggest actionable items provides initial information about their properties, much more information is needed to fully use our patient's genetic information.

BDNF (Brain-Derived Neurotrophic Factor) rs6265

The Met-positive polymorphism may confer less ability to manufacture BDNF. Exercise, zinc, and lithium[259] supplementation may be of use to naturally support BDNF production.

COMT (Catechol O-Methyltransferase) rs769224, rs4680, and rs4633

SNPs of this gene can alter catecholamine degradation and may be key in function of the prefrontal cortex's input in personality, behavior, and emotion. Estrogen metabolism may also be altered as well. Knowing this predisposition, correlating with clinical symptoms may help clinicians choose recommendations designed to boost or lower neurotransmitters and modulate estrogens.

CYP2R1 rs10741657 and rs7041

This gene allows for production of the precursor to 25-hydroxy vitamin D_3, which in turn is converted to the more active $1,25(OH)_2$ vitamin D. Certain alleles may result in lower active vitamin D levels. Extra vitamin D may be of value for these patients as correlated with laboratory testing.

DBH (Dopamine Betahyrdoxylase) rs1108580

DBH manufactures the enzyme that breaks down dopamine. Research on personality traits has found that DBH overactivity is associated with impulsiveness traits, and low activity is associated with sensation-seeking.

DRD2 (Dopamine Receptor D2) rs1800497

This gene is responsible for structural components of the dopamine receptor. Gene polymorphisms may be associated with greatly increased risk of addiction and may suggest a poorer result with prescribed SSRIs.

FADS and FADS1 (Fatty Acid Delta-5-Desaturase) rs174537, rs174546, and rs174547

These code for a desaturase enzyme necessary for conversion of plant fats to essential fatty acids in the body. Essential fatty acids may be of special benefit for patients with this genetic SNP who have concomitant affective disorders and low levels of essential fatty acids.

GAD1 (Glutamic Acid Decarboxylase 1) rs2241165

This gene encodes for enzymes needed to convert L-glutamic acid into the calming neurotransmitter GABA. SNPs will contribute to higher levels of anxiety and extremely tight muscles and may contribute to the rare condition known as Stiff Person Syndrome. Patients with this genetic SNP may benefit from more exercise, which can upregulate GAD gene function to enhance GABA production.[260] Extra supplemental vitamin B_6, a cofactor for the glutamic acid decarboxylase enzyme, can help enhance GABA production. Giving supplemental GABA, along with GABA-supportive nutrients such as theanine,[261] lithium orotate, and/or calming botanicals like *passiflora,* may be of value in patients with anxiety who have this polymorphism.

GC (Vitamin D Binding Protein) rs2282679

This gene is responsible for structure of a transporter for vitamin D. Hetero- or homozygous positive genotypes will be at higher risk for lower vitamin D levels, which will predispose for affective disorders. Higher intakes of vitamin D may be required.

IL-6 (Interleukin-6) rs1800795

Meta-analyses indicated that IL-6 is the most consistently elevated cytokine in the blood of patients with major depression.[262] SNP alterations in this gene may predispose to higher levels of inflammation in the CNS and periphery. Recommendations to reduce inflammation may be of use.

MAOA and B (Monoamine Oxidase A and B) Multiple rs Numbers

This gene encodes mitochondrial enzymes that catalyze the oxidative deamination of amines, including dopamine, norepinephrine, and serotonin. Knowing this predisposition may help the practitioner correlate clinical symptoms to choose recommendations to boost or lower monoamines.

MTHFR (Methylene Tetrahydrofolate Reductase) rs1801133 and rs1801131

Polymorphisms predispose to reduced folate conversion to active forms. Patients with this SNP and high homocysteine suggest poor methylation abilities, which will affect neurotransmitter creation. Rs1801131 specifically affects neurotransmitter production by poor cycling of the tetrahydrobiopterin (BH_4) pathway. Concomitant COMT alleles may predispose to further neurotransmitter imbalances. Consider increasing intake of folate-containing foods (green leafy vegetables) and supplementation with methyl-folate, and avoiding synthetic folic acid.

MTR (Methionine Synthase) rs1805087 and MTRR (MTR Reductase) rs1801394

Presence of SNPs in either or both of these might increase requirements for B_{12}, as these support B_{12} recycling. Checking serum B_{12} and methylmalonic acid might be valuable to confirm clinical significance.

OXTR (Oxytocin Receptor) rs53576

Oxytocin was discussed earlier in this chapter. This gene is response for building the oxytocin receptor. The A allele typically predisposes individuals toward poorer stress-management skills, such as the inability to seek help, and these individuals tend to be lonelier.[263] Possibly using natural remedies known to raise oxytocin, such as hugging therapy, massage,[264] or supplemental lithium,[265] would be of value.

SLC39A13 (Solute Carrier Family 39 Member 13)

This gene encodes zinc transporter proteins and may be related to mood disorders.[266] Polymorphisms may suggest additional zinc would be beneficial for the person with affective disorder.

TPH 1 and 2 (Tryptophan Hydroxylase 1 and 2) rs1799913, rs4570625, and rs429027

This gene helps govern the conversion of tryptophan to 5-HTP, and the T allele may affect available serotonin and mood state as a result. Variants affect the circadian-regulating function of suprachiasmatic nuclei, which is a master controller of circadian rhythm.[267] Light therapy, tryptophan, 5-HTP, melatonin, and its cofactor (such as vitamin B_6) might be useful with this genetic SNP.

PRIMARY PREVENTION: THE PRENATAL ENVIRONMENT AND CHILDHOOD EXPERIENCE

Although beyond the scope of this chapter, clinicians need to be aware of the critical effect of the prenatal environment and childhood experiences as dominant factors in the overall tone of the HPA axis. Prenatal and childhood stress will greatly affect CRH and cortisol levels as adults.[268,269] From a holistic standpoint, it should also be noted that besides emotional stressors, dietary imbalances such as poor nourishment and low birth weight, maternal overeating, and prenatal high-fat diets will also contribute to HPA and mood disorder in the next generation. Along with proper nutrition, mind–body modalities in the prenatal and childhood period may hold the greatest promise in preventing affective disorders. Multimodal psychoeducation approaches, yoga, and meditation interventions have shown outcomes like higher birth weight, shorter labor, fewer instrument-assisted births, and reduced perceived stress and anxiety.[270]

PERTINENT LABORATORY TESTING

It will nearly impossible, due to cost and practicality, to order all possible testing. It is important to have an excellent intake with the patient to gather clinical evidence to support the need for looking down various paths with specific tests.

Blood Tests

Blood work can be used to assess multiple factors, including those related to red blood cell, nutrient, inflammation, hormonal and mitochondrial status.

- Blood Sugar: fasting glucose / Serum Insulin / HgbA1C
- Complete Blood Count
- Chemistry Panel
- Iron Panel: ferritin and serum iron
- Lipid Panel
- Homocysteine
- Histamine
- TSH, T3, T4
- DHEA/DHEA sulfate
- Pregnenolone
- Estrogens (E1, E2, E3)
- Progesterone (preferably day 22 of a premenopausal woman's menstrual cycle)
- Free and total testosterone, estrogen, and testosterone
- 25(OH) Vitamin D
- Zinc and Copper
- Vitamin B_{12} and folic acid
- Serum methylmalonic acid
- Serum glutathione
- Serum carnitine
- Serum lactic acid
- Serum CoQ10
- Celiac Panel
- Serum heavy metals: mercury, cadmium, arsenic, lead, aluminum

Food Sensitivity/Food Allergy Testing

Food testing may elucidate which foods are more likely to create a sensitivity or histaminic reaction in the body. See Chapter 14, Food Hypersensitivities, for discussion.

Saliva and Urine Testing

These tests are valuable to took further into HPA-axis dysfunction and can also further elaborate on hormonal status.

Organic Acid Testing

Organic acids look at urine samples to help suggest mold toxicity metabolites. See Chapter 29, Organic Acids Profiling, to learn about this test.

Leaky Gut Tests

Lactulose Mannitol Testing can help identify "gut permeability," which can play a role in altered gut microbiota brain and CNS inflammation.[271] Review Chapter 19, Intestinal Permeability.

Small Intestinal Bowel Overgrowth (SIBO) Test: May help create an effective treatment plan for Irritable Bowel Syndrome, which is highly correlated with anxiety and depression symptoms. See Chapter 9, Bacterial Overgrowth of the Small Intestine Breath Test, for more discussion.

Hair Analysis: Can help discern mineral status as well as heavy metal status. See Chapter 16, Hair Mineral Analysis, for discussion.

Urine Toxic Metal Testing: Both unprovoked and provoked tests are used to evaluate heavy metal status in a patient and need for detoxification techniques, covered in other chapters of this book. Please see Chapter 22, Metal Toxicity: Assessment of Exposure and Retention.

THERAPEUTIC APPROACH

General therapeutic approaches for affective disorders, whether depression, anxiety or bipolarity are as follows.

Diet

Helps address gastrointestinal dysfunction, dysglycemias, nutrient depletions, and inflammation. Focus on whole foods, fiber, and anti-inflammatory diet. Consider a Mediterranean diet, keeping in mind food allergies and sensitivities. Assuring proper

protein for neurotransmitter support, as well intake and small frequent meals, may be ideal to avoid fluctuations in blood sugar. Unsaturated fats (fish, olive oil) are encouraged for optimal fatty acid intake. For a healthy microbiome, incorporate fermented foods to help balance microbiota and fiber foods for prebiotic support.

Sleep

Assure 7 to 9 hours of quality sleep, preferably getting to bed by 10 p.m. Keep the bedroom dark and at an average of 68°F (20°C) or less.

Exercise

Assure a balanced exercise regimen. Five days a week of moderate to vigorous exercise for 30 minutes may be a starting point. For those less vital or motivated, a gentler program might be indicated. See Chapter 36 on The Exercise Prescription.

Lifestyle

Avoid all alcohol and avoid excess caffeine (avoid all caffeine if insomnia is present). Minimize screens and social media.

Psychological Work

Regular cognitive behavioral therapy to work on negative thoughts.

Relaxation Work

- Spending time in nature
- Working with yoga
- Participating in mindfulness-based cognitive therapy (MBCT)

Nature

Patients need to spend ample time outdoors, in green areas when possible.

Environmental Toxicity

Evaluate for toxin load and use detoxification techniques if patient history is suggestive.

Supplementation

Choose supplements most salient to a patient's circumstance and laboratory values.

- Hormone support: supplements, botanicals for supporting the physiology, or actual hormone: thyroid, estrogen, progesterone, melatonin, cortisol, testosterone DHEA
- Probiotics: *Lactobacillus* and *bifidus* spp.
- Essential fatty acids: 1000 to 2000 mg fish oil per day
- Vitamin D: 1000 IU to 5000 IU. Check labs to assure proper dosing. Assess and address status of vitamins A and K_2.
- Vitamin B_6 (pyridoxine 5′ phosphate form): 25 to 50 mg a day
- Vitamin B_{12} (methyl or Adenosylcobalamin form): 1000 up to 10,000 mcg a day
- Methyl folate: 500 mcg up to 5 mg a day
- Magnesium: 125 mg to 500 mg a day
- Iron: 25 mg to 150 mg a day in divided doses, as indicated by laboratory testing
- Zinc: 15 to 30 mg a day
- St. John's wort: 300 mg three times a day. Be mindful of interactions with conventional medications.
- Curcumin: 500 to 1000 mg/day
- Rhodiola: 340 mg up to 1340 mg a day
- Homeopathic medicines: per patient's individual presentation and constitution

SPECIFIC THERAPEUTIC CONSIDERATIONS ACCORDING TO AFFECTIVE DISORDER

Depression

Diet

Depressed patients without insomnia or anxiety may want to try one to two cups of coffee in the morning and early afternoon.

Supplements

- 5-HTP: 50 mg to 100 mg three times a day. May be best avoided in the long term as a monotherapy in patients with depression who are predisposed to be low in catecholamines are not taking catecholamine supports.
- Phenylalanine
- D phenylalanine: for depressed mood, 350 mg per day
- DL phenylalanine: for depression along with a pain picture: 100 to 500 mg per day
- Note: Those with phenylketonuria should not supplement with phenylalanine.
- Tyrosine: 500 to 1000 mg doses two or three times a day
- Acetyl L-carnitine: 1 to 3 grams a day
- Inositol: 12 to 18 grams a day
- Glycine: best avoided in depression
- SAMe: 200 mg twice a day up to 400 mg three times a day; ramp up slowly.

Anxiety

Diet

May be best to avoid all caffeine, except for small percentage of patients with low dopamine status

Supplements

- Glycine: for anxiety only, one to three teaspoons a day. Studies suggest up to 3 tablespoons can be beneficial without side effects.
- GABA: 500 mg three times a day
- Phenibut: 300 mg three times day, do not use more than 2 weeks at a time, with a week in between to avoid reliance. Be aware this is not a natural product, and at the time of this writing the FDA has sent warning letters to manufacturers.
- Lithium orotate: 5 to 20 mg a day
- CBD oil: 15 mg twice a day
- Passiflora: ⅓ tsp of extract in a little warm water three times a day

Bipolar Disorder

Diet

- Gluten-free and casein-free diet

Supplements to Use

- Taurine: 500 mg three times a day
- NAC: 1000 mg twice a day
- Triacetyluridine: 25 mg to 18 grams a day, for mitochondrial support and low symptoms

Supplements to Avoid

- Mucuna
- Creatine
- SAMe
- Tyrosine
- Kava
- Rhodiola
- Ginseng[272]
- D and L phenylalanine

Seasonal Affective Disorder

Light Therapy

10,000-lux full-spectrum white light for at least 30 minutes every morning. This is best initiated in the early fall and discontinued in early spring months.

A NOTE ABOUT INTEGRATIVE USE OF NATURAL MEDICINES AND CONVENTIONAL DRUGS

There are emerging studies looking at the adjunctive use of natural supplementation with pharmaceuticals. A recent Cochrane review suggests many supplements are effective and safe when used in combination with drugs for mood.[273]

It is highly probable that the underlying mechanisms of affective disorders are, in part, due to physiological imbalances and nutrient deficiencies. For example, we know that low serum folic acid and zinc increase the likelihood that antidepressants will not work. Using various supplements with medications, in many cases, may help treatments work best. Table 142.2 provides a selected list of studies using natural medicines along with medications:

Curcumin administration was safe and well tolerated even when combined with antidepressants. Curcumin was more efficacious than placebo in improving MADRS scores, with significant differences between curcumin and placebo emerging at weeks 12 and 16.

Alcohol Dependence

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Physical signs of excess alcohol consumption: alcohol odor on breath, flushed face, tremor, ecchymoses
- Alcoholic binges, benders (i.e., 48 or more hours of drinking associated with failure to meet usual obligations), or blackouts
- Evidence of alcohol-induced illnesses: cirrhosis, gastritis, pancreatitis, myopathy, polyneuropathy, cerebellar degeneration
- Psychological/social signs of excess alcohol consumption: depression, loss of friends, arrest for driving while intoxicated, surreptitious drinking, drinking before breakfast, frequent accidents, unexplained work absences
- Alcohol dependence manifested when alcohol is withdrawn: tremulousness, convulsions, hallucinations, delirium

GENERAL CONSIDERATIONS

Alcohol dependence, alcohol-use disorder, or, as it was formerly known, alcoholism is a disabling addictive disorder characterized by alcohol consumption that exceeds acceptable cultural limits or injures health or social relationships. Although alcohol (ethanol) can be directly toxic, with resulting symptoms occurring quickly and transiently, toxicity is dose-dependent, and small amounts may be beneficial. Excess is clearly a serious clinical problem in North America, with a prevalence of lifetime alcohol abuse of 17.8% and a prevalence of 12-month alcohol abuse of 4.7%. In the last edition of the TBNM, estimates were that a prevalence of lifetime and 12-month alcohol dependence in the United States is 12.5% and 3.8%, respectively.[1] Alcohol dependence is significantly more prevalent among men, whites, Native Americans, younger and unmarried adults, and people with lower incomes. Alcohol dependence affects more than 18 million Americans, making it one of the most serious health problems facing physicians today.[1] The total number of Americans affected, either directly or indirectly, is much greater when one considers disruption of family life, automobile accidents, crime, decreased productivity, and mental and physical diseases. With more than 100,000 deaths annually attributed to alcohol misuse, alcohol-related problems are a cause of considerable mortality.[2] As indicated in Box 143.1, the health, social, and economic consequences of alcohol dependence are alarming.

Physicians should consider alcohol dependence when the information provided by the patient and the doctor's own analysis seems to indicate a missing factor. Often, alcohol dependence is a "hidden" disease. The natural consequences of the alcoholic's behavior may be disguised by sympathetic family and friends. This circumstance allows the alcoholic to target other factors as the "real problem," without identifying his or her drinking behavior. Table 143.1 provides an alcohol-dependence–screening questionnaire.

The etiology of alcohol dependence remains obscure. It represents a multifactorial condition involving genetic, physiological, psychological, and social factors, each of which seems to be important. Serious drinking often starts in younger people; approximately 35% of alcoholics develop their first symptoms between 15 and 19 years of age, and more than 80% develop their first symptoms before age 30.[3]

Alcohol dependence is most common in men, but the incidence has been increasing in women. Although the figures were once more disparate, the female-to-male ratio for alcohol dependence has tapered to 1:2.[1,2] Women generally seem to develop disease at a lower level of intake than men do. This difference may be partially because of women's lower volume of distribution for alcohol and may also be related to increased gut permeability to endotoxins.[4]

Genetic Susceptibility

Research indicates that genetic and epigenetic factors may be particularly important (Fig. 143.1).[5] For example, individuals with the inactive ALDH2 allele are poor eliminators of acetaldehyde. The resulting accumulation of acetaldehyde produces unpleasant effects from alcohol (e.g., nausea, vomiting, flushing, increased heart rate), and consequently, these individuals consume little to no alcohol. The finding of a genetic marker for susceptibility to alcohol dependence could result in the diagnosis of the disease in its initial and most reversible stage. Some case–control studies suggest that non–gender-based gene polymorphisms encoding cytokines and other immune modulators may play a role in the predisposition to alcoholism. The gene patterns associated

BOX 143.1 Consequences of Alcohol Dependence

Increased Mortality
- 10- to 12-year decrease in life expectancy
- Double the usual death rate in men, triple in women
- Six times greater suicide rate
- Major factor in the four leading causes of death in men between the ages of 25 and 44: Accidents, homicides, suicides, cirrhosis

Economic Toll (Yearly)
- Lost production: $14.9 billion
- Health care costs: $8.3 billion
- Accident and fire losses: $5 billion
- Cost of violent crime: $1.5 billion
- Total costs (health care, accidents, violence, lost productivity): $136 billion

Health Effects
- Metabolic damage to every cell
- Intoxication
- Abstinence and withdrawal syndromes
- Nutritional diseases
- Cerebellar degeneration
- Cerebral atrophy
- Psychiatric disorders
- Esophagitis, gastritis, ulcer
- Increased cancers of the mouth, pharynx, larynx, and esophagus
- Pancreatitis
- Fatty degeneration and cirrhosis of the liver
- Arrhythmias
- Myocardial degeneration
- Hypertension
- Angina
- Hypoglycemia
- Decreased protein synthesis
- Increased serum and liver triglycerides
- Decreased serum testosterone
- Myopathy
- Neuropathy
- Osteoporosis
- Rosacea, spider veins
- Coagulation disorders

Effects on Fetus
- Growth retardation
- Mental retardation
- Fetal alcohol syndrome
- Teratogenicity

Modified from Hyman SE, Cassem NH. Alcoholism. In Dale DC, Federman DD, eds. *Scientific American Medicine*. New York: Scientific American; 1997:III:1-12, 13.

TABLE 143.1 The Brief Michigan Alcohol Dependence Screening Test

1.	Do you feel you are a normal drinker?	Yes (0)	No (2)
2.	Do friends or relatives think you are a normal drinker?	Yes (0)	No (2)
3.	Have you ever attended a meeting of Alcoholics Anonymous (AA)?	Yes (5)	No (0)
4.	Have you ever lost friends or girlfriends or boyfriends because of drinking?	Yes (2)	No (0)
5.	Have you ever gotten into trouble at work because of drinking?	Yes (2)	No (0)
6.	Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking?	Yes (2)	No (0)
7.	Have you ever had delirium tremens (DTs), severe shaking, heard voices, or seen things that were not there after heavy drinking?	Yes (2)	No (0)
8.	Have you ever gone to anyone for help about your drinking?	Yes (5)	No (0)
9.	Have you ever been in a hospital because of drinking?	Yes (5)	No (0)
10.	Have you ever been arrested for drunk driving or driving after drinking?	Yes (2)	No (0)

Alcohol dependence is indicated by a score above 5.
Modified from Hyman SE, Cassem NH. Alcoholism. In Dale DC, Federman DD, eds. *Scientific American Medicine*. New York: Scientific American, 1997:III, 1-12, 13

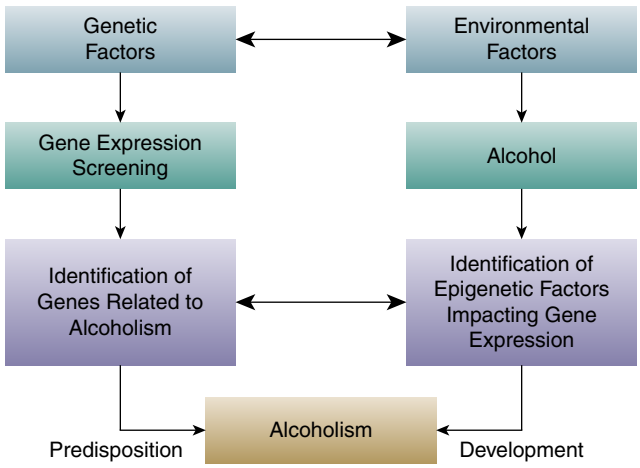

Fig. 143.1 A hypothetical model for the interactions of genetic and environmental factors in the predisposition to and development of alcoholism. (From Starkman BG, Sakharkar AJ, Pandey SC. Epigenetics—beyond the genome in alcoholism. *Alcohol Res*. 2012;34[3]:293-305. PubMed PMID: 23134045.)

with risk reveal that antibody-mediated mechanisms may play a role in disease pathogenesis.[4] The genetic basis of alcohol dependence has also been supported by the following:

- Genealogical studies showing that alcohol dependence is a family condition
- Studies of adopted children of alcoholic parents raised by foster parents demonstrating a continued higher risk of alcohol dependence
- Twin studies showing differences between identical and nonidentical twins
- Association with genetic markers: color vision, nonsecretor ABH, HLA-B_{13}, and low platelet monoamine oxidase (MAO)
- Biochemical studies showing the importance of alcohol dehydrogenase polymorphism in racial susceptibility to alcohol dependence.[5]

Several studies have shown that the incidence of alcohol dependence is four to five times more common in the biological children of alcoholic parents than in biological children of nonalcoholic parents.[5] Although it would be ultimately useful, knowledge of family history suggests that clear evidence of a biological marker may not be necessary for the implementation of a relatively innocuous primary prevention program.

Alcohol Toxicity and Glutathione

The diverse toxic effects of alcohol result not only from the variation in the levels of breakdown products but also from the depletion of glutathione. This depletion results in the upregulation of gamma glutamyl transferase (GGT) to provide more glutathione, likely for Phase II conjugation, as well as to neutralize oxidative stress. Cellular GGT metabolizes extracellular GSH, allowing the precursor cysteine to be reused for de novo synthesis of intracellular GSH.

There are some major limitations in the use of GGT as a measure of excessive alcohol consumption:

1. GGT also elevates by exposure to other chemicals, especially persistent organic pollutants (POPs) and several prescription drugs.
2. Genetics and nutrient availability will affect GGT's sensitivity to alcohol consumption.
3. Some chronic imbibers (upward of 9 drinks per day) have GGT in the "normal" range.

Individuals have great variation in their ability to produce glutathione in response to toxic and oxidative challenge. Nonetheless, GGT is most beneficial when baseline levels are determined on an individual basis. In a uniform population, GGT will increase in direct proportion to alcohol consumption. In a nonuniform population, 40 g of ethanol per day will elevate GGT ~15%, whereas 60 g per day for 5 weeks in young men will almost double GGT from 27 to 52 u/L. However, there is much individual variation. In general, GGT goes back to "normal" after abstinence for 1 month. Early research shows promise in using glutathione transferase (GSTA1) as a measure for advising patients on their alcohol consumption, as GSTA1 has been shown to be a sensitive and reliable marker in ethanol-induced hepatic injury.[6]

INTOXICATION AND WITHDRAWAL

The signs of alcoholic intoxication are typical of a central nervous system depressant: drowsiness, errors of commission, disinhibition, dysarthria, ataxia, and nystagmus. Fifteen milliliters of pure alcohol (the equivalent of 1 oz of whiskey, 4 oz of wine, or 10 oz of beer) raise the blood level of alcohol by 25 mg/dL in a 70-kg person. Table 143.2 shows the effects of varying blood levels of alcohol.

Withdrawal symptoms usually occur 1 to 3 days after the last drink. Animal models, as well as findings obtained in humans, have shed light on the effects that acute and chronic alcohol exposure have on signaling systems involving the neurotransmitters glutamate, gamma-aminobutyric acid (GABA), dopamine, and serotonin, as well as on other signaling molecules, including endogenous opioids and corticotrophin-releasing factor (CRF) (Fig. 143.2).[7] Adaptation to chronic

TABLE 143.2 Effects of Varying Levels of Blood Alcohol

Blood Level (MG/DL)	Effect
<50	No significant motor dysfunction
100	Mild intoxication—decreased inhibitions, slight visual impairment, slight muscular incoordination, slowing of reaction time
	Legally intoxicated in most jurisdictions
150	Ataxia, dysarthria, slurring of speech, nausea and vomiting
350	Marked muscular incoordination, blurred vision, approaching stupor
500	Coma and death

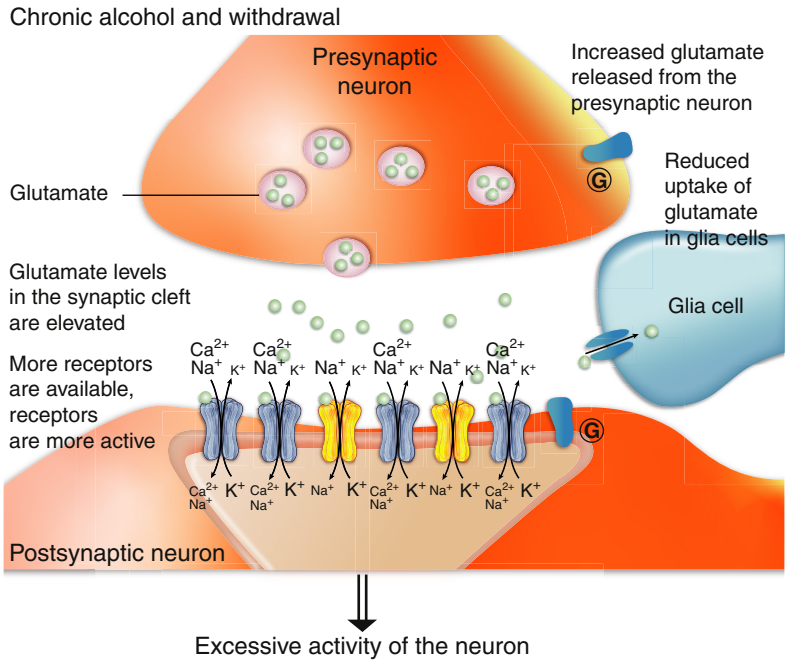

Fig. 143.2 Actions of the brain's glutamate system. After chronic alcohol exposure and during withdrawal, glutamate release at the synapse is enhanced and the number of synaptic N-methyl-d-aspartate receptors (NMDARs) and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptors (AMPARs) is increased. As a result, glutamate induces excessive activity of the postsynaptic neuron. (From Clapp P, Bhave SV, Hoffman PL. How adaptation of the brain to alcohol leads to dependence: a pharmacological perspective. *Alcohol Res Health*. 2008;31[4]:310-339. PubMed PMID: 20729980.)

alcohol exposure by these systems has been associated with several effects ranging from anxiety and tremulousness to mental confusion, tremor, sensory hyperactivity, visual hallucinations, autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances, seizures, and cardiovascular abnormalities.

METABOLIC EFFECTS OF ALCOHOL AND ALCOHOL DEPENDENCE

Ethanol Metabolism

The primary metabolic processes that regulate the rate of alcohol catabolism in normal individuals are[8]:

- The rate of ethanol absorption
- The concentration and activity of liver alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH)
- The reduced nicotinamide adenine dinucleotide (NADH)/nicotinamide adenine dinucleotide (NAD)+ ratio in the liver mitochondria.

It is generally accepted that the availability and regeneration of NAD+ are the dominant rate-limiting factors for ethanol oxidation.[9] Ethanol is converted to acetaldehyde by ADH, with NAD+ as a necessary cofactor.

The aldehyde product of ethanol metabolism is believed to be responsible both for many of the harmful effects of alcohol consumption and for the addictive process itself. Acetaldehyde has been shown to promote cancer by interfering with the replication of DNA and by inhibiting the body's ability to repair damaged DNA.[10] Alcohol use increases the risk of developing a variety of cancers, including colon, liver, breast, throat, mouth, and upper respiratory tract cancers. Higher-than-normal blood aldehyde levels have been found in alcoholics and their relatives after alcohol consumption.[9] This finding suggests either increased ADH activity or depressed ALDH activity in people susceptible to alcohol dependence. Acetaldehyde is converted by ALDH to acetate, with little entering the Krebs cycle; most is converted to long-chain fatty acids.[8]

Fatty Liver

All active alcoholics display fatty infiltration of the liver, with the severity roughly proportional to the duration and degree of alcohol excess. Even moderate doses of ethanol may produce both acute and chronic fatty liver infiltrates. The pathogenesis is due to the following[8,11]:

- Increased endogenous fatty acid synthesis
- Diminished triglyceride utilization
- Impaired lipoprotein excretion
- Direct damage to endoplasmic reticulum by free radicals produced by ethanol metabolism
- The high-fat diet of the alcoholic (as is typical of the average American diet).

Leptin is a peptide hormone involved in the regulation of appetite and energy metabolism. It is most likely directly related to liver pathology in alcoholics. High levels of leptin are known to contribute to liver pathology, including increased rates of fibrosis, a known factor in liver steatosis.[12] Research has demonstrated increased circulating leptin levels in a dose-dependent manner in chronic alcohol dependence regardless of nutritional status.[13]

Hypoglycemia

Alcohol induces reactive hypoglycemia. The resultant drop in blood sugar produces a craving for food, particularly foods that quickly elevate blood sugar (e.g., sugar and alcohol). Increased sugar consumption aggravates the reactive hypoglycemia, particularly in the presence of alcohol, owing to alcohol-induced impairment of gluconeogenesis.[8] Hypoglycemia aggravates the mental and emotional problems of the alcoholic and the withdrawing alcoholic with symptoms such as:

- Sweating
- Tremor
- Tachycardia
- Anxiety
- Hunger
- Dizziness
- Headache
- Visual disturbance
- Decreased mental acuity
- Confusion
- Depression

THERAPEUTIC CONSIDERATIONS

Nutrition

Although many of the nutritional problems of alcoholics relate directly to the effects of alcohol, a major contributing factor is that alcoholics tend not to eat, substituting alcohol for food. As a result, the alcoholic has to deal not only with nutritional deficiencies caused by excessive alcohol consumption but also with true nutritional deficiencies due to inadequate intake.

Zinc

One of the key nutrients involved in the metabolic handling of alcohol is zinc, because both ADH and ALDH are zinc-dependent enzymes, with the latter being more sensitive to deficiency.[14] Both acute and chronic alcohol consumption result in zinc deficiency.[14,15] Several factors contribute to the development of zinc deficiency in alcoholics:

- Decreased dietary intake
- Decreased ileal absorption (probably due to interference with the zinc-binding ligand, picolinic acid, and nonspecific mucosal damage)
- Hyperzincuria

On hair analysis, higher zinc and copper values have been observed in male alcoholics versus nonalcoholics.[16] Hair copper was significantly related to the amount of ethanol consumed, whereas hair zinc was higher in consumers of distilled beverages. These data may indicate abnormal metabolism and loss of these minerals in the alcoholic. The clinical symptoms of hypozincemia and copper deficiency in individuals addicted to alcohol often relate to disorders in central nervous system functioning, and they result in decreases in physical and mental quality of life. Low serum zinc levels are associated with impaired alcohol metabolism, a predisposition to cirrhosis, impaired testicular function, and other complications of alcohol abuse.[14,17] Zinc supplementation, particularly when combined with ascorbic acid, greatly increases alcohol detoxification and survival in rats.[18]

Vitamin A

Vitamin A deficiency is also common in alcoholics and appears to work synergistically with zinc deficiency to produce the major complications of alcohol dependence.[11,17] The mechanism has been hypothesized as reduced intestinal absorption of zinc and vitamin A in conjunction with impaired liver function (reduced extraction of zinc, mobilization of retinol binding protein [RBP], and storage of vitamin A), resulting in reduced blood levels of zinc, vitamin A, RBP, and transport proteins as well as a shift to nonprotein ligands. These cause the tissues to have reduced concentrations of zinc and vitamin A, abnormal enzyme activities and glycoprotein synthesis, and impaired DNA/RNA metabolism and cause the kidneys to increasingly lose zinc. These metabolic abnormalities then lead to the common disorders of alcohol dependence[17]:

- Night blindness
- Skin disorders

- Cirrhosis of the liver
- Reduced skin healing
- Decreased testicular function
- Impaired immune function

Vitamin A supplementation inhibits alcohol consumption in female rats, an effect inhibited by testosterone administration.[19] Further research supports the significance of the endocrine system in alcohol preference. Ovariectomized and adrenalectomized rats show a decreased preference for alcohol, whereas corticosterone injections increase alcohol preference.[20]

Vitamin A supplementation in the alcoholic has corrected vitamin A deficiency, as noted by improvements in night blindness and sexual function.[11] Despite the importance and benefits of vitamin A to the alcoholic, great care must be employed in recommending vitamin A supplementation. Excessive amounts of vitamin A are contraindicated owing to the fact that a liver damaged by excessive alcohol consumption significantly loses its ability to store vitamin A. As a result, the alcoholic is at great risk for developing vitamin A toxicity when it is supplemented at dosages above 5000 IU a day.

Antioxidants

Ethanol consumption increases lipid peroxidation in humans, resulting in increased lipoperoxide levels in both the liver and serum. This increase is aggravated, considering that alcoholics are typically deficient in key antioxidant nutrients, particularly vitamin E, selenium, and vitamin C.[21,22] There is a significant correlation between serum lipid peroxide levels, serum glutamic oxaloacetic transaminase (SGOT) activity, and liver cell necrosis.[23] Antioxidant administration, either before or together with ethanol intake, inhibits lipoperoxide formation and prevents fatty infiltration of the liver.[24] Effective antioxidants include vitamins C and E, zinc, selenium, and cysteine.

Carnitine

Although the use of lipotropic agents appears warranted in treating alcoholic fatty liver disease, many commonly used lipotropic agents (e.g., choline, niacin, cysteine) appear to have little value.[25,26] One lipotropic agent, carnitine, significantly inhibits alcohol-induced fatty liver disease. It has been suggested that chronic ethanol consumption results in a functional deficiency in carnitine.[27-29] Because carnitine normally facilitates fatty acid transportation and oxidation in the mitochondria, a high liver carnitine level may be necessary to handle the increased fatty acid load produced by alcohol consumption. Supplemental carnitine reduces serum triglycerides and levels of SGOT while also elevating high-density-lipoprotein cholesterol.[27]

Amino Acids

Amino acid chromatography patterns are aberrant in alcoholics; restoration to normal levels greatly aids the alcoholic patient.[30-33] Because the liver is the primary site of amino acid metabolism, it is not surprising that alcoholics develop abnormal amino acid patterns. Normalization of plasma amino acids is particularly indicated in those patients showing signs or symptoms of hepatic cirrhosis or depression. The branched-chain amino acids—valine, isoleucine, and leucine—inhibit the hepatic encephalopathy and increased protein catabolism that are common sequelae of cirrhosis.[33] Methionine, a known lipotropic, must be activated to S-adenosylmethionine. However, in severe liver disease, the activity of the corresponding enzyme is depressed. In this case supplementation with methionine is not as useful. S-adenosylmethionine would be indicated to ameliorate associated deficiencies and resulting pathology.[34] Derangement of neurotransmitter profiles, particularly due to the low plasma levels of tryptophan typically seen in withdrawing alcoholics, will result if these profiles are not normalized, leading to depression, encephalopathy, and coma.[30,32]

Anomalous amino acid profiles are aggravated by the low-protein diet used as standard therapy for cirrhosis, but this problem can be avoided through the use of free-form amino acids without the risk of hepatic encephalopathy.[30,32] (See "Depression" later for a further discussion of amino acid imbalances.)

Although there are some characteristic amino acid abnormalities in alcoholics, an individual approach is indicated owing to differences in nutritional status, biochemistry, and the amount of liver damage. Correction of the imbalances probably requires amino acid chromatography for best results.

Vitamin C

In one study, a deficiency of ascorbic acid was found in 91% of patients with alcohol-related diseases.[35] Supplemental ascorbic acid helped ameliorate the effects of acute and chronic ethanol toxicity in experimental studies involving humans and guinea pigs, two species unable to synthesize their own ascorbic acid.[18,36] There is a direct correlation between leukocyte ascorbic acid levels (a good index of actual body ascorbic acid status), the rate of ethanol clearance from the blood, and the activity of hepatic ADH.[17] The evidence suggests that ascorbic acid, a strong reducing agent, can function as an electron donor similar to NAD in ethanol metabolism, thereby increasing the conversion of ethanol to acetaldehyde and the further catabolism of acetaldehyde.[18,36]

Selenium

Plasma selenium is clearly lower in alcoholic patients. Serum, erythrocyte, and whole-blood levels of selenium are also decreased in patients with alcohol dependence.[22] Low selenium status encourages depressed mood, whereas high dietary or supplementary selenium has been shown to improve mood.[37] Research has consistently reported that low selenium status was associated with a significantly increased incidence of depression, anxiety, confusion, and hostility.[22] Furthermore, when alcohol dependence and depression occur together, there is an increased risk for suicide.[38]

Given the propensity for low selenium status in alcoholic patients and the relation between selenium levels and mood disorders, selenium supplementation is warranted in an attempt to ameliorate the untoward comorbid psychological and physical profile of patients with alcohol abuse or dependence.

B Vitamins

Alcoholics are classically deficient in most of the B vitamins.[1,11,35] These deficiencies result from various mechanisms:

- Low dietary intake
- Deactivation of the active form
- Impaired conversion to the active form by ethanol or acetaldehyde
- Impaired absorption
- Decreased storage capacity.

Alcohol diminishes thiamine absorption in the intestine and reduces hepatic thiamine storage. It also decreases the phosphorylation of thiamine, leading to a reduction of the active form of thiamine, which also may contribute to development of thiamine deficiency.[39] A thiamine deficiency is both the most common (55% in one study[35]) and the most serious of the B vitamin deficiencies, because a deficiency causes beriberi and the Wernicke-Korsakoff syndrome. In addition, evidence indicates that a thiamine deficiency results in greater intake of alcohol, suggesting that thiamine deficiency is a predisposing factor for alcohol dependence.[40] It should be noted that, once present, Wernicke-Korsakoff syndrome is refractory to oral doses of thiamine; therefore, rapid replacement of depleted brain thiamine levels by repeated parenteral therapy is required.[41]

A functional pyridoxine deficiency is also common in alcoholics, mostly due to impaired conversion to its active form, pyridoxal-5-phosphate, and enhanced degradation.[42] In addition to inhibiting conversion to more active forms, alcohol also decreases the absorption and utilization by the liver and increases the urinary excretion of many B vitamins, especially folic acid.[11,43]

Magnesium

Magnesium deficiency is common in alcoholics. In fact, hypomagnesemia is present in as many as 60% of alcoholics and is strongly linked to delirium tremens.[44] In alcohol-dependent patients, studies suggest measuring ionized magnesium in erythrocytes and plasma as a diagnostic parameter as opposed to total serum magnesium, because this intracellular biologically active form provides a more complex picture of the body's condition.[45] The lower the concentration of ionized magnesium, the worse the quality of life an alcohol-dependent person might experience. It is thought to be the major reason for the increased cardiovascular disease noted in alcoholics.[46] This deficiency is due primarily to a reduced magnesium intake coupled with alcohol-induced renal hyperexcretion of magnesium,[1,44] which continues during withdrawal despite low serum magnesium levels. Alcoholic cardiomyopathy, often associated with thiamine deficiency, may instead be due to a magnesium deficiency.

Essential Fatty Acids

Ethanol has been shown to interfere with essential fatty acid (EFA) metabolism and may produce symptoms of essential fatty acid (EFA) deficiency if consumed in excess.[47] A 5-year study of alcohol-consuming rhesus monkeys linked a marginal EFA diet to alcoholic amblyopia, a rare neuropathy characterized by blurred vision, diminished retinal function, and a reduction in visual acuity.[48] Brain biopsies showed that the fatty acid docosahexaenoic acid (DHA) composition of brain specimens had decreased significantly in comparison with controls. In the retinas of the alcohol-consuming animals at 5 years, there was a similar decrease in DHA. It may be useful to support neurological function by giving EFAs to prevent these ophthalmological sequelae.

Glutamine

Glutamine supplementation (1 g per day) has been shown to reduce voluntary alcohol consumption in uncontrolled human studies and experimental animal studies.[49-51] Although this research occurred more than 50 years ago, there has never been any follow-up to these preliminary studies. The failure to follow up this line of research is unfortunate, because the results were promising and showed the supplement to be safe and relatively inexpensive.

Psychosocial Aspects

Psychological and social measures are critical in the treatment of the alcoholic patient. It is important for the physician to maintain a nonjudgmental but not passive attitude toward the patient. Alcohol dependence should be viewed as a chronic, progressive, addictive, and potentially fatal disease, although many aspects of the alcoholic's behavior may make it difficult to maintain this objectivity.[1]

Social support for both patient and family is important, and success often appears proportional to the involvement of Alcoholics Anonymous (AA), counselors, and other social agencies. Because most physicians have not had adequate training or experience in handling the psychosocial aspects of this problem, it is important to establish a close working relationship with an experienced counselor and AA. Al-Anon and Ala-Teen are useful resources for family members.

Successful initiation of treatment requires the following:

- The patient's agreement that he or she has an alcohol problem
- Education of the patient and family about the physical and psychosocial effects of alcohol dependence
- Immediate involvement of the patient in a treatment program.

Successful programs usually include strict control of drinking and replacement of the alcohol addiction with another addiction that is nonchemical, time consuming, and heavily supported by family, friends, and peers. Although strict abstinence may not be absolutely necessary, at this time it appears the safest and most effective choice.[1]

Depression

Depression is common among alcoholics and is known to lead to their high suicide rate. Many alcoholics are depressed first and later become alcoholic (primary depressives), whereas others become alcoholic first and later develop a depressive condition in the context of their alcohol dependence (secondary depressives). Alterations in the metabolism of serotonin and the availability of its precursor, tryptophan, have been implicated in some forms of depression, whereas other forms have been linked to alterations in catecholamine metabolism and tyrosine availability.

Alcoholics have severely depleted levels of tryptophan, which may explain both the depression and sleep disturbances common in alcohol dependence, because brain serotonin levels depend on circulating tryptophan levels.[52] Ethanol impairs tryptophan transport into the brain. The enzyme tryptophan pyrrolase, considered to be rate-limiting in tryptophan catabolism, is more active in rats during alcohol withdrawal.[31] In one study, 5 of 6 chronic alcoholics had no detectable plasma tryptophan on withdrawal.[30] The tryptophan levels returned to normal after 6 days of treatment and abstinence.

Another factor influencing tryptophan uptake into the brain is competition from amino acids—tyrosine, phenylalanine, valine, leucine, isoleucine, and methionine—that share the same transport; many of these are elevated in malnourished alcoholics.[30,31] Alcoholics have significantly depressed ratios of tryptophan to these amino acids in comparison with normal controls, with depressed alcoholics having the lowest ratios.[31]

The major amino acids, whose elevated levels help lower this ratio, are the catecholamine precursors, tyrosine and phenylalanine. Elevated plasma catecholamine levels are common in alcoholics and may contribute to depression.[53] An interesting finding is that taurine is also low in depressed alcoholics, with the lowest levels being reported in psychotic alcoholics.[30]

Miscellaneous Factors

Intestinal Flora

The intestinal microflora is severely deranged in alcoholics.[54] Clinical and preclinical data suggest that alcohol-related disorders are associated with quantitative and qualitative dysbiotic changes in the intestinal microbiota and may be associated with increased GIT inflammation, intestinal hyperpermeability resulting in endotoxemia, systemic inflammation, and tissue damage/organ pathologies, including ALD (Fig. 143.3).[55] Colonization of the small intestine by endotoxin-producing bacteria may lead to malabsorption of fats, carbohydrates, protein, folic acid, and vitamin B_{12}. This is probably the cause of the abnormalities of the small intestine commonly found in alcoholics. Alcohol ingestion also increases intestinal permeability to endotoxins and macromolecules, allowing increased toxic and antigenic effects.[56] The ensuing allergic reactions and deposition of immune complexes probably contribute to the many complications of alcohol dependence and, considering the addictive tendency of food allergies, may also contribute to alcoholic cravings.

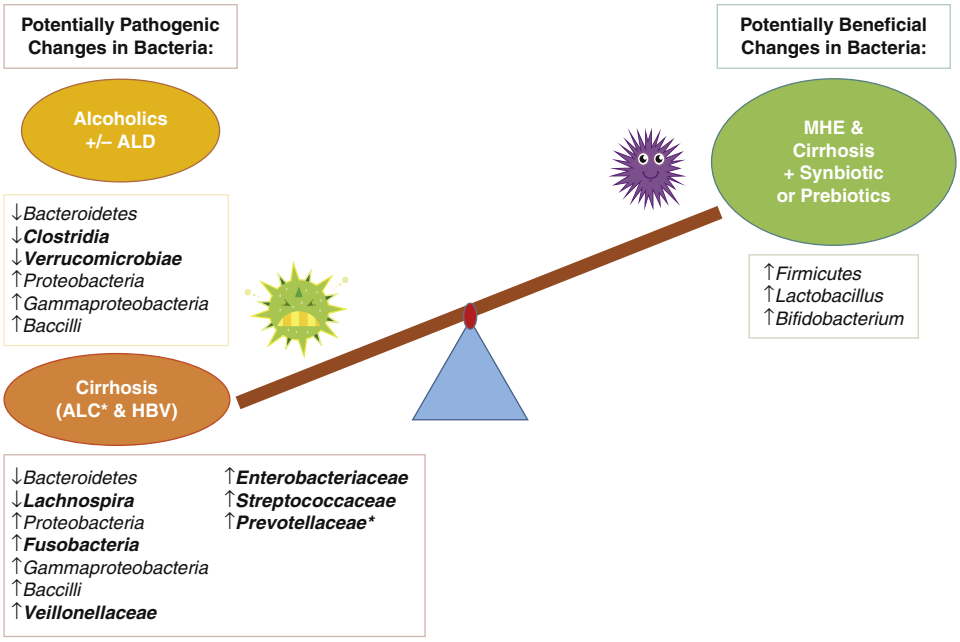

Fig. 143.3 Alcohol-induced imbalances in the microbiome of the gastrointestinal tract (dysbiosis) have been associated with promoting potentially pathogenical changes in bacteria in alcoholics with and without liver disease and in patients with cirrhosis caused by hepatitis B or alcohol. (From Engen PA, Green SJ, Voigt RM, Forsyth CB, Keshavarzian A. The gastrointestinal microbiome: alcohol effects on the composition of intestinal microbiota. *Alcohol Res.* 2015;37[2]:223-236. PubMed PMID: 26695747.)

Exercise

Involvement of the alcoholic patient in a graded, individually tailored fitness program has been shown to improve the likelihood of maintaining abstinence.[57] Research has shown that regular exercise is effective in alleviating anxiety and depression and enables individuals to respond better to stress. Improved fitness may allow for more effective responses to emotional upset, thereby reducing the patient's likelihood of resorting to alcohol when he or she is involved in conflict.

Kudzu *(Pueraria lobata)*

Kudzu is one of the earliest medicinal plants used in traditional Chinese medicine. It has many profound pharmacological actions, including antidipsotropic (antialcohol abuse) activity.[58,59] Two of its isoflavones, daidzin and daidzein, account for this effect. It appears to act by inhibiting aldehyde dehydrogenase 2 (ALDH-2).[59] A deficiency of this enzyme reduces the risk of alcohol dependence. Decreased drinking due to ALDH-2 inhibition is attributed to the aversive properties of acetaldehyde accumulated during alcohol consumption. However, daidzin can reduce drinking in some rodents without necessarily increasing acetaldehyde.

In human studies, the results have been mixed. In one study, kudzu treatment resulted in a significant reduction in the number of beers consumed, which was paralleled by an increase in the number of sips and the time to consume each beer and a decrease in the volume of each sip.[60] However, in a double-blind trial, kudzu root extract (1.2 g twice a day) produced no statistically significance difference in craving and sobriety scores in comparison with the placebo group.[61] It may be that kudzu reduces alcohol intake without significantly affecting cravings.

Milk Thistle *(Silybum marianum)*

The flavonoid complex of milk thistle (silymarin) appears to be useful for the alcoholic, especially in the presence of considerable liver involvement or cirrhosis. Silymarin has been shown to be effective in the treatment of the full spectrum of alcohol-related liver disease, from relatively mild to serious cirrhosis. Perhaps the most significant benefit is extending the life span of these patients. In one study, 87 cirrhotics (46 with alcoholic cirrhosis) received silymarin, and 83 cirrhotics (45 with alcoholic cirrhosis) received a placebo.[62] The mean observation period was 41 months. In the treatment group, there were 24 deaths, among which 18 were related to liver disease; among the controls, there were 37 deaths with 31 related to liver disease. The 4-year survival rate was 58% in the treatment group compared with 39% in the controls.

Silymarin can also improve immune function in patients with cirrhosis.[63] Whether this effect is involved in the hepatoprotective action or a result of improved liver function has yet to be determined.

THERAPEUTIC APPROACH

Alcohol dependence is difficult to treat. Although many therapeutic regimens have been attempted, there has been little documented long-term success except for that of AA (and even the overall success of this program is highly controversial). The approach presented here is unique in that we have attempted to develop an integrated, whole-person, stage-oriented program.

The treatment of the alcoholic patient must be optimized for the four stages of alcohol dependence: active alcohol consumption, withdrawal, recovery, and recovered. The recovery stage is defined here as the period between withdrawal and full reestablishment of normal metabolic function. All alcoholics, at whatever stage, benefit the most by employing simultaneous counseling, lifestyle, and metabolism-balancing therapies. The following are the recommended therapies in the usual context, with additional recommendations for each stage. Also, a complete diagnostic workup is necessary owing to the high risk that the alcoholic patient will develop a wide variety of clinical and subclinical diseases.

Recommendations for All Four Stages

Diet

Stabilization of blood sugar levels is critical to successful treatment. Although a strict hypoglycemic diet may not be warranted, most of the dietary guidelines must be followed. These guidelines include elimination of all simple sugars (foods containing added sucrose, fructose, or glucose; fruit juice; dried fruit; and low-fiber fruits such as grapes and citrus fruits); limitation of processed carbohydrates (e.g., white flour, instant potatoes, white rice); and an increase in complex carbohydrates (e.g., whole grains, vegetables, beans).

Supplements

- Vitamin A: 5000 IU a day
- Vitamin B complex: 20 times the recommended daily allowance
- Vitamin C: 1 g two times a day
- Vitamin E: 400 IU a day (d–α-tocopherol)
- Magnesium: 250 mg two times a day
- Selenium: 200 mg a day
- Zinc: 30 mg a day (picolinate)
- Carnitine: 500 mg two times a day (L-carnitine)
- Glutamine: 1 g a day
- *Lactobacillus acidophilus:* 1 tsp a day

Exercise

A graded program should be established, using heart-rate response to determine intensity. The patient should exercise 5 to 7 times a week for 20 to 30 minutes at an intensity sufficient to raise the heart rate to 60% to 80% of maximum for the age group.

Counseling

The physician dealing with alcoholism should have a good working relationship with AA and an experienced counselor who has particular expertise in working with alcoholics.

Additional recommendations for the four stages follow.

Specific Recommendations for Each Stage

Stage I: Active Alcohol Consumption

The physician should work with family, peers, social contacts, and whomever else is involved with the patient to elicit his or her recognition of an alcohol problem and willingness to enter a treatment program.

Additional supplements include the following:

- Pyridoxal-5-phosphate: 20 mg a day
- Riboflavin: 100 mg a day
- Vitamin A: 5000 IU a day
- Zinc: 30 mg a day

Stage II: Withdrawal

The severity of symptomatology varies widely, although it is usually proportional to the degree of physiological dependence and duration of the disease. Milder cases usually start within a few hours after cessation of drinking and typically resolve within 48 hours. More severe cases usually occur only in patients older than 30 years of age and usually develop after about 48 hours of abstinence. These patients should be admitted to an inpatient facility. Some institutions may not allow the use of supplements; this policy should be checked before a patient is admitted.

Additional supplements include the following:

- Tryptophan: 3 g a day
- Riboflavin: 100 mg a day
- Electrolyte replacement as necessary
- Flaxseed oil: 1 tbsp three times a day

Stage III: Recovering

A strong network of caring family, friends, and peers should be established, if possible, to regularly support the patient, who would do well to become involved and busy with intense, people-oriented activities. It is also vital for the patient to recognize that alcohol is no answer to the stresses of life; he or she should be helped to develop more effective ways of handling adversity.

Stage IV: Recovering to Advanced Recovery

The patient's support group must always be maintained. Continued total abstinence is the best policy, although carefully controlled drinking may be possible. After a 6-month abstinence, supplement dosages may be slowly reduced to 25% of the initial dosages.

Alzheimer's Disease

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Progressive mental deterioration, loss of memory and cognitive functions, inability to carry out activities of daily life
- Characteristic symmetrical, usually diffuse electroencephalographic (EEG) pattern
- Diagnosis usually made by exclusion
- Definitive diagnosis can be made only by postmortem biopsy of the brain, demonstrating atrophy, senile plaques, and neurofibrillary tangles

GENERAL CONSIDERATIONS

Alzheimer's disease (AD) is a neurodegenerative disorder that clinically manifests itself as a progressive deterioration of memory and cognition or dementia. In the United States the prevalence of AD is now estimated to be 1.6% before the age of 74, with the rate increasing to 19% in the 75- to 84-age group and to 42% in those above 84 years of age. These numbers are striking compared with data from the 1960s, indicating an incidence of only 2% in people over the age of 85 years. The tremendous increase in AD in people over 85 years of age is often referred to as the "Alzheimer's epidemic."

Neuropathology

AD has distinctive neuropathologic features that include[1]:

- Plaque formation
- Amyloid deposition
- Neurofibrillary tangles
- Granulovacuolar degeneration
- The massive loss of telencephalic neurons.

These findings are particularly evident in the cerebral cortex and hippocampal formation.

The clinical features of AD are believed to be related to cholinergic dysfunction due to appreciable reductions in the activity of the enzyme choline acetyltransferase, the enzyme that synthesizes acetylcholine, and the neuronal transfer of choline.

Etiology

The core pathological hallmarks of AD are an accumulation of β-amyloid, neuroinflammation, and the formation of neurofibrillary tangles. *Amyloid* is a general term for protein fragments that the body produces normally. Beta-amyloid is a fragment snipped from an amyloid precursor protein (APP). In a healthy brain, these fragments are broken down and eliminated. In AD, β-amyloid protein fragments accumulate to form hard plaques between neurons, blocking the transmission of messages and leading to the death of brain cells, neurofibrillary tangles, and ultimately, dementia. Tau, a microtubule-associated protein, is the major constituent of neurofibrillary tangles and is produced in soluble hyperphosphorylated form when β-amyloid levels become toxic. Persistent activation of glial cells, a hallmark of neuroinflammation, is now considered a key abnormality in AD.[2]

Genetic factors play a major role and are estimated to account for up to 70% of cases of AD. Several genes have been linked to AD: the APP on chromosome 21 (explaining the close association between Down syndrome and AD); the presenilin genes on chromosomes 14 and 1; and the apolipoprotein E *(ApoE)* gene on chromosome 19. The first two mutations are rare and associated with symptoms developing before the age of 50. The most significant genetic finding is the link with the ApoE gene. *ApoE*, a cholesterol carrier in the brain, works to clear amyloid deposits from the parenchyma of the brain; however, at

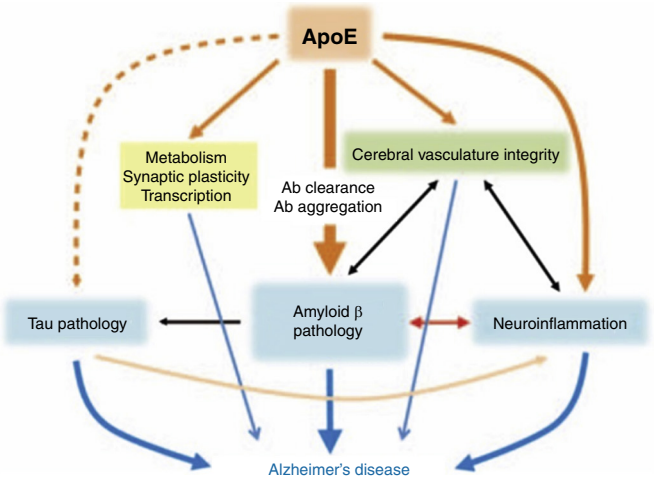

Fig. 144.1 ApoE-mediated pathogenical pathways, leading to Alzheimer's disease. (From Liao F, Yoon H, Kim J. Apolipoprotein E metabolism and functions in brain and its role in Alzheimer's disease. *Curr Opin in Lipidol.* 2017;28[1]:60-67.)

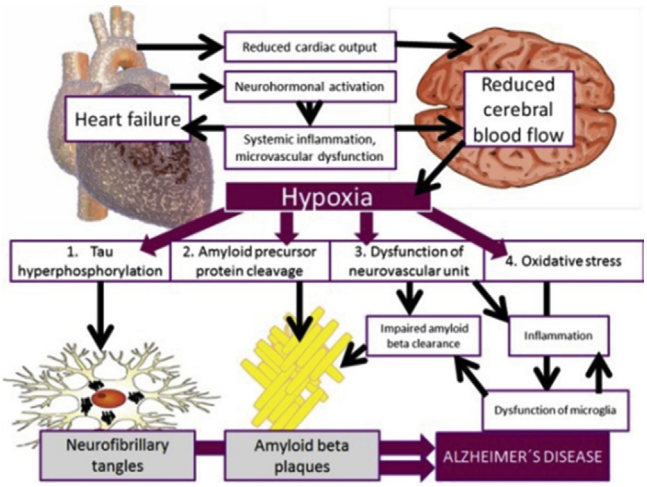

Fig. 144.2 Model of the relationship between heart failure and Alzheimer's disease. (From Carmakova P, Eriksdotter M, Lund LH, Winblad B, Religa P, Religa D. Heart failure and Alzheimer's disease. *J Intern Med.* 2015;277[4]:406-25.)

least 40% of all patients with AD have a genetic variant of APOe4 gene that increases this protein, leading to a significantly greater risk for AD. The e2-type is associated with significant protection. Although the effect of ApoE isoforms on amyloid β metabolism have been considered as its main role in Alzheimer's disease, emerging data suggest that ApoE may also affect AD pathogenesis through amyloid β independent pathways (Fig. 144.1).

Literature is also accumulating regarding the role of genetically linked aberrant immune system regulation of inflammation as a possible contributor to AD. Although innate immune function in the brain is normally modulated to remove plaque in an attempt to maintain health, research is beginning to characterize a chronic and excessive reaction to immune protofibrils of amyloid proteins in the brain that can promote disease.[3] As a result, immunotherapeutic approaches have recently been developed for the treatment of AD. Chief among these strategies is to immunize AD patients with Aβ peptides so that they will generate antibodies that bind to Aβ protein and enhance its clearance.[4] Although preclinical studies were successful, the initial human clinical trial of an active Aβ vaccine was halted owing to the development of meningoencephalitis in approximately 6% of the vaccinated AD patients.

Although genes play a significant role in determining susceptibility to AD, lifestyle and environmental factors also play significant roles. Emerging research reveals that dietary factors are important. Poor-quality diets with excess saturated or trans–fatty acids may predispose neurons to environmental toxicities.[5,6] Some data suggest that abnormal sleep–wake cycles and decreased morning light exposure may play a role in the expression of AD. Traumatic injury to the head; chronic exposure to aluminum, silicon, or both; exposure to neurotoxins from environmental sources; and free radical damage have all been implicated as causative factors as well. As in the pathophysiology of other chronic degenerative diseases, there is considerable evidence that increased oxidative damage plays a central role. Therapies designed to support antioxidant mechanisms may be quite helpful in the prevention of AD.[7]

The tremendous increase in AD parallels the rise in type 2 diabetes and insulin resistance, suggesting a possible connection. It is well established that individuals with type 2 diabetes have a 1.5- to 4-fold higher than normal risk for AD and for vascular dementia. Impaired insulin signaling and insulin resistance in the brain or the decrease in cerebral insulin receptors associated with aging may be another important factor in the pathogenesis of AD. Furthermore, hyperglycemia induces increased peripheral utilization of insulin, resulting in reduced insulin transport into the brain. Insufficient insulin signaling make neurons energy-deficient and vulnerable to oxidizing or other metabolic insults, leading to the destruction of mitochondria and ultimately the neuron. Cerebral hypoinsulinemia (as well as hyperinsulinemia) leads to β-amyloid accumulation and increased tau phosphorylation. Measures to improve glycemic control and improve both peripheral and brain insulin sensitivity appear to be important steps in the prevention of AD.[8,9]

Other known risk factors include family history, hypertension and hypotension, high cholesterol levels, low levels of physical activity, obesity, and heart failure. Reduced cerebral blood flow and dysfunction of the neurovascular unit appear to be the main reasons heart failure contributes to the development of AD (Fig. 144.2).[10] However, multiple cardiovascular conditions often coexist, suggesting that several mechanisms underlying cardiovascular dysfunction may contribute to cognitive decline.

Environmental Toxins

Aluminum

Considerable attention has focused on the association of aluminum concentration in the neurofibrillary tangle (NFT). Whether the aluminum concentration develops in response to AD or whether it initiates the lesions has not yet been determined, but significant evidence shows that it contributes, possibly significantly, to the disease.

Aluminum has a strong affinity for the paired helical filament tau (PHF-t), which is involved in the formation of the NFTs. In fact, studies have demonstrated that aluminum is the cofactor along with this tau filament in the formation of the NFTs.[11] The aluminum selectively binds to PHF-t, induces PHF-t to aggregate, and retards the brain's ability to break down PHF-t. Aluminum's role in AD is further supported by an animal study that evaluated long-term exposure to ecologic doses of aluminum. In this study, researchers found ghostlike neurons with cytoplasmic and nuclear vacuolations, together with aluminum deposits. The hippocampus contained neuritic plaques, and the cerebrovasculature exhibited amyloid deposits. Researchers also found behavioral changes in these rats reminiscent of those observed in AD.[12]

A great deal of circumstantial evidence links chronic aluminum exposure to AD. Increasing aluminum concentrations in the brain could explain why AD increases with increasing age. A study of 356 healthy people showed that serum aluminum concentration increases as people age.[13] Individuals with AD have significantly higher aluminum levels than both healthy people and patients with other types of dementias, such as those due to alcohol, atherosclerosis, and stroke. Efforts to remove the aluminum appear to help somewhat, but such measures are probably too late once the disease is well established. For example, intramuscular injections of deferoxamine (a chelating agent for the removal of iron and aluminum) over a 2-year period showed a significant slowing of the rate of decline in 48 AD patients.[14]

Even in people without mental disease, elevated aluminum levels are associated with poorer mental function. In a study of patients undergoing dialysis, the 13 patients who had a positive aluminum deferoxamine test (a measure of the amount of aluminum in the body) were compared with 13 who had a negative test. Subjecting the entire group to four attention tests and two memory tests revealed that those with higher levels of aluminum had a moderate to considerable disturbance of mental function.[14]

The aluminum appears to come from the water supply, food, antacids, and antiperspirants. The most significant source is drinking water, because the aluminum in water is in a more bioavailable and thus potentially a more toxic form. Researchers measured the aluminum absorption of tap water by adding a small amount of soluble aluminum in a radioactive form to the stomachs of animals. They discovered that the trace amounts of aluminum from this single exposure immediately entered the animals' brain tissue. The frightening news is that aluminum in water occurs not only naturally but is also added (in the form of alum) to treat some water supplies.[15]

Particulate Matter

Air pollution, already shown to begin and fuel neuroinflammation, has also been implicated in increased levels of amyloid deposits and tau protein formation. Particulate matter (PM) can penetrate throughout the body, including the brain, where it is closely linked to inflammation. Making PM particularly toxic is the adsorption of toxic volatile organic compounds (VOCs) to their surface, bypassing normal protective systems. Postmortem assessment of the brains of cognitively intact persons revealed that those who lived in areas of higher vehicular air pollution had greater inflammatory markers and β-amyloid in their frontal cortex and hippocampus (the areas needed for memory function) along with their olfactory lobe.[16]

Children living in the metropolitan area of Mexico City with both pre- and postnatal exposure to high levels of $PM_{2.5}$ have been found to have increased hyperphosphorylation of tau, along with increased levels of β-amyloid.[17] Those children also exhibited decreased cognitive function (attention, memory and IQ) and decreased olfactory sense. The children with APOe4 had greater problems, especially with olfaction.[18]

Pesticides

Pesticide use and exposure has also been strongly associated with higher risks for developing AD. A large study in the southern Spain comprised 17,420 subjects whose hospital records were reviewed between 1998 and 2005. The subjects were classified according to the agricultural pesticide usage in the regions that they lived in. Person living in regions with higher pesticide use were over twice as likely to develop AD and 87% more likely to commit suicide.[19] A study of 1507 elderly French individuals revealed that those who had been occupationally exposed to pesticides in their younger years were 2.39 times more likely to develop AD than were individuals in other occupations.[20]

The largest prospective study to look at the relationship between pesticide use and AD was done in Cache County, Utah.[21] More than 3000 individuals above the age of 65 were enrolled and screened for dementia at baseline and classified according to pesticide-exposure levels. Cognitive function was reassessed after 3, 7, and 10 years. After adjusting for various factors, including APOE4 allele status, it was found that study participants with higher pesticide exposures were 38% more likely to have dementia and 42% more likely to develop AD. When just organophosphates and organochlorine pesticides were singled out, researchers found that chlorinated pesticide exposure increase AD risk by 49%, and organophosphate use increased it by 53%.

DIAGNOSTIC CONSIDERATIONS

A comprehensive diagnostic workup is paramount in the approach to the patient with dementia. It is important to rule out conditions that can mimic dementia. For example, depression, which can mimic dementia in the elderly, is common. Table 144.1 lists other possible causes of dementia. The most common reversible cause of dementia is drug toxicity. Other important causes are metabolic and nutritional disorders, such as hypoglycemia; thyroid disturbances; and vitamin B_{12}, folate, and thiamine deficiencies.

A comprehensive evaluation should include[22]:

- A detailed history
- Neurological and physical examinations
- Psychological evaluation with particular attention to depression
- A general medical evaluation with emphasis on the detection of subtle metabolic, toxic, or cardiopulmonary disorders that can precipitate confusion, especially in the elderly
- A series of standardized neurophysiology tests such as the Mini Mental State Examination or Folstein test to document the type and severity of cognitive impairment.

Table 144.2 lists recommended tests for appropriate laboratory assessment.

The EEG is an important diagnostic tool serving to differentiate types of dementia. Although a normal EEG does not rule out the diagnosis of dementia, particularly in its early stages, it does provide valuable information. AD is associated with a characteristic symmetrical, usually diffuse slowing of the EEG. More important, the EEG differentiates focal (e.g., intracranial mass or vascular disease) from diffuse (e.g., metabolic disorders or normal-pressure hydrocephalus) brain dysfunction.

Computed tomography or magnetic resonance imaging with single photon emission computed tomography (SPECT) or positron emission tomography (PET) can help exclude other cerebral pathology or subtypes of dementia.

A technique known as PiB PET has been developed for directly and clearly imaging amyloid deposits in vivo, using a chemical tracer that binds selectively to the Aβ deposits. This modality shows tremendous promise.

Fingerprint Patterns

Abnormal fingerprint patterns are associated with both AD and Down syndrome.[23] In comparison with the normal population, AD and Down syndrome patients show an increased number of ulnar loops on the fingertips, with a concomitant decrease in whorls, radial loops, and arches. Ulnar loops (pointing toward the ulnar bone, away from the thumb) are frequently found on all 10

TABLE 144.1 Causes of and Mechanisms in the Development of Senile Dementia

Etiology	Pathogenesis
Degenerative etiology	Disturbances of gene expression and thus of protein metabolism
Altered genetic code	Disturbance of the synthesis of specific proteins
Alzheimer's disease	Reduction in acetylcholine synthesis resulting from decreased choline acetyltransferase activity
Huntington's chorea	Disturbance of the GABA-nergic system
Idiopathic dementia	
Localized form	Decline in cognitive function
Parkinson's disease	Reduction in dopamine turnover
Pick's disease	Reduction in cholinergic activity
Loss of neuronal redundancy	Disturbance of cerebral metabolism after infection or trauma
	Reduction in cholinergic activity caused by loss of neurons and synapses
Cerebrovascular disease	
Chronic meningitis	
Tuberculous, mycotic	
Encephalomyelitis	
Encephalopathy after head injury (boxers)	
Epileptic dementia	
Virus encephalopathy	
Nutritive etiology	
Chronic alcoholism	
Diabetes mellitus	
Disturbances of electrolyte metabolism	
Hypoglycemia	Insulin, starvation
Hyponatremia	Diuretics
Hypothyroidism	
Korsakoff's syndrome	Thiamine transketolase deficiency
Nicotinamide deficiency	
Vitamin B deficiency	Disturbances of energy formation
Toxic etiology	
Addiction to barbiturates, psychotropic drugs, etc.	
Chronic carbon monoxide intoxication	
Chronic cesium intoxication	
Mycotoxins	
Renal/hepatic encephalopathy	
Vincristine intoxication	

fingertips. Radial loops (pointing toward the thumb), when they do appear, tend to be shifted away from the index and middle fingers—where they most commonly occur—to the ring and little fingers. In patients with this fingerprint pattern, which is characteristic of AD, it is recommended that an aggressive preventive approach be instituted immediately.

TABLE 144.2 Recommended Laboratory Tests Used in the Diagnosis Dementia

Test	Rationale
CBC	Anemia, infection
VDRL	Syphilis
Electrolytes	Metabolic dysfunction
Liver function tests	Hepatic dysfunction
BUN	Renal dysfunction
TSH, T_4, T_3, T_3U	Thyroid dysfunction
Serum B_{12} and RBC folate	Deficiency
Urinalysis	Renal/hepatic dysfunction

THERAPEUTIC CONSIDERATIONS

The primary areas of intervention from a natural medicine perspective involve prevention by addressing suspected pathophysiology, avoiding environmental neurotoxins, and using natural measures to improve mental function. In the advanced stages of AD, natural measures provide only limited benefit.

Diet

Dietary factors are clearly important in the etiology of AD. Food choices consistent with the standard American diet are associated with a significant risk for the development of AD. A diet high in saturated fat and trans–fatty acids and low in dietary antioxidants may lead to increased serum and brain concentrations of aluminum and transition metal ions, which are implicated in oxidative stress, potentially leading to the neurological damage characteristic of AD. In addition, poor-quality diets may also increase the prevalence of AD by eliciting cerebral inflammation, which may cause the neurological damage that results in AD.[5,6,14]

Many dietary risk factors for AD are shared with those implicated in atherosclerosis. Likewise, adherence to a Mediterranean diet is associated with decreased cognitive decline, just as it is with a reduced risk for cardiovascular disease. Prospective studies have provided clear evidence that following a Mediterranean diet is associated with slower cognitive decline, reduced risk of progression from mild cognitive impairment (MCI) to AD, reduced risk of AD, and a decreased all-cause mortality in AD patients. These findings suggest a lower risk not only for AD, but also for predementia syndromes and their progression to overt dementia.[24,25]

The key dietary factors from epidemiological data that reduce AD risk are higher fish consumption (and omega-3 fatty acids), monounsaturated fatty acids (primarily from olive oil), light to moderate alcohol use (primarily red wine), and increased nonstarchy vegetable and fruit consumption. It is likely that the combination of all these factors rather than any single one provides the highest degree of protection.[24,25]

Given the ability of the Mediterranean diet to reduce inflammation and improve insulin sensitivity, it is assumed that this action may

be of extreme importance in its ability to reduce AD. However, in a 4-year prospective study, the lower risk of AD demonstrated with the Mediterranean diet did not seem to be mediated by C-reactive protein, fasting insulin, or adiponectin levels.[26] Other aspects of the diet or specific foods are likely responsible, including dietary components that work directly on reducing β-amyloid formation or deposition. For example, polyphenols found in grapes, grape seed extract, and red wine have been shown to prevent β-amyloid formation and promote tau disassembly.[27,28] Pharmacokinetic studies in animals with radiolabeled grape polyphenols show absorption into the brain after oral administration.[29]

Even something as simple as celery (*Apium graveolens*) consumption may offer significant protection against AD. Celery and celery seed extracts contain a unique compound, 3-n-butylphthalide (NBP), that is responsible for both the characteristic odor of celery and its health benefits. In an animal model of AD, NBP treatment significantly improved learning deficits as well as long-term spatial memory. Furthermore, NBP treatment also significantly reduced total cerebral β-amyloid plaque deposition and lowered brain β-amyloid levels. It was also shown that NBP markedly directed amyloid precursor protein processing toward a pathway that precludes β-amyloid formation. The researchers concluded, "NBP shows promising preclinical potential as a multitarget drug for the prevention and/or treatment of AD."[30]

The research on grape polyphenols and NBP stimulates a powerful question. How many other foods contain unique compounds that address the pathophysiology of AD? From preliminary investigations, it appears there are many; especially promising are sources of phenols and polyphenols.[31–35]

Estrogen

Estrogen has been asserted to offer protective and possibly therapeutic benefits in AD. However, the epidemiological and clinical evidence to support the potential benefits of estrogen is contradictory. Sixteen population-based studies have indicated that women on hormone replacement therapy (HRT) had a lower rate of AD.[36] However, the problem with these studies is that the women taking HRT were much healthier before taking the hormones compared with the control group (i.e., women who are prescribed HRT are less likely to have hypertension, diabetes, and history of stroke than nonusers).[36] A randomized, double-blind, placebo-controlled clinical trial evaluated the effects of hormone therapy on amyloid-β deposition in recently postmenopausal women. [37] Participants within 5 to 36 months past menopause in the Kronos Early Estrogen Prevention Study, were randomized to: 1) 0.45mg per day oral conjugated equine estrogens (CEE); 2) 50 μg per day transdermal 17β-estradiol; or 3) placebo pills and patch for 4 years. Oral progesterone (200 mg per day) was given to active treatment groups for 12 days each month. PET imaging was performed in 68 of the 118 participants at the Mayo Clinic approximately 7 years post randomization and 3 years after stopping randomized treatment. Transdermal 17β-estradiol therapy in recently postmenopausal women was associated with a reduced amyloid-β deposition, particularly in apolipoprotein E (APOE)-epsilon4 allele (APOEε4) carriers. Data from the only large randomized controlled trial published to date, the Women's Health Initiative Memory Study, did not confirm these observations and even suggested an increase in dementia risk for women using HRT compared with controls, especially in the cases of women given HRT after menopause.[38] Clinical trials in women with AD have concluded that estrogen therapy does not improve dementia symptoms in women with AD and should definitely be avoided postmenopause.[39–41] Given the cloud of uncertainty about the benefits of HRT, it seems most reasonable to consider that at this point the risks of conventional estrogen therapy to prevent AD outweigh the benefits. See Chapter 196 on menopause for a discussion of the critical differences.

Environmental Toxins

Encouraging the avoidance of all known sources of environmental neurotoxins, especially aluminum and pesticides, is strongly recommended. Eliminating aluminum-containing antacids, using aluminum-containing antiperspirants, cooking in aluminum pots and pans, wrapping food in aluminum foil, and consuming nondairy creamers—certainly seem appropriate. Aluminum is also found in baking powder and table salt to keep them from becoming lumpy. In addition, citric acid, as well as calcium citrate supplements, appear to increase the efficiency of absorption of aluminum (but not lead) from water and food.[42] Aluminum absorption can be decreased by magnesium, because magnesium competes with aluminum for absorption, not only in the intestines but also at the blood-brain barrier.[43] A diet rich in magnesium is recommended, focusing on unprocessed foods, avoiding milk and dairy products, and increasing the consumption of vegetables, whole grains, nuts, and seeds.

The most effective ways to decrease pesticides are to eat organically grown foods and avoid use of pesticides in homes and yards.

NUTRITIONAL CONSIDERATIONS

Nutritional status is directly related to cognitive function in the elderly.[44] Given the frequency of nutrient deficiency in the elderly population, it is likely that many cases of impaired mental function may have a nutritional etiology. As pointed out earlier in this chapter, diet is critically important in the prevention and arrest of AD, with various components working together in a synergistic fashion to address many of the key underlying pathophysiological features of AD.

Antioxidants

Considerable evidence indicates that oxidative damage plays a major role in the development and progression of AD.[7,45,46] Epidemiological evidence suggests that antioxidant nutrients offer significant protection against AD.[5,48] Prospective and clinical studies have primarily focused on vitamins C and E and β-carotene with somewhat favorable results (Table 144.3).[45,48–51] As with other chronic degenerative diseases, better results may be achieved with a broader range of supplemental nutrients. For example, in a French cohort of middle-aged adults, 13 years of daily supplementation of 120 mg of ascorbic acid, 30 mg of vitamin E, 6 mg of β-carotene, 100 mcg of selenium, and 20 mg of zinc compared with placebo was significantly associated with better verbal memory, a cognitive domain that is particularly vulnerable to pathological aging and AD. These results appear to be significantly better than those achieved with vitamins C, E, and β-carotene either alone or in combination.

It is entirely possible (and likely probable) that vitamins E and C, and β-carotene may simply be markers of increased "phytochemical antioxidant" intake rather than playing a significant role on their own. Fruits and vegetables contain an array of antioxidant compounds beyond nutritional antioxidants. Some of these compounds may exert specific effects of considerable benefit against the pathophysiology of AD. Often researchers make the mistake of thinking that the antioxidant activity of a particular fruit or vegetable is due solely to its vitamin C, E, or β-carotene content. However, these nutrient antioxidants often account for only a small fraction of a food's antioxidant effect. For example, these nutrients account for only about 0.5% of the total antioxidant activity of an apple. The overwhelming antioxidant activity of fruits and vegetables comes

TABLE 144.3 Prospective Studies of Antioxidants and the Risk of Alzheimer's Disease

Study	Follow-Up	Findings
Rotterdam Study	6 years	Dietary vitamin E effective (more among current smokers)
Canadian Study of Health and Aging	5 years	Combination of vitamins E and C supplementation and/or multivitamin consumption effective
Chicago Health Aging Study	3.9 years	Dietary vitamin E effective only among non-apoE4 carriers
Washington Heights-Inwood Columbia Aging Project	4 years	No effect of vitamin E (diet or supplement)
Cache County Study	3 years	Vitamin E alone not effective but effective when combined with vitamin C
Honolulu-Asia Aging Study	30 years	Dietary vitamin E not effective
Duke Established Populations for Epidemiological Studies of the Elderly	10 years	No effect of vitamins C and/or E
Group Health Cooperative	5.5 years	No effect of supplemental vitamins E and C alone or in combination

Data from Practico D. Oxidative stress hypothesis in Alzheimer's disease: a reappraisal? *Trends Pharmacol Sci*. 2008;29(12):609-615.

from phytochemicals, such as flavonoids, phenols, and other carotenoids.[52] Several phytochemicals are showing tremendous promise in protecting against AD by interfering with the formation and deposition of β-amyloid.[31–33]

Thiamine

Although severe thiamine deficiency is relatively uncommon except in people with alcoholism, many Americans do not consume even the recommended daily allowance (RDA) of 1.5 mg, especially elderly people. In an attempt to gauge the prevalence of thiamine deficiency in the geriatric population, 30 unselected consecutive patients visiting a university outpatient clinic in Tampa, Florida, were tested for thiamine levels. Depending on the thiamine measurement (plasma vs. red blood cell thiamine), low levels (defined as a level below the lowest reference range for younger age groups) were found in 57% and 33%, respectively.[53]

In addition to its role as a nutrient, thiamine also demonstrates some pharmacological effects on the brain. Specifically, it mimics the important neurotransmitter involved in memory—acetylcholine. Thiamine has been shown to potentiate and mimic the effects of acetylcholine in the brain.[54] This effect explains the positive clinical results that have been noted for thiamine, (3 to 8 g per day) in improving mental function in AD and age-related impaired mental function (senility).[55,56] High-dose thiamine supplementation exerts its benefits without side effects.

These results highlight the growing body of evidence that a significant percentage of the geriatric population is deficient in one or more of the B vitamins. Given the essential role of thiamine and other B vitamins in normal human physiology, especially cardiovascular and brain function, routine B-vitamin supplementation appears to be worthwhile in this age group.

Vitamin B_{12}

Vitamin B_{12} deficiency results in impaired nerve function, which can cause numbness, paresthesia, or a burning feeling in the feet as well as impaired mental function, which in the elderly population can mimic AD. Vitamin B_{12} deficiency is thought to be quite common in elders and is a major cause of depression in this age group. Determination of vitamin B_{12} deficiency is best achieved by measuring the level in the blood (serum cobalamin) or the level of methylmalonic acid in the urine. In addition, measurement of the level of plasma homocysteine is an additional method to determine the status of both vitamin B_{12} and folate.

Several investigators have found that the level of vitamin B_{12} declines with age and that vitamin B_{12} deficiency is found in 3% to 42% of persons age 65 and older. Diagnosing cobalamin deficiency early in the elderly population is important because it is easily treatable and, if left untreated, can lead to impaired neurological and cognitive function.[57,58]

In one study among 100 consecutive geriatric outpatients who were seen in office-based settings for various acute and chronic medical illnesses but not for vitamin B_{12} deficiency–related diseases like pernicious anemia, 11 patients had serum cobalamin levels at 148 pmol/L or below; 30 patients had levels between 148 and 295 pmol/L; and 59 patients had levels above 296 pmol/L.[59] After the initial cobalamin determination, the subjects were followed for up to 3 years. The patients with cobalamin levels below 148 pmol/L were treated and not included in the analysis of declining cobalamin levels. The average annual decline in serum cobalamin level was 18 pmol/L for patients who had higher initial serum cobalamin levels (actual range, 224–292 pmol/L). For patients with lower initial cobalamin levels, the average annual serum cobalamin decline was much higher, at 28 pmol/L.

These results indicate that measurement of the level of vitamin B_{12} in the blood (serum cobalamin), the urinary excretion of methylmalonic acid or the level of homocysteine[60] as a screening test for vitamin B_{12} deficiency appears to be indicated in elderly patients, given the positive cost-benefit ratio.[61,62] To test for vitamin B_{12} deficiency, the urinary methylmalonic acid assay is perhaps the best because it is sensitive as well as noninvasive and relatively convenient for the patient. Correction of an underlying vitamin B_{12} deficiency can significantly improve mental function and quality of life in these patients. A growing body of literature demonstrates clear correlations between high levels of serum homocysteine and cardiovascular disease and, more recently, dementia and AD. High homocysteine levels (>14 mmol/L) nearly double the risk of AD.[63]

The importance of a detailed examination in elderly patients with mental symptoms is highlighted by results from a study that analyzed the plasma homocysteine, serum cobalamin, and blood folate in 296 consecutive patients referred to a geriatric psychiatric ward in Sweden for the diagnosis of mental disease.[64] Patients who were deficient in vitamin B_{12} or folic acid or who had elevated levels of homocysteine were given vitamin B_{12} (dosage not specified) or folic acid (10 mg per day), or both. When individuals with low cobalamin levels were supplemented with vitamin B_{12}, significant clinical improvements were noted.

In other studies, supplementation with vitamin B_{12} has shown tremendous benefit in reversing impaired mental function due to low levels of vitamin B_{12}.[57] In one large study, a complete recovery was observed in 61% of similar cases of mental impairment.[65] The fact that 39% did not respond is probably a result of long-term low levels of vitamin B_{12}. Several studies have shown that the best clinical

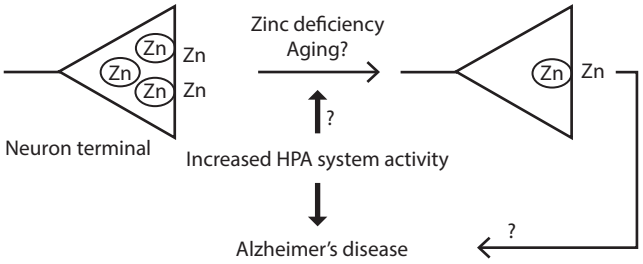

Fig. 144.3 Histochemically reactive zinc level and its relation to the pathogenesis of Alzheimer's disease. (From Takeda A. Insight into glutamate excitotoxicity from synaptic zinc homeostasis. *Int J Alzheimers Dis*, 2011; 491597.)

responders are those who have been showing signs of impaired mental function for less than 6 months.[34] In one study, 18 subjects with low levels of serum cobalamin and evidence of mental impairment were given vitamin B_{12}. Only those patients who had symptoms for less than 1 year showed improvement.[66] The importance of diagnosing and correcting low vitamin B_{12} levels in the elderly population cannot be overstated.

Serum vitamin B_{12} levels are significantly low and vitamin B_{12} deficiency is significantly common in AD patients.[57,67,68] It has been demonstrated that an oral daily dose as low as 50 mcg can significantly increase serum vitamin B_{12} levels in vitamin B_{12}–deficient elderly persons.[69] Supplementation of vitamin B_{12}, folic acid, or both may result in complete reversal in some patients, but generally there is little improvement in patients who have had AD symptoms for more than 6 months. It has been hypothesized that prolonged low levels of vitamin B_{12} may lead to irreversible changes that will not respond to supplementation. Vitamin B_{12} supplementation for elderly subjects with AD will improve hematological parameters but will not usually improve mental function.[70]

Vitamin B_{12} is available in several forms. The most common form is cyanocobalamin; however, vitamin B_{12} is active in the human body in only two forms: methylcobalamin and adenosylcobalamin. Although methylcobalamin and adenosylcobalamin are active immediately on absorption, cyanocobalamin must be converted to either methylcobalamin or adenosylcobalamin by removal of the cyanide molecule and addition of either a methyl or adenosyl group. This conversion may be reduced with aging and may be another factor responsible for the vitamin B_{12} disturbances noted in the elderly population.

Zinc

Zinc deficiency is one of the most common nutrient deficiencies in elderly people and has been suggested to be a major factor in the development of AD.[71] Included in the list of zinc-containing enzymes are most enzymes involved in DNA replication, repair, and transcription. It has been suggested that dementia, possibly because of a long-term zinc deficiency, may represent the long-term cascading effects of error-prone or ineffective DNA-handling enzymes in nerve cells.[72] In addition, zinc is required by many antioxidant enzymes, including superoxide dismutase. The end result could be the destruction of nerve cells and the formation of NFTs and plaques. The levels of zinc in the brain and cerebrospinal fluid in patients with AD are markedly decreased, and there is a strong inverse correlation between serum zinc levels and the senile plaque count.[73]

Dietary zinc deficiency readily decreases serum zinc levels in mice and rats, although it increases serum corticosterone levels through the increased hypothalamic-pituitary-adrenal (HPA) axis activity (Fig. 144.3).[74] Zinc deficiency can reduce histochemically reactive zinc levels, which are estimated to be susceptible to aging. Zinc deficiency, as well as aging, appear to be significant risk factors for AD.

Zinc supplementation has demonstrated good benefits in people with AD. In one study, 10 patients with AD were given 27 mg per day of zinc (as zinc aspartate). Only two patients failed to show improvement in memory, understanding, communication, and social contact. In one 79-year-old patient, the response was labeled "unbelievable" by both medical staff and family.[75] Unfortunately there does not seem to be much interest in the scientific community in following up these impressive results with zinc therapy.

The medical literature acknowledges zinc's apparent duality as "The Zinc Paradox."[76] Fueling this ambivalence is conflicting information that zinc may be problematic for AD patients because, in vitro, it accelerates the formation of insoluble β-amyloid peptide.[77] Although zinc is neurotoxic at high concentrations and accumulates at sites of degeneration, total tissue zinc is markedly reduced in the brains of AD patients. Other research has shown a much higher concentration of copper-zinc superoxide dismutase in and around the damaged brain tissue of AD patients.[78] This finding suggests that the increased concentration of zinc in the damaged areas is due to the body's efforts to neutralize free radicals through the increased local production of dismutases. A possible corollary is that the higher focal levels of zinc result in increased amyloid formation when the free radical scavenging mechanisms have been inadequate.

Phosphatidylcholine

Because dietary phosphatidylcholine can increase acetylcholine levels in the brain in normal patients and AD is characterized by a decrease in cholinergic transmission, it seems reasonable to assume that phosphatidylcholine supplementation would benefit AD patients. However, the basic defect in cholinergic transmission in AD relates to impaired activity of the enzyme acetylcholine transferase. This enzyme combines choline (as provided by phosphatidylcholine) with an acetyl molecule to form acetylcholine, the neurotransmitter. Providing more choline does not necessarily increase the activity of this key enzyme, so phosphatidylcholine supplementation is not beneficial in the majority of patients with AD. Not surprisingly, clinical trials using phosphatidylcholine have largely been disappointing. Studies have shown inconsistent improvements in memory from choline supplementation in both normal and AD patients.[79–82] The studies have been criticized for small sample size, low dose of phosphatidylcholine, and poor design. Furthermore, some researchers are questioning the form of choline used.[83] Other forms, such as phosphatidylserine or choline alphoscerate,[84] may prove more useful in supporting cholinergic transmission.

In a patient with mild to moderate dementia, the use of a high-quality phosphatidylcholine preparation may be worth a try. A dosage of 15 to 25 g per day of phosphatidylcholine is required. If there is no noticeable improvement within 2 weeks, supplementation should be discontinued.

Phosphatidylserine

Phosphatidylserine is the major phospholipid in the brain, where it plays a major role in determining the integrity and fluidity of cell membranes. Normally, the brain can manufacture sufficient levels of phosphatidylserine, but a deficiency of methyl donors like S-adenosylmethionine (SAMe), folic acid, and vitamin B_{12} or essential fatty acids may inhibit the production of sufficient phosphatidylserine. Low levels of phosphatidylserine in the brain are associated with impaired mental function and depression in the elderly.

The primary use of phosphatidylserine is in the treatment of depression, impaired mental function, or both in the elderly, and also

in the treatment of AD. To date, the 11 double-blind published studies have all reported the successful use of phosphatidylserine in the treatment of age-related cognitive decline, AD, or depression.[85–95] In the largest study, a total of 494 elderly patients (between 65 and 93 years of age) with moderate to severe senility were given either phosphatidylserine (100 mg three times a day) or a placebo for 6 months.[95] The patients were assessed for mental performance, behavior, and mood at the beginning and end of the study. Statistically significant ($P < 0.01$) improvements were noted in mental function, mood, and behavior for the phosphatidylserine group.

Acetyl- L-Carnitine

A great amount of research has been conducted over the past decade with acetyl- L-carnitine (LAC) in the treatment of AD, senile depression, and age-related memory defects. LAC is composed of acetic acid and L-carnitine bound together. This reaction occurs naturally in the human brain. Therefore it is not exactly known how much more of an effect is achieved with LAC versus L-carnitine. However, LAC is thought to be substantially more active than other forms of carnitine in conditions involving the brain.[95,96]

The close structural similarity between LAC and acetylcholine led to an interest in using LAC in AD. Research has shown that LAC does mimic acetylcholine and is of benefit, not only in patients with early-stage AD, but also in elderly patients who are depressed or have impaired memory.[96] It has also been shown to act as a powerful antioxidant in the brain cell, to stabilize cell membranes, and to improve energy production in the brain cell, as well as enhance or mimic the function of acetylcholine.[97]

The latest meta-analysis involving studies of LAC in mild cognitive impairment and mild (early) AD is promising in terms of showing both clinical and psychometric improvements. Double-blind, placebo-controlled prospective parallel-group comparison studies of at least 3 months' duration were reviewed. Using a dose range of 1.5 to 3 g per day, treatment time points were assessed at 3, 6, 9, and 12 months. This analysis showed a significant advantage for acetyl-L-carnitine, compared with placebo. The advantage for acetyl-L-carnitine was seen by the time of the first assessment at 3 months and increased over time. Additionally, acetyl-L-carnitine was well tolerated in all studies.[98]

Further studies also show efficacy regarding the use of LAC in situations where AD patients were unresponsive to acetylcholinesterase inhibitors. One study evaluated the effect of LAC, using 2 g per day orally for 3 months in association with donepezil or rivastigmine in 23 patients with mild AD who had not responded to treatment with acetylcholinesterase inhibitors (AChE-Is). Clinical effects were evaluated by assessing cognitive functions, functional status, and behavioral symptoms. The response rate, which was 38% after AChE-I treatment, increased to 50% after the addition of LAC, indicating that the combination of both the pharmaceutical and LAC works better than the pharmacological treatment alone.[99]

The memory impairment need not be as severe as in AD for LAC to demonstrate benefit.[100–102] In one double-blind study of 236 elderly subjects with mild mental deterioration, as evidenced by detailed clinical assessment, the group receiving 1500 mg per day of LAC demonstrated significant improvement in mental function, particularly in memory and constructional thinking.[103]

OTHER THERAPIES

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is the most abundant hormone in the bloodstream and is found in extremely high concentrations in the brain. As DHEA levels decline dramatically with aging, low levels of DHEA in the blood and brain are thought to contribute to many symptoms associated with aging, including impaired mental function.

Although DHEA itself has no known function, it does serve as the source of all other steroid hormones in the body, including sex hormones and corticosteroids. Therefore the function of DHEA seems to lie in supplying the body with what it needs to maintain optimal levels and balance of all the steroid hormones that regulate the body's activities.

Over the past 15 years it has been demonstrated that declining levels of DHEA are linked to conditions such as diabetes, obesity, elevated cholesterol levels, heart disease, arthritis, and other age-related diseases. In addition, DHEA shows promise in enhancing memory and improving cognitive function.[103–105] As of this writing, the only double-blind, placebo-controlled study was a small pilot study (58 subjects) in which 50 mg of DHEA was given twice a day. Although some benefit was reported at 3 months, DHEA did not significantly improve cognitive performance or overall ratings of change in severity in this small-scale pilot study.[106]

The levels of DHEA necessary to improve brainpower in men older than 50 years of age appear to be 25 to 50 mg per day. For women, a dose of 15 to 25 mg appears to be sufficient in most cases. As men and women reach their 70s, they may require higher levels (e.g., 50–100 mg). Excessive dosages of DHEA can cause acne and, in women, menstrual irregularities. Although most elderly people probably need DHEA, laboratory assessment before prescription may help determine whether DHEA would be beneficial in an individual case and to assess the needed doses.

Melatonin

Formed by the body from serotonin and released by the pineal gland, melatonin is considered by many to be "the master hormone" of the body. It is well known for its use in normalizing circadian rhythms and sleep cycles and as a powerful antioxidant for cancer therapies. Medical research is beginning to value its ostensibly commanding role in many physiological processes.

In vitro studies have shown that melatonin protects neuronal cells from heavy metal cobalt damage. Cobalt is a transition metal found in high levels in AD patients. It was found that both the induction of oxidative damage and β-amyloid release were avoided with melatonin treatment. Because cobalt is an essential nutrient, often bound to vitamin B_{12}, melatonin may prove to be an important preventive treatment in AD-susceptible individuals.[107]

One double-blind, placebo-controlled study has studied melatonin in AD patients. Researchers from Nippon Medical School, who previously reported on bright light therapy as a means to improve cognitive function in AD, evaluated the effectiveness of melatonin. Three milligrams of melatonin were given to 11 subjects at 8:30 PM every day for a month, and 9 other subjects were given placebo (mean age of 79.2 years). Based on standard dementia and AD assessment scales, the melatonin group had a significantly increased sleeping time and decreased nighttime activity, with improved levels of cognitive and noncognitive functions. Even though the authors noted that these results were significant and clearly supported the use of melatonin in AD, they acknowledged that morning bright light therapy showed greater improvements in AD patients.[108]

A randomized, double-blind, parallel-group study investigated the effects of add-on prolonged-release melatonin (PRM) (2 mg) to standard therapy on cognitive functioning and sleep in 80 patients diagnosed with mild to moderate AD, with and without insomnia comorbidity, and receiving standard therapy (acetylcholinesterase inhibitors with or without memantine).[109] Patients were treated for

2 weeks with placebo and then randomized (1:1) to receive 2 mg of PRM or placebo nightly for 24 weeks, followed by placebo for 2 weeks. Patients treated with PRM had significantly better cognitive performance, as well as improved sleep efficiency compared with those treated with placebo. The authors concluded that a possible causal link exists between poor sleep and cognitive decline.

Botanical Medicines

Ginkgo Biloba Extract

Ginkgo biloba extract (GBE) standardized to contain 24% ginkgo flavonglycosides exerts many effects beneficial in the prevention and early treatment of AD (see Chapter 82). It must be pointed out that GBE should be taken consistently for at least 12 weeks to determine its effectiveness. Although some people experience benefits within a 2- to 3-week period, most will need to take GBE for a longer time to see any significant changes.

Huperzine A

Huperzine A is an alkaloid isolated from the moss *Huperzia serrata,* long used in China to treat primarily fever and inflammation. Although it has been shown to have no antipyretic or anti-inflammatory properties in experimental models, Huperzine A is a potent inhibitor of acetyl-cholinesterase. In fact, it is significantly more selective and substantially less toxic than the acetylcholinesterase (AChE) inhibitors currently used in conventional medicine (e.g., physostigmine, tacrine, and donepezil). Toxicity with synthetic AChE inhibitors has been a major drawback in their clinical use. In contrast, Huperzine A, purified from *H. serrata,* has been used as a prescription drug in China since the early 1990s and has reportedly been used by more than 100,000 people with no serious adverse effects.[110] Huperzine A may be an effective and well-tolerated agent to both suppress seizures and improve cognition in AD by enhancing cholinergic and GABAergic signaling and mitigating AD-related neurotoxicity (Fig. 144.4). [111]

Initial clinical studies with Huperzine A conducted in China, which first focused on its use in myasthenia gravis, showed considerable benefit in the treatment of dementia. One double-blind clinical study found that Huperzine A at a dose of 200 mcg twice a day produced measurable improvements in memory, cognitive function, and behavioral factors in 58% of AD patients.[112] In contrast, 36% in the placebo group showed improvement.

In a double-blind study, 210 individuals with AD were randomized to receive placebo or Huperzine A (200 mcg or 400 mcg twice a day), for at least 16 weeks. Huperzine A 200 mcg twice a day did not influence any change in the Alzheimer's Disease Assessment Scale–cognitive subscale (ADAS-Cog), but this agent at 400 mcg twice a day showed a 2.27-point improvement in ADAS-Cog at 11 weeks versus a 0.29-point decline in the placebo group and a 1.92-point improvement versus a 0.34-point improvement in the placebo arm at week 16. Changes in clinical global impression of change and activities of daily living were not significant at either dose.[113]

Bacopa Monniera

Bacopa monniera (BM) is an Ayurvedic botanical medicine used for memory enhancement, epilepsy, insomnia, and as a mild sedative. Additionally, it has been able to reduce memory dysfunction in rat models of AD. One study evaluated an extract of BM on a culture of purified rat astrocytes exposed to toxins mimicking the effect of excess nitric oxide exposure, a condition shown to be a factor in AD. Results showed that the extract of BM inhibited the formation of reactive species and DNA damage in a dose-dependent manner.

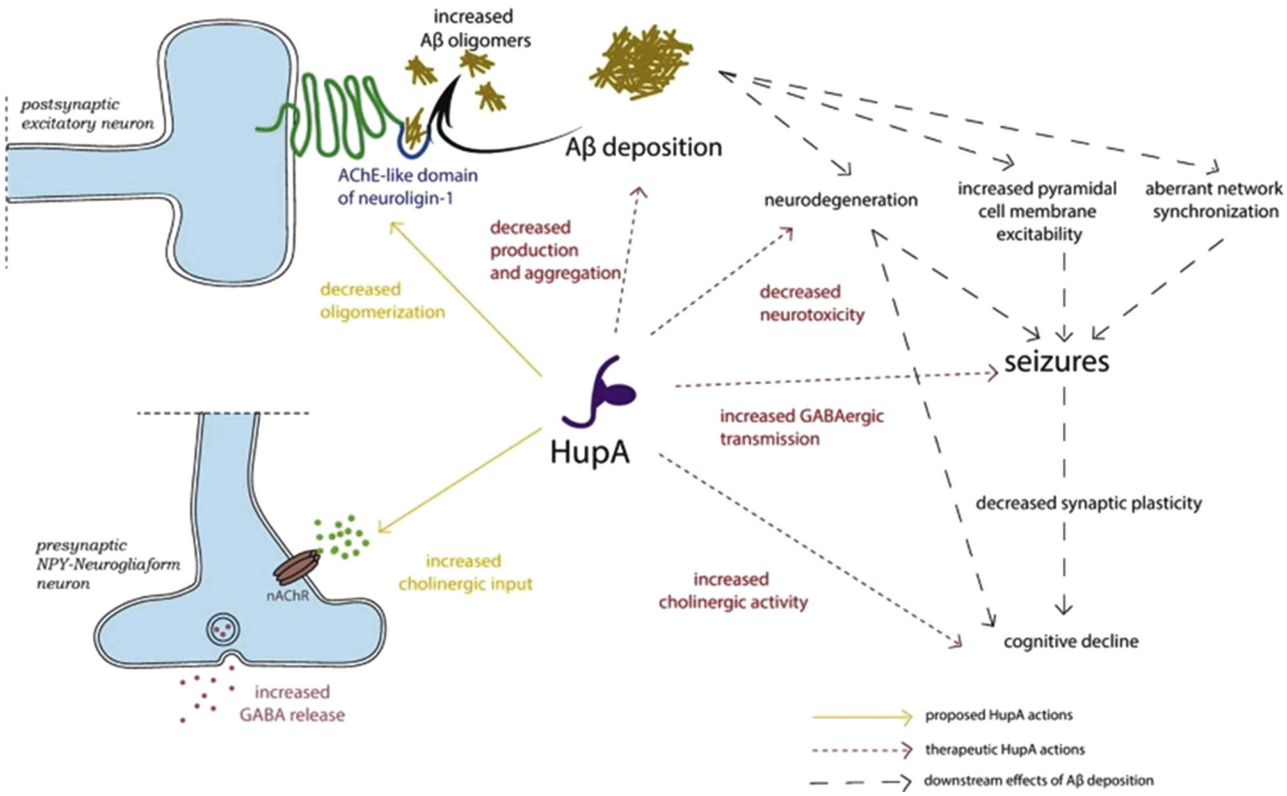

Fig. 144.4 Actions of Huperzine A in seizures and cognitive decline. (From Damar U, Gersner R, Johnstone JT, Scachter S, Rotenberg A, Huperzine A. A promising anticonvulsant, disease modifying, and memory enhancing treatment option in Alzheimer's disease. *Med Hypotheses.* 2017;99:57–62.)

These data support the traditional use of BM and indicate that this medicinal plant has therapeutic potential in the treatment or prevention of AD.[114–116]

Curcuma Longa (Turmeric)

There is considerable experimental evidence that curcumin protects against age-related brain damage and AD in particular. Researchers began exploring this effect after noting that elderly (age 70 to 79) residents of rural India who eat large amounts of turmeric have been shown to have the lowest incidence of AD in the world and 4.4 times lower than that of Americans. In in vitro studies, curcumin has been reported to inhibit amyloid-β-protein (Aβ) aggregation, and Aβ-induced inflammation, as well as the activities of β-secretase and acetylcholinesterase. In in vivo studies, oral administration of curcumin has resulted in the inhibition of Aβ deposition, Aβ oligomerization, and tau phosphorylation in the brains of AD animal models and improvements in behavioral impairment in animal models. Unfortunately, the two clinical trials conducted to date have failed to show any benefit to consuming curcumin.[117] However, the failure to produce positive results may have been due to the poor pharmokinetic profile of the curcumin used in the trials. For more information on curcumin, see Chapter 73.

Studies in stroke models have also suggested a neuroprotective role of curcumin,[9] as well as the ability to reduce plaque burden in models of AD. Curcumin has also been shown to decrease naphthalene and 4-hydroxy-2-nonenal–induced cataract formation on the lens by decreasing the rate of apoptosis and subsequent opacification resistance of the lens.[65,66] The authors postulate that induction of the glutathione S-transferase, which acts to decrease lipid peroxidation, was probably responsible for the cataractogenesis-inhibiting effects.

THERAPEUTIC APPROACH

The primary therapeutic goal is prevention or initiation of therapy as soon as any dementia is noted.

Dietary and Lifestyle Recommendations

- Avoid aluminum (found in many antiperspirants, antacids, and cookware).
- Eat organically grown foods instead of conventional foods contaminated by pesticides
- Follow a generally healthful dietary and lifestyle plan.
- Achieve ideal body weight and take measures to improve insulin sensitivity.
- Increase intake of whole-food products, including fish, cereals, vegetables, and monosaturated fats.
- Employ the principles of the Mediterranean diet.
- Decrease total calories, high-glycemic-load foods, and unhealthy fats.
- Use morning light therapy.

Supplements

- High-potency multivitamin/multimineral supplement
- Vitamin C: 500 to 1000 mg three times a day
- Vitamin E (mixed tocopherols): 400 IU daily
- Thiamin: 3 to 8 g daily
- Fish oils: 1000 to 3000 mg EPA+DHA daily
- Phosphatidylserine: 100 mg three times a day
- L-Acetylcarnitine: 500 mg three times a day
- Methylcobalamin: 1,000-3,000 mcg upon arising
- Melatonin: 3 mg in the evening at least a half hour before bed

Botanical Medicines

- GBE (24% *Ginkgo* flavonglycosides): 240 to 320 mg daily
- Huperzine A: 400 mcg twice a day

Anemia

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Pallor, weakness, and a tendency to become fatigued easily
- Low volume of blood, low level of total red blood cells, or abnormal size or shape of red blood cells
- Reduction in hemoglobin (less than 13.5 g/dL in men, less than 12.0 g/dL in women) or hematocrit (less than 41.0% in men, less than 36.0% in women)

GENERAL CONSIDERATIONS

Anemia refers to a condition in which the blood is deficient in red blood cell numbers or oxygen carrying capacity. Anemia is not a specific diagnosis, per se, but rather the presentation of an underlying condition. Anemia can be defined as a reduction in hemoglobin (less than 13.5 g/dL in men, less than 12.0 g/dL in women) or hematocrit (less than 41.0% in men, less than 36.0% in women) or red blood cell count. The primary function of the red blood cell (RBC) is to transport oxygen from the lungs to the tissues of the body in exchange for carbon dioxide. More recent experimental evidence indicates that RBCs are important interorgan communication systems with additional functions, including participation in control of systemic nitric oxide metabolism, redox regulation, blood rheology, and viscosity.[1] In anemia, there is a decrease in the oxygen carrying capacity of the blood, leading to tissue hypoxia that adversely affects systemic hemodynamics and myocardial performance. According to the National Cancer Institute, anemia can be graded as the following:

- Mild: hemoglobin 10.0 g/dL to lower limit of normal
- Moderate: hemoglobin 8.0 to 10.0 g/dL
- Severe: hemoglobin 6.5 to 7.9 g/dL
- Life-threatening: hemoglobin < 6.5 g/dL

Anemic conditions can be classified according to the size/morphology of red blood cells (i.e., normocytic, macrocytic, and microcytic; assessed as the mean corpuscular volume [MCV]) and/or the concentration of Hb in RBCs (i.e., normochromic, hypochromic, and hyperchromic; assessed by mean corpuscular hemoglobin [MCH]). In addition, there are three major etiopathologies of anemia: (1) anemia due to excessive blood loss; (2) anemia due to excessive RBC destruction (i.e., hemolysis); and (3) anemia due to deficient RBC or hemoglobin production. Although an exhaustive description of all types of anemia is beyond the scope of this chapter, a few examples of the most common forms of anemia are discussed in more detail elsewhere in this chapter.

TYPES OF ANEMIA

Excessive Blood Loss

Anemia can develop secondary to acute or chronic blood loss. Acute blood loss can be fatal if more than one third of total blood volume is lost (roughly 1.5 L). Because acute blood loss is usually quite apparent, there is little difficulty in diagnosis. Often blood transfusion is required.

Chronic blood loss resulting from conditions such as slow-bleeding peptic ulcer, bleeding hemorrhoids, or excessive menstruation can lead to anemia. In the case of chronic blood loss, identifying the cause through a complete diagnostic workup is essential for proper treatment.

Excessive Red Blood Cell Destruction

Hemolysis is the destruction of old or abnormal RBCs, and when this process exceeds the body's ability to manufacture new RBCs, anemia can result. Old RBCs, as well as abnormal RBCs, are removed from the

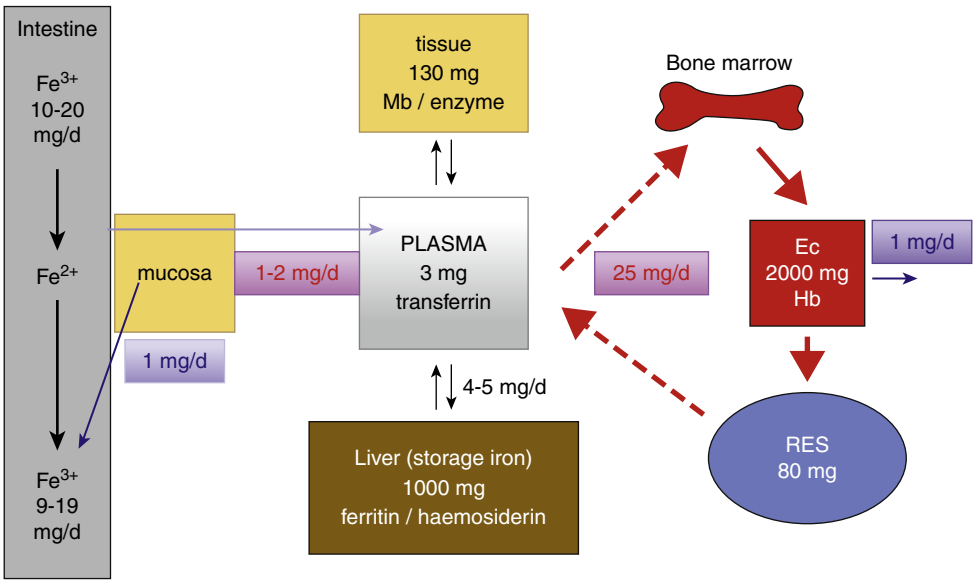

Fig. 145.1 Distribution of iron in the human body (70 kg). (From Rogler G, Vavricka S. Anemia in inflammatory bowel disease: an under-estimated problem? *Front Med (Lausanne).* 2015;1:58.)

circulation primarily by the spleen. The most common cause of excessive destruction of RBCs is abnormal RBC shape. Several processes can lead to increased hemolysis, including: synthesis of defective hemoglobin, as seen in hereditary conditions like sickle-cell anemia; mechanical injury due to trauma or turbulence within arteries; hereditary RBC enzyme defects; presence of antibodies against surface antigens on RBCs, such as antibodies anti-A or anti-B blood group antigens; chronic disease; and chronic inflammation.

Deficient Red Blood Cell or Hemoglobin Production

Impaired erythropoiesis (i.e., insufficient production of RBCs or hemoglobin) is the most common category of anemia, and the most common cause is nutritional deficiency. Although deficiency of several vitamins and minerals can produce anemia, the most common include iron, vitamin B_{12}, and folic acid. Iron-deficiency anemia is characterized as a microcytic anemia, whereas folic acid and B_{12} deficiency anemias are classified as macrocytic.

Iron-Deficiency Anemia

Iron is critical to human life. Less than 10% of the daily iron uptake of around 20 mg is absorbed by the intestinal mucosa.[2] Most of the functional iron in the body is present in the heme proteins, such as hemoglobin of red blood cells, where it functions in transporting oxygen from the lungs to the body's tissues and the transportation of carbon dioxide from the tissues to the lungs (Fig. 145.1). The liver contains the second-highest amount of iron, which is bound to ferritin and hemosiderin as iron storage. Iron is also found in cytochromes, which are involved in mitochondrial electron transfer, in oxygen transport and in the liver Phase I detoxification enzymes. In addition, iron functions in several key enzymes involved with energy production and metabolism including DNA synthesis.

Iron deficiency is the most common mineral deficiency in the United States, and iron-deficiency anemia is one of the most common hematological problems worldwide. The groups at highest risk for iron deficiency are infants under 2 years of age, teenage girls, pregnant women, and elderly persons. Studies have found evidence of iron deficiency in as high as 30% to 50% of people in these groups. Some degree of iron deficiency occurs in 35% to 58% of young, healthy women. During pregnancy, the number is even higher.

Measuring serum ferritin is the best laboratory test for determining body iron stores.[3] However, it must be pointed out that iron deficiency occurs in many stages, and anemia is the last stage of iron deficiency. Iron-dependent enzymes involved in energy production and metabolism are the first to be affected by low iron levels. Patients with a serum ferritin level less than 25 ng/mL have a very high probability of being iron deficient, whereas serum ferritin values greater than 100 ng/mL are associated with a very low likelihood of iron-deficiency anemia.[4] Investigating total iron-binding capacity (TIBC), transferrin saturation, serum iron, and serum transferrin receptor levels may be helpful if the ferritin level is between 46 and 99 ng per mL (Fig. 145.2); bone-marrow biopsy may be necessary in these patients for a definitive diagnosis.[5] A trial of iron is a reasonable approach in children, adolescents, and women of reproductive age if the review of symptoms, history, and physical examination are negative for other causes. However, if there is not a 1 to 2 g per dL (10–20 g per L) increase in the hemoglobin level in a reasonable amount of time, possibilities include malabsorption of oral iron, continued bleeding, or unknown lesion.

Iron deficiency may be caused by an increased iron requirement, decreased dietary intake, diminished iron absorption or utilization, blood loss, or a combination of these factors. Increased requirements for iron occur during the growth spurts of infancy and adolescence as well as during pregnancy and lactation. Most pregnant women are routinely given iron supplements during their pregnancy, as the dramatically increased need for iron during pregnancy cannot usually be met through diet alone. Inadequate intake of iron is common in many parts of the world, especially in areas where people consume primarily a vegetarian diet.

Many standard infant diets in developed countries (high in milk and cereals) are also low in iron. The adolescent who consumes a "standard American diet" is at high risk for iron deficiency. However, the population at greatest risk of dietary iron deficiency is the low-income elderly population; this deficiency is enhanced by impaired iron absorption resulting from decreased hydrochloric acid secretion in the stomach—a common complication in the elderly population.

Other causes of decreased absorption in the general population include chronic diarrhea or malabsorption, the surgical removal of the stomach, and antacid or acid-blocking drug use. Blood loss is the most

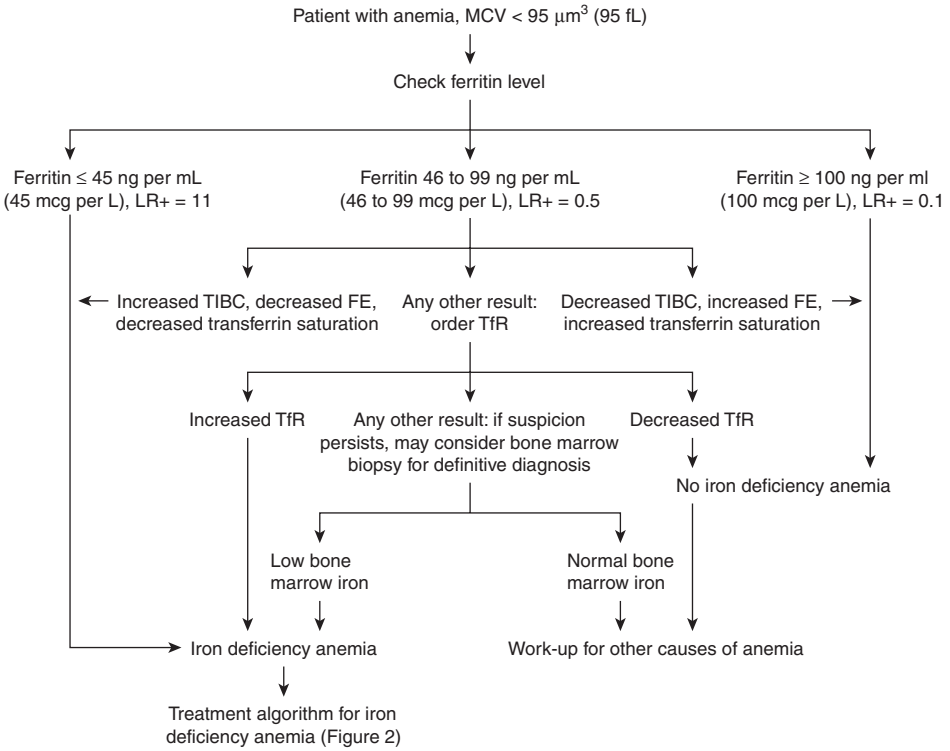

Fig. 145.2 Diagnostic algorithm for iron deficiency anemia. *FE*, Serum iron; *LR+*, positive likelihood ratio; *MCV*, mean corpuscular volume; *TfR*, serum transferrin receptor, *TIBC*, total iron-binding capacity. (From Killip S, Bennett JM, Chambers MD. Iron deficiency anemia. *Am Fam Physician*. 2007;75[5]:671–678.)

common cause of iron deficiency in women of childbearing age, often due to excessive menstrual bleeding. Interestingly, iron deficiency is a common cause of excessive menstrual blood loss, which can create a cycle of cause and effect.[6,7] Other common causes of blood loss include blood donation and bleeding from peptic ulcers and hemorrhoids.

The negative effects of iron deficiency are due largely to the impaired delivery of oxygen to the tissues and the impaired activity of iron-containing enzymes in various tissues. Iron deficiency can lead to anemia, excessive menstrual blood loss, learning disabilities, and impaired immune function, as well as decreased energy levels, detoxification function, and physical performance. Even mild iron-deficiency anemia leads to a reduction in physical work capacity and productivity.

Supplementation with iron has produced rapid improvements in work capacity among iron-deficient individuals. A systematic review of animal and human studies evaluated the causal relationship between iron deficiency and physical work capacity.[8] Iron deficiency was examined along a continuum from severe iron-deficiency anemia (SIDA) to moderate iron-deficiency anemia (MIDA) to iron deficiency without anemia (IDNA). Results demonstrated a strong causal effect of SIDA and MIDA on aerobic capacity in animals and humans, likely a result of reduced oxygen transport associated with anemia. In addition, tissue iron deficiency may play a role through reduced cellular oxidative capacity. The review concluded that energetic efficiency was affected at all levels of iron deficiency in humans, with the reduced work productivity observed in field studies likely due to anemia and reduced oxygen transport. However, impaired physical performance due to iron deficiency is not dependent on anemia because the iron-dependent enzymes involved in energy production and metabolism will be impaired long before anemia occurs.

Vitamin B_{12}–Deficiency Anemia

Vitamin B_{12} (cobalamin) deficiency is most often due to a defect in absorption or cobalamin metabolism rather than a dietary lack of the vitamin. For vitamin B_{12} from food to be absorbed, it must be liberated by hydrochloric acid and bound to intrinsic factor. The B_{12}-intrinsic factor complex is absorbed in the small intestine with the aid of the pancreatic enzyme trypsin.

Intrinsic factor is secreted by the parietal cells of the stomach. These cells are responsible for the secretion of hydrochloric acid. Hence, the secretion of intrinsic factor parallels that of hydrochloric acid. Pernicious anemia (PA) is a consequence of intrinsic factor loss and neutralizing intrinsic factor antibody that impairs cobalamin absorption. The defect is rare before the age of 35. Use of the Schilling test for detection of PA has been mostly supplanted by serological testing for parietal cell and intrinsic factor antibodies. Although PA has been reported in virtually every ethnic group, it is more common in individuals of Scandinavian, English, and Irish descent. The loss of hydrochloric acid leads to iron-deficiency anemia, which often precedes cobalamin-deficient pernicious anemia by 20 years.

A dietary lack of vitamin B_{12} is most often associated with a strict vegetarian or vegan diet. Unlike other water-soluble nutrients, vitamin B_{12} is stored in the liver, kidney, and other body tissues. Because normal body stores of vitamin B_{12} may last an individual 3 to 6 years, signs and symptoms of vitamin B_{12} deficiency arise after years of low dietary intake or inadequate secretion of intrinsic factor. In addition, it appears that a deficiency of vitamin B_{12} also affects the brain and nervous system before the development of pernicious anemia. In other words, waiting for a finding of anemia to diagnose a vitamin B_{12} deficiency may result in significant patient harm.

Symptoms of severe B_{12} deficiency can include pallor, fatigue, shortness of breath, diarrhea, heart palpitations, and a sore, beefy

red, and swollen tongue. Common nervous system symptoms include numbness and tingling of the arms or legs, depression, mental confusion, loss of vibration sense, and loss of deep tendon reflexes. In elderly persons, a vitamin B_{12} deficiency can mimic Alzheimer's disease.

The presence of macrocytosis and characteristic symptoms provide the physician with important clues suggesting B_{12} deficiency. Deficiency of cobalamin, whether nutritional or the result of inborn errors of vitamin B_{12} metabolism, inactivate methionine synthase and mitochondrial methylmalonyl-CoA mutase, leading to the accumulation of homocysteine and methylmalonic acid (Fig. 145.3). Thus homocysteine and methylmalonic acid (MMA) are the preferred serum biomarkers used to determine B_{12} status. Stand-alone serum levels of vitamin B_{12} have limited diagnostic value because low serum levels of vitamin B_{12} do not always represent deficiency, and likewise, severe functional deficiency of the micronutrient has been documented in the presence of normal and even high levels of serum vitamin B_{12}.[9]

FOLATE DEFICIENCY

Folate (or folic acid) deficiency is one of the most common vitamin deficiencies in the world. Unlike vitamin B_{12}, the body does not accumulate a surplus of folate, storing only enough to sustain the body for 1 to 2 months.

Folate deficiency is extremely common among alcoholics, as alcohol consumption impairs folate absorption, disrupts folate metabolism, and causes the body to excrete folate. Folic acid deficiency is also common among pregnant women, resulting from an increased demand. Folate is vital to cell reproduction in the fetus, and a deficiency of folate during development presents an increased risk for the development of birth defects such as neural tube defects. The lowering of folic acid levels by alcohol during pregnancy further increases the risk of fetal alcohol syndrome and/or neural tube defects. In addition to alcohol, several pharmaceuticals can induce a folate deficiency, including anticancer drugs, drugs for epilepsy, and oral contraceptives.

Folic acid deficiency is also common among patients who have chronic diarrhea or malabsorption states such as celiac disease, Crohn's disease, or tropical sprue. Because a deficiency of folate will result in diarrhea and malabsorption, often a vicious circle ensues. The administration of the active form of folate (5-methyltetrahydrofolate) as a preventive measure is warranted in anyone experiencing chronic diarrhea. Often this has a therapeutic effect as well.

Folate deficiency will result in macrocytic anemia similar to that caused by a vitamin B_{12} deficiency. The most sensitive test to assess folic acid deficiency is determining the folate content of the serum and RBC. The reference range for serum folate is 2.5 to 20 ng/mL. In addition to anemia, other symptoms of folic acid deficiency include fatigue, pallor, headaches, palpitations, diarrhea, depression, and a swollen, red tongue.

Note: It is always necessary to supplement vitamin B_{12} along with 5-MTHF to prevent the folate supplement from masking a vitamin B_{12} deficiency. Supplementing with 5-MTHF will correct the anemia of a vitamin B_{12} deficiency, but it cannot overcome the problems that vitamin B_{12} deficiency causes in the brain. Also, a high level of folate will aggravate the problems caused by vitamin B_{12} deficiency.

BONE MARROW AND STEM CELL DYSFUNCTION

Bone marrow and stem cell problems may prevent the body from producing enough red blood cells. If stem cells are too few, defective, or replaced by other cells such as metastatic cancer cells, anemia may result. Anemias resulting from bone marrow or stem cell problems include the following.

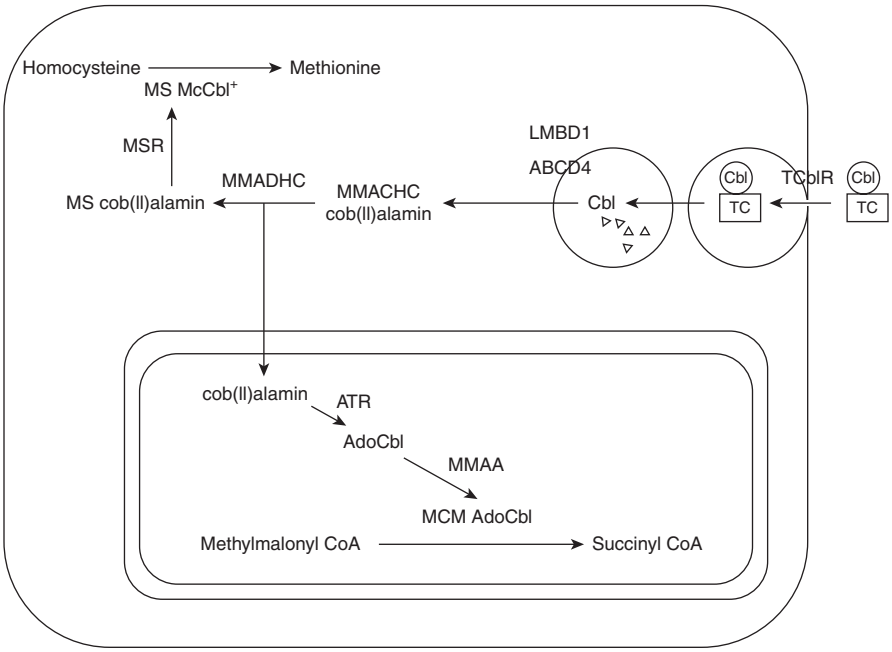

Fig. 145.3 Intracellular processing of cobalamin. *AdoCbl*, Adenosylcobalamin; *Cbl*, cobalamin; *MCM*, methylmalonylCoA mutase; *MeCbl*, methylcobalamin; *MS*, methionine synthase; *MSR*, methionine synthase reductase; *TC*, transcobalamin; *TCblR*, TC receptor. Identification and key management of non-transfusion-dependent thalassemia patients: not a rare but potentially under-recognised condition. *Orphanet J Rare Dis.* 2014;9:131.)

Aplastic Anemia

Aplastic anemia is a hematological disease characterized by hematopoietic failure of the bone marrow, resulting in a marked reduction in the number of stem cells or the absence of stem cells. It can be inherited, can occur without apparent cause, or can occur when the bone marrow is injured by medications, radiation, environmental toxins, chemotherapy, autoimmune disorders, or infection. Aplastic anemia can be either severe or not severe, and it may occur abruptly or may develop slowly and worsen over time.

Inherited Hemoglobin Disorders

Thalassemia and sickle cell disease are the most common inherited monogenic diseases worldwide characterized by deformed and/or inadequate hemoglobin. This inadequacy results in immature and deformed red blood cells and a decrease in oxygen transport. Several clinical forms of α-thalassemia and β-thalassemia have been described, and severity can range from mild to life threatening. Blood analyses of almost all thalassemias show a reduction in the size and Hb content of mature RBCs, which is evident by a reduced MCV (less than 80 femtoliters/cell) and mean cell MCH (less than 27 picograms/cell) (Fig. 145.4). The most severe form is called Cooley's anemia.

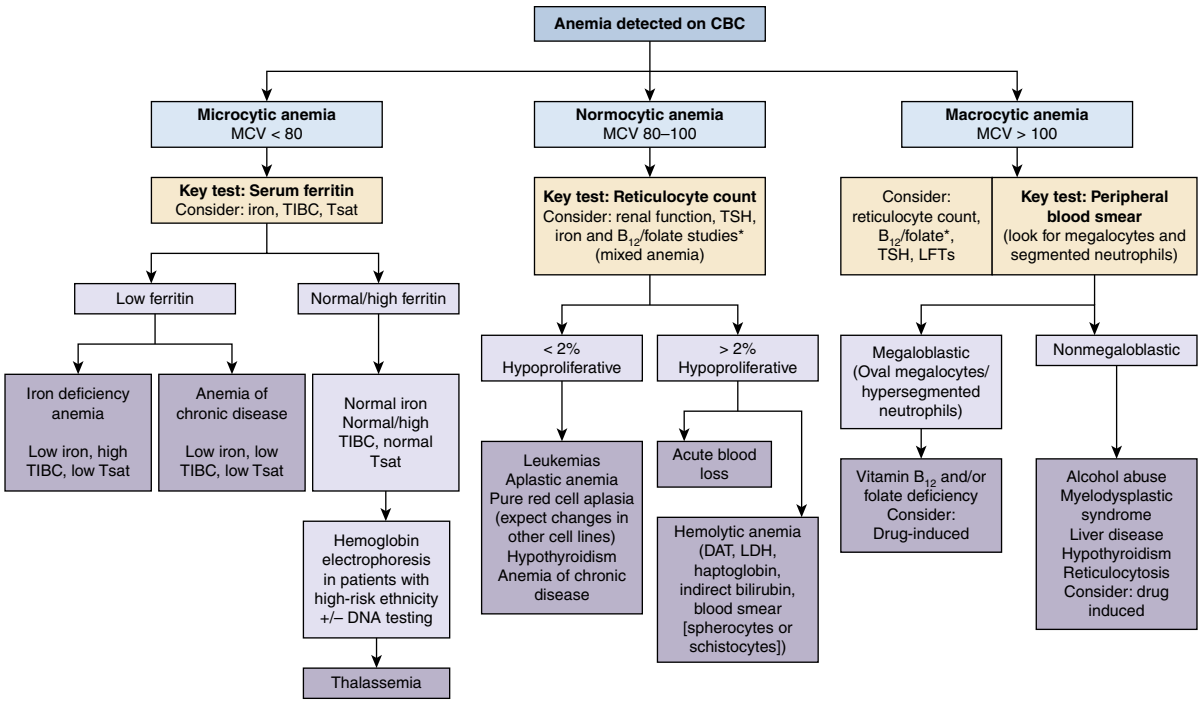
Sickle cell anemia occurs in individuals who are homozygous for a single-nucleotide substitution of the beta-globin gene, often producing a rigid, sicklelike shape of the red blood cells. Several subtypes exist depending on the exact mutation, with clinical manifestations including chronic hemolysis, increased susceptibility to infections, and vaso-occlusive complications.[10] Individuals with a single abnormal copy of the gene often do not have symptoms and are classified as carriers.

Lead Toxicity

Lead is a persistent toxic metal. At least 50% of all lead is stored in the bones, where it has a half-life of years to decades. Lead is readily absorbed through both the respiratory and gastrointestinal tracts. Gastrointestinal absorption of lead in children can be up to five times greater than in adults who are exposed to the same sources. Once absorbed, lead is bound to the red blood cells and moved into soft tissue and bones, with some excretion via the urine. Chronic, low-level lead exposure is associated with several adverse health conditions. In persons with blood lead levels (BLLs) higher than 35 μg/dL, the heme enzyme delta-aminolevulinic acid dehydratase (ALAD) is inhibited, leading to anemia.

DIAGNOSTIC CONSIDERATIONS

Anemia cannot be reliably diagnosed by clinical presentation. Fatigue, the most common presenting symptom, is caused by anemia in approximately 1 out of 52 patients in primary care practice.[11] It is imperative that a comprehensive laboratory analysis of the blood be performed. Fig. 145.5 provides a flow chart of suggested labs as well as potential diagnoses.



DAT = direct antiglobulin test (direct Coombs' test): LFT = liver function tests; LDH = lactate dehydrogenase; MCV = mean corpuscular volume; TIBC = total iron-binding capacity; TSH = thyroid-stimulating hormone. Tsat=transferrin saturation

THERAPEUTIC CONSIDERATIONS

Treatment of anemia is dependent on proper clinical evaluation to determine the origin of the anemia. It is critical that the underlying cause of the anemia be uncovered if the correct therapy is to be employed.

GENERAL NUTRITIONAL SUPPORT FOR ALL TYPES

Increasing iron levels in food may help partially or completely overcome poor iron absorption. Animal proteins are a rich source of heme iron, and dark green leafy vegetables are among the best sources of nonheme iron. Although many individuals shy away from organ meats, liver is an excellent source of iron as well as B vitamins. Lamb and venison also contain significant levels of iron and are leaner and less inflammatory than beef.

In addition to iron, green leafy vegetables contain natural fat-soluble chlorophyll and nutrients such as vitamin C and folic acid. The chlorophyll molecule is similar to the hemoglobin molecule. Fat-soluble (but not water-soluble) chlorophyll products may be beneficial. However, water-soluble chlorophyll is not absorbed from the gastrointestinal tract and therefore has no use in the treatment of anemia.

Because a large percentage of individuals with anemia do not secrete enough hydrochloric acid, it is often important for them to take hydrochloric acid supplements with meals. See Chapter 123, Digestive Support.

Iron-Deficiency Anemia

In iron-deficiency anemia, it is essential to determine the reason for the loss of iron (e.g., chronic blood loss) or the reason for the poor absorption of dietary iron (e.g., low vitamin C or high tannins in diet). Lack of hydrochloric acid is a common reason for impaired iron absorption, especially among elderly persons.

There are two forms of dietary iron: heme iron and nonheme iron. Heme iron is bound to the oxygen-binding proteins hemoglobin and myoglobin. Heme iron is the most efficiently absorbed form of iron. The absorption rate of nonheme iron supplements, such as ferrous sulfate and ferrous fumarate, is 2.9% on an empty stomach and 0.9% with food. This rate is significantly less than the absorption rate of heme iron, which is as high as 35%. In addition, heme iron does not cause the side effects associated with nonheme sources of iron, such as nausea, flatulence, constipation, and diarrhea.

Despite the superiority of heme iron, nonheme iron salts are the most popular iron supplements. Although heme iron is better absorbed, dosing higher quantities of nonheme iron salts results in similar net absorption amounts (i.e., 3 mg of heme iron and 50 mg of nonheme iron will net approximately the same level of absorption).

In adults with iron deficiency anemia, treatment involves the use of 50 to 150 mg elemental iron daily in divided doses. The usual recommendation for any nonheme source is generally up to 60 mg daily in divided doses. For children with iron-deficiency anemia, the dose is 4 to 6 mg/kg per day divided into three doses. High intakes of other minerals, particularly calcium, magnesium, and zinc, can interfere with iron absorption. Therefore, when treating iron deficiency, it is recommended to take iron away from these minerals. In contrast, vitamin C enhances iron absorption.

Ferrous sulfate is the most popular iron supplement, but it is certainly less than ideal, because it often causes constipation or other

TABLE 145.1 Dietary Sources of Iron

Food	Average Serving Size (g)	Iron (mg) Per Serving
Calf or lamb liver	60	9.6
Beef or chicken liver	60	5.2
Beef	90	2.7
Beans cooked	100	2.3
Prunes	100	1.8
Bread (3 slices)	70	1.7
Chicken or turkey	90	1.6
Greens, cooked	75	1.5
Peas	75	1.5
Eggs	50	1.1

TABLE 145.2 Recommended Dietary Allowances (RDA) for Iron

Group	Daily Dose
Infants 7–12 months	11 mg
Children 1–3 years	7 mg
Children 4–8 years	10 mg
Males 9–13 years	8 mg
Males 14–18 years	11 mg
Males ≥ 19 years	8 mg
Females 9–13 years	8 mg
Females 14–18 years	15 mg
Females 19–50 years	18 mg
Females ≥ 51 years	8 mg
Pregnant women	27 mg
Females when lactating between 14–18 years	10 mg
Females when lactating ≥19 years	9 mg

gastrointestinal disturbance. The best forms of nonheme iron are ferrous succinate, glycinate, fumarate, and pyrophosphate. Of these, the preferred form is micronized ferrous pyrophosphate, which is then microencapsulated to allow it to be dispersed and assimilated. Advantages of this form include stability, lack of taste or flavor, and lack of gastrointestinal side effects. In addition, ferrous pyrophosphate provides a sustained-release form of iron (up to 12 hours) with a high relative bioavailability, especially when taken on an empty stomach.[12]

The best dietary source of iron is red meat, as well as liver and fish. Nonmeat sources of iron include beans, molasses, dried fruits, whole-grain and enriched breads, and green leafy vegetables. Nonheme iron absorption is enhanced by vitamin C.

Table 145.1 provides the iron content per serving of some food sources of iron. The table does not factor in absorption. For example, the absorption rate for calf's liver is nearly 30%, whereas the absorption rate for the vegetable sources is approximately 5%. The daily dietary recommended allowance for iron depends on an individual's age and gender (Table 145.2).

Several foods and beverages contain substances that inhibit iron absorption, including tea, coffee, wheat bran, and egg yolk. Antacids and overuse of calcium supplements also decrease iron absorption. These items should be restricted in the diet of individuals who have iron deficiency. Iron supplements can decrease the availability of several medications, including levodopa and levothyroxine, and care should be exercised when simultaneous administration of these substances is indicated.

Cautions and Warnings

Keep all iron supplements out of the reach of children. Acute iron poisoning in infants can result in serious consequences. Severe iron poisoning is characterized by damage to the intestinal lining, liver failure, nausea and vomiting, and shock.

Pernicious Anemia

The usual dietary sources of vitamin B_{12} are animal-derived foods. The richest sources are liver and kidney, followed by eggs, fish, cheese, and meat. Strict vegetarians and vegans have an increased risk of B_{12} deficiency, and therefore it is necessary to identify plant-derived foods that contain high levels of vitamin B_{12}—produced by the bacteria, typically in some kind of fermented form. A survey of naturally occurring and high vitamin B_{12}-containing plant-derived food sources showed that nori is a good vitamin B_{12} source for vegetarians.[13] Consumption of approximately 4 g of dried nori (vitamin B_{12} content: 77.6 μg/100 g dry weight) supplies the RDA of 2.4 μg per day.

Vitamin B_{12} is available in several forms. The most common form is cyanocobalamin. However, vitamin B_{12} is active in only two forms: methylcobalamin and adenosylcobalamin. Both forms are available commercially in tablet form in the United States. Although methylcobalamin is active immediately upon absorption, cyanocobalamin must be converted by the body to either methylcobalamin or adenosylcobalamin by removing the cyanide molecule and adding either a methyl or adenosyl group. Cyanocobalamin is not active in many experimental models, whereas both methylcobalamin and adenosylcobalamin demonstrate high-level activity.

Medical treatment involves injecting vitamin B_{12} at a dose of 1 mg daily for 1 week, until the anemia has resolved. Preventive injections may also be required to prevent deficiency in the future. Oral therapy has been shown to be equally effective.

Oral Versus Injectable B_{12}

Although it is popular to inject vitamin B_{12}, injection is not strictly necessary. Studies show that supplementation with oral vitamin B_{12} is a safe and effective treatment for the B_{12} deficiency state, even in the absence of intrinsic factor. In the United States, oral vitamin B_{12} therapy is rarely used even though it has been shown to be 100% effective in the long-term treatment of pernicious anemia.[14]

Soon after vitamin B_{12} was isolated in 1948, it was introduced in an injectable form, and researchers busily sought an oral alternative. Oral preparations containing intrinsic factor were tried, but some patients developed antibodies against intrinsic factor and therefore would not respond. Studies in the 1950s and 1960s documented that a small but constant proportion of an oral dose of cyanocobalamin at a dosage of 300 mcg to 1000 mcg daily was absorbed even without intrinsic factor through the process of diffusion. Thus by sufficiently increasing the dose, adequate absorption could be attained. A study in 1978 described 64 Swedish patients with pernicious anemia and other vitamin B_{12}-deficiency states who were treated with 1000 mcg of oral cyanocobalamin daily.[15] Complete normalization of serum levels and liver stores for vitamin B_{12}, as well as full clinical remission, was observed in all patients studied over a 3-year period. Since then, several studies have validated the use of oral vitamin B_{12} in the treatment of pernicious anemia.[16]

Despite the research, the use of oral vitamin B_{12} therapy remains uncommon in the United States. In a survey of internists, 91% erroneously believed that vitamin B_{12} could not be absorbed in sufficient quantities without intrinsic factor.[17] Interestingly, 88% of these surveyed doctors also stated that an effective oral vitamin B_{12} therapy would be useful in their practice and further stated that it would be their preferred method of delivery if it were effective. Studies established that the average absorption rate of oral cyanocobalamin by patients with pernicious anemia is 1.2% across a wide range of dosages. Because the daily turnover rate is about 2 mcg, an oral dosage of 200 to 250 mcg daily results in an average absorption of 2.4 to 3 mcg, respectively, which may be adequate for most patients. However, higher doses are often prescribed to ensure effective treatment.

In the treatment of pernicious anemia, the usual intramuscular (IM) dosage recommended by most medical texts is 1000 mcg IM weekly for 8 weeks, then once a month for life. For oral vitamin B_{12}, the recommended dosage is 2000 mcg daily (14,000 mcg weekly) for at least 1 month, followed by a daily intake of 1000 mcg of vitamin B_{12}. Methylcobalamin, the active form of B_{12}, is preferred over cyanocobalamin.

Folic Acid–Deficiency Anemia

Dietary foods high in folic acid include liver, asparagus, dried beans, brewer's yeast, dark green leafy vegetables, and whole grains. Because folic acid is destroyed by heat and light, fruits and vegetables should be eaten fresh or with very little cooking.

To replenish folic acid stores, 800 to 1000 mcg of active folate should be taken every day for up to 1 month. Folic acid is available as folic acid (folate) and folinic acid (5-methyl-tetra-hydrofolate). To utilize folic acid, the body must first convert it to tetrahydrofolate and then add a methyl group to form methyl-tetrahydrofolate (folinic acid). Methyl-tetrahydrofolate is the most active form of folic acid and has been shown to be more efficient at raising body stores than folic acid.[18] Supplying the body with methyl-tetrahydrofolate bypasses these steps and is needed for those with a genetic inability to make the conversion.

THERAPEUTIC APPROACH

General Recommendations

Effective therapy for anemia is dependent on proper classification as to its cause. Blood tests should be performed every 1 to 2 months to determine the efficacy of treatment.

Diet

Perhaps the best food for individuals with anemia is calf's liver. Ingestion of 4 to 6 oz of calf's liver 3 times per week is an option. In addition, the liberal consumption of green leafy vegetables is recommended.

NUTRITIONAL SUPPLEMENTS

Iron-Deficiency Anemia

- Iron: 30 mg, bound to either pyrophosphate, succinate, glycinate, or fumarate, twice per day between meals (if this recommendation results in abdominal discomfort, patients should take 30 mg with meals twice per day)
- Vitamin C: 1 gram 3 times per day with meals

B_{12}-Deficiency Anemia

- Oral vitamin B_{12} (methylcobalamin): 2000 mcg per day sublingually for at least 1 month; adjust dosage according to laboratory results
- 5-MTHF: 800 to 1200 mcg 3 times per day

Folic Acid–Deficiency Anemia

- 5-MTHF: 800 to 1200 mcg 3 times per day
- Vitamin B_{12}: 1000 mcg per day; supplementing vitamin B_{12} with folate prevents the folic acid supplement from masking a vitamin B_{12} deficiency

Angina

Michael T. Murray, ND,* and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Squeezing or pressure-like pain in the chest appearing immediately after exertion. Other precipitating factors include emotional tension, cold weather, or a large meal. Pain may radiate to the left shoulder blade, left arm, or jaw. The pain typically lasts for only 1 to 20 minutes.
- Stress, anxiety, and high blood pressure are typically present.
- Most people demonstrate an abnormal electrocardiographic reading (transient ST-segment depression) in response to light exercise (stress test).

GENERAL CONSIDERATIONS

Angina pectoris results when the supply of oxygen, and occasionally other nutrients, is inadequate to meet the metabolic needs of the heart muscle. The primary cause is atherosclerosis, although platelet aggregation, coronary artery spasm, nonvascular mechanisms such as hypoglycemia, and increased metabolic need (such as in hyperthyroidism) can also be important.

The primary lesion of atherosclerosis is the atheromatous plaque, which progressively narrows and ultimately blocks the coronary artery, resulting in a decreased supply of blood and oxygen to the heart tissue. Symptoms typically begin to appear after a major coronary artery is blocked by more than 50%.

Blood flow to the heart may also be compromised by transient platelet aggregation (discussed in more detail in Chapter 149) and coronary artery spasm. Prinzmetal's variant angina, the most commonly recognized form of coronary artery spasm, is not due to plaque in the coronary arteries and is more apt to occur at rest or at odd times during the day or night. It is more common in women younger than age 50. Magnesium insufficiency–induced coronary artery spasm, more common in men than women, is now recognized as an important cause of myocardial infarction (MI) and may be of significance in angina pectoris (Fig. 146.1).

*Previous edition contributor

DIAGNOSTIC CONSIDERATIONS

The diagnosis of angina is frequently made by history alone. Clinical evaluation of all patients with angina should include an electrocardiogram (ECG) at rest and a chest radiograph. Because more than one half of patients with typical angina and confirmed coronary atherosclerosis have normal 12-lead ECG readings at rest, diagnosis must often be confirmed using ECG stress testing or 24-hour Holter monitoring (ambulatory ECG).

The most common diagnostic ECG changes associated with angina are evidence of previous MI and ST-segment and T-wave changes that occur *during* attacks of pain. The most characteristic change is displacement of the ST segment with or without T-wave inversion (Fig. 146.2). Complicating diagnosis, however, is the observation that hypoglycemia-induced angina does not manifest with rate or ST-segment abnormalities.[1]

THERAPEUTIC CONSIDERATIONS

Angina is a serious condition that requires careful treatment and monitoring. In the severe case as well as in the initial stages of mild to moderate angina, prescription medications may be necessary. Eventually the condition should be controlled with the help of natural measures. If there is significant blockage of the coronary artery, intravenous ethylenediaminetetraacetic acid (EDTA) chelation therapy, angioplasty, or coronary artery bypass may be appropriate.

From the perspective of natural medicine, there are two primary therapeutic goals in the treatment of angina: improving energy metabolism within the heart and improving blood supply to the heart. These goals are interrelated, as an increased blood flow means improved energy metabolism, and vice versa.

The heart uses fats as its major metabolic fuel. It converts free fatty acids to energy in much the same way as an automobile uses gasoline. Defects in the utilization of fats by the heart greatly increase the risk of atherosclerosis, heart attacks, and anginal pains. Specifically, impaired utilization of fatty acids by the heart results in the accumulation of high concentrations of fatty acids within the heart muscle.

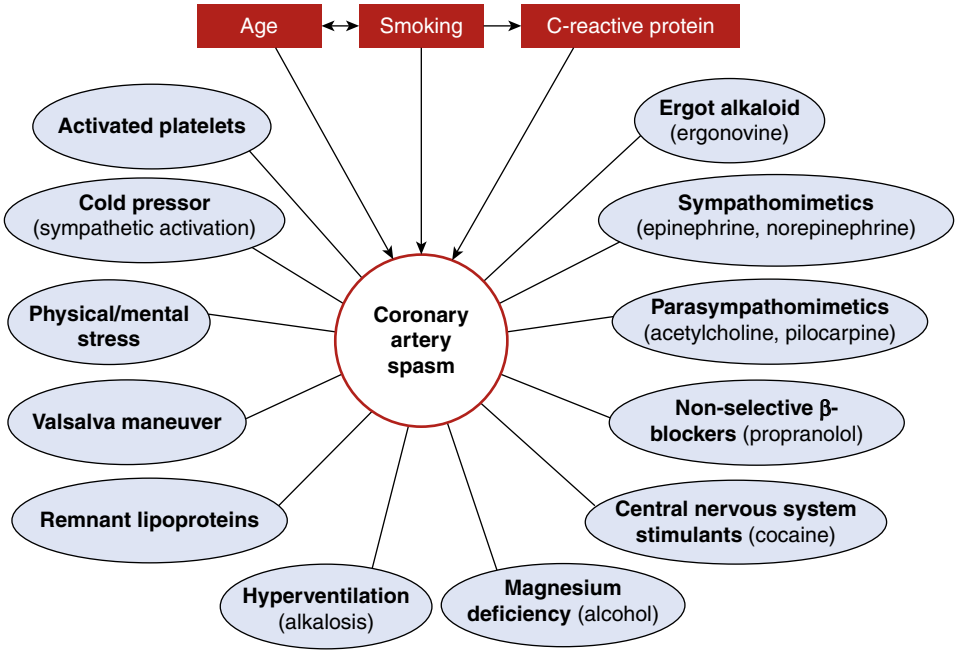

Fig. 146.1 Risk factors and precipitating factors for coronary artery spasm. (From Hung MJ, Hu P, Hung MY. Coronary artery spasm: review and update. *Int J Med Sci.* 2014;11[11],1161-71.)

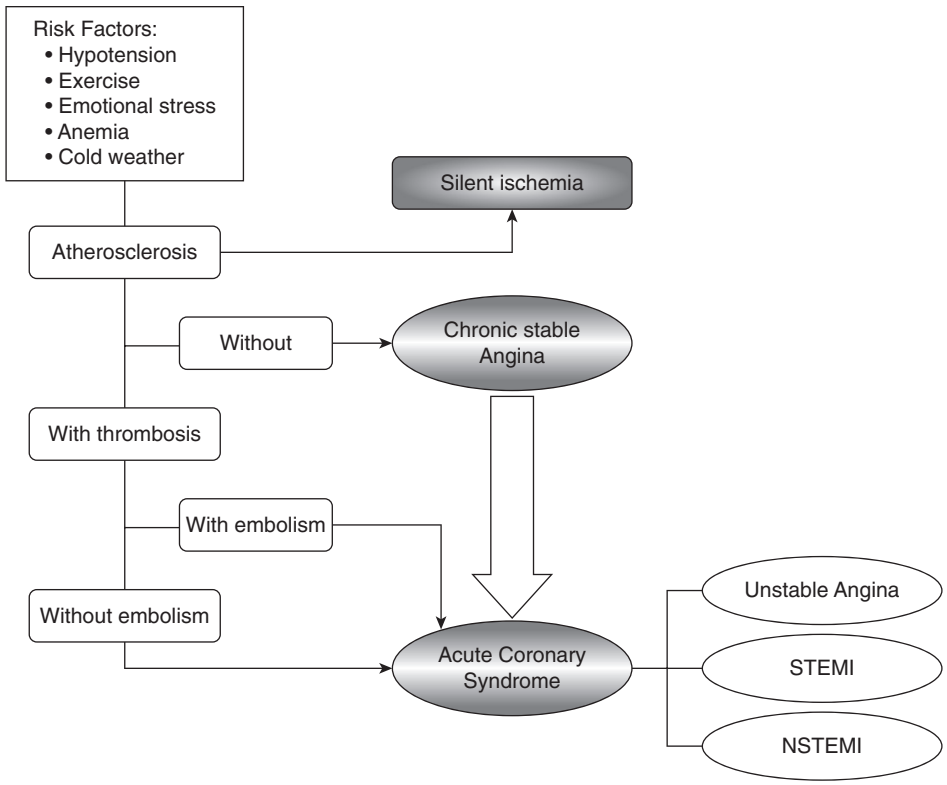

STEMI = ST-Segment Elevation Myocardial Infarction
NSTEMI = Non-ST Segment Myocardial Infarction

Fig. 146.2 Algorithm of diagnostic in coronary artery disease. (Retrieved from Non-Invasive Imaging in Approaching Ischemic Coronary Artery Disease—Scientific Figure on ResearchGate. Available from: https://www.researchgate.net/figure/Algorithm-of-diagnostic-in-coronary-artery-disease-High-risk-of-coronary-artery-disease_fig1_221916523 [accessed May 14, 2019])

This accumulation makes the heart extremely susceptible to cellular damage, which ultimately leads to a heart attack.

Carnitine, pantethine, and coenzyme Q_{10} (CoQ_{10}) are essential compounds in normal fat and energy metabolism and are of extreme benefit to sufferers of angina. These nutrients prevent the accumulation of fatty acids within the heart muscle by improving the conversion of fatty acids and other compounds into energy.

Nutritional Supplements for Angina

The use of antioxidant supplementation in patients with angina is important. In an analysis of normal controls and patients with either stable or unstable angina, the plasma level of antioxidants has been shown to be a more sensitive predictor of unstable angina than the severity of atherosclerosis.[2,3] One group of researchers concluded: "These data are consistent with the hypothesis that the beneficial effects of antioxidants in coronary artery disease (CAD) may result, in part, by an influence on lesion activity rather than a reduction in the overall extent of fixed disease."[2]

Antioxidant nutrients are also important in preventing nitrate tolerance. Oral nitrates are widely used in the conventional treatment of angina, but their continuous administration can result in the rapid development of tolerance. Experimental findings indicate that nitrate tolerance is associated with increased vascular production of superoxide. The superoxide anions generated quickly degrade the nitric oxide formed from the administration of nitroglycerin and result in lower levels of cyclic guanosine monophosphate (an important intracellular regulator that promotes vasorelaxation). Because vitamin C is the main aqueous-phase antioxidant and free radical scavenger of superoxide and vitamin E is the main lipid-phase antioxidant, their importance in preventing nitrate tolerance is obvious. Clinical trials have upheld this connection, showing that high-dose supplementation of vitamins C and E can prevent nitrate tolerance.[4,5]

Carnitine

Carnitine, a vitamin-like compound, stimulates the breakdown of long-chain fatty acids by the energy-producing units in cells—the mitochondria. Carnitine is essential in the transport of fatty acids into the mitochondria. A deficiency in carnitine results in a decrease in fatty-acid concentrations in the mitochondria and reduced energy production.

Normal heart function is critically dependent on adequate concentrations of carnitine. Although the normal heart stores more carnitine than it needs, if the heart does not have a good supply of oxygen, carnitine levels quickly decrease. This decrease leads to decreased energy production in the heart and increased risk for angina and heart disease. Because angina patients have a decreased supply of oxygen, carnitine supplementation makes good sense.

Several clinical trials have demonstrated that carnitine improves angina and heart disease.[6-10] Supplementation with carnitine normalizes heart carnitine levels and allows the heart muscle to use its limited oxygen supply more efficiently. This increased efficiency translates to an improvement in cases of angina. Improvements have been noted in exercise tolerance and heart function and suggest that carnitine is an effective alternative to drugs in cases of angina.

In one study of patients with stable angina, oral administration of 900 mg of L-carnitine increased mean exercise time and the time necessary for abnormalities to occur on a stress test (6.4 minutes in the placebo group compared with 8.8 minutes in the carnitine-treated group).[10] These results indicate that carnitine may be an effective alternative to other antianginal agents such as beta blockers, calcium channel antagonists, and nitrates, especially in patients with chronic stable angina pectoris.

Carnitine, by improving fatty-acid utilization and energy production in the heart muscle, may also prevent the production of toxic fatty-acid metabolites. These compounds are extremely deleterious because they activate various phospholipases and disrupt cellular membrane structures. The changes in the properties of cardiac cell membranes induced by fatty-acid metabolites are thought to contribute to impaired heart muscle contractility and compliance, increased susceptibility to irregular beats, and the eventual death of heart tissue. Supplemental carnitine increases heart carnitine levels and prevents the production of toxic fatty-acid metabolites. This mechanism has been demonstrated clinically, where the early administration of L-carnitine (40 mg/kg per day) in patients having heart attacks was found to considerably reduce heart damage.[11]

Pantethine

Pantethine is the stable form of pantetheine, the active form of pantothenic acid, which is the fundamental component of coenzyme A (CoA). CoA is involved in the transport of fatty acids to and from cells as well as to the mitochondria. The synthetic pathway from pantethine to CoA is much shorter than that of pantothenic acid, making pantetheine the preferred therapeutic substance. In addition, pantetheine has significant lipid-lowering activity, whereas pantothenic acid has very little if any effect in lowering cholesterol and triglyceride levels.

The standard dose for pantethine is 900 mg per day. Like carnitine, pantethine has been shown in clinical trials to significantly reduce serum triglyceride and cholesterol levels and to increase high-density-lipoprotein cholesterol levels.[12-14] Its lipid-lowering effects are most impressive when its toxicity (virtually none) is compared with that of conventional lipid-lowering drugs. Its mechanism of action is due to the inhibition of cholesterol synthesis and acceleration of fatty acid breakdown in the mitochondria.

Pantethine is well indicated in angina. Like carnitine, heart pantethine levels decrease during times of reduced oxygen supply. Demonstrated effects in animals indicate that it would greatly benefit individuals with angina.[15]

Coenzyme Q_{10}

CoQ_{10}, also known as *ubiquinone*, is an essential component of the mitochondria, where it plays a major role in energy production. Like carnitine and pantethine, CoQ_{10} can be synthesized in the body. Nonetheless, deficiency states have been reported. Deficiency can be a result of impaired CoQ_{10} synthesis due to nutritional deficiencies, a genetic or acquired defect in CoQ_{10} synthesis, or increased tissue needs.[16]

Cardiovascular diseases—including angina, hypertension, mitral valve prolapse, and congestive heart failure—are examples of diseases that require increased tissue levels of CoQ_{10}.[16] In addition, many elderly persons may have increased CoQ_{10} requirements; the decline of CoQ_{10} levels that occurs with age may be partly responsible for the age-related deterioration of the immune system.

CoQ_{10} deficiency is common in individuals with heart disease. Heart tissue biopsies in patients with various heart diseases show a CoQ_{10} deficiency in 50% to 75% of cases.[16] One of the most metabolically active tissues in the body, the heart may be unusually susceptible to the effects of CoQ_{10} deficiency. Accordingly, CoQ_{10} has shown great promise in the treatment of heart disease.

In one study, 12 patients with stable angina pectoris were treated with CoQ_{10} (150 mg per day for 4 weeks) in a double-blind crossover trial.[17] In comparison with placebo, CoQ_{10} reduced the frequency of anginal attacks by 53%. In addition, researchers found a significant increase in treadmill exercise–tolerance (time to onset of chest pain and time to development of ECG abnormalities) during CoQ_{10} treatment. The results of this study and others suggest that CoQ_{10} is a safe and effective treatment for angina pectoris.

Carnitine, pantethine, and CoQ_{10} should be considered in all heart disorders, not just angina.

Magnesium

Magnesium deficiency may play a major role in angina, including Prinzmetal's variant. A magnesium deficiency has been shown to produce spasms of the coronary arteries and is thought to be a cause of nonocclusive heart attacks.[18] Furthermore, researchers have observed that men who die suddenly of heart attacks have significantly lower levels of heart magnesium, as well as potassium, compared to matched controls.[19]

Making magnesium the treatment of choice for angina due to coronary artery spasm has been suggested.[19-21] Magnesium administration has also been found to be helpful in the management of arrhythmias and in angina due to atherosclerosis. Its benefit in these situations is presumably via the same mechanisms responsible for its effects in an acute MI.

Since the mid-1980s, eight well-designed studies involving more than 4000 patients have demonstrated that intravenous magnesium supplementation during the first hour of admission to a hospital for an acute MI produces a favorable effect in reducing immediate and long-term complications as well as death rates.[22-24]

The beneficial effects of magnesium in acute MI relate to its ability to:

- Improve energy production within the heart
- Dilate the coronary arteries, resulting in improved delivery of oxygen to the heart
- Reduce peripheral vascular resistance, resulting in reduced demand on the heart
- Inhibit platelets from aggregating and forming blood clots
- Reduce the size of the infarct (blockage)
- Improve heart rate and arrhythmias

Arginine

Arginine supplementation has been shown to be beneficial in several cardiovascular diseases, including angina pectoris. Its benefit is thought to occur via increasing nitric oxide levels, thereby improving blood flow, reducing thrombosis, and improving rheology. The degree of improvement offered by arginine supplementation in angina and other cardiovascular diseases can be quite significant as a result of improved nitric oxide levels. In double-blind studies, it has been shown to be especially effective in increasing exercise tolerance. Typical dosage is 6 g per day in divided dosages.[25-27] In a short-term study, arginine supplementation of 3 g per day for 15 days resulted in increased activity of the free-radical scavenging enzyme superoxide dismutase and increased the levels of total thiols and ascorbic acid, with a concomitant decrease in lipid peroxidation, carbonyl content, serum cholesterol, and the activity of the prooxidant enzyme xanthine oxidase.[28] These beneficial changes point to additional mechanisms for the use of arginine in angina and cardiac ischemia. Use of arginine is cautioned by a report in one study in survivors of MI in whom supplementation with arginine (9 g per day for 6 months) was associated with an increase in mortality compared with the placebo group (8.6% vs. 0%).[29] This effect may have been an aberration or due to the use of higher dosages of arginine.

Botanical Medicines

Crataegus Species

Hawthorn berry and extracts of the flowering tops are widely used in Europe for their cardiovascular activity. They exhibit a combination of effects that are of great value to patients with angina and other heart problems. Numerous experiments and clinical studies have documented the cardiovascular efficacy of the plant through various mechanisms, including positive inotropic and negative chronotropic effects; escalation in coronary blood flow and exercise tolerance; inhibition of the enzymes, such as angiotensinconverting enzyme (ACE) and phosphodiesterase; providing anti-inflammatory and antihyperlipidemic effects; and improving status of antioxidant enzymes, which support its cardioactive efficacy.[30] Studies have demonstrated that hawthorn extracts are effective in reducing anginal attacks as well as in lowering blood pressure and serum cholesterol levels.[31-33]

The beneficial effects in the treatment of angina are due to improvement in the blood and oxygen supply of the heart resulting from dilation of the coronary vessels, as well as improvement of the metabolic processes in the heart.[31-35]

The ability of *Crataegus* species to dilate coronary blood vessels has been repeatedly demonstrated in experimental studies.[31-33] In addition, *Crataegus* extracts have been shown to improve cardiac energy metabolism in human and experimental studies. This combined effect is extremely important in the treatment of angina because it results in improved myocardial function with more efficient use of oxygen. This improvement results not only from increased blood and oxygen supply to the heart muscle but also from hawthorn flavonoids interacting with key enzymes to enhance myocardial contractility.

Because adhesion molecules play an important role in the development and progression of coronary atherosclerosis, one study evaluated the effect of Cratagol herbal tablets, aerobic exercise, and their combination on the serum levels of Intercellular Adhesion Molecule (ICAM)-1 and E-Selectin in patients with stable angina pectoris.[34] Eighty stable angina pectoris patients age 45 to 65 years were randomly divided into four groups including three experimental groups and one control group: aerobic exercise (E), *C. oxyacantha* extract (S), aerobic exercise and *C. oxyacantha* extract (S+E), and control (C). After 12 weeks of treatment, intergroup comparison of the data revealed a significant reduction ($P < 0.01$) in serum levels of ICAM-1 and E-selectin in experimental groups. The authors concluded that aerobic exercise and consuming *C. oxyacantha* extract present an effective complementary strategy to significantly lower the risk of atherosclerosis and heart problems. (See Chapter 71 for a comprehensive discussion of this important botanical.)

Ammi visnaga

Khella is a medicinal plant native to the Mediterranean region, where it has been used in the treatment of angina and other heart ailments since the time of the pharaohs. Several of its components have demonstrated the ability to dilate the coronary arteries. Its mechanism of action appears to be similar to that of the calcium channel blocking drugs.

Since the late 1940s, there have been numerous scientific studies on the clinical effect of khella extracts in the treatment of angina. More specifically, khellin, a derivative of the plant, was shown to be extremely effective in relieving anginal symptoms, improving exercise tolerance, and normalizing ECGs. This finding is evident by the concluding statements in a study by Osher and colleagues[35] in 1951: "The high proportion of favorable results, together with the striking degree of improvement frequently observed, has led us to the conclusion that khellin, properly used, is a safe and effective drug for the treatment of angina pectoris."

At higher doses (120–150 mg per day), pure khellin was associated with mild side effects, such as anorexia, nausea, and dizziness. Although most clinical studies used high dosages, several studies show that as little as 30 mg per day appears to offer as good results with fewer side effects.[36,37]

Rather than using the isolated compound khellin, khella extracts standardized for khellin content (typically 12%) are the preferred form. A daily dose of such an extract would be 250 to 300 mg. Khella appears to work well with hawthorn extracts.

Other Therapies

Acupuncture

Several studies have shown acupuncture to be of benefit in improving angina, specifically in reducing nitroglycerin use, decreasing the number of anginal attacks, and improving exercise tolerance and ECG readings.[38-41]

Relaxation and Breathing Exercises

Relaxation and breathing exercises may be helpful in improving anginal symptoms, especially when anxiety is a significant contributor.[42,43] In one study in patients with cardiac syndrome X, a form of angina in people with otherwise normal coronary arteries, transcendental meditation (20 minutes twice daily of silently chanting a mantra with eyes closed) was found to reduce angina-like chest pain and to normalize ECGs.[42]

Intravenous Ethylenediaminetetraacetic Acid (EDTA) Chelation Therapy

EDTA chelation therapy is an alternative to coronary artery bypass surgery and angioplasty, which may prove to be more effective, safer, and less expensive. EDTA is an amino acid–like molecule that, when slowly infused into the bloodstream, binds with minerals such as calcium, iron, copper, and lead and carries them to the kidneys, where they are excreted. EDTA chelation has been commonly used for lead poisoning, but in the late 1950s and early 1960s it was found to help patients with atherosclerosis.

The discovery of EDTA chelation therapy in the treatment of angina and other conditions associated with atherosclerosis happened accidentally. In 1956 a battery worker whom Norman Clarke was treating with EDTA for lead poisoning noticed that his symptoms of angina disappeared. Clarke and others began using EDTA chelation therapy in patients with angina, cerebral vascular insufficiency, and occlusive peripheral vascular disease.

In a series of 283 patients treated by Clarke and colleagues from 1956 to 1960, a total of 87% showed improvements in their symptoms. Heart patients improved, and patients with blocked arteries in the legs, particularly those with diabetes, avoided amputation.[44,45]

It was originally thought that EDTA opened blocked arteries by chelating out the calcium deposits in the cholesterol plaque. However, the benefit now seems more related to chelating out excess iron and copper, minerals that, in the presence of oxygen, stimulate free radicals. Free radicals damage arterial cells, and this damage is a primary cause of atherosclerosis.

In a review of the progression and regression of atherosclerosis, the authors write that the process of atherosclerosis is "dependent on the presence of some metals (copper and iron) and can be completely inhibited by chelating agents such as EDTA."[46]

Despite obvious benefits to heart patients, EDTA fell out of favor in the mid-1960s. Advocates believe this occurred for two reasons: (1) the lucrative surgical approach to heart and vessel disease was on the rise; and (2) the patent on EDTA that was held by Abbott Laboratories expired, so there was no financial interest for drug companies to fund research.

Fortunately, in 1972 a small group of practicing physicians using EDTA chelation therapy founded an organization now called the American College for the Advancement of Medicine to continue education and research in this important area.

In the early days of EDTA chelation therapy, several serious problems were discovered. Giving too much EDTA or giving it too fast was soon noted to be dangerous. In fact, several deaths attributed to kidney failure were caused by toxicity to EDTA. Fortunately, additional research resulted in more appropriate protocols, and EDTA chelation therapy is now safe. No deaths or significant adverse reactions have occurred in more than 500,000 patients who have undergone EDTA chelation therapy. Because EDTA chelation improves blood flow throughout the body, the "side effects" are usually beneficial and only a few adverse effects are noticed.

A substantial body of scientific evidence exists on the use of EDTA chelation therapy in the treatment of angina, peripheral vascular disease, and cerebral vascular disease.[47-51]

Nonetheless, there is a paucity of well-designed placebo-controlled studies to definitively assess the efficacy of this approach. This shortcoming is unfortunate considering the early successes. The conclusion from a Cochrane Review summarizes the situation well: "At present, there is insufficient evidence to decide on the effectiveness or ineffectiveness of chelation therapy in improving clinical outcomes of patients with atherosclerotic cardiovascular disease." THERAPEUTIC APPROACH

The primary therapy for angina is prevention, because angina is usually secondary to atherosclerosis. Once angina has developed, restoring proper blood supply to the heart and enhancing energy production within the heart are necessary. Particularly important nutrients for accomplishing these results are vitamins C and E, carnitine, pantethine, CoQ_{10}, magnesium, and arginine. Magnesium is of additional benefit because of its ability to relax spastic coronary arteries and improve heart function.

Hawthorn berries or extracts offer several benefits to individuals with angina, including coronary artery dilation and improved heart muscle metabolism.

Patients with unstable angina pectoris (characterized by a progressive increase in the frequency and severity of pain, increased sensitivity to precipitating factors, progression of symptoms over several days, and prolonged coronary pain) should be hospitalized.

Diet

The dietary guidelines given in Chapter 44 are appropriate here. An increase of dietary fiber is recommended, especially the gel-forming or mucilaginous fibers (e.g., flaxseed, oat bran, pectin). Onions and garlic (both raw and cooked), vegetables, and fish should also be increased, and the consumption of saturated fats, cholesterol, sugar, and animal proteins should be reduced. All fried foods and food allergens should be avoided. Patients with reactive hypoglycemia should eat regular meals and carefully avoid simple carbohydrates in all forms (e.g., sugar, honey, dried fruit, and fruit juice).

Lifestyle

The individual with angina should not smoke or drink alcohol or coffee. Stress should be decreased by using stress management techniques such as progressive relaxation, meditation, or guided imagery. A carefully graded progressive aerobic exercise program (30 minutes three times a week) is a necessity. Walking is a good exercise with which to start.

Nutritional Supplements

- Vitamin C: 500 to 1500 mg a day
- Vitamin E: 200 to 400 International Units per day
- CoQ_{10}: 150 to 300 mg a day
- L-Carnitine: 500 mg three times a day

- Pantethine: 300 mg three times a day
- Magnesium, preferably bound to aspartate, citrate, or other Krebs cycle intermediate: 200 to 400 mg three times a day
- Arginine: 1000 to 2000 mg three times a day

Botanical Medicines

- *Crataegus oxyacantha* (three times a day)
  - Berries or flowers (dried): 3 to 5 g or as a tea
  - Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp)
  - Solid extract (10% procyanidins or 1.8% vitexin-4′-rhamnoside): 100 to 250 mg
- *Ammi visnaga* (three times a day)
  - Dried powdered extract (12% khellin content): 100 mg three times a day

Aphthous Stomatitis

Michael Traub, ND, DHANP, FABNO, and *Michael T. Murray*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Single or several discrete, shallow, painful ulcers found anywhere on the oral mucosa: labial and buccal mucosa, maxillary and mandibular sulci, gingiva, soft palate, tonsillar fauces, floor of the mouth, ventral surface of the tongue.
- 75% to 90% of recurrent aphthous ulcers (RAU) are 5 to 10 mm in size, shallow, and classified as minor aphthae
- 10% to 15% of RAU are greater than 10 mm in size, deep, and classified as major aphthae.
- Lesions have fairly even borders, are surrounded by an erythematous halo, and eventually are covered by a fibrous pseudomembrane.
- Lesions usually resolve in 7 to 10 days but are often recurrent; larger ulcers may last several weeks to months and can leave a temporary scar.
- It is often difficult to eat due to the discomfort of chewing food and the ensuing pain from scraping the food against the lesion. When located near the soft palate or esophagus, it becomes difficult to swallow due to odynophagia. Pain from aphthae on the lip or tongue can also cause patients to limit their speech.

GENERAL CONSIDERATIONS

Aphthous stomatitis, recurrent aphthous ulcers (RAUs), or canker sores is a common condition, affecting 1% to 78% of the population, depending on country and on data from clinical examination or information from the patient's history.[1] RAU is an idiopathic multifactorial disorder that can cause significant morbidity (Fig. 147.1). Although usually self-limited, in some individuals recurrence can appear continuous.

Inflammatory bowel disease (IBS), celiac disease, systemic lupus erythematosus, AIDS, and Behçet's syndrome are systemic disorders associated with RAUs. Many people mistakenly identify RAUs as herpes simplex, although there is an uncommon form, known as herpetiform RAU, consisting of clusters of aphthae less than 1 mm in diameter (Fig. 147.2). Table 147.1 lists several conditions included in the differential diagnosis of RAU.[2]

The etiology, based on studies of initiating factors, appears to be related to genetics, food sensitivities (especially gluten sensitivity), nutrient deficiency, and hormonal changes.[3] These factors unify the key underlying feature of RAU—genetic predisposition and dysregulation of the immune system in the oral mucosa. Family history is positive in up to 40% of patients.[4] Genetic risk factors that modify individual susceptibility to RAU include HLA alleles and DNA polymorphisms, especially those related to alterations in the metabolism of interleukins, interferon (IFN)-c and tumor necrosis factor (TNF)-a.[5]

Histologically, RAU consists of mucosal ulcerations with mixed inflammatory cell infiltrates. T-helper cells predominate in the preulcerative and healing phases, whereas T-suppressor cells predominate in the ulcerative phase. Other findings associated with immune dysregulation include:

- Lymphomononuclear infiltrate and hemagglutination antibodies against oral mucosa
- Reduced response of lymphocytes to mitogens
- Circulating immune complexes
- Alterations in natural killer (NK) cell activity
- Increased adherence of neutrophils
- Release of tumor necrosis factor-alpha (TNF-α)
- Significant involvement of mast cells in the pathogenesis of RAU
- Reduced levels and function of regulatory T cells in aphthae
- Reduced expression of heat shock protein 27 and interleukin 10 in lesions[6]
- Elevated salivary and serum cortisol[7]
- Elevated Toll-like receptor activity[8]
- Oxidative stress as measured by glutathione and malonidialdehyde[9]

THERAPEUTIC CONSIDERATIONS

Allergies and Environmental Factors

The oral cavity is obviously the first site of contact for ingested and many inhaled allergens. The histological appearance of the lesions and the association of RAU with increased serum antibodies to food antigens and atopy suggest that an allergic reaction may be involved.[10]

Fig. 147.2 Herpetiform recurrent aphthous stomatitis.

TABLE 147.1 Differential Diagnosis for Recurrent Aphthous Stomatitis

- Herpes zoster
- Pemphigus vulgaris
- Candidiasis
- Acute cutaneous lupus erythematosus
- Allergic contact dermatitis
- Cancers of the oral mucosa
- Cicatricial pemphigoid
- Erythema multiform
- Irritant contact dermatitis
- Langerhans cell histiocytosis
- Lichen planus
- Linear IgA dermatosis
- Paraneoplastic pemphigus
- Sweet syndrome
- Reactive arthritis
- Contact stomatitis
- Oral mucosal manifestations of GI disease
- Oral mucosal manifestations of hand-foot-mouth disease
- Oral manifestations of hematological disease
- Drug-induced bullous disorders
- Drug-induced lupus erythematosus
- Drug-induced pemphigus
- IgA pemphigus
- Sarcoidosis
- Pediatric syphilis
- Morsicatio buccalis
- Traumatic eosinophilic ulcer
- Steven-Johnson syndrome

GI, Gastrointestinal; *IgA*, immunoglobulin A.

Furthermore, immunoglobulin E–bearing lymphocytes are significantly increased in aphthous lesions, and mast cells are increased in tissue sections from prodromal stages of recurrent ulcers.[11] Mast cell degranulation plays an important role in the production of the aphthous lesion.[12] An elimination diet has been shown to have good therapeutic results.[13]

The allergen is not necessarily a food. Additional allergens inducing RAU are[14]:

- Benzoic acid
- Cinnamaldehyde
- Nickel
- Parabens
- Dichromate
- Sorbic acid

Elimination of allergens usually brings significant improvement and in many cases complete resolution.[15]

Local, chemical, or physical trauma often initiates aphthae in susceptible individuals (pathergy). Conclusive evidence is lacking to support the role of an infectious etiology, including herpes simplex virus, human herpes virus, varicella zoster virus, cytomegalovirus, and *Helicobacter pylori*.[16,17] Approximately 66% of HIV-positive individuals have herpetiform ulcers and RAUs, which must be differentiated from those caused by antiretroviral medications and bacterial, viral, or fungal infections.[18] RAU can result from a T cell–mediated response to antigens of *Streptococcus sanguis* that cross-react with heat-shock proteins. One controlled study has shown a statistically significant increase in RAU in subjects taking nonsteroidal anti-inflammatory drugs (NSAIDs).[19] Oral hygiene products, chewing gum, candy, acidic foods, and walnuts have been associated with RAU. The avoidance of toothpaste containing sodium lauryl sulfate may be helpful.[20,21] Two studies of traditional Chinese herbal formulas added to toothpastes have shown significant benefit for RAU patients.[22,23]

Gluten Sensitivity

Considerable evidence indicates that sensitivity to gluten is associated with RAU. The incidence of RAU is increased in patients with celiac disease.[24-27] Jejunal biopsy of 33 patients with RAU showed 8 to have the villous atrophy typical of celiac disease, along with histological signs of immunological reactions to food antigens.[24] The remaining patients also exhibited these types of signs but to a lesser degree. Although villous atrophy is a prerequisite for the diagnosis of celiac disease, gluten sensitivity may take other forms: Gluten may act directly on the oral mucosa or produce functional changes in the small intestine by immunological or other mechanisms that are distinct from those causing the characteristic abnormalities of celiac disease.[26] An underlying gluten-sensitive enteropathy could also contribute to nutritional deficiencies. Withdrawing gluten from the diet results in complete remission of RAU in patients with celiac disease and some improvement in others.[24-27]

Even in the absence of villous atrophy, gluten sensitivity can produce RAU. For example, in one small study, three of four gluten-sensitive patients identified by positive antibodies to alpha-gliadin but with normal small intestinal biopsy responded dramatically to a gluten-free diet.[28]

We recommend ruling out celiac disease by measuring tissue transglutaminase and reticulin antibodies in any patient presenting with RAU.

Dietary Factors

A study of students at Beijing University of Chinese Medicine used a questionnaire to investigate the occurrence of RAU.[29] Researchers found that bedtime later than 11 PM, dry mouth, constant thirst, and frequent intake of carbonated beverages were independent risk factors of RAU. The data also supported avoidance of fried food, sweet drinks, pineapple, and spicy foods, moderate intake of nuts, and cautioned intake of fruits.

Mechanical Injuries

In many RAU patients, lesions appear on the oral mucosa shortly after mechanical trauma to the area.[30] Accidental bites of the mucosal tissue, hard brushing of the mucosal tissue, or injuries from rigid solid foods can lead to posttraumatic aphthae.

Hormonal Changes

RAU may occur or increase in severity during the luteal phase of the menstrual cycle. A case which responded to implants of low doses of testosterone was published in the *British Medical Journal* in 1981.[31]

Stress

Stress is often a precipitating factor in RAU, suggesting a breakdown in normal host protective factors.[32] Elevated urinary and salivary cortisol levels demonstrate a significant correlation as markers for stress in patients with RAU.[33]

Nutrient Deficiency

The oral cavity is often the first place that nutritional deficiency becomes visible to the physician because of the high turnover rate of the mucosal epithelium. Although several nutrient deficiencies can lead to aphthous stomatitis, thiamin appears to be the most significant. In one study seeking to examine whether thiamin deficiency is associated with RAU, the level of transketolase (a thiamin-dependent enzyme) was determined in 70 patients with RAU and 50 patients from a control group.[34] Low levels of transketolase were found in 49 of 70 patients with RAS, compared with only 2 of 50 among the controls. These results clearly demonstrate an association between low levels of thiamin and RAU.

Several other studies show that nutrient deficiencies are much more common in RAU sufferers than in others. For example, a study of 330 patients with recurrent aphthous stomatitis (RAS) found that 47 (14.2%) were deficient in iron, folate, vitamin B_{12}, or a combination of those nutrients.[35] In another study of 60 patients, 28.2% were deficient in thiamin, riboflavin, or pyridoxine.[36] When the patients' deficiencies were corrected, the majority had complete remission. Lower dietary intake of folate and vitamin B_{12} is common in persons with RAU, and treatment with 1000 mcg per day has shown benefit regardless of serum vitamin B_{12} levels.[37] Additional studies have shown similar deficiency rates for the same nutrients and equally positive responses to supplementation.[38]

Zinc supplementation has also been shown to be helpful. A pilot study showed a significant association between zinc deficiency and RAU. In the study, 28% of 25 subjects with RAU had zinc deficiency compared with 4% of 25 healthy controls.[39] In one double-blind study, 40 patients with RAU were given either zinc sulfate (220 mg providing 50 mg of elemental zinc) or a placebo once daily for 1 month.[40] Results showed that the levels of serum zinc before treatment were below the normal value in 42.5% of the patients with RAU. After 1 month of zinc therapy, the aphthae reduced and did not reappear for 3 months.

Low nutrient status may explain why patients with RAU have an increased oxidant/antioxidant ratio in comparison with healthy controls. A small study of adolescents showed a reduction in the incidence of RAU and associated pain from 2000 mg per day of ascorbate.[41] In another study, superoxide dismutase, glutathione peroxidase (GSHPx), and catalase (CAT) activities as well as and malondialdehyde (MDA) and antioxidant potential (AOP) levels were measured in plasma and erythrocytes from 22 patients with RAS and 23 controls.[42] Researchers found decreased CAT and GSHPx activities and AOP levels in the erythrocytes as well as decreased AOP and increased MDA plasma levels in patients with RAU in comparison with control subjects. This study clearly demonstrated that enzymatic and nonenzymatic antioxidant defense systems are impaired in patients with RAU.

In an Italian study, a multivitamin, a proprietary topical drug, and the long-lasting anesthetic ropivacaine were used separately and in combination for patients with RAU.[43] Researchers determined the combination of the three agents was a reliable therapy for patients with oral aphthosis, providing significant reduction of pain and length of healing time.

Oral microbiome research suggests that an imbalance of the oral mucosal microbiome, rather than individual infectious pathogens, may play a role in initiating RAU. The findings raise the question of whether the presence of a lesion alters the microbiota of the oral cavity or a change in microbiota triggers the development of aphthosis. There is likely interplay between the two. One study compared the buccal microbiota of patients with RAU with control subjects and concluded that differences in bacteria were related to the presence of lesions during sampling. Bacterial diversity in the oral microbiota were similar in patients with RAU and controls.[44] Another study found that RAU is associated with dysbiosis of the mucosal and salivary microbiota and identified associations between RAU risk and decreased *Streptococcus salivarius* and increased *Acinetobacter johnsonii*.[45]

Quercetin

Quercetin is known to inhibit mast cell degranulation, basophil histamine release, and the formation of other mediators of inflammation.[46] The antiallergy drug disodium cromoglycate, a compound similar in structure and function to quercetin, has been shown to be effective in the treatment of RAU, resulting in more ulcer-free days and mild symptomatic relief.[47] Other flavonoids (acacetin, apigenin, chrysin, and phloretin but not catechin, flavone, morin, rutin, or taxifolin) have also shown antiallergy effects similar to those of disodium cromoglycate.[46]

Deglycyrrhizinated Licorice

Deglycyrrhizinated licorice (DGL) may be effective in promoting the healing of RAU. In one study, 20 patients were instructed to use a solution of DGL as a mouthwash (200 mg of powdered DGL dissolved in 200 mL of warm water) four times daily.[48] Of the 20 patients, 15 (75%) experienced 50% to 75% improvement within 1 day, followed by complete healing of the ulcers by the third day. DGL in tablet form may be more convenient and effective. Topical preparations containing the solid extract of licorice root are also available (e.g., Canker Cover made by Quantum Health).

A randomized controlled trial showed significant efficacy of a paste containing *Myrtus communis* (myrtle) for RAU when applied four times daily for 6 days.[49]

THERAPEUTIC APPROACH

Data suggests that no single factor is solely responsible for the initiation of aphthous lesions. However, an underlying genetic tendency may be present, the expression of which is facilitated by multiple factors. Considerable evidence suggests that gluten sensitivity may be a contributing factor in some patients. In addition, nutrient deficiencies must be corrected and anti-inflammatory nutrients prescribed. A randomized controlled trial showed significant benefit from individualized homeopathic treatment, when the medicine was administered in 6 c potency as oral liquid for two doses only.[50]

Diet

The patient's diet should be free of known allergens and all gluten sources if gluten sensitivity is present. Fried foods, carbonated sodas, and sweet drinks should be avoided. Acidic foods (tomatoes, citrus, pineapple) should also be avoided if found to trigger aphthae.

Nutritional Supplements

- High-potency multivitamin and mineral formula
- Calcium ascorbate: 2000 mg per day
- Sublingual vitamin B_{12}: 1000 mcg per day
- Zinc lozenges with Echinacea and Vitamin C (available OTC, containing 23 mg of zinc citrate/gluconate)
- "Kanka" liquid treatment for canker sores (an OTC product containing zinc oxide and benzocaine)

Botanical Medicines

- Deglycyrrhizinated licorice (DGL): one to two 380-mg chewable tablets 20 minutes before meals
- Topical licorice root preparations applied as needed

Asthma

John Nowicki, ND, and *Michael T. Murray*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Recurrent attacks of dyspnea, cough, and expectoration of tenacious mucoid sputum
- Prolonged expiration phase with generalized wheezing and musical rales
- Eosinophilia, increased serum immunoglobulin E (Ig E), positive food/inhalant allergy tests

GENERAL CONSIDERATIONS

Bronchial asthma is a hypersensitivity disorder characterized by bronchospasm, mucosal edema, and excessive excretion of viscous mucus that can lead to ventilatory insufficiency. Asthma affects approximately 7% of the population of the United States and causes 4210 deaths per year. Although it occurs at all ages, it is most common in children below age 10. There is a 2:1 male:female ratio in children, which equalizes by the age of 30.[1]

Major factors involved in asthma include the following:

- Hypersensitivity of the airways
- Beta-adrenergic blockade
- Cyclic nucleotide imbalance in airway smooth muscle
- Release of inflammatory mediators from mast cells

The incidence of asthma is rising rapidly in the United States, especially in children. Reasons often given to explain the rise in asthma include the following:

- Increased stress on the immune system due to factors such as greater chemical pollution in the air, water, insect allergens from mites and cockroaches, and food
- Earlier weaning and earlier introduction of solid foods to infants
- Food additives
- Higher incidence of obesity[2]
- Genetic manipulation of plants, resulting in food components with greater allergenic tendencies

In addition, multiple genetic variables may make certain individuals more susceptible to asthma. For example, researchers have demonstrated that a deficiency in the glutathione S-transferase M1, a gene involved in response to oxidative stress, may also make those with this deletion more susceptible to asthmatic attacks, thus supporting the need for antioxidant therapy in these individuals.[3] The *ADAM33* gene on chromosome 20p13 has been linked to the pathogenesis involved in airway remodeling (see later mediators section) and is probably a factor in corticosteroid resistance in some patients with asthma.[4] Other research teams have identified genes on chromosomes 7 and 12 as probable players in the pathogenesis of asthma.[5,6]

Major Categories

Asthma has typically been divided into two categories: extrinsic and intrinsic. Extrinsic or atopic asthma is generally considered an immunologically mediated condition with a characteristic increase in serum IgE. Intrinsic asthma is associated with a bronchial reaction that is due not to antigen–antibody stimulation but rather such factors as chemicals, cold air, exercise, infection, agents that activate the alternative complement pathway, and emotional upset.

*Previous edition contributor

Asthma is often clinically classified according to the frequency of symptoms, forced expiratory volume in 1 second (FEV_1), and peak expiratory flow rate.

Diagnostic Considerations

The U.S. National Asthma Education and Prevention Program (NAEPP) guidelines for the diagnosis and management of asthma (Table 148.1) state that a diagnosis of asthma begins by assessing whether any of the indicators is present:

- Wheezing—high-pitched whistling sounds on expiration—especially in children (Lack of wheezing and a normal chest examination do not exclude asthma.)
- History of any of the following:
  - Cough, particularly worse at night
  - Recurrent wheeze
  - Recurrent difficulty in breathing
  - Recurrent chest tightness
- Symptoms occur or worsen in the presence of:
  - Exercise
  - Viral infection
  - Animals with fur or hair
  - House dust mites (in mattresses, pillows, upholstered furniture, carpets)
  - Mold
  - Smoke (tobacco, wood)
  - Pollen
  - Changes in weather
  - Strong emotional expression (laughing or crying hard)
  - Airborne chemicals or dusts
  - Menstrual cycles
- Symptoms that occur or worsen at night, awakening the patient

Spirometry plays a central role in the management of asthma and should be performed at the time of initial diagnosis, after treatment is initiated and symptoms are stabilized, whenever control of symptoms deteriorates, and every 1 or 2 years on a regular basis.

Causes

Asthma is caused by a complex interaction of environmental and genetic factors. The strongest risk factor for developing asthma is a history of atopic disease. The presence of atopic dermatitis increases the risk of asthma by three- to fourfold. Allergies and the response of the immune system are obviously involved in asthma.

Inflammation and Th1/Th2 Balance

Imbalances in T-helper cell immune responses appear to be a fundamental mechanism of immunologically mediated airway inflammation. $CD4^+$ T-helper cells are generally categorized into Th1 and Th2 cells. Via the release of interferons and interleukin 2, the Th1 pathway is increased in the immunological responses to cancer, multiple sclerosis, viruses, and type IV hypersensitivities. Th2 responses are related to increases in interleukins 4, 6, 9, and 13; IgE, eosinophilia; and activated B-cell humoral immunity. Clinical conditions that reflect increased Th2 responses include asthma and atopic syndromes as well as allergies. Research involving asthmatic subjects demonstrates a normal Th1 gene expression but a constant upregulation of Th2-specific genes, leading to Th2 predominance.[7] Although it is unclear what the cause of this exaggerated Th2 response is in asthma, it seems that genetics, fungi, metal toxicities, nutrition, viruses, and pollution are factors in this upregulation (Fig. 148.1).[8] The "hygiene hypothesis" is also gaining ground in the standard medical literature. It asserts that by minimizing exposure to infectious agents owing to lifestyle choices based on hygienic concerns, the dominance of Th2 immune responses to environmental allergens has been favored and thus also the probable encouragement of asthma and atopic diseases.[9,10]

Mediators

Both extrinsic and intrinsic factors involved primarily with Th2 imbalances trigger the cytokine-activated release of mast cell–derived chemical mediators. These mediators are responsible for bronchoconstriction, mucus production, and other signs and symptoms in the majority of cases. These mediators are either preformed within granules or generated from membrane-bound phospholipids. The preformed mediators include histamine, various chemotactic peptides such as eosinophilic chemolactic factor (ECF) and high-molecular-weight neutrophil

TABLE 148.1 National Asthma Education and Prevention Program (NEAPP) Classification of Asthma Severity Before Treatment in Adults and Youths 12 Years and Older[a]

Component of Severity		PERSISTENT		
	Intermittent	Mild	Moderate	Severe
Symptoms	≤2 days/week	>2 days per week but not daily	Daily	Throughout the day
Night-time awakenings	≤2x/month	3–4×/month	>1×/week but not nightly	Often 7×/week
Short-acting β-agonist use for symptoms	≤days/week	>2 days per week but not > 1×/day	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Pulmonary function	Normal FEV_1 between exacerbations; FEV_1 ≥80% predicted; FEV_1/FVC normal	FEV_1 <80% predicted; FEV_1/FVC normal	FEV_1 ≥60% but <80% predicted; FEV_1/FVC reduced ≥5%	FEV_1 <60%; FEV_1/FVC reduced >5%
Exacerbations (consider frequency and severity)	0–1 per year		≥2 per year	

FEV_1, Forced expiratory volume in 1 second; *FVC*, forced vital capacity.
[a]Severity level is determined in accordance with the worst impairment category.
Data from National Asthma Education and Prevention Program, Third Expert Panel on the Diagnosis and Management of Asthma. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007.

chemotactic factor (NCF), proteases, glycosidases, and heparin proteoglycan. The membrane-derived agents include lipoxygenase products such as leukotrienes (LTs) and the so-called slow-reacting substance of anaphylaxis (SRS-A), prostaglandins (PGs), thromboxanes (TXs), and platelet-activating factor (PAF).

These mediators are diverse in chemical composition and modes of action and account for many of the signs and symptoms of asthma. Their actions include bronchial smooth muscle constriction (histamine, LTC_4, LTD_4 and LTE_4, PGF_{2a}, PGD_2, and PAF), mucosal edema (increased permeability, histamine, LTC_4, LTD_4, and PAF), vasodilation (PGD_2 and PGE_2), mucous plugging (histamine, hydroxyeicosatetraenoic [HETE] acids, and LTC_4), inflammatory cell infiltrate (NCF, ECF-A, HETEs, LTB_4, and PAF), and desquamation of epithelium (proteases and glycosidases, together with lysosomal enzymes and basic proteins derived from neutrophils and eosinophils). In chronic asthma, eventual airway remodeling is a consequence of these mediator effects. The cellular and mediator elements responsible for airway remodeling involve the anomalous interface between the airway epithelium and the underlying mesenchymal tissues. This process is highlighted by the induction of growth factors that encourage fibroblastic and smooth muscle proliferation and the deposition of matrix proteins, which cause the thickening of the airway wall linked to bronchial hyperresponsiveness and fixed airflow obstruction.[4]

Mild episodic asthma differs from moderate to severe sustained asthma in that the latter is largely dependent on a subacute/chronic inflammation of the bronchi with infiltration of eosinophils, neutrophils, and mononuclear cells, whereas episodic asthma is due primarily to bronchial smooth muscle contraction.

Lipoxygenase Products

The most potent chemical mediators in asthma are the lipoxygenase products (i.e., leukotrienes) (Fig. 148.2). The leukotrienes composing SRS-A (LTC_4, LTD_4, LTE_4) are 1000 times more potent as stimulators of bronchial constriction than histamine. Researchers have observed that patients with asthma have an imbalance in arachidonic acid metabolism, leading to a relative increase in lipoxygenase products.[11] Platelets from patients with asthma show a 40% decrease in cyclooxygenase-derived metabolites and a 70%

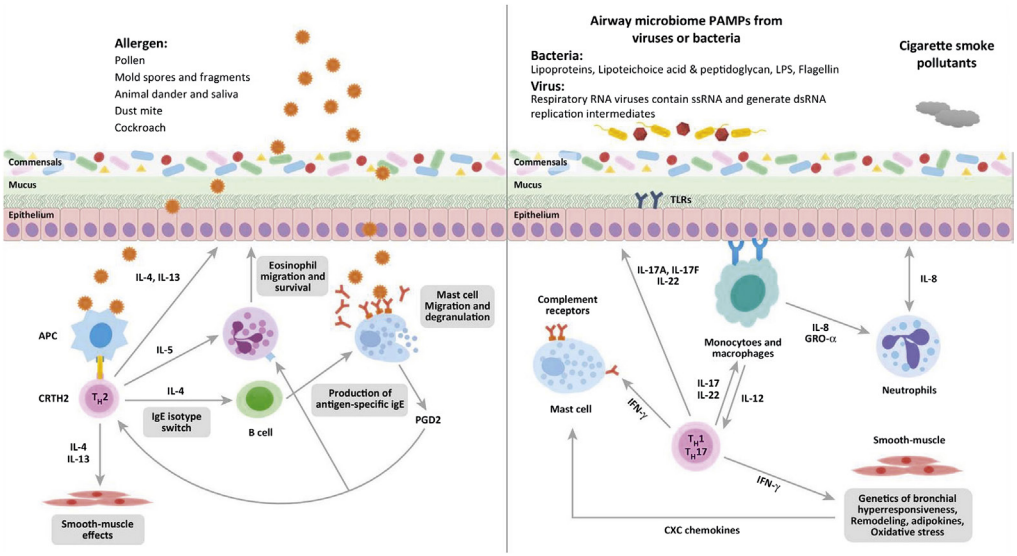

Fig. 148.1 Potential triggers and innate immune response of eosinophilic (Th2-dependent) and neutrophilic (non-Th2-dependent) asthma. (From Earl CS, An SQ, Ryan RP. The changing face of asthma and its relation with microbes. *Trends Microbiol.* 2015;23[7]:408–418. PubMed PMID: 25840766.)

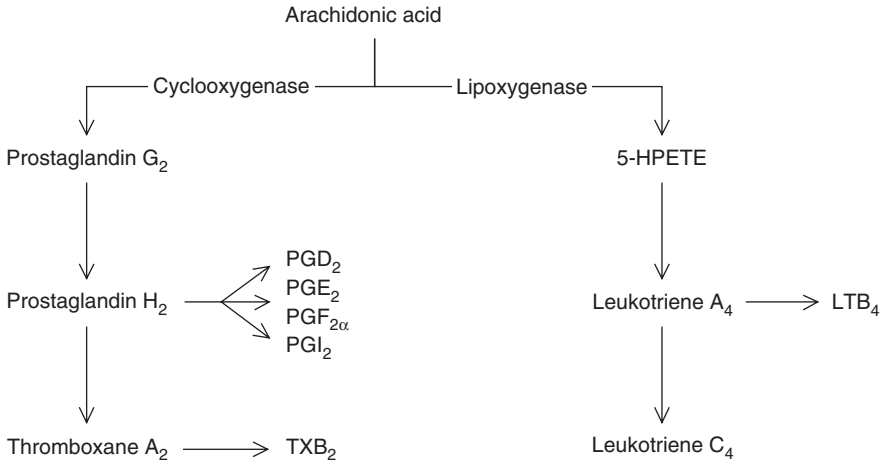

Fig. 148.2 Arachidonic Acid Metabolism.

increase in lipoxygenase products. This pathophysiologic alteration is further aggravated in "aspirin-induced asthma." Aspirin and other nonsteroidal anti-inflammatory drugs (e.g., indomethacin, phenylbutazone) inhibit cyclooxygenase while promoting lipoxygenase.[12,13] The net result is a shunting of arachidonic acid toward the lipoxygenase pathway and the production of excessive levels of leukotrienes.

Autonomic Nervous System

The relationship between the autonomic nervous system and bronchial asthma represents an interaction between parasympathetic and sympathetic innervation and beta$_2$ adrenergic receptors (which are localized in lung tissue and react to circulating catecholamines).[14] Stimulation of the parasympathetic vagus nerve results in airway constriction. This vagal mechanism involves the release of acetylcholine at the synapse, subsequent binding to its receptor on smooth muscle tissue, and subsequent formation of cyclic guanosine monophosphate (cGMP). Accumulation of cGMP or a relative deficiency in cyclic adenosine monophosphate (cAMP), or both, will result in constriction of the airway smooth muscle and degranulation of mast cells and basophils. Decreased sympathetic activity or diminished beta$_2$ receptor numbers or sensitivity also promote the cyclic nucleotide imbalance. Some of the mediators discussed earlier block beta$_2$ receptors and elevate cGMP levels both directly and indirectly.

Adrenal Gland

The activity of the adrenal gland is important in asthma because of the hormones cortisol and epinephrine. Cortisol is an effective prime activator of beta receptors, and epinephrine is considered to be the prime stimulator of beta receptors. It has been suggested that during asthmatic attacks, there is a relative deficiency of cortisol and epinephrine (which stimulates beta$_2$ receptors to catalyze the formation of cAMP from AMP). This leads to a decrease in the cAMP:cGMP ratio, resulting in bronchial constriction.

Vaccinations

Pertussis Vaccine

An evaluation of health criteria among 448 children and adolescents in Britain who had received only breast milk for the first 6 months of life and, in particular, on the first day after birth produced some interesting findings.[15] All of the children were weaned after 1 year of age and were older than 4 years at the time the parents responded. The mean age was 7.87 years. In response to the question "Has your child ever been diagnosed as asthmatic?" there were 30 positive answers (6.72%). The surprise came when the researchers classified the respondents according to whether they had received the pertussis vaccine.

Among the 243 immunized children, 26 were diagnosed as having asthma (10.69%). In contrast, of the 203 children who had not been immunized, only 4 had asthma (1.97%). The relative risk of developing asthma from the pertussis vaccine was 5.43 in this study. Even though all the children who received the pertussis vaccine received other vaccinations, the researchers suspected that the statistical evidence focused on pertussis. Among the children who did not receive the pertussis vaccine, most had received some other vaccination. Of the 91 subjects of the study who received no vaccines, only 1 had asthma, compared with 3 with asthma in the 112 who had other vaccinations. Therefore the relative risk of developing asthma is about 1% in children receiving no immunizations, 3% in those receiving vaccinations other than pertussis, and 11% in those receiving the pertussis vaccine. Another notable finding in the group not immunized to pertussis is that 16 developed whooping cough compared with only 1 in the immunized group.

Influenza Vaccine

One evaluation of more than 9600 children was employed to determine the safety of the cold-adapted trivalent intranasal influenza virus vaccine in children. Although this relatively new vaccination was deemed safe for children and adolescents, a significantly increased relative risk of 4.06 was observed in children 18 to 35 months of age for asthma and associated reactive airways disease.[16]

Environmental Toxins

The atmosphere is awash with a mixture of toxic substances, and inhalation of these toxicants can contribute to significant injury to the pulmonary system. Industrial materials, particulates from mining and combustion, agricultural chemicals, cigarette smoke, ozone, nitrogen oxides, and toxic metals have all been implicated in the pathophysiology of lung disease. Although these agents belong to different classes of chemicals, they may activate similar biochemical pathways, including inducing the recruitment and activation of macrophages, activation of mitogen-activated protein kinases, inhibition of protein synthesis, and production of interleukin-1 beta.[17]

Particulate Matter

Rapid industrialization and urbanization in many parts of the world have exposed more people to air pollutants now than at any point in human history. Exposure to $PM_{0.1}$ activates signaling pathways (e.g., nuclear factor kappa B [NF-κB], nicotinamide adenine dinucleotide phosphate [NADPH] oxidase) that induce inflammation, generate reactive oxygen species, and lead to cell death, which may explain the association between long-term particle accumulation and chronic respiratory diseases.[18] Several studies have explored the relationship between childhood asthma and respiratory problems with exposure to vehicle exhaust. Children in the Netherlands living within 100 m of a freeway had significantly more cough, wheeze, rhinitis, and asthma than those living farther away.[19] Among children living within 150 m of a main road, the risk of wheeze increased with increasing proximity by an odds ratio of 1.17 (95% confidence interval [CI] 1.01–1.36) per 30-m increment.[20]

Fine and ultrafine diesel exhaust particles can reach small airways, including the alveolar/gas-exchange regions of the lung, exacerbating asthma symptoms. Direct exposure to diesel exhaust has been linked to the development of asthma, which persists even after exposure ceases.[21]

Ozone

Asthma-related visits to the emergency department (ED) are associated with ozone levels. A study in New Jersey reported that ED visits for asthma occurred 28% more frequently when the mean ozone levels were greater than 0.06 ppm than when they were less than 0.06 ppm.[22] Children exposed to higher levels of ground-level ozone have greater rates of asthma and rhinitis than children in areas with less ozone.[23]

Acrolein

Acrolein (a contact herbicide used, for example, to control weeds and algae in irrigation canals) is a potent respiratory irritant and may have a prominent role as an environmental trigger of asthma attacks through air-pollutant emissions and tobacco smoke. Chronic residential exposure to outdoor acrolein was found to increase the prevalence-odds of having at least one asthma attack in the previous 12 months by approximately 8%.[24]

Arsenic

Chronic upper and lower respiratory problems, including dyspnea, asthma, and cough, were noted in a study from India with persons

consuming groundwater with arsenic levels between 11 and 50 ppm.[25] A dose-related decrease in lung function exists with increasing levels of baseline water and urinary arsenic.[26] For every 1-standard-deviation increase in baseline water arsenic exposure, there was a decrease in FEV_1 (–46.5 mL; $p = 0.0005$) and forced vital capacity (FVC; –53.1 mL; $p < 0.01$). This inverse association between arsenic exposure and FVC was consistent across sexes, remained significant in never-smokers, and was strongest in male smokers.

Cobalt

Respiratory effects from cobalt inhalation are well documented. Asthma, pneumonia, wheezing, respiratory irritation, and fibrosis have all been reported as occupational health hazards, especially in workers exposed to cobalt metal powder, cobalt salts, and cobalt-containing dusts.[27] Exposure to cobalt alone produces an allergic-like asthmatic condition.

Occupational Agricultural Exposure

Occupational exposures in the agricultural industry are associated with numerous lung diseases, including asthma. Production agriculture produces a variety of exposures, including organic dusts from livestock barns and confinements and chemical toxicants from fermentation and bacterial degradation of grain and animal wastes, pesticides, microorganisms, and bacterial endotoxins. Asthma-like syndrome is associated with swine confinement workers and grain elevator operators, with acute symptoms occurring in as many as 50%.[28]

Pesticides may contribute to asthma among farmers and has been associated with wheeze among U.S. farmers. For farmers, the organophosphates chlorpyrifos, malathion, and parathion have all been positively associated with wheeze.[29] Farmers are more likely to be diagnosed with nonatopic asthma than atopic asthma compared with other occupational groups, although high-pesticide-exposure events have been associated with a doubling of both allergic and nonallergic asthma in farmers.[30] Coumaphos, heptachlor, parathion, and ethylene dibromide all have odds ratios of greater than 2.0 for allergic asthma.

Mold

Exposure to mold and dampness in buildings is a major factor in the asthma epidemic. Studies have shown that dampness or mold in houses causes 21% of asthma in the United States and a 30% to 50% increase in asthma and asthma-related health problems.[31] The incidence may be higher; one study found that 67% of adult-onset asthma developed after working in a water-damaged office building.[32] The primary mechanisms for damp-building toxicity include immunological (e.g., stimulation, suppression, autoimmunity), toxic (e.g., neurotoxicity, genotoxicity, reproductive damage), and inflammatory. The Institute of Medicine report commissioned by the Centers for Disease Control and Prevention (CDC) and released in 2004 concluded that respiratory conditions, including asthma, have sufficient evidence of causation by mold or damp buildings.[33]

Drugs

Aspirin/NSAIDs

Aspirin-exacerbated respiratory disease (AERD) is an asthma phenotype and has a prevalence of 2% to 25% in the asthma population.[34] Precipitation of asthma attacks by the ingestion of aspirin and other NSAIDs is considered a hallmark of this syndrome. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit cyclooxygenase and promote lipoxygenase. The net result is a shunting of arachidonic acid toward the lipoxygenase pathway and the production of excessive levels of leukotrienes. AERD is chronic, and the respiratory mucosal inflammatory disease persists even with avoidance of cyclooxygenase 1 (COX-1) inhibitors.

Beta Blockers

In almost all patients with asthma, nonselective beta blockers cause bronchoconstriction and increase bronchial hyperresponsiveness to methacholine and histamine.[35] The regular use of noncardioselective beta blockers was demonstrated to cause a 13.5% decrease in FEV_1. Topical applications should be avoided as well because severe bronchoconstriction and fatal attacks have been reported with topical ophthalmic application of beta blockers.[36]

Other

Several other medications have been shown to cause bronchospasm or mimic asthma, including angiotensin-converting enzyme (ACE) inhibitors, cholinergic agonists, cholinomimetic alkaloids, chemotherapeutic agents, diuretics, corticosteroids, antibiotics, and radiocontrast dyes.[37]

THERAPEUTIC CONSIDERATIONS

As with many complex diseases, the initial cause or causes of asthma (e.g., hypochlorhydria) may initiate a sequence of events that becomes self-propagating (e.g., hypochlorhydria-induced food allergies leading to increased intestinal permeability and then to increased susceptibility to food allergy). Effective treatment requires control of both the initiating cause or causes and the induced physiological abnormalities.

General

Hypochlorhydria

Fractional gastric analyses in 200 children with asthma showed that 80% of them had gastric acid secretions below normal levels.[38] Hypochlorhydria may initiate a sequence of events that becomes self-propagating. The high occurrence of decreased gastric acid output may predispose these children to food allergies and has a major effect on the success of rotation or elimination diets and, if not corrected, on the development of additional food allergies (i.e., hypochlorhydria-induced food allergies leading to increased intestinal permeability, which then increases the susceptibility to food allergy).

Increased Intestinal Permeability

The presence of food allergies is thought to be responsible for patients with asthma having been shown to have "leaky guts."[39] Altered intestinal barrier function permits increased dietary antigen transport across the intestinal barrier and subsequent exposure of these antigens to the mucosal immune system, leading to the development of antigen-specific responses. This overwhelms the immune system, increasing the likelihood of developing additional allergies as well as increasing the circulation of bronchoconstrictive compounds. It is essential to identify offending foods as soon as possible so as to avoid the development of further allergies.

Candida albicans

An overgrowth of the common yeast *Candida albicans* in the gastrointestinal tract has been implicated as a causative factor in allergic conditions, including asthma. Apparently, the acid protease produced by *C. albicans* is the responsible allergen.[40] Appropriate anticandidal therapy may result in significant clinical improvement of asthma in many cases.

Food Additives

Vitally important in the control of asthma is the elimination of food additives.[41] Artificial dyes and preservatives are widely used in foods, beverages, and drugs. The most common coloring agents are azo dyes—tartrazine (yellow dye no. 5), sunset yellow, amaranth, and coccine (red)—and the nonazo dye pate blue. The most commonly used

preservatives in food are sodium benzoate, 4-hydroxybenzoate esters, and sulfur dioxide.

Tartrazine, benzoates, sulfur dioxide, and sulfites have been reported to cause asthma attacks in susceptible individuals.[41,42] Tartrazine is commonly found in processed foods, vitamin preparations, and prescription drugs and acts as a cyclooxygenase inhibitor, thus inducing asthma, especially in children. Approximately 4% to 14% of individuals with asthma are sensitive to acetylsalicylic acid and may react to this dye.[43]

Various sulfites are commonly used in prepared foods. It is estimated that 2 to 3 mg of sulfites are consumed each day by the average U.S. citizen, whereas an additional 5 to 10 mg are ingested by wine and beer drinkers.[42] The largest sources are the salads, vegetables (particularly potatoes), and avocado dip served in restaurants. A customer can ingest 25 to 100 mg of metabisulfite in as little as one restaurant meal. It has been postulated that a molybdenum deficiency may be responsible for sulfite sensitivity.[44] Sulfite oxidase, the enzyme responsible for neutralizing sulfites, is molybdenum dependent.

Salt

Strong evidence indicates that an increased intake of salt increases bronchial reactivity and mortality from asthma.[45,46] Dietary patterns of high fat, sugar, and salt are significantly associated with asthma prevalence (odds ratio [OR] = 1.13, 95% confidence interval [CI] = 1.03, 1.24) and current severe asthma (OR = 1.23, 95% CI = 1.03, 1.48).[47] The degree of bronchial reactivity to histamine is positively correlated with the 24-hour urinary sodium excretion and rises with increased dietary sodium. Because the severity of asthma correlates with the degree of bronchial reactivity, the severity of asthma can clearly be influenced by alterations in dietary sodium consumption.

Estrogen and Progesterone

For female patients who experience severe asthma symptoms, it may be useful to consider therapeutic regimens that encourage a decrease in hormonal fluctuations. Some studies find estrogen withdrawal to increase lung contractility.[48] However, other studies find little relationship between estrogen use and asthmatic symptoms.[49–51] Estrogen[52] and progesterone are both known to act as smooth muscle relaxants. It may be that the airways of premenopausal and postmenopausal women may respond differently to exogenous hormone replacement and therefore need to be assessed independently with this intervention.

One interesting review of more than 90 papers published from 1966 to 2001 found that during the premenstrual and menstrual phases, when hormone levels are low, women with asthma have been found to experience increased asthma exacerbations, increased hospitalizations for asthma, and decreased pulmonary function. Additionally, women who experienced decreased fluctuations in hormone levels either by becoming pregnant or by starting oral contraceptive therapy tended to have improvements in pulmonary function and fewer requirements for medication.[48] Natural hormone replacement may offer a safer approach than synthetic hormones, although no studies to verify the safety or efficacy of these natural forms of female sex hormones have been conducted. In the longer term, natural therapeutics designed to balance estrogen and progesterone, along with specific recommendations from this chapter, may offer the most risk-free relief for those premenopausal and postmenopausal women who suffer from asthmatic exacerbations (see Chapters 196 and 212).

Dehydroepiandrosterone

Decreased levels of dehydroepiandrosterone (DHEA) have been shown to be common in postmenopausal women with asthma compared with matched controls.[53] One study of 55 asthmatic and 20 healthy postmenopausal women aged 48 to 60 before hormone replacement therapy and after 6 months of transdermal 17b-estradiol (E2) and medroxyprogesterone acetate treatment demonstrated a significant increase in serum DHEA levels in the asthmatic group, with no change in the control group.[54] Whether DHEA itself produces any therapeutic benefit in asthma remains to be demonstrated; however, given its important role in proper immune function, an ability to produce positive effects is certainly possible.

Melatonin

There is some concern regarding elevated melatonin levels contributing to increased airway inflammation in patients with nocturnal asthmatic exacerbations.[55,56] In a study of people with nocturnal asthma, the peak measured serum melatonin level was significantly and inversely correlated with overnight change in FEV_1 in subjects with nocturnal asthma but not in those with nonnocturnal asthma or healthy controls. An interesting note is that this study observed a delayed release of melatonin in the patients with nocturnal asthma. Therefore it is theoretically possible that supplementation combined with an earlier sleep regimen may help regulate this late peaking of melatonin and possibly mitigate symptoms. Nevertheless, the practitioner may want to avoid giving this supplement to patients with asthma, especially the nocturnal type, until more studies are conducted regarding melatonin's immunotherapeutic effect.

Diet

Beneficial Foods

A number of publications corroborate the notion that people who have a diet rich in fruits and vegetables have a lower risk of poor respiratory health.[57–59] This effect is most likely due to the increased levels of antioxidants in such foods. One epidemiological review[60] found that among children, consumption of fresh fruit, particularly fruit high in vitamin C, has been related to a lower prevalence of asthma symptoms and better lung function. This effect was observed even at low levels of fruit consumption (one or two servings per week vs. fewer than one serving per week), which suggests that a small increase in fruit intake could be beneficial. This same review discussed the consumption of fish as also being related to lower airway hyperreactivity among children and better lung function in adults.

A study of Scottish adults also found a dose–response relationship between fruit consumption and pulmonary function, whereby increased fruit consumption led to decreases in phlegm and better pulmonary function.[61] In addition, a "reasonable" intake of fruit (>180 g/day), whole grains (>45 g/day), and moderate alcohol consumption (one to three glasses a day) was associated with a 139-mL-higher FEV_1 and a 50% lower prevalence of chronic obstructive pulmonary disease versus diets that did not meet these intake requirements.[57] Finally, one study of 607 asthma patients and 864 controls highlighted apples and moderate red wine consumption as sources of antioxidants that decreased asthma severity.[62]

Dietary intake of soy foods may be helpful because the soy isoflavone genistein is associated with reduced severity of asthma. Although this effect may be due to some antioxidant action, studies have also shown that genistein is able to block eosinophil leukotriene C(4) synthesis and inhibit the pathway of NF-κB and tumor necrosis factor-α (TNF-α) in patients with asthma.[63–65]

Food Allergy

Many studies have indicated that food allergies play an important role in asthma (see Chapter 14).[66–70] Adverse reactions to food may be immediate or delayed. Double-blind food challenges in children have

shown that immediate-onset sensitivities are usually due (in decreasing order of frequency) to egg, fish, shellfish, nuts, and peanuts, whereas the foods most commonly associated with delayed onset include (in decreasing order of frequency) milk, chocolate, wheat, citrus, and food colorings.[68] Elimination diets have been successful in identifying allergens and treating asthma and are a particularly valuable diagnostic and therapeutic tool in infants.[71] Elimination of common allergens during infancy (first 2 years) has been shown to reduce allergic tendencies in high-risk children (e.g., strong familial history).[72]

Breastfeeding

Many studies have demonstrated the protective effect of breastfeeding in the prevention of asthma. One study examined the association of breastfeeding and the presence of chronic respiratory symptoms among 5182 Brazilian schoolchildren 7 to 14 years of age. Ninety percent of the mothers in this population had breastfed their infants. After adjusting for potential confounding factors, these researchers revealed that children who had not been breastfed were more likely to have a medical diagnosis of asthma.[73] One Iraqi study additionally showed that the vitamin C content of breast milk was significantly correlated with the maternal intake of vitamin C; low vitamin C intake by the mother translates to low intake by the child, thus leaving him or her more susceptible to oxidative stress.[74]

The Canadian Asthma Primary Prevention study collected 2 years of data in which researchers chose 545 infants who were considered at high risk for asthma on the basis of a history of familial atopy. These children were broken down into control and intervention groups. The interventions included (1) measures to control house dust; (2) recommendations for avoidance of pets, environmental tobacco smoke, and day care during the first year; and (3) only breastfeeding or the use of partially hydrolyzed whey formula until at least the age of 4 months. At 1 year of age, the risk of asthma was significantly reduced by 34%. At 2 years of age, significantly fewer children had asthma in the intervention group than in the control group (16.3% vs. 23%), and 60% fewer of those in the intervention group had persistent asthma. A 90% reduction in recurrent wheeze was seen in the intervention group compared with the control group.[75] Studies like these are quite useful to elucidate the multitude of changes necessary to affect multifactorial diseases like asthma in an effective manner.

Antibiotics, Probiotics, and Mucosal IgA

In a combined analysis of seven studies involving more than 12,000 youngsters, researchers at the University of British Columbia found that those prescribed antibiotics before their first birthday were more than twice as likely as untreated kids to develop asthma.[76] Additionally, if they had multiple courses of antibiotics, it bumped up the risk even higher—16% for every course of the drugs taken before age 1. There are a couple of explanations for this association between antibiotic use and asthma. One is that antibiotics contribute to a state of "excess hygiene," leading to a reduced exposure to microbes. This, in turn, creates an oversensitive immune system, mounting an over-the-top allergic reaction to pollen and dust mites and ultimately resulting in asthma. The second explanation is that antibiotics have a negative effect on the normal flora of the gastrointestinal tract and respiratory passages. Some studies have shown that giving probiotics (active cultures of *Lactobacillus* and *Bifidobacterium* species) lowers the risk of atopic allergic diseases like asthma and eczema. Some of this protective effect may be mediated by mucosal IgA, which participates in antigen elimination. In a cohort of 237 allergy-prone infants given a combination of four probiotic strains or placebo, it was shown that supplementation with probiotics increased fecal IgA and calprotectin while reducing inflammatory markers (e.g., α_1-antitrypsin and TNF-α).[77] In infants with a high fecal IgA concentration at the age of 6 months, the risk of having any allergic disease or any IgE-associated (atopic) disease before the age of 2 years was cut by nearly 50%. High intestinal IgA in early life is associated with minimal intestinal inflammation and indicates a reduced risk for IgE-associated allergic diseases.

Vegan Diet

A long-term trial of a vegan diet (elimination of all animal products) provided significant improvement in 92% of the 25 treated patients who completed the study (9 dropped out).[78] Improvement was determined by a number of clinical variables, including vital capacity, FEV_1, and physical working capacity, as well as by biochemical indices such as haptoglobin, IgM, IgE, cholesterol, and triglyceride levels in the blood. The researchers also found a reduction in the vulnerability to infection. Importantly, although 71% of the patients responded within 4 months, 1 year of therapy was required before the 92% level was reached.

The diet excluded all meat, fish, eggs, and dairy products. Drinking water was limited to spring water (chlorinated tap water was specifically prohibited). Coffee, ordinary tea, chocolate, sugar, and salt were also excluded. Herbal spices were allowed, and water and herbal teas were allowed up to 1.5 L/day. Vegetables eaten freely were lettuce, carrots, beets, onions, celery, cabbage, cauliflower, broccoli, nettles, cucumber, radishes, Jerusalem artichokes, and all beans except soybeans and green peas. Potatoes were allowed in restricted amounts. A number of fruits were also eaten freely: blueberries, cloudberries, raspberries, strawberries, black currants, gooseberries, plums, and pears. Apples and citrus fruits were not allowed, and grains were either restricted or eliminated.

The beneficial effects of this dietary regimen are probably related to three areas:

- Elimination of food allergens
- Altered prostaglandin metabolism
- Increased intake of antioxidant nutrients and magnesium

In regard to altered prostaglandin metabolism, the avoidance of dietary sources of arachidonic acid (derived from animal products) appears to be significant. The prostaglandins and leukotrienes derived from arachidonic acid contribute significantly to the allergic reaction in asthma. The decreased availability of arachidonic acid as a substrate of these inflammatory compounds appears to explain some aspects of the efficacy of the vegan diet. The benefits of altering prostaglandin metabolism are further discussed later, as is the role of increased dietary antioxidants in preventing asthma.

Aside from the patients' improvement in health from the vegan diet, there was a significant reduction in healthcare costs (the patients had been receiving corticosteroids and other drugs and therapies for an average of 12 years), and according to the authors, patients changed their attitudes in terms of taking greater responsibility for their own health.

Nutrition

Omega-3 Fatty Acids

Epidemiological studies have shown that children who eat fish more than once a week have one-third the risk of asthma of children who do not eat fish regularly.[79] Several clinical studies have shown that increasing the intake of omega-3 fatty acids through supplementation with fish oils containing eicosapentaenoic acid and docosahexaenoic acid offers significant benefits in asthma, as noted by improvements in airway responsiveness to allergens as well as improvements in respiratory function.[80,81] These benefits are related to an increased ratio of omega-3 to omega-6 fatty acids in cell membranes, thereby reducing

the availability of arachidonic acid. In particular, the ingestion of omega-3 fatty acids leads to a significant shift in leukotriene synthesis from the extremely inflammatory 4-series to the less inflammatory 5-series leukotrienes. This shift is directly related to improvements in asthma symptoms.[82] The benefits may take as long as 1 year to become apparent because it seems to take time to turn over cellular membranes in favor of the omega-3 fatty acids.

Tryptophan Metabolism and Pyridoxine Supplementation

Children with asthma have been shown to have a metabolic defect in tryptophan metabolism and reduced platelet transport for serotonin.[83,84] Tryptophan is converted to serotonin, a known bronchoconstricting agent in asthmatics. High serotonin levels in the blood and sputum are common findings in patients with asthma and are reflected by an elevated urinary level of 5-hydroxyindoleacetic acid (5-HIAA), the breakdown product of serotonin. The levels of 5-HIAA in the urine correlate well with the severity of asthmatic symptoms. Double-blind clinical studies have shown that patients benefit from either a tryptophan-restricted diet[83] or pyridoxine supplementation[84,85] to correct the blocked tryptophan metabolism.

Pyridoxine may also be of direct benefit to patients with asthma. In one study, plasma and erythrocyte pyridoxal phosphate levels in 15 adult patients with asthma were significantly lower than in 16 controls.[84] Oral supplementation with 50 mg of pyridoxine twice daily to seven of the patients failed to produce a substantial elevation of these low levels. However, all patients reported a dramatic decrease in the frequency and severity of wheezing as well as asthma attacks while taking the supplements. In a study of 76 children with asthma, pyridoxine at a dosage of 200 mg daily produced significant reductions in symptoms and in dosages of bronchodilators and corticosteroids. However, a double-blind study failed to demonstrate any significant improvement with vitamin B_6 supplementation in patients who depended on steroids to control symptoms.[86]

Although vitamin B_6 supplementation may not help patients on steroids, it is definitely indicated in patients with asthma being treated with the drug theophylline. Theophylline significantly depresses pyridoxal-5-phosphate levels.[87] In addition, another study has shown that vitamin B_6 supplementation can significantly reduce the typical side effects of theophylline (e.g., headaches, nausea, irritability, sleep disorders).[88]

Antioxidants

The substantial increase in the prevalence of asthma over the past 20 years can be partially explained by the reduced dietary intake of antioxidant nutrients like beta-carotene and vitamins A, C, and E, as well as the mineral cofactors essential for antioxidant defense mechanisms, such as zinc, selenium, and copper.[89] Patients undergoing acute asthmatic distress are known to have lowered serum total antioxidants.[90] Genetic influences may also play a role in the need for antioxidants (see "General Considerations" earlier in the chapter).[3]

One study of 158 children with moderate to severe asthma revealed that supplementation of 50 mg/day of vitamin E and 250 mg/day of vitamin C conferred significant protection against ozone-induced reductions in pulmonary function.[91] Antioxidants are thought to provide important defense mechanisms for maintaining the redox state of the lungs. This protection is significant because oxidizing agents can both stimulate bronchoconstriction and increase hyperactivity to other agents. Asthma appears to be another disease process that is influenced greatly by antioxidant mechanisms. Analgesics like acetaminophen, known to deplete antioxidant levels such as glutathione in animals, should be used with caution in asthmatic patients.[92]

Vitamin C

Vitamin C is the major antioxidant substance present in extracellular fluid lining the airway surfaces.[93] Vitamin C intake in the general population appears to correlate with asthma, indicating that low vitamin C (in the diet and the blood) is an independent risk factor for asthma. In a survey of 771 persons with current asthma, 352 with former asthma, and 15,418 without asthma, lower vitamin C concentrations were observed among those with current or former asthma than those who had never had asthma.[94] Children of smokers have a higher rate of asthma (cigarette smoke is known to deplete respiratory vitamins C and E levels), and symptoms of ongoing asthma in adults appear to be increased by exposure to environmental prooxidants and decreased by vitamin C supplementation.[74]

Nitrogen oxides are examples of oxidants that can arise from both endogenous and exogenous sources. Vitamin C has been shown to offer significant protection against nitrogen oxide damage in the lungs of animal models.[95]

Both treated and untreated patients with asthma have been shown to have significantly lower levels of ascorbic acid in serum and leukocytes.[95] From a clinical perspective, it appears that patients with asthma have a higher need for vitamin C, with the majority of studies demonstrating significant improvements in respiratory measures and asthma symptoms as a result of supplementing the diet with 1 to 2 g of vitamin C daily.[96] This dosage is recommended based on the increasing exposure to inhaled oxidants, along with the growing appreciation of the antioxidant function of vitamin C in the respiratory system.

High-dose vitamin C therapy may also help asthma by lowering histamine levels.[97] The importance of vitamin C as a natural antihistamine has emerged for several reasons, including concern over the safety of antihistamine medications and the recently recognized immune-suppressing effects of histamine. In the initial stages of an immune response, histamine amplifies the immune response by increasing capillary permeability and smooth muscle contraction, thus enhancing the flow of immune factors to the site of infection. Subsequently, histamine exerts a suppressive effect on the accumulated white blood cells (WBCs) in an attempt to contain the inflammatory response.

Vitamin C prevents the secretion of histamine by WBCs and increases the detoxification of histamine. One study examined the antihistaminic effect of acute and chronic vitamin C administration and its effect on WBC (neutrophil) function in healthy men and women. In the chronic administration arm, 10 subjects ingested a placebo during weeks 1, 2, 5, and 6 and 2 g/day of vitamin C during weeks 3 and 4. Fasting blood samples were collected after the initial 2-week period (baseline) and at the end of weeks 4 and 6. Blood vitamin C levels rose significantly after vitamin C administration, whereas blood histamine levels fell by 38% during the weeks vitamin C was given. The ability of WNCs to move in response to an infection (chemotaxis) increased by 19% during vitamin C administration and fell 30% after vitamin C withdrawal. However, these changes were linked to histamine concentrations. Chemotaxis was greatest when histamine levels were the lowest. In the part of the study looking at the acute effects of vitamin C, blood histamine concentrations and chemotaxis did not change 4 hours after a single dose of vitamin C. This result suggests that vitamin C will lower blood histamine only if it is taken over time. Individuals prone to allergy or inflammation are encouraged to increase their consumption of vitamin C through supplementation.[97]

In a small study of patients with asthma and documented exercise-induced bronchoconstriction, the subjects participated in a randomized, placebo-controlled, double-blind crossover trial.[98] They entered the study on their usual diets and were placed on either 2 weeks of ascorbic acid supplementation (1500 mg/day) or placebo, followed

by a 1-week washout period, before crossing over to the alternative treatment. The ascorbic acid diet significantly reduced ($P < 0.05$) the maximum fall in postexercise FEV_1 (–6.4 %) compared with the usual diet (–14.3%) and a placebo diet (–12.9%). Asthma symptom scores significantly improved on the ascorbic acid diet compared with the placebo and usual diets. Postexercise inflammatory mediators were also significantly lower with ascorbic acid supplementation.

Flavonoids

Flavonoids appear to be key antioxidants in the treatment of asthma. Various flavonoids, chief among them being quercetin, have been shown to inhibit the following[99–102]:

- Histamine release from mast cells and basophils when stimulated by antigens and other ligands
- Phospholipase A2 in neutrophils
- Lipoxygenase
- Anaphylactic contraction of smooth muscle
- Phosphodiesterase in the lung (resulting in increased cAMP levels)
- Biosynthesis of SRS-A
- Calcium influx

In addition, quercetin has both a vitamin C–sparing effect and a direct stabilizing effect on membranes, including mast cells.

Flavonoid-rich extracts such as those from grape seed, pine bark, green tea, or *Ginkgo biloba* may prove even more helpful than quercetin in the treatment of asthma because of their enhanced bioavailability. In particular, the proanthocyanidins from grape seed or pine bark extracts appear to have an affinity for the lungs (for more information, see Chapter 106). In a randomized, placebo-controlled, double-blind study involving 60 subjects 6 to 18 years of age, a proprietary pine bark extract (Pycnogenol) significantly improved pulmonary function and asthma symptoms compared with placebo. Specifically, the Pycnogenol group was able to reduce or discontinue the use of rescue inhalers more often than the placebo group. There was also a significant reduction of urinary leukotrienes in the Pycnogenol group.[103]

In another study, a flavonoid preparation derived from purple passion fruit peel (PFP) was studied in a 4-week randomized, placebo-controlled, double-blind trial in asthma patients. The dosage of the PFP extract was 150 mg daily. The prevalence of wheeze, cough, and shortness of breath was reduced significantly in the group treated with PFP extract, whereas the placebo caused no significant improvement. PFP extract supplementation also resulted in a marked increase in FEV_1, whereas placebo showed no effect.[104]

Carotenes

Carotenes are powerful antioxidants that may increase the integrity of the epithelial lining of the respiratory tract and act as substrates for lipoxygenase, possibly competing with arachidonic acid and thereby decreasing leukotriene formation.[105] Some studies have shown that patients with asthma have reduced plasma antioxidant potential due to low whole-blood carotenoids (beta-carotene, lycopene, alpha-carotene, beta-cryptoxanthin, lutein/zeaxanthin),[106] in particular low lycopene levels,[107] thus making them more susceptible to the damaging effects of oxidative stress. Lycopene may emerge as the most useful supplemental carotenoid. In animal models of asthma, lycopene supplementation suppressed Th2 responses and reduced eosinophilic infiltrates in the bronchoalveolar lavage fluid, lung tissue, and blood as well as the number of mucus-secreting cells in the airways.[108]

In a proof-of-concept human study, asthmatic adults ($n = 32$) consumed a low-antioxidant diet for 10 days and then commenced a randomized crossover trial involving three 7-day treatment arms (placebo, tomato extract [45 mg lycopene per day], and tomato juice [45 mg lycopene per day]).[109] With the consumption of a low-antioxidant diet, plasma carotenoid concentrations decreased, Asthma Control Score worsened, lung function (FEV_1 and FVC) decreased, and sputum neutrophils increased. Treatment with both tomato juice and extract reduced airway neutrophil influx. Treatment with tomato extract also reduced sputum neutrophil elastase activity. This short-term study indicates that antioxidant status, particularly in terms of carotenoids, modifies some parameters in asthma.

There have been two double-blind studies of lycopene supplementation (30 mg/day) in exercise-induced asthma. One failed to show any benefit,[110] whereas another showed that in some patients, it prevented airway constriction and reduced FEV_1.[111]

Vitamin E

Vitamin E's activity as an antioxidant, lipoxygenase inhibitor, and phospholipase inhibitor makes it a useful supportive agent in asthma treatment.[112]

Selenium

Reduced selenium levels have been demonstrated in asthma patients.[113–115] Glutathione peroxidase, a selenium-dependent metalloenzyme, is important for reducing hydroperoxyeicosatetraenoic acid (HPETE) to HETE acid, thereby reducing leukotriene formation. Reduced levels of glutathione peroxidase have also been reported for patients with asthma.[113] Supplemental selenium appears warranted to address any deficiency of glutathione peroxidase. In addition, supplemental selenium may reduce the production of leukotrienes by ensuring the optimal activity of glutathione peroxidase.

Vitamin B_{12}

Jonathan Wright, MD, believes that "B_{12} therapy is the mainstay in childhood asthma."[116] In one clinical trial, weekly intramuscular injections of 1000 mg produced definite improvements in patients with asthma.[117] Of 20 patients, 18 showed less shortness of breath on exertion as well as improved appetite, sleep, and general condition. Vitamin B_{12} appears to be especially effective in sulfite-sensitive individuals. It offers the best protection when given orally (1–4 mcg) before challenge compared with other pharmacological agents (e.g., cromolyn sodium, atropine, doxepin).[118] The mode of action is the formation of a sulfite–cobalamin complex that blocks sulfite's effect.

Magnesium

In 1912 Trendelenburg demonstrated that magnesium relaxed bovine bronchial smooth muscle in vitro.[119] Later, uncontrolled clinical studies revealed magnesium's beneficial effect in the treatment of patients with acute attacks of bronchial asthma.[120] Unfortunately, this promising line of research was dropped as antihistamines and bronchodilators became available. However, the advent of calcium channel blockers for the treatment of asthma generated renewed interest in the therapeutic use of magnesium for asthma. In fact, intravenous magnesium (2 g of magnesium sulfate infused every hour up to a total of 24.6 g) is now a well-proven and clinically accepted measure to halt an acute asthma attack as well as acute exacerbations of chronic obstructive pulmonary disease.[121–125]

Although these initial studies used injectable magnesium, it has been demonstrated that this is not necessary to restore magnesium status except in the case of an emergency situation such as an acute heart attack or an acute asthma attack.[126] Oral magnesium therapy is an effective measure to raise body magnesium stores, but it will usually take 6 weeks to achieve significant elevations in tissue magnesium concentrations. Oral supplementation appears to be warranted because low levels of plasma magnesium have been found in asthmatic patients,[92] and dietary magnesium intake is independently related to lung function and the severity of asthma.[127] Several double-blind studies in adults and children with asthma have demonstrated improvements in respiratory function, antioxidant status (i.e., increased glutathione

concentrations), reduced reactivity to chemical challenge to methacholine, and measures of asthma control and quality of life.[128–130] The dosages used ranged from 300 mg a day in children to 340 mg a day in adults, usually in divided dosages.

Isotonic nebulized magnesium has also proved useful as an adjunct treatment to standard bronchodilation therapies in patients with severe asthma, with a greater response in those with life-threatening asthma.[131] A randomized controlled trial investigated the effect of inhaled magnesium sulfate on the treatment response in emergency department (ED) patients with moderate to severe asthma.[132] Subjects allocated to the study group were treated with a standard protocol, plus 3 mL of 260 mmol/L solution of magnesium sulfate every 20 to 60 minutes. The control group was treated with nebulized saline as a placebo in addition to the standard protocol. The results demonstrate that adding nebulized magnesium sulfate to standard therapy in patients with moderate to severe asthma attacks led to greater and faster improvement in PEFR, respiratory rate, oxygen saturation, and respiratory rate and reduces hospitalization rates.

Vitamin D

Vitamin D deficiency is linked to increased airway reactivity, poorer lung function, and worse asthma control.[133] One study in more than 1000 children with asthma showed that 35% were vitamin D–insufficient, as defined by a level of 30 ng/mL or less of 25-hydroxyvitamin D.[134] After adjusting for age, sex, body mass index, income, and treatment group, insufficient vitamin D status was associated with higher odds of hospitalization or emergency department visits (OR 1.5). In addition to correcting a vitamin D insufficiency, vitamin D supplementation may improve asthma control by blocking the cascade of inflammation-causing proteins in the lung as well as increasing the production of interleukin-10, which has anti-inflammatory effects. Preliminary clinical evidence is encouraging, especially in the prevention of childhood asthma, at a dosage of 1200 IU per day of vitamin D_3.[135] Although there is conflicting evidence from clinical trials, results from in vivo and in vitro studies in animals and humans have suggested that supplementation with vitamin D may ameliorate several hallmark features of asthma, and vitamin D deficiency may influence the inflammatory response in the airways.[136]

Botanical Medicines

Asthma patients commonly employ self-treatment with botanicals. A cross-sectional analysis of 601 adults with asthma found that 14% used either herbal products, coffee, or black tea to treat their condition. Unfortunately, this study illustrated that those who used these methods had a higher incidence of hospitalizations.[137] Because of the possibility of improper use of botanicals and the inability of the users to recognize the need for acute conventional interventions, it is recommended that before using natural therapies, patients with asthma consult a naturopathic physician or other qualified practitioner who understands the proper use of botanicals and can assess the asthmatic patient's severity of risk.

The most popular historical herbal treatment of asthma involved the use of *Ephedra sinensis* (Ma huang) in combination with herbal expectorants. This approach appeared to have considerable merit because *Ephedra* and its alkaloids have proven to be effective as bronchodilators in treating mild to moderate asthma and hay fever.[138,139] *Ephedra* preparations containing ephedrine alkaloids are no longer sold in the United States because of safety concerns. However, ephedra extracts without ephedrine are still legally sold.

Hedera helix (Ivy)

In Europe, herbal preparations containing extracts from the leaves of ivy are popular for the relief of cough as well as asthma. In 2007 more than 80% of herbal expectorants prescribed in Germany comprised ivy extract and amounted to nearly 2 million prescriptions nationwide. Ivy leaf contains saponins that show expectorant, mucolytic, spasmolytic, bronchodilatory, and antibacterial effects. The mucolytic and expectorant actions of ivy are based on indirect $beta_2$ adrenergic effects, and these actions are due to the saponins α-hederin and hederacoside C, the latter of which is metabolized to α-hederin when ingested.[140] The indirect effect involves α-hederin, which inhibits the intracellular uptake of $beta_2$ receptors and leads to an increased $beta_2$-adrenergic response of the cell.

A 2003 meta-analysis of three double-blind studies in children showed that the ivy preparations used were significantly superior to placebo.[141] Among the three trials, one study compared ivy leaf extract cough drops to placebo, one compared suppositories to drops, and one tested syrup against drops. The reviewers concluded that ivy leaf extract preparations are effective with respect to the improvement of respiratory function in children with chronic bronchial asthma but noted that the study had a meager database to assess. In the only placebo-controlled double-blind study reviewed, 24 children with asthma between the ages of 4 and 12 were given a dry ivy leaf extract (35 mg) in cough drops or placebo for 3 days with a washout of 3 to 5 days before crossing over to the other treatment. The superiority of ivy leaf extract over placebo was noted by small improvements in airway resistance, residual volume, vital capacity, FVC, and FEV_1 when the baseline measurements were compared with day 3 at 3 hours postdosing (morning dose).

Glycyrrhiza glabra

Licorice root has a long history of use as an anti-inflammatory and anti-allergic agent, as documented in the scientific literature (see Chapter 85). The primary active component of licorice root in this application is glycyrrhetinic acid, a compound that has shown cortisol-like activity. In particular, glycyrrhetinic acid has been shown to inhibit phospholipase A_2, the enzyme responsible for cleaving arachidonic acid from the phospholipid membrane pool and initiating eicosanoid synthesis.[142] Licorice is also an expectorant, which is useful in the treatment of asthma.

Lobelia inflata

Indian tobacco contains the alkaloid lobeline, an efficient expectorant. Although it has a long history of use in asthma, it does promote bronchoconstriction and is a respiratory stimulant in vitro.[143] This appears to suggest a cholinergic effect in the respiratory system; it also binds to nicotine acetylcholine receptors in the ganglions, thus promoting the release of epinephrine and norepinephrine. It is this action on adrenal hormone secretion that is responsible for lobelia's therapeutic effects.[144] Lobelia has traditionally been used in combination with other botanical agents, such as *Capsicum frutescens* and *Symphlocarpus factida.*

Capsicum frutescens

Experimental evidence has shown that capsaicin, cayenne pepper's major active component, induces long-lasting desensitization of airway mucosa to various mechanical and chemical irritants.[145] This effect is probably due to capsaicin-induced depletion of substance P (which normally increases vascular permeability and flow) in the respiratory tract nerves. Substance P is an undecapeptide associated with "neurogenic inflammation" via a direct effect and a synergistic action with histamine on the peripheral nervous system.[146] The respiratory

and gastrointestinal tracts have large numbers of substance P–containing neurons. Because of its location and physiological action, it is believed to play an important role in atopic conditions such as asthma and atopic dermatitis. Therefore depletion of substance P may be beneficial in these conditions.

Zizyphi fructus

The jujube plum has been used extensively in Chinese medicine for the treatment of asthma and allergic rhinitis.[147] It contains 100 to 500 nmol/g of cyclic-AMP (cAMP) per dry weight, a concentration 10 times greater than that of any other plant or animal tissue thus far reported in the literature.[148] It also contains a beta-adrenergic receptor stimulator that raises cAMP levels. These experimental findings, in conjunction with *Zizyphi*'s long historical use, strongly support its clinical use.

Thea sinensis

Green tea is useful as an adjunctive in asthma treatment due to its methylxanthine and antioxidant components (see Chapter 60).

Allium Family

Onions and garlic inhibit lipoxygenase and cyclooxygenases, which generate TxA_2, PGD_2, and PGE_2.[149] Oral pretreatment of guinea pigs (that were sensitized to ovalbumin) with 1 mL of an alcohol/onion extract markedly reduced the asthmatic response to allergen inhalation challenges. Onion contains quercetin, which may account for some of its pharmacological effect,[150] but the major protective actions appear to be related to its content of benzyl and other isothiocyanates (mustard oils).[151] Although the mechanism of action is unknown, it has been suggested that it is due to the inhibition of the biosynthesis of arachidonic acid metabolites.

Tylophora asthmatica

The leaves of *Tylophora asthmatica* have been used extensively in Ayurvedic medicine in asthma and other respiratory tract disorders. The mode of action of *Tylophora* is unknown but is thought to be due to the alkaloids, especially tylophorine, which have been reported to possess antihistamine and antispasmodic activity, as well as inhibition of mast-cell degranulation.[152,153] However, a more central mechanism may be responsible for the clinical effects in asthma.

Several double-blind clinical studies have shown *Tylophora* to be beneficial for asthma.[154–157] In one study of 135 patients, those given 200 mg of *Tylophora* leaves twice daily for 6 days demonstrated improvements in symptoms and respiratory function during the treatment period and for up to 2 weeks after treatment.[154]

In another double-blind study of 103 patients, those receiving 40 mg of the dry alcoholic extract of *Tylophora indica* daily for only 6 days demonstrated significant improvement in symptoms of asthma compared with a placebo group.[156] At the end of the first week, 56% had complete to moderate improvement, compared with 31.6% of the 92 patients receiving the placebo. At the end of 4 weeks, the respective figures were 32% and 23.8%; at 8 weeks, 23.8% and 8.4%; and at 12 weeks, 14.8% and 7.2%. The incidence of side effects such as nausea, partial diminution of taste for salt, and slight mouth soreness was 16.3% in the *Tylophora* group and 6.6% in the placebo group. These results, as well as the results from an additional study, indicate that the benefits of *Tylophora* are short-lived.[157,158]

Ginkgo biloba

G. biloba contains several unique terpene molecules known collectively as ginkgolides that antagonize platelet-activating factor (PAF), a key chemical mediator in asthma, inflammation, and allergies. Ginkgolides compete with PAF for binding sites and inhibit the various events induced by PAF. The antiasthmatic effects of orally administered or inhaled ginkgolides have been shown to produce improvements in respiratory function and to reduce bronchial reactivity in several double-blind studies.[158,159] Treatment consisted of 120 mg of the pure ginkgolides daily—a dosage that is currently expensive to achieve using the 24% ginkgo flavonglycoside and 6% total terpenoid *G. biloba* extract.

Aloe vera

In one study, the oral administration of an extract of *Aloe vera* for 6 months was shown to produce good results in the treatment of asthma in some individuals of various ages.[160] The extract was produced from the supernatant of fresh leaves stored in the dark at 4°C for 7 days. Subjecting the leaves to dark and cold results in an increase in the polysaccharide fraction. One gram of the crude extract obtained from leaves stored in a cold, dark environment produced 400 mg of neutral polysaccharide, compared with only 30 mg produced from leaves not subjected to cold or dark. The dosage was 5 mL of a 20% solution of the *A. vera* extract in saline twice daily for 24 weeks, and 11 of 27 patients (40%) without corticosteroid dependence felt better at the study's conclusion. The mechanism of action is thought to be via restoration of protective mechanisms, followed by augmentation of the immune system.

Coleus forskohlii

Coleus forskohlii extracts may be particularly useful in asthma because increasing intracellular levels of cAMP result in relaxation of bronchial muscles and relief of respiratory symptoms. Forskolin has been shown to have remarkable effects in relaxing constricted bronchial muscles in patients with asthma (see Chapter 69).[161,162] These studies used inhaled doses of pure forskolin. Whether orally administered forskolin in the form of *C. forskohlii* extract would produce similar bronchodilatory effects has yet to be determined. However, on the basis of the plant's historic use and additional mechanisms of action, it appears likely.

Boswellia

The Indian Ayurvedic botanical *Boswellia* is known for its ability to inhibit leukotriene biosynthesis.[163] In one double-blind, placebo-controlled study, bronchial asthma was reduced in 70% of 40 patients treated with gum resin at 300 mg three times daily for 6 weeks, whereas only 27% of the control group improved. The disappearance of physical symptoms and signs such as dyspnea and rhonchi; fewer attacks; increased FEV_1, vital capacity, and peak expiratory flow rate (PEFRs); and decreased eosinophilia counts and sedimentation rates were recorded as measures of improvement.[163]

Acupuncture and Acupressure

In traditional Chinese medicine, chronic asthmatic symptomatology is usually characterized as a lung or spleen deficiency. This model considers that acute symptoms may be caused by environmental invasion from cold wind (environmental factors) or an internal condition stemming from a lung heat condition (increased inflammation and eosinophilia). Chronic asthma is considered more of a weakness in the lung itself or a weakness of the spleen, which is responsible for nourishing the lung *qi* (or vitality). In traditional Chinese medicine, the emotion of grief is also said to weaken lung *qi.*

In one prospective randomized study of patients with chronic asthma, 41 patients with chronic obstructive asthma were randomly assigned to receive acupuncture in addition to standard care, acupressure and standard care, or standard care alone. For each subject, 20 acupuncture treatments were given, and self-administered acupressure was performed daily for 8 weeks. On the St. George's Respiratory

Questionnaire, the acupuncture subjects showed an average 18.5-fold improvement, whereas the improvement for the acupressure-only subjects was 6.57-fold. Additionally, for patients who received acupressure, the irritability domain score exhibited an 11.8-fold improvement.[164] Another study involved 44 patients receiving bona fide or sham acupressure. They received five treatments per week lasting 16 minutes each for 4 weeks. Using pulmonary function and dyspnea scores, 6-minute walking distance measurements, and State Anxiety Scale scores, the acupressure group had significant improvements in breathing and less anxiety compared with those of the sham group.[165]

THERAPEUTIC APPROACH

The effective treatment of asthma requires the consideration and control of many aspects. In particular, the specific underlying defects and initiating factors must be determined because many different defects and metabolic abnormalities result in the same clinical picture of asthma. The development of an appropriate treatment plan includes the following five steps:

1. Determining and rectifying the underlying defect that allows the development of sensitization
2. Determining and balancing the underlying metabolic defect that causes an excessive inflammatory response
3. Finding potential allergens and developing a lifestyle, diet, and environment that allow the allergens to be avoided
4. Modulating the inflammatory process to limit the severity of the response
5. Preparing an effective treatment for the bronchoconstriction of the acute attack

Environment

The most important preventative measures are to decrease exposure through decreased pollution in the work and home environments, the use of airway protection during the most-exposed work tasks, and cessation of smoking. Airborne allergens such as pollen, dander, and dust mites[166] are often difficult to avoid entirely, but measures can be taken to reduce exposure. Eliminating dogs, cats, carpets, rugs, upholstered furniture, and other surfaces where allergens can collect is a great first step. Also, methods to discourage the presence of dust mite and cockroach antigen should be used, although pesticide exposure should be minimized. If environmental exposures cannot be controlled entirely, make sure that the bedroom is as allergy-proof as possible. Have the patient encase the mattress in an allergen-proof plastic; wash sheets, blankets, pillowcases, and mattress pads every week; consider using bedding material made from Ventflex, a special hypoallergenic synthetic material; and install an air purifier. The best mechanical air purifiers are high-efficiency particulate-arresting filters that can be attached to central heating and air-conditioning systems. These units are available from suppliers of heating and air-conditioning units.

Environmental chemicals around the home should be removed. These include paints, solvents, new furniture, chemical cleaners, and scented candles/air fresheners, to name a few. Building materials containing formaldehyde (e.g., carpeting, cabinetry) should also be avoided. Perfume, cologne, hair spray, lotions, antiperspirant, and scented soaps and shampoos often contain several chemicals that should be avoided.

Water-damaged buildings must be repaired, and all mold, bacterial, and other organism growth must be addressed by professionals experienced in mold remediation.

Diet

Organic, mostly plant-based foods should be consumed when possible. Any foods known to cause adverse reactions should also be avoided. Elimination of the offending foods and incorporation of an oligoantigenic diet are primary in reducing inflammation. Elimination diets have been successful in identifying allergens and treating asthma, especially in infants. The patient who has many food allergies may have to use a 4-day rotation diet. In the early stages of treatment, mild dietary tryptophan reduction should be useful but is not critical unless there is a metabolic defect in tryptophan metabolism. Garlic and onions should be used liberally unless the patient reacts to them. If the patient is willing or his or her asthma is unresponsive to this recommended therapy, a vegan diet should be tried (for a minimum of 4 months), with the possible exception of coldwater fish. Moderate fruit consumption, especially of apples, should also be encouraged.

Supplements

- Vitamin B_6: 25 to 50 mg two times a day
- Vitamin B_{12}: 1000 mcg/day (oral) or weekly injection; evaluate for efficacy after 6 weeks
- Vitamin C: 10 to 30 mg/kg in divided dosages
- Vitamin D: 1000 to 8000 IU daily. Monitor blood levels to determine needed dosage because there is wide variability. Those whose blood levels do not rise in response to supplementation should have their $1,25(OH)2D_3$ checked. Also, Vitamin K_2 should always be prescribed with Vitamin D.
- Vitamin E: 100 to 200 IU daily
- Magnesium: 200 to 400 mg three times a day
- Quercetin: 400 mg 20 minutes before meals or enzymatically modified isoquercitrin (EMIQ) 100 mg daily.
- Grape seed extract (95% PCO content) or pine bark extract (e.g., Pycnogenol): 150 to 300 mg daily
- Lycopene: 30 to 45 mg/day
- Selenium: 200 mcg/day

Botanical Medicines

Choose one or more of the following botanical medicines.

Hedera helix

Ivy leaf is available primarily in tincture and fluid extract, and the dry-powdered extract comes in the form of capsules and tablets. Based on clinical studies, the daily dosages should deliver the following equivalent to dried herbal substance: 1 to 5 years: 150 mg; 6 to 12 years: 210 mg; over 12 years: 420 mg. The typical dosage of a 4:1 powdered extract for adults and children over 12 years of age is 100 mg daily.

Lobelia inflata

- Dried herb: 0.2 to 0.6 g three times a day
- Tincture: 15 to 30 drops three times a day
- Fluid extract: 8 to 10 drops three times a day

Glycyrrhiza glabra

- Powdered root: 1 to 2 g
- Fluid extract (1:1): 2 to 4 mL (½–1 Tsp)
- Solid (dry-powdered) extract (4:1): 250 to 500 mg

Camellia sinensis

Liberal use (green tea only)

Tylophora asthmatica

200 mg of *Tylophora* leaves or 40 mg of the dry alcoholic extract two times daily

Coleus forskolii

Extract standardized to contain 18% forskolin: 50 mg (9 mg of forskolin) two to three times daily

Counseling

For patients who respond to emotional crises with asthmatic attacks, counseling is important. Counseling is also important for children with moderate to severe asthma, who may develop behavioral problems.

Acupuncture and Acupressure

Regular acupuncture and home acupressure treatments should be used.

IN ACUTE ATTACK

An acute asthma attack can be a medical emergency. If necessary, the patient should be referred to an emergency department immediately.

There are two more natural approaches that can be considered, but research support is only anecdotal. Intravenous (IV) magnesium can quickly relieve bronchial spasm. This should only be done by those with proper training and facilities. Dr. Bastyr recommended an herbal protocol using 1 tsp every 15 minutes of a tincture containing equal parts capsicum, lobelia, and skunk cabbage, which the senior editor found consistently effective. Before prescribing, practitioners are advised to try this intense intervention themselves first. If the patient does not immediately respond to either of these two interventions, then emergency intervention is required.

Atherosclerosis

John Nowicki, ND, and *Michael T. Murray*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Characteristically associated with high blood pressure, weak pulse, and wide pulse pressure
- Symptoms and signs depend on the arteries involved and degree of obstruction: angina, leg cramps (intermittent claudication), gradual mental deterioration, weakness, or dizziness
- May also occur without symptoms
- Diagonal earlobe crease

GENERAL CONSIDERATIONS

Atherosclerosis refers to the process that is the underlying pathology in a group of clinical entities collectively referred to as cardiovascular disease (CVD) including: heart disease (atherosclerosis of the coronary arteries); coronary artery disease (CAD); and myocardial, pulmonary, and cerebral infarction. Despite a steady decline in the age-adjusted death toll since 1980, CVD remains the number-one cause of death in the United States, where it is responsible for 1 of every 2.8 deaths. In 2015 nearly 634,000 deaths were attributed to heart disease and nearly 140,000 deaths to stroke in the United States.

Understanding Atherosclerosis

To fully understand the important ways in which various natural measures described in this chapter affect the health of the arteries and treatment of CVD, it is necessary to examine closely the structure of an artery and the process of atherosclerosis.

Structure of an Artery

An artery is divided into three major layers:

- The intima, representing the endothelium or internal lining of the artery, consists of a layer of endothelial cells lined by glycosaminoglycans (GAGs) to protect them from damage as well as to promote repair. Beneath the surface cells is the internal elastic membrane, composed of a layer of GAGs and other ground substance compounds, which supports the endothelial cells and separates the intima from the smooth muscle layer.
- The media consists primarily of smooth muscle cells. Interposed among the cells are GAGs and other ground substance structures that provide support and elasticity to the artery.
- The adventitia, or external elastic membrane, consists primarily of connective tissue, including GAGs; it provides structural support and elasticity to the artery.

The Process of Atherosclerosis

The lesions of atherosclerosis are initiated in response to injury to or a disruption of the normal functioning of the arterial endothelium.[1] The progression of atherosclerosis is detailed as follows:

1. The initial step is damage or dysfunction of the vascular endothelium. Damage results from weakening of the GAG layer, which protects the endothelial cells, due to the same factors that damage the endothelial cells (e.g., insulin resistance, reactive oxygen and

* Previous edition contributor

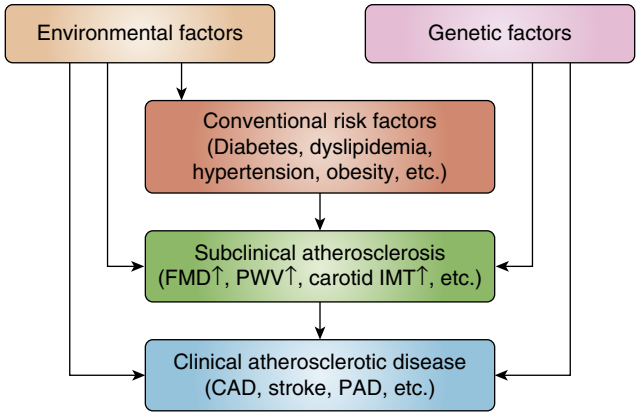

Fig. 149.1 Atherosclerosis is a multifactorial disease, and the development of atherosclerotic disease involves the interaction of many genetic and environmental factors, as well as conventional risk factors, such as diabetes, dyslipidemia, hypertension and obesity. *CAD*, coronary artery disease; *FMD*, flow-mediated vasodilation; *IMT*, intima-media thickness; *PAD*, peripheral artery disease; *PWV*, pulse wave velocity. (From Katakami N, Kaneto H, Shimomura I. Carotid ultrasonography: a potent tool for better clinical practice in diagnosis of atherosclerosis in diabetic patients. *J Diabetes Investig*. 2014;5[1]:3-13.)

nitrogen species, impaired repair processes, metal toxicity, hyperhomocysteinemia, and inhibition of either nitric oxide production or availability).

2. Once the endothelial cells have been sufficiently damaged, sites of injury become more permeable to plasma constituents, especially lipoproteins. The binding of lipoproteins to GAGs leads to a breakdown in the integrity of the ground substance matrix and causes an increased affinity for cholesterol. Simultaneously, monocytes, T lymphocytes, and platelets adhere to the damaged area, where they release growth factors that stimulate smooth muscle cells to migrate from the media into the intima and replicate.
3. Local concentration of lipoproteins, monocytes, and platelets leads to the migration of smooth muscle cells from the media into the intima, where they undergo proliferation. Smooth muscle cells dump cellular debris into the intima, leading to the further development of plaque.
4. Formation of a fibrous cap (consisting of collagen, elastin, and GAGs) over the intimal surface occurs. Fat and cholesterol deposits accumulate.
5. Plaque continues to grow until eventually it either blocks the artery directly or ruptures to form a clot that travels the general circulation until it occludes a blood vessel. Plaque instability is associated with a significantly greater risk for myocardial infarction (MI) or stroke.[1] Thus targeting plaque stabilization appears to be more clinically important than simply enlarging the lumen.

Causative Factors

Prevention of CVD involves reducing and, when possible, eliminating various risk factors (Fig. 149.1). Risk factors are divided into two primary categories: major risk factors and other risk factors. Box 149.1 lists the major risk factors. Risk for a heart attack increases with the number of major risk factors (Table 149.1).

In addition to these well-accepted major risk factors, numerous others have occasionally been shown to be more significant (Box 149.2). It is also important to develop a strategic approach to plaque stabilization by addressing endothelial dysfunction, increased local and systemic inflammation, increased reactive oxygen species, the activation of mast cells, and the infiltration and activation of macrophages.

BOX 149.1 Major Risk Factors for Atherosclerosis

- Smoking
- Elevated blood cholesterol levels
- High blood pressure
- Diabetes
- Physical inactivity
- Other risk factors

TABLE 149.1 Association of Risk Factors With the Incidence of Atherosclerosis

Major Risk Factors	Increase In Incidence
Presence of one of the major risk factors	30%
High cholesterol and high blood pressure	300%
High cholesterol and a smoker	350%
High blood pressure and a smoker	350%
Smoker, high blood cholesterol, and high blood pressure	720%

BOX 149.2 Other Risk Factors for Atherosclerosis

- Insulin resistance
- Low thyroid function (see Chapter 182)
- Low antioxidant status
- Elevations of C-reactive protein
- Low levels of essential fatty acids
- Increased platelet aggregation
- Increased fibrinogen formation
- Low levels of magnesium and potassium
- Elevated levels of homocysteine
- "Type A" personality

Determining a Patient's Risk

To help determine a patient's overall risk for having a heart attack or stroke, the following risk-determinant scale may prove useful. Although this risk assessment does not take into consideration several other important factors—such as the level of C-reactive protein, lipoprotein(a)[Lp(a)], fibrinogen, and coping style—the score provides a good indication of a patient's risk for a heart attack or stroke (Table 149.2).

Clinical Evaluation

Clinical cardiovascular assessment may include various laboratory and imaging such as the tests listed in Box 149.3.

Risk Factors

Smoking

Statistical evidence reveals smokers have a 70% greater risk of death from CVD than nonsmokers.[2] The more cigarettes smoked and the longer the period of years a person has smoked, the greater the risk of dying from a heart attack or stroke. Overall, the average smoker dies 7 to 8 years sooner than the nonsmoker.

Tobacco smoke contains more than 4000 chemicals, of which more than 50 have been identified as carcinogens. These chemicals are extremely damaging to the cardiovascular system. Many of these

TABLE 149.2 Risk-Determination Scale for Heart Disease and Stroke

	SCALE OF RISK				
	1	2	3	4	5
Blood pressure (systolic)	<125	125–134	135–149	150–164	≥165
Blood pressure (diastolic)	<90	90–94	95–104	105–114	≥115
Smoking (cigarettes per day)	None	1–9	10–19	20–29	≥30
Heredity I[a]	None	>65	50–64	35–49	<35
Heredity II[b]	0	1	2	4	≥4
Diabetes duration (years)	0	1–5	6–10	11–15	>15
Total cholesterol (mg/dL)	<200	200–224	225–249	250–274	≥275
HDL-C (mg/dL)	≥75	65–74	55–64	35–54	<35
Total cholesterol/ HDL-C ratio[c]	<3	3–3.9	4–4.9	5–6.4	≥6.5
Exercise (hours per week)	>4	3–4	2–3	1–2	0.1
Supplemental EPA/ DHA (mg) intake	>600	400–599	200–399	100–199	<100
Supplemental vitamin C (mg) and vitamin E (IU) intake	>400	251–499	250	125–249	0–124
Average daily servings of fruits and vegetables	>5	4–5	3	1–2	0
Age	<35	36–45	46–55	56–65	>65
Subtotals					

HDL-C, high-density-lipoprotein cholesterol.
[a]Age of patient when he or she had a heart attack or stroke.
[b]Number of immediate family members having had a heart attack before the age of 50.
[c]The value of the total cholesterol is to be divided by the value of the HDL-C. Risk = sum of all five columns; 14–20 = very low risk; 21–30 = low risk; 31–40 = average risk; 41–50 = high risk; ≥51 = very high risk.

BOX 149.3 Assessment of the Cardiovascular System

- Laboratory tests
- Total cholesterol
- Low-density-lipoprotein cholesterol
- High-density-lipoprotein cholesterol
- C-reactive protein
- Lipoprotein(a)
- Fibrinogen
- Homocysteine
- Ferritin (an iron-binding protein)
- Lipid peroxides
- Exercise stress test
- Electrocardiography
- Echocardiography

chemicals are carried in the bloodstream on LDL cholesterol where they either directly damage the lining of the arteries, or they oxidize the LDL molecule, which then damages the arteries. Exposure of human plasma to the gas phase of cigarette smoke produces oxLDL which strongly correlates with cardiovascular disease. An elevated cholesterol level makes the effect of smoking on the cardiovascular system even worse because more cigarette toxins will be carried through the vascular system. Smoking also contributes to elevated cholesterol presumably by damaging feedback mechanisms in the liver that control how much cholesterol is being created.[3] Smoking promotes platelet aggregation and elevated fibrinogen levels, two other significant independent risk factors for heart disease and strokes. In experimental models, PAHs found in the tar fraction of cigarette smoke have been shown to accelerate atherosclerosis.[4] In addition, cigarette smoking is a contributing factor to high blood pressure.[5]

Convincing evidence links environmental (secondhand or passive) smoke to heart disease mortality and morbidity. In the United States it is estimated that more than 37,000 coronary heart disease (CHD) deaths each year are attributable to environmental smoke. Meta-analysis of ten epidemiological studies indicates a consistent dose–response effect related to exposure.[6] Individuals exposed to secondhand smoke have higher homocysteine and fibrinogen (biomarkers of cardiovascular disease risk) levels than nonsmokers.[7] Evidence suggests that nonsmokers appear to be more sensitive to smoke, including its deleterious effects on the cardiovascular system. Environmental tobacco smoke actually has a higher concentration of some toxic constituents. Pathophysiological and biochemical data after short- and long-term environmental tobacco smoke exposure show changes in the lining of the arteries and in platelet function as well as exercise capacity, similar to those in active smoking. Passive smoking is a relevant risk factor for CVD.

The magnitude of risk reduction achieved by smoking cessation in patients with CVD is quite significant. Results from a detailed meta-analysis showed a 36% reduction in relative risk of mortality for patients with CAD who quit compared with those who continued smoking.[8]

Various measures, including nicotine-containing skin patches or chewing gum, acupuncture, and hypnosis, have been shown to provide some benefit in helping patients quit smoking. In a systematic review of the efficacy of interventions intended to help people to stop smoking, data were analyzed from 188 randomized controlled trials.[9] Encouragement to stop smoking by physicians during a routine office call resulted in a 2% cessation rate after 1 year. Supplementary measures such as follow-up letters or visits had an additional effect. Behavioral modification techniques such as relaxation, rewards and punishments, and avoiding trigger situations in group or individual sessions led by a psychologist had no greater effect than the 2% rate achieved by simple advice from a physician. Eight studies with acupuncture have produced an overall effectiveness rate of roughly 3%. Hypnosis has been judged to be ineffective, even though trials have shown a success rate of 23%. Hypnosis was judged to be ineffective because no biochemical marker was used to accurately determine effectiveness. Nicotine replacement therapy (gum or patch) is effective in about 13% of smokers who seek help in quitting. All together, these results are not encouraging. It appears that the best results occur when people quit "cold turkey." Box 149.4 lists 10 tips to help patients stop smoking.

Elevated Blood Cholesterol Levels

The evidence overwhelmingly demonstrates that elevated cholesterol levels greatly increase the risk of death due to CVD. It is recommended that the total blood cholesterol level should be less than 200 mg/dL. In

BOX 149.4 Tips to Help Patients Stop Smoking

- List all the reasons why you want to quit smoking and review them daily.
- Set a specific day to quit, tell at least ten friends that you are going to quit smoking, and then . . . DO IT!
- Throw away all cigarettes, butts, matches, and ashtrays.
- Use substitutes. Instead of smoking, chew on raw vegetables, fruits, or gum. If your fingers seem empty, play with a pencil.
- Take one day at a time.
- Realize that 40 million Americans have quit. If they can do it, so can you!
- Visualize yourself as a nonsmoker with a fatter pocketbook, pleasant breath, unstained teeth, and the satisfaction that comes from being in control of your life.
- Join a support group. Call the local branch of the American Cancer Society and ask for referrals. You are not alone.
- When you need to relax, perform deep breathing exercises rather than reaching for a cigarette.
- Avoid situations that you associate with smoking.
- Each day, reward yourself in a positive way. Buy yourself something with the money you have saved or plan a special reward as a celebration for quitting.

addition, it is recommended that the LDL-C should be less than 100 mg/dL, the high-density-lipoprotein cholesterol (HDL-C) should be greater than 40 mg/dL in men and 50 mg/dL in women, and the triglyceride level should be less than 150 mg/dL. Keep in mind, however, that except at very high levels, cholesterol is not the culprit but rather an indirect measure of oxLDL which is the culprit.

Cholesterol is transported in the blood by lipoproteins. The major categories of lipoproteins are very-low-density lipoprotein (VLDL), LDL, and HDL. Because VLDL and LDL are responsible for transporting fats (primarily triglycerides and cholesterol) from the liver to body cells, whereas HDL is responsible for returning fats to the liver, elevations of either VLDL or LDL are associated with an increased risk for developing atherosclerosis, the primary cause of a heart attack or stroke. In contrast, elevations of HDL-C are associated with a lower risk of heart attacks.

The ratios of total cholesterol to HDL-C and LDL-C to HDL-C are referred to as the *cardiac risk factor ratios* because they reflect whether cholesterol is being deposited into tissues or broken down and excreted. The ratio of total cholesterol to HDL-C should be no higher than 4.2, and the ratio of LDL-C to HDL-C should be no higher than 2.5. The risk of heart disease can be reduced dramatically by lowering LDL-C while simultaneously raising HDL-C levels. For every 1% drop in the LDL-C level, the risk of a heart attack drops by 2%. Conversely, for every 1% increase in HDL-C level, the risk for a heart attack drops by 3% to 4%.[10]

Further refinement of determining risk. Although LDL-C is referred to as "bad cholesterol," some forms are worse than others. For example, oxidized LDL-C is a persistent proinflammatory trigger for the progression of atherosclerosis and plaque rupture and highly predictive of cardiovascular disease. LDL-C molecules of higher density are associated with greater risk than larger, less dense molecules. Small, dense LDL-C has a greater content of apolipoprotein CIII (apo CIII); in addition, apoB particles are more atherogenic than larger, less dense LDL-Cs and are markers for CVD risk.[11] In a small trial of nondiabetic subjects, researchers determined that these smaller particles were more heavily and preferentially glycated over the larger, more buoyant LDL-C particles, strongly suggesting an explanation for why these particles are more likely to participate in atherogenesis and highlighting the importance of avoiding hyperglycemia and excessive glycation.[12]

Another marker that deserves mention is Lp(a), a plasma lipoprotein whose structure and composition closely resemble those of LDL-C but with an additional molecule of an adhesive protein called apolipoprotein(a). Elevated plasma levels of Lp(a) are an independent risk factor for CHD, particularly in those patients with elevated LDL-C levels. In one analysis, a high level of Lp(a) was shown to carry with it a ten times greater risk for heart disease than an elevated LDL-C level.[13] That is because LDL-C alone lacks the adhesive apolipoprotein(a). As a result, LDL-C does not easily stick to the walls of the artery. An elevated LDL-C level carries less risk than a normal or even low LDL-C combined with an elevated Lp(a). Levels of Lp(a) below 20 mg/dL are associated with a low risk of heart disease; levels between 20 and 40 mg/dL are associated with a moderate risk; and levels above 40 mg/dL are associated with an extremely high risk of heart disease.

Elevations of triglycerides. A large body of accumulating evidence indicates that hypertriglyceridemia (HTG) is an independent risk factor for CVD. Multivariate analysis of 8-year follow-up data from the large-scale Prospective Cardiovascular Munster Study found HTG to be an independent risk factor for major coronary events after controlling for LDL-C and HDL-C.[14] HTG combined with elevated LDL-C and a high LDL-C:HDL-C (>5) increased the risk for a CHD event by approximately sixfold. A large meta-analysis of 17 prospective trials reported that an 88 mg/dL (1.0 mmol/L) increase in plasma triglyceride levels significantly increased the relative risk of CVD by approximately 30% in men and 75% in women. The corresponding rates were somewhat lower (14% and 37%, respectively) but still statistically significant after adjustment for HDL-C level.[15]

This increased risk is mediated through the metabolic interrelationships between serum triglyceride (TG) levels and other risk factors, such as the atherogenic lipid profile (low HDL-C levels and elevated small dense LDL levels), insulin resistance, a prothrombotic propensity, and low-grade systemic inflammation. TG-lowering strategy in patients with HTG is an important clinical goal in reducing the risk of not only atherosclerosis but also the metabolic syndrome and diabetes.

Inherited elevations of cholesterol and triglycerides. Elevations of blood cholesterol, triglycerides, or both can be due to genetic factors. These conditions are referred to as *familial hypercholesterolemia (FH)*, *familial combined hyperlipidemia (FCH)*, and *familial hypertriglyceridemia (FHTG)*. Relatively speaking, these disorders are among the most common inherited diseases, affecting about 1 in every 500 people.

The problem in FH is a defect in the receptor protein for LDL-C in the liver. Normally, the LDL-C receptor is responsible for removing cholesterol from the blood. When the liver cell takes up the LDL-C after it has bound to the receptor, it signals the liver cell to stop making cholesterol. In FH, the defect in the LDL-C receptor results in the liver not receiving the message to stop making cholesterol.

Damage to the LDL-C receptor occurs with normal aging and in several disease states. Diabetes may be the most significant disease owing to increased glycosylation of the receptor proteins. As a result of damage to the LDL-C receptor, cholesterol levels tend to rise with age. In addition, a diet high in saturated fat and cholesterol decreases the number of LDL-C receptors, thereby reducing the feedback mechanism that tells the liver cell to decrease cholesterol synthesis.

Lifestyle and dietary changes can increase the function or number of LDL-C receptors or both. The most dramatic effects are in people without inherited causes of elevated cholesterol or triglycerides or both, but even people with FH can benefit.

FCH and FHTG result in defects that are similar to those of FH. In FCH, the basic defect appears to be an accelerated production of VLDL

in the liver. These individuals may have only a high blood triglyceride level, only a high cholesterol level, or both. In FHTG, there is only an elevation in blood triglyceride levels, and HDL-C levels tend to be low. The defect in FHTG is that VLDL particles made by the liver are larger than normal and carry more triglycerides. FHTG is aggravated by diabetes, gout, and obesity.

Diabetes

Atherosclerosis is one of the key underlying factors in the development of many chronic complications of diabetes. Individuals with diabetes have a twofold to threefold higher risk of dying prematurely of heart disease or stroke than persons who do not have diabetes, and 55% of deaths in patients with diabetes are caused by CVD. However, even mild insulin resistance and poor glucose control have both been shown to have a dramatic effect on the incidence and progression of CVD. For more information, see Chapter 165.

Elevated Blood Pressure

Elevated blood pressure is often a sign of considerable atherosclerosis and a major risk factor for heart attack or stroke. In fact, the presence of hypertension is generally regarded as the most significant risk factor for stroke. For more information, see Chapter 179.

Physical Inactivity

Physical activity refers to "bodily movement produced by skeletal muscles that requires energy expenditure" and produces healthy benefits. Exercise, a type of physical activity, is defined as "a planned, structured, and repetitive bodily movement done to improve or maintain one or more components of physical fitness." Physical inactivity denotes a level of activity less than that needed to maintain good health. Physical inactivity characterizes most Americans, because roughly 54% of adults report little or no regular leisure physical activity, and there is also a sharp decline in regular exercise among children and adolescents.[1]

Physical activity protects against the development of CVD and favorably modifies other CVD risk factors, including high blood pressure, blood lipid levels, insulin resistance, and obesity. Physical activity is also important in the treatment and management of patients with CVD or increased risk including those who have hypertension, stable angina, a prior MI, peripheral vascular disease, heart failure, or who are recovering from a cardiovascular event.

Environmental Toxins

Particulate matter. Cumulative epidemiological and experimental data have shown that exposure to air pollutants leads to increased cardiovascular ischemic events and enhanced atherosclerosis. In approximately 43 million adults from the APHEA2 (Air Pollution and Health: A European Approach) study, it was found that daily cardiovascular mortality increased 1.5% for every 20 μg/m^3 increase in PM_{10}.[16] Ultrafine particles (<0.18 μm) enhance early atherosclerosis, partly due to their high content in redox cycling chemicals and their ability to synergize with known proatherogenic mediators in the promotion of tissue oxidative stress as well as through alterations of the anti-inflammatory function of plasma HDL (Fig. 149.2).[17]

$PM_{2.5}$ levels are also positively associated with increases in carotid intima-media thickness (CIMT). A study of 798 residents of the Los Angeles area found that for each 10 μg/m^3 of $PM_{2.5}$, CIMT increased by 5.9%.[18] Those patients on lipid-lowering agents had almost triple the increase in CIMT (15.8%) for each 10 μg/m^3 rise in $PM_{2.5}$, and in women over the age of 60, CIMT increased an average of 19.2%.

Persistent and nonpersistent organic pollutants

PCBs. Swedish seniors with higher levels of polychlorinated biphenyls (PCBs) 206, 170, 156, 153, 138, and 118 had more carotid artery atherosclerosis than those with lower PCB levels.[19] PCBs 170 and 156 both doubled the risk, and PCBs 206 and 153 increased the risk by 65%, 138 by 46%, and 118 by 16%.

Bisphenol A (BPA) and Phthalates. The Metabonomics and Genomics in Coronary Artery Disease study in the United Kingdom found that participants without coronary artery disease had a mean urinary BPA of 1.28 ng/mL, whereas participants with severe CAD had a mean of 1.53 ng/mL.[20] The PIVUS study found a positive association between BPA and carotid atherosclerosis with both thickness of the carotid intima and echogenicity of plaque in Swedish seniors.[21] Data from this study also revealed a positive association between carotid atherosclerosis and monomethyl phthalates (MMP), monoisobutyl phthalate (MiBP), and mono-2-ethylhexyl phthalate (MEHP).

Toxic metals

Mercury. Mercury is a powerful cardiac toxicant, and its presence in fish may completely negate the positive benefit of the omega-3 oils. Elevated hair mercury is associated with a 60% increase in risk of having an acute MI, a 68% greater likelihood of having CVD, and a 56% greater risk of having coronary heart disease.[22] As hair mercury increases, CIMT also increases.

Cadmium. The 1999 to 2006 NHANES trial found a 50% increase in blood cadmium was associated with a 35% increase in the risk of stroke and a 48% increased risk for heart failure.[23] Swedish adults (46–67 years of age) with blood cadmium levels in the fourth quartile were 80% more likely to have an acute coronary event and 90% more likely to have a stroke.[24]

Other Risk Factors

In addition to the major risk factors for CVD (e.g., smoking, elevations in cholesterol, elevated blood pressure, diabetes, and physical inactivity/obesity), a number of other factors have, on occasion, been shown to be more significant. See Box 149.2 for a list of several of the more than 300 different risk factors that have been identified.

Although there is considerable evidence that all these risk factors can play significant roles in the pathogenesis of atherosclerosis, much of the research has focused on the central roles of inflammatory processes and insulin resistance.[25] Inflammatory mediators influence many stages of atheroma development, from initial leukocyte recruitment to eventual rupture of the unstable atherosclerotic plaque. In particular, C-reactive protein (CRP), an acute-phase reactant that reflects different degrees of inflammation, has been identified as an independent risk factor for CAD. Although the CRP level has been shown to be a stronger predictor of cardiovascular events than the LDL-C level, screening for both biological markers provides better prognostic information than screening for either alone.[26]

Elevations in CRP are closely linked to insulin resistance and the metabolic syndrome.[27] The diagnostic criteria for the metabolic syndrome comprise the presence of at least three of the following metabolic risk factors in one person:

- Central obesity (a waist-to-hip ratio >1 for men and >0.8 for women)
- Atherogenic dyslipidemia (mainly triglycerides >150 mg/dL and low HDL-C [<40 mg/dL in men and <50 mg/dL in women])
- Hypertension (≥130/85 mm Hg)
- Insulin resistance or glucose intolerance (fasting blood sugar levels >101 mg/dL or HbA_{1c} 5.7%–6.4%)
- Prothrombotic state (e.g., high fibrinogen or plasminogen activator inhibitor in the blood)
- Proinflammatory state (e.g., elevated high-sensitivity CRP in the blood)

The metabolic syndrome has become increasingly common in the United States, affecting more than 60 million U.S. adults. Insulin

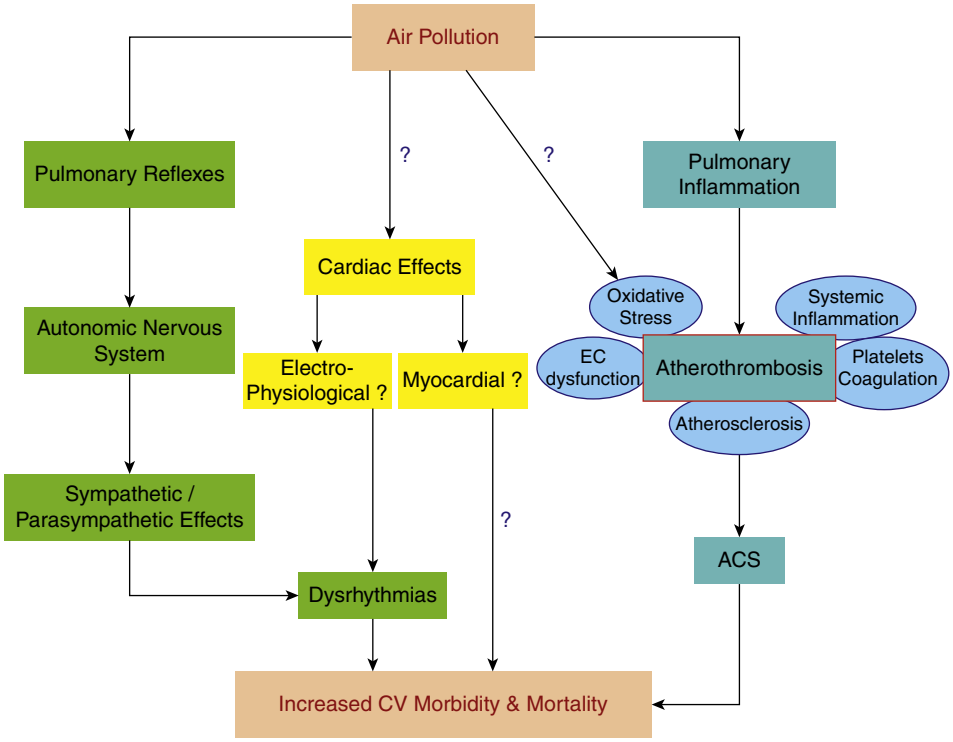

Fig. 149.2 Possible mechanisms that link air pollution with increased cardiovascular morbidity and mortality. (From Araujo JA, Nel AE. Particulate matter and atherosclerosis: role of particle size, composition and oxidative stress. *Part Fibre Toxicol.* 2009;6:24.)

resistance and metabolic syndrome are closely tied to obesity (particularly abdominal obesity), elevations in CRP, and a significant risk for CAD.

THERAPEUTIC CONSIDERATIONS—GENERAL GUIDELINES

Prevention of a heart attack or stroke involves reducing risk factors. The major risk factor of smoking was discussed earlier, and obesity, physical inactivity, diabetes, and hypertension are detailed in separate chapters. Significant evidence shows that simply adopting a healthy diet and lifestyle dramatically reduces CVD-related mortality. In a prospective trial enrolling more than 20,000 men and women, it was found that the combination of four healthy behaviors (nonsmoking, not physically inactive, moderate alcohol intake, and a plasma vitamin C indicative of at least 5 servings of fruit and vegetables per day) reduced total mortality fourfold compared with those who had none of these behaviors.[28]

Diet—General Guidelines

The dietary program detailed in Chapter 44 features a comprehensive dietary approach for both the prevention and treatment of CVD as well as the improvement of blood lipid profiles. It is important to reduce the intake of saturated fat and trans fatty acids and to increase the consumption of vegetables, fruit, dietary fiber, monounsaturated fats, and omega-3 fatty acids. One important dietary goal is improving the structure and composition of cell membranes by incorporating essential structural components, such as monounsaturated and omega-3 fatty acids, and by preventing oxidative and free radical damage to these structures by consuming a high level of antioxidants and phytochemicals.

Mediterranean Diet

One of the most widely studied dietary interventions in CAD is the traditional "Mediterranean diet,"[29] which reflects food patterns typical in some Mediterranean regions in the early 1960s. Unfortunately, the modern Mediterranean diet has deviated significantly from its healthful origin.

The original Mediterranean diet had the following characteristics:

- Olive oil is the principal source of fat.
- The diet centers on an abundance of plant food (fruits; potatoes, beans, and other vegetables; breads; pasta; nuts; and seeds).
- Foods are minimally processed, and people focus on seasonally fresh and locally grown foods.
- Fresh fruit is the typical daily dessert, with sweets containing concentrated sugars or honey consumed only a few times a week at the most.
- Dairy products (principally cheese and yogurt) are consumed daily in low to moderate amounts.
- Fish is consumed regularly.
- Poultry and eggs are consumed in moderate amounts (up to four times a week) or not at all.
- Red meat is consumed in low amounts.
- Wine is consumed in low to moderate amounts, normally with meals.

In one study, the effect of the Mediterranean diet on endothelial function and vascular inflammatory markers was studied in patients with metabolic syndrome.[30] Patients in the intervention group were instructed to follow the Mediterranean diet and received detailed advice on how to increase their daily consumption of whole grains, fruits, vegetables, nuts, and olive oil; patients in the control group followed the American Heart Association (AHA) diet. After 2 years, patients following the Mediterranean diet consumed more foods rich in monounsaturated fat, polyunsaturated fat, and fiber and had a lower

ratio of omega-6 to omega-3 fatty acids. In comparison with patients consuming the control diet, patients consuming the intervention diet had significantly reduced serum concentrations of CRP and other inflammatory mediators, improved endothelial function, and greater weight loss.

A study in elderly individuals analyzed the relationship between polyphenol intake from a Mediterranean diet and circulating inflammatory biomarkers and cardiovascular risk factors.[31] A total of 1139 high-risk participants were randomly assigned to a low-fat control diet or to two Mediterranean diets, supplemented with either extra virgin olive oil or nuts. Results showed increases in polyphenol intake measured as urinary total urinary polyphenol excretion (TPE) were associated with decreased inflammatory biomarkers, suggesting a dose-dependent anti-inflammatory effect of polyphenols. In addition, systolic and diastolic blood pressure (BP) decreased and plasma high-density lipoprotein cholesterol increased in parallel with increasing urinary TPE.

Although several components of the Mediterranean diet deserve special mention, it is important to stress that the total benefits reflect an interplay among many beneficial compounds rather than any single factor.[32]

Although the consumption of seafood has been shown to have beneficial effects on cardiovascular risk, these benefits can be challenged by the toxic metal content of the seafood. A cross-sectional study explored the association of seafood consumption and its estimated toxic metal contents (arsenic [As], cadmium [Cd], mercury [Hg], and lead [Pb]) with the lipid profile and lipid oxidation biomarkers in adults from a Spanish Mediterranean area without risk factors for CVD.[33] Researchers observed a mean seafood consumption of 74.9g per day (95% CI: 59.9–89.9), including 22.7g of shellfish per day (95% CI: 13.5–31.9) with moderate adherence to the Mediterranean diet. The estimated toxic metal contents were: 21.12 μg/kg per week As, 0.57 μg/kg per week InAs, 0.15 μg/kg per week Cd, 1.11 μg/kg per week Hg and 0.28 μg/kg per week Pb. An increase in shellfish consumption was associated with increases in the levels of LDLc, non-HDLc, APOB/A, and plasma oxLDL. The study authors concluded that in adults without risk factors for CVD, increasing shellfish consumption, even by a moderate amount, could favor a proatherogenic lipid profile and a higher level of oxidized LDL.

In addition, it is critical to follow a low-glycemic diet. A prospective trial with more than 48,000 participants highlighted the importance of good glycemic control for preventing CVD. Following a study population for an average of 8 years, researchers found that the consumption of foods with a high glycemic load increased the risk of CHD in women by 68%; women in the highest glycemic-load quartile had a relative risk of 2.2 for CHD compared with those in the lowest quartile.[34]

Olive Oil and Omega-3 Fatty Acids

One of the most important aspects of the Mediterranean diet may be the combination of olive oil (a source of monounsaturated fats and antioxidants) and the intake of omega-3 fatty acids. Olive oil consists not only of monounsaturated fatty acid (oleic acid), but also of several antioxidant agents that may also account for some of its health benefits. In addition to a mild effect in lowering LDL-C and triglycerides, olive oil increases the HDL-C level and helps prevent LDL-C from being damaged by free radicals.[35] Bioactive compounds in olive oil have also been shown to exhibit a potent capability to attenuate oxidative stress and improve endothelial function through their anti-inflammatory, antioxidant, and antithrombotic properties, therefore reducing the risk and progression of atherosclerosis.[36] Ironically, olive oil has often been inappropriately used as the placebo in trials of fish oils.

In addition to olive oil, the benefits of the longer-chain omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) for cardiovascular health has been demonstrated in more than 300 clinical trials. These fatty acids exert considerable benefits in reducing the risk for CVD. Supplementation with EPA and DHA has little effect on cholesterol levels but does lower triglyceride levels significantly, as well as producing myriad additional beneficial effects, including reduced platelet aggregation; improved endothelial function and arterial flexibility; improved blood and oxygen supply to the heart; and a mild effect in lowering blood pressure by vasodilation and promotion of sodium excretion.[37]

The levels of EPA and DHA within red blood cells have been shown to be highly significant predictors of heart disease and is known as the omega-3 index. An omega-3 index of 8% is associated with the greatest protection, whereas an index of 4% is associated with the least protection. In one analysis, the omega-3 index was shown to be the most significant predictor of CAD compared with CRP; total cholesterol, LDL-C, or HDL-C; and homocysteine. Researchers subsequently determined that a total of a combined 1000 mg of EPA and DHA daily is required to achieve or surpass the 8% target of the omega-3 index.[38,39]

The findings with the omega-3 index are not surprising, because a wealth of information has documented a clear relationship between dietary intake of omega-3 fatty acids and the likelihood of developing CHD: the higher the omega-3 fatty acid intake, the lower the likelihood of CHD. It has been estimated that raising the levels of long-chain omega-3 fatty acids through diet or supplementation may reduce overall cardiovascular mortality by as much as 45%.[40,41]

In general, for preventive effects against CVD, the dosage recommendation is 1000 mg of EPA plus DHA a day; for lowering triglycerides, the dosage is 3000 mg. In a double-blind study, after 8 weeks of supplementation, a daily dosage of 3.4 g EPA plus DHA lowered triglycerides by 27%, but a lower dosage of 0.85 g had no effect. These results clearly indicate that the effective dosage for lowering triglycerides with fish oils requires dosages of 3 g EPA plus DHA a day.[42] In comparison with other triglyceride-lowering therapies, EPA has been found to inhibit cholesterol crystal formation, inflammation, and oxidative modification of atherogenic lipoprotein particles, thus interfering with the mechanisms of atherosclerosis, resulting in reduced numbers of cardiovascular events.[43]

Although the longer-chain omega-3 fatty acids exert more pronounced effects than alpha-linolenic acid (ALA), the shorter omega-3 fatty acid from vegetable sources, it is important to point out that the two populations with the lowest rates of heart attack have a relatively high intake of ALA: the Japanese population who inhabits Kohama Island and the inhabitants of Crete.[44,45] Typically, Cretans have a threefold higher serum concentration of ALA than members of other European countries, owing to their frequent consumption of walnuts and the vegetable purslane.[44] Of course, another important dietary factor in both the Kohamans and Cretans is their use of oleic acid–containing oils. However, although the oleic acid content of their diets offers some degree of protection, the rates of heart attack among the Kohamans and Cretans are much lower than rates in populations that consume only oleic acid sources and little ALA. The intake of ALA is viewed as a more significant protective factor than oleic acid.

Nuts and Seeds

Higher consumption of nuts and seeds has been shown to significantly reduce the risk of CVD in large epidemiological studies including the Nurses' Health Study, the Iowa Health Study, and the Physicians' Health Study.[46] Researchers estimate that substituting nuts for an equivalent amount of carbohydrates in an average diet resulted in a

30% reduction in heart disease risk. Researchers calculated an even more impressive risk reduction, 45%, when fat from nuts was substituted for saturated fats (found primarily in meat and dairy products). Nuts have a cholesterol-lowering effect, which partly explains this benefit, but they are also a rich source of arginine. By increasing nitric oxide levels, arginine may help to improve blood flow, reduce blood clot formation, and improve blood fluidity (i.e., the blood becomes less viscous and therefore flows through blood vessels more easily).

Walnuts appear to be especially beneficial because they are also a rich source of both antioxidants and ALA. In one study, hypercholesterolemic men and women were randomized to a cholesterol-lowering Mediterranean diet and a diet of similar energy and fat content in which walnuts replaced approximately 32% of the energy from monounsaturated fat (olive oil). Participants followed each diet for 4 weeks. In comparison with the Mediterranean diet, the walnut diet improved endothelial cell function (i.e., it increased endothelium-dependent vasodilation and reduced levels of vascular cell adhesion molecule-1). The walnut diet also significantly reduced total cholesterol (–4.4%) and LDL-C (–6.4%).[47]

Vegetables, Fruits, and Red Wine

An important contributor to the benefits noted with the Mediterranean diet is the focus on carotene- and flavonoid-rich fruits, vegetables, and beverages (e.g., red wine). Numerous population studies have repeatedly demonstrated that a higher intake of dietary antioxidants significantly reduces the risk of heart disease and stroke. Higher blood levels of antioxidant nutrients are also associated with lower levels of CRP.[48]

Two valuable sources of antioxidants in the Mediterranean diet are tomato products and red wine. Tomatoes are a rich source of the carotene lycopene. A systematic review and meta-analysis evaluated the effect of supplementing tomato and lycopene on CV risk factors and determined that the available evidence supports the view that increasing the intake of these has positive effects on blood lipids, blood pressure, and endothelial function.[49] In large clinical studies evaluating the relationship between carotene status and heart attack (acute MI), lycopene but not beta-carotene was shown to be protective. Lycopene exerts greater antioxidant activity compared with beta-carotene in general but specifically against LDL-C oxidation.[50]

The cardiovascular protection offered by red wine is popularly referred to as the "French paradox." Because the French population consumes more saturated fat than people in the United States and the United Kingdom do yet have a lower incidence of heart disease, red wine consumption has been suggested to be the reason. Presumably this protection is the result of flavonoids and other polyphenols in red wine that protect against oxidative damage to LDL-C as well as help reduce the levels of inflammatory mediators.[30,51] Moderate alcohol consumption alone has also been shown to be protective in some studies by exerting positive effects on ratios of HDL-C to LDL-C and CRP as well as levels of fibrinogen, although red wine typically exerts the most significant effects.[52]

Importantly, the effects of alcohol on CVD risk, morbidity, and total mortality are counterbalanced by alcohol's addictive and psychological effects.

The major benefits of red wine consumption in protecting against CVD may ultimately be the effects that the polyphenols have on improving endothelial cell function. In one study, 30 male patients with CHD were randomly assigned to take a red grape polyphenol extract (600 mg) or placebo. Flow-mediated dilation was measured after fasting and 30, 60, and 120 minutes after intake of the grape extract or placebo. The intake of the red grape polyphenol extract caused an increase in flow-mediated dilation, peaking at 60 minutes, which was significantly higher than the baseline values and the corresponding values at 60 minutes after the intake of placebo (4.52% vs. 2.64%).[53]

The consumption of green tea, like that of red wine, has also been shown in population studies to be associated with a reduced risk for CVD. As with red wine, much of the benefit of green tea consumption may be the result of several different mechanisms, including improving endothelial cell function. Green tea polyphenols (catechins) have been shown to decrease the oxidation of LDL-C, lower LDL-C levels, and improve the LDL-C:HDL-C ratio. In vitro studies have shown a dose-dependent response with green tea polyphenols in reducing several biomarkers associated with atherosclerosis and ischemia, including the inhibition of the endothelial cell–derived vascular cell adhesion molecule-1 as well as angiotensin II, platelet derived growth factor-BB, apolipoprotein E, and inducible nitric oxide synthase.[54]

Another mechanism of action for red wine and green tea polyphenols involves inhibiting the formation of new blood vessels within the vascular lesion. During the angiogenic process, new blood vessels develop from the existing microvascular bed. The initial event involves dilation of an existing blood vessel followed by an increase in vascular permeability and the degradation of extracellular matrices. This process allows endothelial cells to migrate into the lesion and proliferate, and these events are followed by the maturation of new blood vessels. The angiogenic process is controlled by two major proangiogenic factors: matrix metalloproteinases (MMPs), which degrade extracellular matrices, and vascular endothelial growth factor (VEGF), which strongly stimulates endothelial cell migration and proliferation and the formation of new blood vessels. Both red wine and green tea polyphenols have been shown to inhibit this process in vitro at concentrations conceivably achievable with oral intake.[54]

Foods and beverages rich in antioxidant content have shown benefit in fighting atherosclerosis. Pomegranate *(Punica granatum)* juice appears to be particularly useful. It is remarkably rich in antioxidants, such as soluble polyphenols, tannins, and anthocyanins. Animal research has indicated that components of pomegranate juice can retard atherosclerosis, reduce plaque formation, and improve arterial health. Human clinical studies have supported the role of pomegranate juice in benefiting heart health.[55–57]

In a randomized, placebo-controlled, double-blind study, the daily consumption of pomegranate juice for 3 months was evaluated for its effect on myocardial perfusion in 45 patients who had CHD and myocardial ischemia. Patients were randomly assigned into one of two groups: a pomegranate juice group (240 mL per day) or a placebo group, who drank a beverage of similar caloric content, amount, flavor, and color. Participants underwent electrocardiographic-gated myocardial perfusion single-photon emission computed tomographic scintigraphy at rest and during stress at baseline and 3 months. After 3 months, the extent of stress-induced ischemia decreased in the pomegranate group but increased in the control group. This benefit was observed without changes in cardiac medications, blood sugar, hemoglobin A_{1c}, weight, or blood pressure in either group.[55]

In another study, 10 patients with carotid artery stenosis (CAS) were evaluated to gauge the effect of pomegranate juice consumption on the progression of carotid lesions and changes in oxidative stress and blood pressure. The patients were supplemented with pomegranate juice (50 mL) for 1 year, and 5 patients continued for up to 3 years. In the control group (which did not consume pomegranate juice), common carotid intimal-medial thickness (IMT) increased by 9% during 1 year, whereas pomegranate juice consumption resulted in a significant IMT reduction, by up to 30%, after 1 year. In comparison with values obtained before pomegranate juice consumption, the patients' serum paraoxonase 1 (PON 1) activity was increased by 83%,

whereas serum LDL-C basal oxidative state and LDL-C susceptibility to copper ion–induced oxidation were both significantly reduced, by 90% and 59%, respectively, after 12 months. Furthermore, serum levels of antibodies against oxidized LDL-C were decreased by 19%; in parallel, serum total antioxidant status was increased by 130% after 1 year of pomegranate juice consumption. Systolic blood pressure was reduced after 1 year of pomegranate juice consumption by 21%. For all studied parameters, the maximal effects were observed after 1 year of pomegranate juice consumption.[56]

THERAPEUTIC CONSIDERATIONS—LOWERING CHOLESTEROL

Lowering total cholesterol (TC), as well as LDL-C and triglycerides (TG), is clearly associated with reducing CVD risk. Most of the benefits noted with lowering LDL-C are based on a large number of randomized clinical trials involving the use of the HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors known collectively as statin drugs. Statins owe their origin to red yeast *(Monascus purpureus)* fermented on rice. This traditional Chinese medicine has been used for its health-promoting effects in China for more than 2000 years. Red yeast rice is the source of a group of compounds known as monacolins (e.g., lovastatin, also known as monacolin K, one of the key monacolins in red yeast rice extract). The marketing of an extract of red yeast fermented on rice standardized for monacolin content as a dietary supplement in the United States caused controversy in 1997, because this agent contained a natural source of a prescription drug. The U.S. Food and Drug Administration (FDA) eventually ruled that red yeast rice products could be sold only if they were free of monacolin.

Although the data are clear that statin drugs can produce decreases in total mortality, cardiovascular events, hospitalizations, and the need for revascularization procedures in high-risk patients, the debate remains whether statin therapy represents the optimal treatment approach to the primary prevention of CAD in patients with only the risk factor of elevated LDL-C, especially in light of the growing acceptance of risk factors like CRP and the emerging role of nutrition.[58,59] For example, one study compared the "portfolio diet," comprising plant-based cholesterol-lowering foods, with lovastatin.[60] The participants were randomly assigned to undergo one of three interventions on an outpatient basis for 1 month: a diet low in saturated fat, based on milled whole-wheat cereals and low-fat dairy foods; the same diet plus lovastatin, 20 mg per day; or a diet high in plant sterols (1 g/1000 kcal), soy protein (21.4 g/1000 kcal), viscous fibers (9.8 g/1000 kcal), and almonds (14 g/1000 kcal). The control, statin, and dietary portfolio groups had mean (SE) decreases in LDL-C of 8%, 30.9%, and 28.6%, respectively. Respective reductions in CRP were 10%, 33.3%, and 28.2%. This study and subsequent studies showed that by diversifying the cholesterol-lowering components in the same dietary portfolio, the effectiveness of diet as a treatment of hypercholesterolemia was increased. Moreover, results comparable with those of a statin drug (with lipid-lowering effects similar to statins in terms of both LDL-C and size of LDL-C) were produced.[61,62]

Although individual dietary changes may produce benefit in improving blood lipids, the best clinical approach is to incorporate a broad-spectrum dietary approach that incorporates a wide array of dietary components shown to have a positive effect on lipid levels. For example, although a meta-analysis of 27 randomized controlled trials in which isolated soy protein supplementation was the only intervention demonstrated that soy protein supplementation was associated with a significant dose-dependent reduction in mean serum total cholesterol, LDL-C, and triglycerides, the effect shown (–5.26 mg/dL, –4.25 mg/dL, and –6.26 mg/dL, respectively) was less than when the soy protein was used in conjunction with other dietary interventions.[63] In addition, the effects of isolated soy protein appear to be considerably less than those achieved by increasing soy food consumption in general. Much of the cholesterol-lowering effect of soy foods may relate more to the isoflavone and soluble fiber content than to the protein. In an earlier meta-analysis based more on soy protein intake from other sources in addition to soy protein isolate, reductions were much more significant for total cholesterol (–23.2 mg/dL), LDL-C (–21.7 mg/dL), and triglycerides (–13.3 mg/dL) but still relatively modest from a clinical perspective.[64] Although these results do support the recommendation to increase soy protein intake in the dietary approach to hypercholesterolemia, given the relatively small effect of soy protein on lipids, it is imperative that other dietary recommendations also should be promoted, such as reducing the dietary intake of saturated fat, trans-fatty acids, and cholesterol, as well as increasing the dietary intake of monounsaturated fats, soluble fiber, and nuts.

Despite research documenting the benefits of nonpharmacological approaches, it is unlikely that lowering LDL-C with statin drugs will be supplanted as the primary therapy in lipid management and the prevention of CAD at any time in the near future. In 2011 it was estimated that more than one of every six adults—nearly 40 million people—was taking a statin drug to lower LDL-C. Therefore the focus with many patients will be on the support of statin therapy. For example, it appears that individuals taking statin drugs must supplement with coenzyme Q_{10} (CoQ_{10}). For the synthesis of cholesterol, not only is HMG-CoA reductase required, but CoQ10 is as well. Thus administration of these drugs might compromise the status of CoQ_{10} by decreasing its synthesis. Even modest dosages of various statins have been shown to lower serum levels of CoQ_{10}. Researchers have concluded that inhibition of CoQ_{10} synthesis by statin drugs could explain the most commonly reported adverse effects, especially fatigue and muscle pain, as well as more serious side effects such as rhabdomyolysis.[65,66] CoQ_{10} supplementation in subjects on statin drugs has also been shown to reduce markers of oxidative damage.

Statins are also gaining popularity as a prescription method to lower CRP. In one study, a group of 186 individuals with type 2 diabetes was selected to receive 10 mg of atorvastatin (Lipitor), 80 mg of atorvastatin, or a placebo for 30 weeks. In individuals given placebo, CRP levels increased by 6.6%, decreased by 15% in the 10-mg group, and by 47% in the 80-mg group. In a study with pravastatin, 40 mg daily lowered CRP levels by 13%.[67]

The Importance of Soluble Dietary Fiber in Lowering Cholesterol

Chapter 132 provides a complete discussion of the benefits of dietary fiber. It is well established that the soluble dietary fiber found in legumes, fruit, and vegetables is effective in lowering cholesterol levels.[68] The greater the degree of viscosity or gel-forming nature, the greater the effect a particular dietary fiber has on lowering cholesterol levels. Highly viscous, soluble fiber blends are showing greater effect than previously used fiber sources, leading to more reasonable dosage recommendations (the cholesterol-lowering effect of soluble fiber is clearly dose-dependent).[69,70] Table 149.3 shows the average dosages and reductions noted in clinical trials with soluble fiber supplements.

Many of the studies featured oat preparations containing either oat bran or oatmeal.[71] The overwhelming majority of these studies demonstrated that individuals with high cholesterol levels see significant reductions with frequent oatmeal or oat bran consumption. In contrast, individuals with normal or low cholesterol levels see little change. In individuals with high cholesterol levels (above 200 mg/dL), the consumption of the equivalent of 3 g of soluble oat fiber typically lowers total cholesterol by 8% to 23%. This finding is highly

TABLE 149.4 Comparison of Niacin With Lovastatin

Lipoprotein	Group	Week 10	Week 18	Week 26
LDL-C reduction	Lovastatin	26%	28%	32%
	Niacin	5%	16%	23%
HDL-C increase	Lovastatin	6%	8%	7%
	Niacin	20%	29%	33%
Lp(a) lipoprotein reduction	Lovastatin	0%	0%	0%
	Niacin	14%	30%	35%

HDL-C, High-density-lipoprotein cholesterol; *LDL-C,* low-density-lipoprotein cholesterol.

TABLE 149.3 Effect of Various Sources of Fiber on Serum Cholesterol Levels

Fiber	Dosage (g)	Typical Reduction in Total Cholesterol
Oat bran (dry)	50–100	20%
Guar gum	9–15	10%
Pectin	6–10	5%
Psyllium	10–20	10–20%
Vegetable fiber	27	10%

significant, because with each 1% drop in serum cholesterol level, there is a 2% decrease in the risk of developing heart disease. One bowl of ready-to-eat oat bran cereal or oatmeal contains approximately 3 g of fiber. Although oatmeal's fiber content (7%) is less than that of oat bran (15%–26%), it has been determined that the polyunsaturated fatty acids contribute as much to the cholesterol-lowering effects of oats as the fiber content. Although oat bran has a higher fiber content, oatmeal is higher in polyunsaturated fatty acids.

In an effort to lower cholesterol with dietary fiber, patients should be encouraged to eat 35 g of fiber daily from fiber-rich foods, a full listing of which can be found in Chapter 132. Achieving higher fiber intake is associated not only with lower cholesterol levels but also with lower inflammatory mediators like CRP.[72]

Natural Products to Lower Cholesterol Levels

In many cases, dietary therapy, although important, is not sufficient alone to reduce lipid levels to the desired ranges. Fortunately, several natural compounds can lower cholesterol levels and other significant risk factors for CAD. In fact, when all factors are considered (e.g., cost, safety, effectiveness), the natural alternatives presented here may offer significant advantages to the standard drug therapy.

Niacin

Since the 1950s niacin (vitamin B_3) has been known to be effective in lowering blood cholesterol levels. In the 1970s the famed Coronary Drug Project demonstrated that niacin was the only cholesterol-lowering agent to actually reduce overall mortality. Niacin typically lowers LDL-C levels by 16% to 23% and raises HDL-C levels by 20% to 33%. These effects, especially the effect on HDL-C, compare quite favorably with those of conventional cholesterol-lowering drugs.[73,74]

It is now known that niacin does much more than lower total cholesterol. Specifically, niacin has been shown to lower LDL-C, the more harmful Lp(a) lipoprotein, as well as triglyceride, CRP, and fibrinogen levels and simultaneously raise levels of beneficial HDL-C. Although niacin has demonstrated better overall results in reducing risk factors for CHD compared with other cholesterol-lowering agents, physicians are often reluctant to prescribe niacin. The reason is a widespread perception that niacin is difficult to work with because of the bothersome flushing of the skin associated with its use. In addition, because niacin is a widely available "generic" agent, no pharmaceutical company stands to generate the huge profits that the other lipid-lowering agents have brought them. As a result, niacin does not benefit from the intensive advertising that focuses on the statin drugs. Despite the advantages of niacin over other lipid-lowering agents, it accounts for less than 10% of all cholesterol-lowering prescriptions.

Several studies have compared niacin with standard lipid-lowering drugs including the statin drugs. These studies have shown significant advantages for niacin. In the first published clinical study comprising 136 patients, niacin was compared with lovastatin directly in the following groups of subjects: (1) those with LDL-C levels greater than 160 mg/dL and CHD, (2) those with more than two CHD risk factors, (3) those with both elevated LDL-C levels and more than two CHD risk factors, (4) those with LDL-C levels greater than 190 mg/dL and without CHD, and (5) those with fewer than two CHD risk factors.[75] This controlled, randomized, open-label, 26-week study was performed at five lipid clinics. Patients were first placed on a 4-week diet run-in period, after which eligible patients were randomly assigned to receive treatment with either lovastatin (20 mg per day) or niacin (1.5 g per day). On the basis of the LDL-C response and patient tolerance, the doses were sequentially increased to 40 and 80 mg per day of lovastatin or 3 and 4.5 g per day of niacin after 10 and 18 weeks of treatment, respectively. In the two patient groups, 66% of patients treated with lovastatin and 54% of patients treated with niacin underwent full dosage titration. Table 149.4 shows the results.

These results indicate that, although lovastatin produced a greater reduction in LDL-C, niacin provided better overall results despite the fact that fewer patients were able to tolerate a full dosage of niacin because of skin flushing. The percentage increase in HDL-C, a more significant indicator for CHD, was dramatically in favor of niacin (33% vs. 7%). Equally impressive was the percentage decrease in Lp(a) for niacin. Although niacin produced a 35% reduction in Lp(a) levels, lovastatin did not produce any effect. Niacin's effect on Lp(a) in this study confirmed a previous study showing that niacin (4 g per day) reduced Lp(a) levels by 38%. Moreover, a subsequent study showed similar reductions in Lp(a) in patients with diabetes.[76,77]

Another comparative study evaluated the lipoprotein responses to niacin, gemfibrozil, and lovastatin in patients with normal total cholesterol levels but low levels of HDL-C.[78] The first phase of the study compared lipoprotein responses with lovastatin and gemfibrozil in 61 middle-aged men with low levels of HDL-C. In the second phase, 37 patients agreed to take niacin; 27 patients finished this phase at a dose of 4.5 g per day. In the first phase, gemfibrozil therapy increased HDL-C levels by 10% and lovastatin did so by 6%. In the second phase, niacin therapy was shown to raise HDL-C by 30%.

Another comparative study involved niacin versus atorvastatin (Lipitor).[79] The average dosage was 3000 mg for niacin and 80 mg for atorvastatin. The patients selected had abnormal particle size of LDL-C in that the molecules were small and dense—these LDL-C molecules are considerably more atherogenic than larger, less dense LDL-Cs. The patients selected also had low levels (<40%) of a specific fraction of HDL-C associated with a greater protective effect than HDL-C alone. Although atorvastatin reduced total LDL-C levels substantially more than niacin, niacin was more effective in increasing LDL-C particle size and raising HDL-C and HDL2-C than atorvastatin (Table 149.5).

Because taking niacin at higher dosages (e.g., ≥3000 mg) can impair glucose tolerance, many physicians have avoided niacin therapy in

TABLE 149.5 The Effects of Atorvastatin (Lipitor) and Niacin on Lipid Profiles

	ATORVASTATIN		NIACIN		ATORVASTATIN + NIACIN	
Parameter	**Before**	**After**	**Before**	**After**	**Before**	**After**
Total LDL-C (mg/dL)	110	56	111	89	123	55
LDL-C peak diameter	251	256	253	263	250	263

HDL-C, high-density-lipoprotein cholesterol; *LDL-C,* low-density-lipoprotein cholesterol.

diabetic patients, but newer studies with slightly lower dosages (1000–2000 mg) of niacin have not shown it to adversely affect blood sugar regulation.[80] For example, during a 16-week, double-blind, placebo-controlled trial, 148 patients with type 2 diabetes were randomized to placebo or 1000 or 1500 mg per day of niacin; in the niacin-treated groups, there was no significant loss of glycemic control, and the favorable effects on blood lipids were still apparent.[81] Other studies have actually shown hemoglobin A_{1C} to drop, indicating improvement in blood sugar control.[82]

The most common blood lipid abnormalities in patients with type 2 diabetes are elevated triglyceride levels, decreased HDL-C levels, and a preponderance of smaller, denser LDL-C particles. Niacin has been shown to address all of these areas more significantly than the statins or other lipid-lowering drugs.

In addition to lowering cholesterol and triglycerides, niacin exerts additional benefits in battling atherosclerosis. Specifically, niacin produces beneficial lipid-altering effects on particle distribution in patients with CAD that are not well reflected in typical lipoprotein analysis. In addition, systemic markers of inflammation decrease in patients receiving niacin. In one study, when a modest dosage of niacin (1000 mg daily) was added to existing therapy for 3 months in 54 subjects with stable CAD, participants experienced a 32% increase in large-particle HDL-C, an 8% decrease in small-particle HDL-C, an 82% increase in large-particle LDL-C, and a 12% decrease in small-particle LDL-C.[83] Niacin therapy also decreased lipoprotein-associated phospholipase A2 and CRP levels (20% and 15%, respectively). No significant changes from baseline were seen in any tested parameter in subjects who received placebo. These results indicate that the addition of niacin to existing medical regimens for patients with CAD and already well-controlled lipid levels improves the distribution of lipoprotein particle sizes and inflammatory markers in a manner expected to improve protection against a cardiovascular event.

Although niacin exerts significant benefit on its own, it does not appear to enhance the benefits of statins in well-controlled patients. The AIM-HIGH study funded by the National Heart, Lung, and Blood Institute recruited 3400 patients who were at risk for heart trouble despite the fact that their LDL-C was under control (<70 mg/dL) with the use of a statin drug [simvastatin (Zocor)]. The study ended 18 months early because no additional cardiovascular benefit was found in those taking niacin despite increases in HDL-C and reductions in triglycerides.[84]

In the Carotid Plaque Composition Study, 126 subjects with a history of CVD were randomized to atorvastatin or a combination of atorvastatin and niacin to evaluate the relationship between these therapies and the concentration of high-density lipid particles (HDL-p) and cholesterol efflux capacity (i.e., the ability of serum HDL [serum depleted of apolipoprotein B-containing lipoproteins] to remove cholesterol from macrophages).[85] Atorvastatin significantly reduced LDL-C levels by 39% (−65 mg/dL, $P<0.0001$) and apoB by 35% (−47 mg/dL, $P<0.0001$). Adding niacin to atorvastatin reduced both LDL-C and apoB levels by an additional 11% (−83 mg/dL and −63 mg/dL, respectively). After 1 year of treatment with atorvastatin, HDL-C levels increased by 11%, and combination therapy raised HDL-C by an additional 18%. Combination therapy also increased macrophage cholesterol efflux capacity but failed to improve ATP-binding cassette transporter A1 (ABCA1)-specific cholesterol efflux capacity, which may explain why clinical trials have shown that although niacin increases HDL-C levels, it does not reduce cardiac risk.

The side effects of niacin. The side effects of niacin are well known. The most common and bothersome side effect is the skin flushing that typically occurs 20 to 30 minutes after the niacin is taken. Other occasional side effects of niacin include gastric irritation, nausea, and liver damage. In an attempt to combat the acute reaction of skin flushing, several manufacturers began marketing "sustained-release," "timed-release," or "slow-release" niacin products. These formulations allow the niacin to be absorbed gradually, thereby reducing the flushing reaction. However, although these forms of niacin reduce skin flushing, earlier timed-release preparations proved to be more toxic to the liver than regular niacin. In one analysis, 52% of the patients taking the earlier sustained-release niacin preparations developed liver toxicity, whereas none of the patients taking immediate-release niacin did so.[86] "Intermediate-release" preparations appear to have solved this problem, as relatively large clinical trials have shown them to be extremely well tolerated even when combined with statin drugs.[87–89]

The safety and tolerability of intermediate-release niacin preparation have been evaluated in a multicenter study of 566 patients.[90] The target dose was achieved by 65% of patients. Flushing was the most common side effect (42%), as expected, and 9.7% withdrew because of this. Other drug-related adverse reactions occurred at low frequency (18.6%), and 8.7% withdrew for an adverse reaction other than flushing. Most adverse reactions were mild or moderate in severity. There was no hepatotoxicity or serious adverse event involving muscle. The researchers concluded that intermediate-release nicotinic acid was well tolerated, and these results support its use in the management of patients with an increased cardiovascular risk due to low HDL-C.

Inositol hexaniacinate has long been used in Europe to lower cholesterol levels and to improve blood flow in intermittent claudication. It yields slightly better clinical results than standard niacin but is much better tolerated in terms of both flushing and, more importantly, long-term side effects.[91,92]

Regardless of the form of niacin being used, periodic checking (at least every 3 months) of cholesterol and liver function is indicated. Niacin should not be used in patients with preexisting liver disease or elevations in liver enzymes. For these patient groups, policosanol, garlic, or pantethine are recommended.

For best results, niacin should be taken at night, because most cholesterol synthesis occurs during sleep. If pure crystalline niacin is being used, it should begin with a dosage of 100 mg a day and be carefully increased over 4 to 6 weeks to the full therapeutic dosage of 1.5 to 3 g per day. If a timed-released preparation or inositol hexaniacinate is being used, a 500-mg dose should be given at night and increased to 1500 mg after 2 weeks. If after 1 month of therapy the dosage of 1500 mg per day fails to effectively lower LDL-C, the dosage should be increased to 3000 mg.

Plant Sterols and Stanols

Phytosterols and phytostanols are structurally similar to cholesterol and can act in the intestine to lower cholesterol absorption by displacing cholesterol from intestinal micelles. Because phytosterols and phytostanols are poorly absorbed themselves, blood cholesterol levels will likely drop owing to increased excretion. These compounds are showing up in functional foods (e.g., margarine and other spreads, orange juice), as well as in dietary supplements.[93]

Phytosterols and phytostanols are effective in lowering LDL-C in some people. A meta-analysis of 41 trials showed that a daily intake of 2 g of stanols or sterols reduces LDL-C by 10%.[93] Administration of higher dosages produced little additional benefit. Effects of phytosterols and phytostanols are additive with diet or drug interventions: Eating foods low in saturated fat and cholesterol and high in stanols or sterols can reduce LDL-C by 20%; adding sterols or stanols to statin medication is more effective than doubling the statin dose alone. Individuals most likely to respond have been identified as having high cholesterol absorption and low cholesterol biosynthesis. Phytosterols and phytostanols have been shown to have antiplatelet and antioxidant effects as well.[94–97]

Phytosterol or phytostanol intake at higher dosages may reduce carotenoid absorption. Human subjects consuming 6.6 g per day phytosterols showed cholesterol-adjusted plasma reduction of alpha- and beta-carotene levels (–19% to –23%), lutein (–14%), and lycopene (–11%). However, this effect was partially reversed by increased fruit and vegetable intake.[98]

Pantethine

Pantethine is the stable form of pantetheine, the active form of vitamin B_5 or pantothenic acid. Pantothenic acid is the most important component of coenzyme A (CoA). This enzyme is involved in the transport of fats to and from cells, as well as to the energy-producing compartments in cells. Without coenzyme A, the cells' fats could not be metabolized to energy.

Pantethine has significant lipid-lowering activity, whereas pantothenic acid has little if any effect in lowering cholesterol and triglyceride levels owing to pantethine's ability to be converted to cysteamine. Pantethine administration (standard dosage 900 mg per day) has been shown to significantly reduce serum triglyceride (−32%), total cholesterol (−19%), and LDL-C (−21%) levels and to increase HDL-C (+23%) levels.[99,100] It appears to be especially useful in lowering blood lipids in diabetic patients.[101–103]

The lipid-lowering effects of pantethine are most impressive when its toxicity (virtually none) is compared with that of conventional lipid-lowering drugs. Its mechanism of action is due to the inhibition cholesterol synthesis and acceleration of the use of fat as an energy source.

Garlic (*Allium sativum*) and Onion (*Allium cepa*)

Garlic offers significant protection against heart disease and stroke by lowering blood cholesterol levels even in apparently healthy individuals. According to the results of numerous double-blind placebo-controlled studies in patients with initial cholesterol levels above 200 mg/dL, supplementation with commercial preparations providing a daily dose of at least 10 mg of alliin or a total allicin potential of 4000 mg can lower total serum cholesterol levels by about 10% to 12% and LDL-C by about 15%. HDL-C usually increases by about 10%, and triglyceride levels typically drop by 15%. However, most trials using lower dosages of allicin fail to produce a lipid-lowering effect.[104–108]

Although the effects of supplemental garlic preparations on cholesterol levels are modest, the combination of lowering LDL-C and raising HDL-C can greatly improve the HDL-C:LDL-C ratio, a significant goal in the prevention of heart disease and stroke. Garlic preparations have also demonstrated blood pressure–lowering effects, inhibition of platelet aggregation, reduction of plasma viscosity, promotion of fibrinolysis, prevention of LDL-C oxidation, and an ability to exert positive effects on endothelial function, vascular reactivity, and peripheral blood flow (see Chapter 51 for more information).

TABLE 149.6 Comparative Effects on Blood Lipids of Several Natural Compounds

	Niacin	Garlic	Policosanol	Pantethine
Total cholesterol (% decrease)	18	10	24	19
LDL-C (% decrease)	23	15	25	21
HDL-C (% increase)	32	31	15	23
Triglycerides (% decrease)	26	13	5	32

HDL-C, high-density-lipoprotein cholesterol; *LDL-C,* low-density-lipoprotein cholesterol.

Comparing Natural Cholesterol-Lowering Agents

Numerous natural compound products can effectively improve cholesterol and triglyceride levels. Of the several described earlier, niacin produces the best overall effect. However, the others do have a place in the clinical management of hyperlipidemia and the prevention of atherosclerosis (Table 149.6).

Typically, along with dietary and lifestyle recommendations, niacin (1500–3000 mg at night) reduces total cholesterol by 50 to 75 mg/dL within the first 2 months in patients with initial total cholesterol levels above 250 mg/dL. In patients with initial cholesterol levels above 300 mg/dL, it may take 4 to 6 months before cholesterol levels begin to reach recommended levels. Once cholesterol levels are reduced below 200 mg/dL, the dosage of niacin is reduced by 500 mg for 2 months. If the cholesterol levels creep up above 200 mg/dL, the dosage of niacin is raised back up to previous levels. If the cholesterol level remains below 200 mg/dL, then the niacin is dropped by another 500 mg and the cholesterol levels are rechecked in 2 months, with niacin therapy at previous levels if levels have exceeded 200 mg/dL. Continue with this reduction in dosage until niacin can be stopped entirely and cholesterol levels remain below 200 mg/dL.

Pantethine is recommended primarily to patients who have HTG, especially patients with diabetes. As stated earlier, pantethine has demonstrated excellent effects in diabetics. It not only improves cholesterol and triglyceride levels but also normalizes platelet lipid composition and function as well as blood viscosity.

With regard to elevations in Lp(a), both niacin and vitamin C have shown an ability to reduce Lp(a) levels dramatically (35% and 27% reductions, respectively). In addition, it is important to rule out low thyroid function (hypothyroidism) in all cases of elevated blood lipids, especially elevated Lp(a).

It is well established that patients with overt hypothyroidism are prone to CAD because of increased LDL-C and decreased HDL-C. What is not as well established is the significance of "subclinical" hypothyroidism in terms of risk for cardiovascular mortality. One study demonstrated that patients with subclinical hypothyroidism (defined in the study as normal T3 and free thyroxine index with a raised TSH) were shown to have significantly elevated levels of LDL-C as well as elevated Lp(a).[109] For more information, see Chapter 180.

THERAPEUTIC CONSIDERATIONS—ANTIOXIDANT STATUS

Dietary antioxidant nutrients like lycopene, lutein, selenium, vitamin E, and vitamin C have been shown in epidemiological studies to offer significant protection against the development of CVD. Fats and cholesterol are particularly susceptible to free radical damage. When damaged, fats and cholesterol form lipid peroxides and oxidized cholesterol, which can then damage the artery walls and accelerate the progression of atherosclerosis. Antioxidants block the formation of these damaging compounds.

Although diets rich in antioxidant nutrients have consistently shown tremendous protection against CVD, clinical trials using antioxidant vitamins and minerals have produced inconsistent results.[110,111] The human antioxidant system represents a complex scenario of interacting components, which may explain the inconsistent findings. It is unlikely that any single antioxidant would prove to be effective, especially in the absence of a supporting cast. Most antioxidants require some sort of "partner" antioxidant, allowing them to work more efficiently. The most salient example of this is the partnership between the two primary antioxidants in the human body—vitamins C and E. Vitamin C is an "aqueous phase" antioxidant, and vitamin E is a "lipid phase" antioxidant. Although some studies have shown that supplementation with these nutrients reduces atherosclerotic lesions, more protection is likely required to ensure optimal effect.[112]

In addition to vitamin C, vitamin E also requires selenium and CoQ_{10} to work efficiently. Further adding to the shortcomings of many of the studies on antioxidant nutrients is the lack of consideration of the importance of phytochemicals and plant-derived antioxidants that, in addition to exerting benefit on their own, are well known to potentiate the activities of vitamin and mineral antioxidants. Phytochemicals like carotenes (especially lycopene and lutein) and flavonoids are especially important in fighting against free-radical damage. Most scientific reviews on antioxidant supplements devote significant attention to the studies using beta-carotene, because they have involved more than 70,000 subjects, but such studies fail to differentiate the facts that synthetic beta-carotene was used, and that beta-carotene is of little importance in protecting against LDL-C oxidation. (Unlike lycopene and lutein, beta-carotene does not become incorporated into LDL-C effectively, although it may help protect the endothelium.)

Lutein may be one of the most significant carotenes in the battle against atherosclerosis. Based on analysis of the different subtypes of LDL-C, lycopene, beta-carotene, and cryptoxanthin were mainly located in the larger, less dense LDL-C particles, whereas lutein and zeaxanthin were found preferentially in the smaller, denser LDL-C particles.[113] Because the smaller, denser LDL-C subtype is most easily oxidized, lutein and zeaxanthin are particularly important in protecting against damage to LDL-C.

The support of nonantioxidant vitamins and minerals may also be important in supporting the effectiveness of antioxidants. Taking a multivitamin/multimineral supplement seems appropriate. In one double-blind study, CRP levels were significantly lower in the multivitamin group than in the placebo group, with the reduction in CRP levels most evident in patients who had elevated levels (≥1 mg/L) at baseline.[114] Researchers found that serum vitamin B_6 and vitamin C levels were inversely associated with CRP level.

TABLE 149.7 Effect of Increasing Doses of Vitamin E on Oxidation Parameters

Dosage (mg/day)	Lag Time[a]	Propagation Rate[b]
0	94	7.8
25	99	8
50	100	7.9
100	106	7.7
200	111	7.5
400	116	6.8
800	120	6.5

[a]The time before oxidation occurs after the addition of an oxidizing agent. The higher the number, the greater the beneficial effect.
[b]The rate at which lipid peroxidation progresses. The lower the number, the greater the beneficial effect.

Vitamin E

Oxidation of LDL to oxLDL is a crucial step in the development of atherosclerosis. Although clinical studies have shown inconsistent effects, vitamin E plays a role in the protection against oxidation of LDL-C because it can be easily incorporated into the LDL-C molecule (Table 149.7). In a placebo-controlled, randomized study, 12 weeks of vitamin E supplementation (800 International Units (IU) per day) increased LDL resistance to oxidation without changing the serum lipid profile or lipoprotein lipid composition.[115] There is a clear-cut dosage effect (i.e., the higher the dosage of vitamin E, the greater the degree of protection against oxidative damage to LDL-C). Doses greater than 400 IU are often required to produce clinically significant effects.[116–118]

Improvements have also been noted in insulin sensitivity and plasma lipids in non–insulin-dependent diabetic patients.

Several large population studies have demonstrated that vitamin E levels may be more predictive of incipient heart attack or stroke than total cholesterol levels.[117–120] Although the consumption of red wine has been suggested as the reason behind the French paradox, described earlier, higher vitamin E levels also provide a viable explanation.[117–119]

Vitamin E may offer additional benefit in protecting against heart disease and strokes by its ability to:

- Reduce LDL-C peroxidation and increase plasma LDL-C breakdown
- Inhibit excessive platelet aggregation
- Increase HDL-C levels
- Increase fibrinolytic activity
- Reduce CRP levels
- Improve endothelial cell function
- Improve insulin sensitivity

Two early large-scale studies with relatively low dosages of vitamin E supplementation demonstrated a significant reduction in the risk of heart attack or stroke. The Nurses' Health Study of 87,245 nurses concluded that those who took 100 IU of vitamin E daily for more than 2 years had a 41% lower risk of heart disease compared with nonusers of vitamin E supplements.[119] The Physicians' Health Study of 39,910 male health care professionals found similar results: a 37% lower risk of heart disease with the intake of more than 30 IU of supplemental vitamin E daily.[120] Subsequent studies have been equivocal.[110]

Large-scale studies examining the effect of vitamin E supplementation in patients with existing CAD have also shown somewhat conflicting results.[111,112] Some of the disappointing results may have been due to the choice of synthetic vitamin E (DL-alpha tocopherol) in one of

TABLE 149.8 Intervention Trials With Vitamin E for Secondary Prevention

Study	Number of Subjects	Dosage	Duration	Outcome
HOPE (2000)	9541	400 IU (d-alpha)	4.5 years	No effect
SPACE (2000)	196	800 IU (d-alpha)	1.4 years	-70%
GISSI (1999)	11,324	300 IU (synthetic)	3.5 years	-35% (vs. placebo)
CHAOS (1996)	9541	400–800 IU (d-alpha)	1.4 years	-47%

CHAOS, Cambridge Heart Antioxidant Study; *HOPE,* Heart Outcomes Protection Evaluation Trial; *GISSI,* Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico; *SPACE,* Secondary Prevention with Antioxidants of Cardiovascular Disease in Endstage Renal Disease.

the large studies versus the more active natural form (D-alpha tocopherol). In addition, interference by statin drugs in vitamin E and CoQ_{10} metabolism increases the needs for both compounds (Table 149.8).

Vitamin E and CoQ_{10} work synergistically, and each is required for the regeneration of the other. For example, CoQ_{10} is present in the blood in both oxidized (inactive) and reduced (active) forms. During times of increased oxidative stress or low vitamin E levels, more CoQ_{10} will be converted to its oxidized (inactive form). Thus by providing higher levels of vitamin E, the biological activity and function of CoQ_{10} are enhanced, and vice versa. Several studies in humans and animals have shown that the combination of vitamin E and CoQ_{10} works better than either one alone. For example, in a study in baboons, where supplementation with vitamin E alone reduced CRP levels, cosupplementation with CoQ_{10} significantly enhanced this effect of vitamin E. Similar results have been seen in other animal studies on other factors associated with atherosclerosis, including LDL-C oxidation and lipid peroxide content within the aorta.[120–123]

In addition to CoQ_{10}, vitamin E also requires adequate selenium status for optimal antioxidant effects. Selenium functions primarily as a component of the antioxidant enzyme glutathione peroxidase. This enzyme works closely with vitamin E to prevent free-radical damage to cell membranes. Studies looking only at vitamin E's ability to reduce cancer and heart disease are often faulty because they fail to factor in the critical partnership between selenium and vitamin E, not to mention the interrelationship between vitamin E and CoQ_{10}. Several studies have clearly demonstrated that low selenium status is significantly associated with CAD.[124,125] Failure to cosupplement with selenium as well as vitamin C and CoQ_{10} may be a major reason for the inconsistent results in intervention trials with vitamin E supplementation alone.

Finally, the importance of prescribing the full complement of the eight vitamin E isomers cannot be overstated. Most of the cardiovascular research with vitamin E has been on the synthetic DL alpha-tocopherol. The problem with this approach is more fully discussed in Chapter 127, Vitamin Toxicities and Therapeutic Monitoring.

Vitamin C

Vitamin C works as an antioxidant in aqueous (water) environments in the body—both outside and inside human cells. It is the first line of antioxidant protection in the body. Its primary antioxidant partner is vitamin E, as this antioxidant is fat-soluble. Along with CoQ_{10}, vitamin C is also responsible for regenerating oxidized vitamin E in the body, thus potentiating the antioxidant benefits of vitamin E.[126] Vitamin C also works along with antioxidant enzymes such as glutathione peroxidase, catalase, and superoxide dismutase. Vitamin C has been shown to be extremely effective in preventing LDL-C from being oxidized, even in smokers.[127] Vitamins C and E supplementation (500 mg and 272 IU daily, respectively) for 6 years has been shown to reduce the progression of carotid atherosclerosis by 53% in men and 14% in women.[128]

A high dietary intake of vitamin C has been shown to significantly reduce the risk of death from heart attacks and strokes, as well as all other causes including cancer in numerous population studies.[129] One of the most detailed studies analyzed the vitamin C intake of 11,348 adults over 5 years and divided them into three groups: (1) less than 50 mg dietary intake daily; (2) greater than 50 mg daily dietary intake with no vitamin C supplementation; and (3) greater than 50 mg dietary intake a day plus vitamin C supplementation (estimated to be ≥300 mg).[129] Analysis showed that the standardized mortality ratio, a comparison with the average death rate, was up to 48% lower in the high vitamin C intake group than in the low-intake group for CVD and overall mortality. These differences correspond to an increase in longevity of 5 to 7 years for men and 1 to 3 years for women.

Dozens of observational and clinical studies have shown that vitamin C levels correspond to total cholesterol and HDL-C.[130–132] In one of the best-designed studies, it was shown that the higher the vitamin C content of the blood, the lower the total cholesterol and triglycerides and the higher the HDL-C.[132] The benefits for HDL-C were particularly impressive. For each 0.5 mg/dL increase in vitamin C content of the blood, there was an increase in HDL-C of 14.9 mg/dL in women and 2.1 mg/dL in men. This study demonstrates that the association of vitamin C and HDL-C levels persists even in well-nourished individuals with normal serum levels of vitamin C who supplement their diets with additional vitamin C. Vitamin C therapy also has positive effects on the fibrinolytic system, and has been shown to reduce CRP and Lp(a)

In summary, vitamin C lowers the risk of CVD by[126–134]:

- Acting as an antioxidant
- Strengthening the collagen structures of the arteries
- Lowering total cholesterol, Lp(a), and blood pressure
- Raising HDL-C levels
- Inhibiting platelet aggregation
- Promoting fibrinolysis
- Reducing markers of inflammation

Grape Seed and Pine Bark Extracts

One of the most beneficial groups of plant flavonoids are the proanthocyanidins (also referred to as *procyanidins* or *procyanidolic oligomers* [PCOs]). Although PCOs exist in many plants, as well as in red wine, commercially available sources of PCO include extracts from grape seeds and the bark of the maritime pine (Landes).[135] These extracts offer protection via several different mechanisms, including their antioxidant activity and effects on endothelial cells. For more information, see Chapter 106.

THERAPEUTIC CONSIDERATIONS—MISCELLANEOUS RISK FACTORS

Platelet Aggregation

Excessive platelet aggregation is another independent risk factor for heart disease and stroke. Once platelets aggregate, they release potent

compounds that dramatically promote the formation of the atherosclerotic plaque, or they can form a clot that can lodge in small arteries and produce a heart attack or stroke. The adhesiveness of platelets is determined largely by the types of fats in the diet and the level of antioxidants. Although saturated fats and cholesterol increase platelet aggregation, omega-3 oils (both short-chain and long-chain) and monounsaturated fats have the opposite effect.[136,137]

In addition to the monounsaturated and omega-3 fatty acids, antioxidant nutrients, and flavonoids, vitamin B_6 also inhibits platelet aggregation and lowers blood pressure and homocysteine levels.[138,139] In one study, the effect of vitamin B_6 (pyridoxine HCl) supplementation on platelet aggregation, plasma lipids, and serum zinc levels was determined in 24 healthy male volunteers (19–24 years old) given either pyridoxine at a dosage of 5 mg/kg body weight or a placebo for 4 weeks.[138] Results demonstrated that pyridoxine inhibited platelet aggregation by 41% to 48%, but there was no change in the control group. Pyridoxine prolonged both bleeding and coagulation time but not over the physiological limits. It had no effect on platelet count. Pyridoxine was also shown to lower total plasma lipids and cholesterol levels considerably from pretreatment levels. Total plasma lipids were reduced from 593 to 519 mg/dL, and total cholesterol was reduced from 156 to 116 mg/dL. HDL-C increased from 37.9 to 48.6 mg/dL. Serum zinc levels increased from 96 to 138 mg/dL.

In another study, a significant inverse graded relation was observed between the serum level of pyridoxal-5-phosphate (P5P) and both CRP and fibrinogen.[140] The odds ratio for CAD risk related to low P5P concentrations after adjustments for the major classic CAD risk factors, including CRP and fibrinogen, was 1.89. In addition, the CAD risk as a result of low P5P was additive when considered in combination with elevated CRP concentrations or with an increased LDL-C:HDL-C ratio.

These results provide clear evidence of the possible role of vitamin B_6 supplementation in reducing the risk of atherosclerotic mortality.

Garlic preparations standardized for alliin content as well as garlic oil have also demonstrated inhibition of platelet aggregation. In one study, 120 patients with increased platelet aggregation were given either 900 mg per day of a dried garlic preparation containing 1.3% alliin or a placebo for 4 weeks.[141] In the garlic group, spontaneous platelet aggregation disappeared, the microcirculation of the skin increased by 47.6%, plasma viscosity decreased by 3.2%, diastolic blood pressure dropped from an average of 74 to 67 mm Hg, and fasting blood glucose concentration dropped from an average of 89.4 to 79 mg/dL.

Fibrinogen

Early clinical studies encouraged detailed epidemiological investigations into the possible link between fibrinogen and CVD.[142] The first such study was the Northwick Park Heart Study in the United Kingdom. This large study involved 1510 men 40 to 64 years of age who were randomly recruited and tested for a range of clotting factors including fibrinogen. At the 4-year follow-up, there was a stronger association between cardiovascular deaths and fibrinogen levels than that for cholesterol. This association has now been confirmed in at least five other prospective epidemiological studies.

Natural therapies designed to promote fibrinolysis include exercise, omega-3 oils, niacin, garlic, and nattokinase. In addition, the Mediterranean diet alone significantly reduces fibrinogen and other markers of inflammation.[143] Adherence to the Mediterranean diet was shown to be associated with a 20% lower CRP level, 17% lower interleukin-6 level, 15% lower homocysteine level, and 6% lower fibrinogen level.

Natto is a traditional Japanese food prepared from fermented soybeans by *Bacillus subtilis.* Nattokinase is a serine proteinase isolated from natto that has potent fibrinolytic and thrombolytic activity. An open-label, self-controlled clinical trial was conducted on subjects of the following groups: healthy volunteers (healthy group), patients with cardiovascular risk factors (cardiovascular group), and patients undergoing dialysis (dialysis group). All subjects ingested two capsules of nattokinase (2000 fibrinolysis units per capsule) daily orally for 2 months. The laboratory measurements were performed on the screening visit and then regularly after the initiation of the study. After 2 months of administration, fibrinogen, factor VII, and factor VIII decreased by 9%, 14%, and 17%, respectively, for the healthy group; 7%, 13%, and 19%, respectively, for the cardiovascular group; and 10%, 7%, and 19%, respectively, for the dialysis group. These results highlight the potential of nattokinase as a natural fibrinolytic.[144]

Homocysteine

Homocysteine is an intermediate in the conversion of the amino acid methionine to cysteine. If a person is functionally deficient in folic acid, vitamin B_6, or vitamin B_{12}, there will be an increase in homocysteine. Elevated homocysteine levels are an independent risk factor for developing a heart attack, stroke, or peripheral vascular disease. Elevations in homocysteine are found in approximately 20% to 40% of patients with heart disease and are significantly associated with CAD.[145–147] A meta-analysis found that for each increase of 5 μmol/L in homocysteine, the risk of CHD events increased by approximately 20%, independently of traditional CHD risk factors.[148]

A number of interrelated atherogenic mechanisms are thought to be involved with hyperhomocysteinemia. These mechanisms include advanced thickening and smooth muscle cell proliferation of endothelial vessel wall intima, enhanced lipid deposition in the vessel wall, forced detachment of endothelial cells, activation of leukocytes and thrombocytes, increased LDL-C oxidation, initiation of platelet thromboxane synthesis, enhanced oxidative stress induced by peroxide formation during homocysteine oxidation, and prothrombotic coagulation interference. Homocysteine is thought to promote atherosclerosis by directly damaging the artery, reducing the integrity of the vessel wall, and interfering with the formation of proper collagen.

Although supplementation with the active form of folate, 5-methylfolate (400 mcg daily), alone can reduce homocysteine levels in many subjects, given the importance of vitamins B_{12} and B_6 for proper homocysteine metabolism, all three should be used together. In one study, the suboptimal levels of these nutrients in men with elevated homocysteine levels were 56.8%, 59.1%, and 25% for folic acid, vitamin B_{12}, and vitamin B_6, respectively, indicating that folate supplementation alone would not lower homocysteine levels in many cases.[149] In other words, folate supplementation will lower homocysteine levels only if there are adequate levels of vitamins B_{12} and B_6.

In 1998 the FDA mandated the fortification of food products with folic acid. Although homocysteine levels have decreased modestly since then, the effect on mortality has been minor at best.[150] This reflects the importance of more aggressive supplementary measures to reduce homocysteine-associated cardiovascular risk, as well as the importance of supplementing with the most active forms to enhance bioavailability.

"Type A" Personality

"Type A" behavior is characterized by an extreme sense of time urgency, competitiveness, impatience, and aggressiveness. This behavior carries with it a twofold increase in CHD compared with non–type A behavior.[151-152] Particularly damaging to the cardiovascular system is the regular expression of anger. In one study, the relationship between habitual anger coping styles, especially anger expression, and serum lipid concentrations were examined in 86 healthy subjects.[153] Habitual

anger expression was measured on four scales: aggression, controlled affect, guilt, and social inhibition. A positive correlation between serum cholesterol level and aggression was found. The higher the aggression score, the higher the cholesterol level. A negative correlation was found between the ratio of LDL-C to HDL-C and controlled affect score—the greater the ability to control anger, the lower this ratio. In other words, people who learn to control anger experience a significant reduction in the risk for heart disease, whereas an unfavorable lipid profile is linked with a predominantly aggressive (hostile) anger coping style.

Anger expression also plays a role in CRP levels. In one study, greater anger and severity of depressive symptoms, separately and in combination with hostility, were significantly associated with elevations in CRP in apparently healthy men and women.[154] Other mechanisms explaining the link between the emotions, personality, and CVD include increased cortisol secretion, endothelial dysfunction, hypertension, and increased platelet aggregation and fibrinogen levels.[138] These associations are independent of potential confounding factors.

Ten tips that can help patients improve their coping strategies include:

1. Do not starve your emotional life. Foster meaningful relationships. Provide time to give and receive love in your life.
2. Learn to be a good listener. Allow the people in your life to really share their feelings and thoughts uninterruptedly. Empathize with them; put yourself in their shoes.
3. Do not try to talk over somebody. If you find yourself being interrupted, relax; do not try to outtalk the other person. If you are courteous and allow someone else to speak, eventually (unless he or she is extremely rude) he or she will respond likewise. If not, explain that he or she is interrupting the communication process. You can do this only if you have been a good listener.
4. Avoid aggressive or passive behavior. Be assertive but express your thoughts and feelings in a kind way to help improve relationships at work and at home.
5. Avoid excessive stress in your life as best you can by avoiding excessive work hours, poor nutrition, and inadequate rest. Get as much sleep as you can.
6. Avoid stimulants like caffeine and nicotine. Stimulants promote the fight-or-flight response and tend to make people more irritable in the process.
7. Take time to build long-term health and success by performing stress-reduction techniques and deep breathing exercises.
8. Accept gracefully those things over which you have no control. Save your energy for those things that you can do something about.
9. Accept yourself. Remember that you are human and will make mistakes from which you can learn along the way.
10. Be more patient and tolerant of other people. Follow the golden rule.

Other Nutritional Factors

Magnesium and Potassium

Magnesium and potassium are absolutely essential to the proper functioning of the entire cardiovascular system. Their critical roles in preventing heart disease and strokes are now widely accepted. In addition, there is a substantial body of knowledge demonstrating that magnesium or potassium supplementation or both are effective in treating a wide range of CVDs, including angina, arrhythmias, congestive heart failure, and high blood pressure. In many of these applications, magnesium or potassium supplementation or both have been used for more than 50 years.

Because the role of potassium in the cardiovascular system is described in detail in Chapter 179, the focus here is on magnesium. Most Americans do not consume enough of this important mineral. The average intake of magnesium by healthy adults in the United States ranges from 143 to 266 mg/day. This level is well below even the recommended daily allowance (RDA) of 350 mg for men and 300 mg for women. Food choices are the main reason. Because magnesium occurs abundantly in whole foods, most nutritionists and dietitians assume that most Americans get enough magnesium in their diets. However, most Americans are not eating whole, natural foods. They are consuming large quantities of processed foods. Because food processing refines a large portion of magnesium, most Americans are not getting the RDA for magnesium.

The best dietary sources of magnesium are tofu, legumes, seeds, nuts, whole grains, and green leafy vegetables. Fish, meat, milk, and most commonly eaten fruits are quite low in magnesium. Most Americans consume a low-magnesium diet because their diet is high in low-magnesium foods such as processed foods, meat, and dairy products.

People dying of heart attacks have been shown to have lower heart magnesium levels than people of the same age dying of other causes.[155] Low serum magnesium (≤0.80 mmol/L) has been associated with an increased risk of coronary heart disease mortality (hazard ratio: 1.36, 95% CI: 1.09–1.69) and sudden cardiac death (hazard ratio: 1.54, 95% CI: 1.12–2.11) as well as subclinical atherosclerosis (expressed as increased carotid intima-media thickness: +0.013 mm, 95% CI: 0.005–0.020).[156] Low magnesium levels contribute to atherosclerosis and CVD via many mechanisms including the promotion of endothelial dysfunction by generating a proinflammatory, prothrombotic, proatherogenic environment.[157]

Intravenous magnesium therapy has emerged as a valued treatment measure in acute MI.[158–160] The major obstacle to it becoming the preferred method for saving a person's life may be a financial interest. Magnesium is inexpensive compared with high-tech, high-priced, genetically engineered drugs currently being promoted by drug companies. The treatment of acute MI is big business in the United States. Each year more than 1.5 million U.S. citizens experience acute MI. Although many other parts of the world are now using magnesium therapy for acute MI because of its effectiveness, low cost, safety, and ease of administration, it plays second fiddle to the high-tech drugs in the United States.

Several well-designed studies involving more than 4000 patients have demonstrated that intravenous magnesium supplementation during the first hour of admission to a hospital for acute MI produces a favorable effect in reducing immediate and long-term complications as well as death rates. The beneficial effects of magnesium in acute MI relate to its ability to:

- Improve energy production within the heart
- Dilate the coronary arteries, resulting in improved delivery of oxygen to the heart
- Reduce peripheral vascular resistance, resulting in reduced demand on the heart
- Inhibit platelets from aggregating and forming blood clots
- Reduce the size of the infarct (blockage)
- Improve heart rate and arrhythmias

Vitamin D Deficiency

Data from more than 8000 individuals enrolled in the NHANES 2001 to 2004 study indicate that individuals with vitamin D (25-OH) levels below 30 ng/mL were more likely to be at high risk for CVD (OR 1.32), for CHD (OR 1.48), and for both CHD and heart failure (OR 3.52).[161] A prospective cohort study of more than 3000 men and women found that those in the lowest quartile of 25-hydroxy vitamin D had a hazard ratio of 2.22 for cardiovascular mortality and 2.08 for all-cause mortality.[162]

THERAPEUTIC CONSIDERATIONS—PREVENTING A RECURRENT HEART ATTACK

People who have experienced a heart attack or stroke and live through it are extremely likely to experience another. The primary prevention of subsequent cardiovascular events is to control the major cardiac risk factors (e.g., hyperlipidemia, hypertension, cigarette smoking, diabetes, physical inactivity). The most popular "secondary" recommendation to reduce the risk of a subsequent heart attack being given by most physicians is low-dose aspirin (e.g., 325 mg per day or every other day). However, there may be effective alternatives, especially for those who cannot tolerate aspirin therapy. It is becoming standard to recommend dosages of aspirin lower than 325 mg (e.g., 50–150 mg per day or every other day). To date these lower dosages have not been shown to be effective in reducing CVD mortality.

Aspirin

Aspirin has been shown to decrease the risk of CVD events in both primary and secondary trials. The first primary prevention study was the Physicians' Health Study, a randomized double-blind placebo-controlled trial of 22,071 apparently healthy men. The study was terminated early owing principally to a statistically extreme 44% reduction in the risk of a first MI with the use of 325 mg of aspirin every other day. Since this study, three additional randomized trials including both men and women have shown aspirin to be effective in the primary prevention of MI: the Thrombosis Prevention Trial, the Hypertension Optimal Treatment Study, and the Primary Prevention Project. Among the 55,580 subjects, aspirin use was associated with a statistically significant 32% reduction in the risk of a first MI and a significant 15% reduction in the risk of all other important vascular events, but it had no significant effects on nonfatal stroke or vascular death. Evaluation of the data from the Physicians' Health Study indicated that those with the highest CRP had the greatest decrease in risk, 55.7%, versus 13.9% in those with the lowest CRP. It seems reasonable to reserve the use of aspirin as a primary prevention strategy for individuals with high CRP values.[163]

Regarding the secondary prevention of MI, there have been seven prospective randomized placebo-controlled trials involving almost 15,000 survivors of heart attack that have examined the use of aspirin to reduce the incidence of recurrent heart attack and death. These trials used several doses of aspirin, ranging from 325 to 1500 mg per day and enrolled patients at various intervals after infarction ranging from 4 weeks to 5 years. None of the studies demonstrated a statistically significant reduction in mortality with aspirin use. However, when all the results from these studies were pooled, aspirin was shown to reduce the mortality rate from all causes as well as cardiovascular deaths. The mortality rate for all causes in the aspirin group was 5.8%, compared with 8.3% in the placebo group, indicating a reduction in mortality by 30% with aspirin.[164,165]

Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with a significant risk of peptic ulcer. However, most studies documenting the relative frequency of peptic ulcers as a consequence of NSAIDs have focused on their use in the treatment of arthritis and headaches. The risk of gastrointestinal bleeding due to peptic ulcers has been evaluated for aspirin at daily dosages of 300, 150, and 75 mg, respectively. Essentially there is an increased risk of gastrointestinal bleeding due to peptic ulcers at all dosage levels. However, the dosage of 75 mg per day was associated with a 40% reduction in ulcers compared with 300 mg per day and 30% compared with 150 mg per day.[166]

Because it is unknown whether 75 mg per day of aspirin is helpful in preventing a second heart attack, most physicians recommend at least 100mg. To prevent stroke, the dosage necessary appears to be 160mg. These dosage recommendations carry with them a significant risk for developing a peptic ulcer but may be appropriate for high-risk patients unwilling to adopt the natural approach.

Dietary Alternatives to Aspirin

Several studies have shown that dietary modifications are not only more effective in preventing recurrent heart attack than aspirin but can also reverse the blockage of clogged arteries. In addition to the studies with the Mediterranean diet, three famous studies deserve special mention. The first was the Lifestyle Heart Trial conducted by Dean Ornish.[167] In this study, subjects with heart disease were divided into a control group and an experimental group. The control group received regular medical care, and the experimental group was asked to eat a low-fat vegetarian diet for at least 1 year. The diet included fruits, vegetables, grains, legumes, and soybean products. Subjects were allowed to consume as many calories as they wished. No animal products were allowed except egg whites and 1 cup of nonfat milk or yogurt daily. The diet contained approximately 10% fat; 15% to 20% protein; and 70% to 75% carbohydrates—that is, predominantly complex carbohydrates from whole grains, legumes, and vegetables.

The experimental group was also asked to perform stress reduction techniques such as breathing exercises, stretching exercises, meditation, imagery, and other relaxation techniques for an hour each day and to exercise for at least 3 hours each week. At the end of the year, the subjects in the experimental group showed significant overall regression of atherosclerosis of the coronary blood vessels. In contrast, subjects in the control group who were being treated with regular medical care and following the standard AHA diet actually showed progression of their disease. Ornish stated, "This finding suggests that conventional recommendations for patients with CHD (such as a 30% fat diet) are not sufficient to bring about regression in many patients."

Numerous population studies have demonstrated that people who consume a diet rich in omega-3 oils from either fish or vegetable sources have a significantly reduced risk of developing heart disease. Two famous intervention trials upheld this protective effect. In the Dietary and Reinfarction Trial (DART), it was only when the intake of omega-3 fatty acids (from fish) was increased that future heart attacks were reduced.[168] In another study, the Lyon Diet Heart Study, increasing the intake of omega-3 fatty acids from plant sources (alpha-linolenic acid) was found to offer the same degree of protection as increased fish intake.[169]

Preventing a Subsequent Stroke

To prevent a subsequent stroke and promote recovery from a stroke, *Ginkgo biloba* extract should be added to the program as described earlier for preventing a subsequent heart attack. The extract of *G. biloba* leaves standardized to contain 24% ginkgo flavonglycosides and 6% terpenoids has been the subject of more than 300 published scientific papers and more than 40 double-blind studies in the treatment of decreased blood supply to the brain (cerebrovascular insufficiency). *G. biloba* extract has also been shown to enhance stroke recovery (see Chapter 93 for more information).

Other Considerations

Angiography, Coronary Artery Bypass Surgery, or Angioplasty

A significant challenge for the clinician is determining when a patient should be referred for angiography, coronary artery bypass surgery, or angioplasty. As is fully discussed in Chapter 82, these procedures are used far more frequently than is justified by objective evaluation of their appropriateness and efficacy. Chapter 145 also provides advice for patient care when angiography, coronary artery bypass surgery, or angioplasty is unavoidable.

TABLE 149.9 Food Choices for Lowering Cholesterol

Decrease Consumption of the Following:	Substitute With the Following:
Red meat	Fish and white-meat poultry
Hamburgers and hot dogs	Soy-based alternatives
Eggs	Egg Beaters and similar products, tofu
High-fat dairy products	Low-fat or nonfat dairy products
Butter, lard, and other saturated fats	Vegetable oils
Ice cream, pies, cake, cookies, etc.	Fruits
Refined cereals, white	Whole grains, whole wheat bread, etc.
Fried foods, fatty snack foods	Vegetables, fresh salads
Salt and salty foods	Low-sodium foods, light salt
Coffee and soft drinks	Herbal teas, fresh fruit, and vegetable juices

Intravenous Chelation Therapy

Intravenous ethylenediamine tetraacetic acid chelation therapy is a useful yet controversial procedure and is fully discussed in Chapter 146.

Earlobe Crease

The presence of a diagonal earlobe crease has been recognized as a sign of CVD since 1973. More than 30 studies have been reported in the medical literature. The earlobe is richly vascularized, and a decrease in blood flow over an extended period of time is believed to result in collapse of the vascular bed. This collapse leads to a diagonal crease.[170,171]

In one study, angiographs performed on 205 consecutive patients showed an 82% accuracy in predicting heart disease, with a false-positive rate of 12% and a false-negative rate of 18%. In another study of 112 consecutive patients, the earlobe crease was highly correlated with demonstrable heart disease and less strongly with previous MI.[171]

The crease is seen more commonly with advancing age, until the age of 80, when the incidence drops dramatically. However, the association with heart disease is independent of age. Although the presence of an earlobe crease does not prove heart disease, it strongly suggests it, and examination of the earlobe is an easy screening procedure. The correlation does not hold with Asians, Native Americans, or children with Beckwith's syndrome.[171]

THERAPEUTIC APPROACH

There is little doubt that in most cases atherosclerosis is directly related to diet and lifestyle. Treatment and prevention include reducing all known risk factors. For many patients, this goal requires a major change in diet and lifestyle. Because so many factors are known to be involved in atherosclerosis, any treatment plan must be individualized to assure optimal results. What follows is a general approach that must be tailored according to the clinical picture and the patient's willingness to adopt it.

BOX 149.5 Foods Typically Containing Partially or Totally Hydrogenated Vegetable Oils and Trans Isomers

- Virtually all refined and processed foods
- Margarine
- Cakes
- Cookies
- Candies
- Doughnuts
- Bread
- Canned soups
- Crackers
- Processed cheese
- Canned foods
- Cerealsd
- Snack foods
- Salad oils, except olive oil, which is recommended

Dietary Recommendations

Follow the dietary guidelines given in Chapter 44 (a modified version of the Mediterranean diet). Table 149.9 provides additional guidance in dietary selections, and Box 149.5 lists foods to avoid because of their trans-fatty acid content. Specifically, it is important to:

- Eat less saturated fat and cholesterol by reducing or eliminating the amounts of animal products in the diet.
- Increase the consumption of fiber-rich plant foods (fruits, vegetables, grains, legumes, and raw nuts and seeds).
- Increase the consumption of monounsaturated fats and omega-3 fatty acids.
- Follow a low-glycemic diet.

Lifestyle Recommendations

- Achieve ideal body weight.
- Exercise aerobically on a regular basis.
- Do not smoke.

Supplements

- High-potency multivitamin and mineral formula
- Vitamin C: 250 to 500 mg 3 times a day
- Vitamin E (mixed tocopherols): 200 to 400 IU per day
- Grape seed or pine bark extract: 100 mg per day
- Fish oil supplement: minimum 1000 mg of EPA + DHA
- Vitamin D: 1000 to 4000 IU/day (should usually be complemented with vitamin K_2)

Atopic Dermatitis (Eczema)

Michael Traub, ND, DHANP, FABNO

OUTLINE

DIAGNOSTIC SUMMARY

- Chronic, pruritic, inflammatory skin
- Dry, hyperkeratotic skin
- Lesions include excoriations, papules, eczema (patches of erythema, exudation, and scaling with small vesicles formed within the epidermis), and lichenification (hyperpigmented plaques of thickened skin with accentuated furrows)
- Scratching and rubbing lead to lichenification, most commonly in the antecubital and popliteal flexures
- Personal or family history of atopy

GENERAL CONSIDERATIONS

Atopic dermatitis (eczema) is a common condition with a prevalence in the United States of up to 10.2% of the adult population and 13% of children.[1] This prevalence is four times higher than when this textbook was first published in 1985.

The current etiopathogenesis of atopic dermatitis (AD) involves the interplay of the following:

- Cutaneous barrier dysfunction and mutations in genes coding for skin proteins (filaggrin)
- Dysregulation of the immune system and the role of thymic stromal lymphopoietin in allergic inflammation
- Environmental factors

Filaggrin and Epidermal Barrier Dysfunction

A genetic basis for AD has long been recognized. Family history of atopic disease is a major risk factor. Before characterization of the human genome, heritability studies combined with family-based linkage studies supported the understanding of AD as a complex trait, in that interactions between genes and environmental factors and the interplay between multiple genes contribute to disease manifestation. More than 100 published reports on genetic association studies through mid-2009 implicated 81 genes, in 46 of which at least one positive association with AD had been demonstrated. Of these, the gene encoding filaggrin (FLG) has been most consistently replicated. Most candidate gene studies to date have focused on adaptive and innate immune response genes, but there is increasing interest in genes governing skin barrier dysfunction.[2]

Filaggrin is a protein that facilitates the aggregation of keratin filaments; it is otherwise known as filament aggregating protein. It binds cytokeratin into tonofilaments and, when proteolyzed, forms small hygroscopic molecules including amino acids, which comprise natural moisturizing factor (NMF). NMF is responsible for hydration of the stratum corneum. Robust associations of filaggrin mutations have been replicated in several populations, especially in those with northern European ancestry, and it is now accepted that 15% of cases of AD are attributable to such mutations.[3] If an individual is born with one filaggrin mutation, the risk of AD is 40%.

But additional acquired stressors to the skin barrier are required to initiate inflammation. Sustained hapten access through a defective barrier stimulates a Th1-to-Th2 shift in immunophenotype, which in turn further impairs the barrier. Secondary *Staphylococcus aureus* colonization not only amplifies inflammation but also further stresses the barrier in AD. These observations suggest a new "outside-to-inside, back to outside" paradigm for the pathogenesis of AD. This new concept is providing impetus for the development of new categories of "barrier repair" therapy.[4]

Immune Dysregulation, Thymic Stromal Lymphopoietin, and Allergic Inflammation

Immunoglobulin E (IgE) is elevated in up to 80% of patients with AD. It is clear that activation of type 2 T-helper (Th2) cells in response to

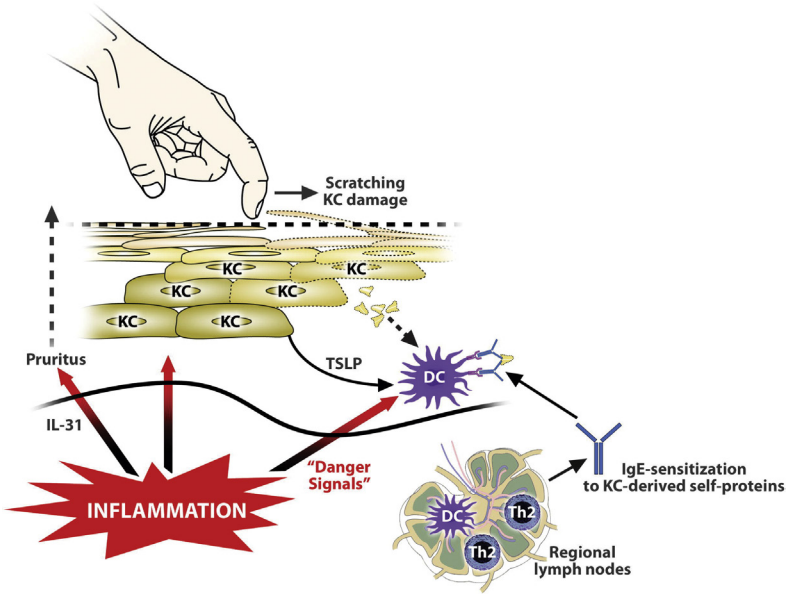

Fig. 150.1 Mechanisms of immunoglobulin E (IgE) sensitization to epidermal self-proteins in patients with atopic dermatitis. Inflammation induces pruritus through interleukin (IL)-31 production. Scratching results in cellular damage and release of membranous and intracellular compounds from keratinocytes (KCs) and possibly other skin cells. The local dendritic cells (DCs) subjected to thymic stromal lymphopoietin (TSLP) will induce a Th2 response and the generation of specific IgE directed against these self-proteins. IgE will bind to Fc ε RI on dendritic cells in the skin and thereby amplify the immune response and inflammatory reaction in the skin. (From Tang TS, Bieber T, Williams HC. Does "autoreactivity" play a role in atopic dermatitis? *J Allergy Clin Immunol*. 2012;129:1209–1215.)

antigens plays a major role in AD. Thymic stromal lymphopoietin (TSLP) is an IL-7–like cytokine secreted by barrier-defective skin and is found at high levels in skin biopsies from patients with lesional AD.[5] TSLP is a critical factor linking responses at interfaces between the body and environment (skin, airway, gut, ocular tissues, etc.) to Th2 responses (Fig. 150.1). Environmental factors such as Toll-like receptor ligands, a Nod2 ligand, viruses, microbes, allergen sources, helminths, diesel exhaust, cigarette smoke, and chemicals trigger TSLP production. Proinflammatory cytokines, Th2-related cytokines, and IgE also induce or enhance TSLP production, indicating cycles of amplification. Skin barrier injury, increased epidermal endogenous protease activity, and less epidermal Notch signaling, all of which have been reported in AD, and keratinocyte-specific loss of retinoid X receptors and treatment of skin with agonists for vitamin D receptor in mice induce TSLP production, Th2 response, or AD-like inflammation.[6]

TSLP profoundly triggers Th2 commitment and is increased when stimulated by phthalates.[7] Phthalates are used in a large variety of products, from enteric coatings of pharmaceutical pills and nutritional supplements to viscosity control agents, gelling agents, film formers, stabilizers, dispersants, lubricants, binders, emulsifying agents, and suspending agents. End applications include adhesives and glues, agricultural uses, building materials, personal care products, medical devices, detergents and surfactants, packaging, children's toys, modeling clay, waxes, paints, printing inks and coatings, pharmaceuticals, food products, and textiles. Phthalates are also frequently used in soft plastic fishing lures, caulk, paint pigments, and sex toys made of "jelly rubber." Phthalates are used in a variety of household applications, such as shower curtains, vinyl upholstery, adhesives, floor tiles, food containers and wrappers, and cleaning materials. Pervasive exposure to phthalates may therefore play a role in the pathogenesis of AD. Cosmetic colorants have also been shown to upregulate TSLP and aggravate dermatitis.[8]

TSLP sensitizes the lungs to allergens and may help explain the frequently observed evolution of AD to asthma, known as the *atopic march*.

Development of atopic disease is also strongly influenced by the colonization of skin and intestinal microflora in early infancy. The microflora in the skin is dependent on the degree of hydration and the integrity of the skin barrier. Dry skin predisposes to *Staphylococcus aureus* colonization. Low gut microbiota diversity is associated with a Th2-dominant pattern as well as with food sensitization.[9]

Dupilumab is a fully humanized, monoclonal antibody targeting the alpha subunit of the interleukin (IL)-4 receptor to block signaling of IL-4 and IL-13. An in-depth study of lesional and nonlesional skin during dupilumab therapy found that modulating IL-4/IL-13 signaling through IL-4Rα antagonism in patients with AD led to statistically significant improvement in AD after 4 weeks of treatment, compared with placebo.[10]

The study also demonstrated that dupilumab suppressed mRNA expression in lesional skin of genes related to activation of T cells, dendritic cells, eosinophils, inflammatory pathways, type 2 cytokines, and downregulated genes responsible for epidermal hyperplasia (S100A and K16 genes). Blocking IL-4/IL-13 may not only improve inflammation in AD but may also restore skin barrier function as a result of significant increases in claudin, loricrin, filaggrin, and lipid product levels. These results show promising new insights into the role of type 2 cytokines in AD and suggest that inhibition of IL-4/IL-13 has the potential to reverse multiple molecular defects in patients with AD.

Gastric *Helicobacter pylori* directly stimulates epidermal cells to secrete TSLP, and *H. pylori* antibody is positive in up to 70% of patients with AD.[11] One study has shown that the treatment of infection, demonstrated by a reduction in C-urea breath test and anti–*H. pylori* antibody titers, resulted in partial improvement in patients with AD.[12] Another study found an inverse relationship between *H. pylori* positivity and AD in children.[13]

Galectins are a family of β-galactoside-binding lectins with one or two conserved carbohydrate-recognition domains (CRDs) that play various roles in skin physiology and pathology.[14] Galectin-3 contains one CRD following a nonlectin region of some 120 amino acids made of tandem repeats of short proline-/glycine-rich sequences. Galectin-3 is a proinflammatory mediator in AD by its promotion of polarization toward a Th2 immune response by regulating the functions of dendritic cells (DCs) and T cells.[15] Galectin-3 can enhance IgE synthesis by B cells and thus may play a role in the hyperactive immune response in IgE-associated atopic eczema/dermatitis syndrome.[16] Therapies that reduce galectin-3 may therefore be beneficial in AD (see section on treatment).

Environmental Factors: Atopic Dermatitis and Allergy

Sensitization to foods triggers isolated skin symptoms in about 30% of children. These symptoms include immediate reactions within minutes after ingesting food without exacerbation of AD and early and late exacerbations of AD. It is important to identify clinically relevant sensitizations to foods using skin-prick tests; atopy patch testing; specific IgE and IgG4 blood tests; and double-blind, placebo-controlled food challenges to initiate appropriate dietary interventions and avoid unnecessary dietary restrictions. A defective skin barrier and increased intestinal permeability appear to facilitate allergen sensitization. Appropriate skin care to maintain skin barrier function and dietary avoidance of identified food allergens during infancy may help prevent further allergen sensitization, thereby reducing the severity of AD and food allergies.[17] However, a study published in 2017 identified clinically active food allergies in 26.13% of 88 children with AD. No association with disease severity was found. This may be explained by this study only looking at IgE, which misses other food-related immunological factors.[18]

In February 2018 the first pilot study was published that identified microbial signatures specific for food allergy in children with AD using 16S rRNA sequencing techniques followed by statistical machine-learning approaches.[19] Six bacterial species discriminated between the presence and absence of food allergy in these children with AD. The fecal microbiome of children with AD and food allergy harbored significantly more *Escherichia coli* and *Bifidobacter pseudocatenulatum,* and less *Bifidobacter breve, Bifidobacter adolescentis, Faecalibacterium prausnitzii,* and *Akkermansia muciniphila* than children with AD without food allergy ($p = 0.001$). *F. prausnitzii* and *A. muciniphila* have gained interest because of their immunemodulatory and mucosal tolerance properties. *F. prausnitzii* is one of the most abundant species in the human intestinal microbiome. Its decreased abundance has been associated with several diseases, including allergic disease and AD *F. prausnitzii* is the chief source of butyrate in the colon, used as fuel by colonocytes, with important anti-inflammatory effects. *F. prausnitzii* also secretes anti-inflammatory modulators, stimulates IL-10–producing Treg cells and regulates the balance between effector and regulatory T cells. *A. muciniphila* plays a role in the immunological homeostasis of the gut mucosa and gut barrier.

Bifidobacteria and *E. coli* have been associated with food allergy and AD in other studies. *Bifidobacteria* is reduced in the feces of children with a confirmed cow's milk allergy.

Predictors of Severity

One longitudinal study of children examined a number of risk factors that may predict the severity of AD in children.[20] This study surveyed 137 children and followed them through four visits over a period of 1½ years. Parameters such as age at onset, social class, ethnic group, child's atopy, family history of atopy, and other potential risk factors were recorded. This study revealed the following: (1) Children with AD whose eczema started during the first year of life were more likely to have severe disease than were those whose eczema started later, (2) a history of atopy (asthma, hay fever, or both) was associated with severe AD, and (3) children with eczema who lived in an urban area were at increased risk of severe disease compared with their counterparts who lived in a rural environment. This urban environmental risk was independent of ethnicity.

A study published in 2018 concluded that short duration of breastfeeding, absence of older siblings, parental passive smoking, food allergens along with aeroallergens, and excessive cleanliness should be considered as negative prognostic factors, leading to a higher Scoring Atopic Dermatitis (SCORAD) score in children with AD.[21] Another study found that more than three fast-food meals per week increased the overall risk of AD by 70%. At least one course of a broad-spectrum antibiotic in early life increased the risk of AD by 41%, with an additional 7% increase in risk from each additional course of antibiotics. Reduced diversity of intestinal flora is a recognized risk factor, as is lack of exercise and traffic-related air pollution.

Protective factors include ultraviolet light exposure, which enhances filaggrin breakdown into an immunosuppressive isoform; maternal contact with farm animals during pregnancy, high fish intake during pregnancy (lowers AD risk by 25%–43%); consumption of unprocessed milk; helminth infection during pregnancy; dog and high-level endotoxin exposure in early life (through farm animals); and thumbsucking.[22]

Comorbidities

Three large data sets, including more than 1 million people, found that AD was associated with only a very small increased risk for cardiovascular disease.[23] Obesity in childhood is a positive association, although there is conflicting evidence about obesity in adults and AD.[24]

THERAPEUTIC CONSIDERATIONS

The myriad of prescription and over-the-counter medications commonly used to treat AD fail to address the root cause of the condition. Topical medications used to treat AD include emollients, corticosteroids, antibiotics, calcineurin inhibitors, and crisaborole, a boron-based PDE-4 inhibitor. Oral antihistamines are used for pruritus. Severe eczema has also been treated with systemic immunomodulatory agents (e.g., cyclosporine) and systemic corticosteroids. None of these medications has shown effective long-term ability to cure AD. Side effects such as growth retardation, cutaneous complications, sedation, and allergic reactions are a major concern.[25] Furthermore, a number of these medications can result in a rebound flare-up after discontinuation that is usually worse than the primary lesions.

Naturopathic medicine generally attempts to understand the underlying causes of AD and thus attends to additional factors, including those affecting the digestive system, such as food allergies and microbial overgrowth. Although no one treatment option may be universally effective, patient-specific combination therapeutics acting in synergy are encouraged for optimal efficacy.

Food Allergy, Gut Permeability, and Microbial Overgrowth

Numerous studies have documented the role of food allergy in AD (also see Chapter 14). Studies have also shown that breastfeeding offers significant prophylaxis against AD as well as allergies in general.[26]

One study of 100 infants concluded that breastfeeding should be promoted for the primary prevention of allergy.[27] Interestingly, further studies by the same group suggest that breastfed infants with allergies should be treated by allergen avoidance; in some cases breastfeeding cessation is recommended to avoid traces of food antigens in breast milk.[28] The development of AD in breastfed infants was once believed to be the result of the transfer of allergic antigens in the breast milk, in which mothers were instructed to avoid the common food allergens (especially milk, eggs, and peanuts and, to a lesser extent, fish, soy, wheat, citrus, and chocolate).[29] Maternal avoidance of these common allergens is associated with complete resolution in some cases. However, more recent studies have found that earlier introduction of common food allergens, rather than later, may be more efficacious in preventing the development of food allergies, at least for peanuts. In a prospective controlled study, regular consumption of peanut protein in infants from 4 to 11 months of age with atopic dermatitis or egg allergy was associated with a lower prevalence of peanut allergy (1.9%) at 60 months of age compared with peanut avoidance (13.7%). Other studies demonstrated that earlier introduction of cow's milk protein and egg powder were also associated with decreased risk for milk and egg allergy, respectively.[30]

In older or formula-fed infants, milk, eggs, and peanuts appear to be the most common food allergens inducing AD. In one study, these three foods were implicated in 81% of all cases of childhood AD,[31] whereas in another study, 60% of children with severe AD had a positive food challenge to one or two of the following: egg, cow's milk, peanut, fish, wheat, or soybean. One randomized controlled trial found that in those individuals with a positive radioallergosorbent test to eggs, an egg-free diet was associated with an improvement in the severity of AD, with the greatest effect seen in those most severely affected.[32] Although eggs are a major suspect, virtually any food can be the offending agent.[33]

Diagnosis of food allergy is usually best achieved via the elimination diet and double-blind placebo challenge method. This approach is especially useful in childhood eczema. Elimination of milk products, eggs, peanuts, tomatoes, and artificial colors and preservatives results in significant improvement in at least 75% of cases.[31,33,34] If laboratory methods are used to identify food allergies in eczema, the most useful method (although not perfect) appears to be the enzyme-linked immunosorbent assay (ELISA) IgE and IgG_4 (see Chapter 14).[35]

The presence of food allergies is thought to be partially responsible for persons with AD having a "leaky gut."[36] As a result of this increased gut permeability, there is an increased antigen load on the immune system, which subsequently overwhelms the immune system and increases the likelihood of developing additional allergies. Permeability studies using urinary mannitol and lactulose confirm that hypoallergenic diets do decrease gut permeability and are associated with improvements in atopic eczema. It is essential to identify offending foods as soon as possible to avoid increasing gut permeability. Trying to deal with multiple food allergies is often a difficult task for the patient because the diet is often unrealistically restrictive. The elimination of allergenic foods and restoration of normal intestinal permeability appear to stop the development of new allergies.[37]

Patients should be encouraged to find out whether, if they can avoid offending foods for a period of 6 to 12 months, their antibody levels to allergens will decrease to the point that they can tolerate the reintroduction of some foods at least twice a week. The loss rate of food allergy in patients with AD after 1 year was 26% for the five major allergens (egg, milk, wheat, soy, and peanut) and 66% for other food allergens.[38]

Gluten Sensitivity

Many patients with celiac disease also have atopic disorders. Of patients with gastrointestinal (GI) symptoms and mucosal lesions but negative results from serological or genetic tests for celiac disease, 30% had reduced GI and atopic symptoms when placed on a gluten-free diet.[39]

Candida albicans. An overgrowth of the common yeast *Candida albicans* in the gastrointestinal tract has been implicated as a causative factor in allergic conditions, including AD. Elevated levels of anticandidal antibodies are common in atopic individuals. Furthermore, the severity of lesions tends to correlate with the level of IgE antibodies in relation to candidal antigens. Appropriate anticandidal therapy (see Chapter 159) may result in significant clinical improvement of AD.[40,41]

Nutritional Supplements

Probiotics

Because the intestinal flora plays a major role in the health of the host, especially regarding AD, probiotic therapy is especially indicated. Studies evaluating the administration of the probiotic *Lactobacillus rhamnosus* strain GG alone or in conjunction with *Lactobacillus reuteri* to infants with AD and cow's milk allergy demonstrated a significant reduction of the severity of eczema.[42–45]

However, the one randomized controlled trial[44] that prescribed both probiotic strains used a skim milk powder preparation for the placebo group. Patients were also allowed to continue corticosteroid treatment. Both of these factors may have confounded any beneficial results because it was noted that corticosteroid use increased in the placebo group during the active treatment period, possibly indicating an allergic reaction to the milk proteins in the placebo. Another interesting note is the finding in this study that the positive therapeutic effect of probiotics was more pronounced in patients with an allergic constitution, as evidenced by positive responses to the skin-prick test and increased IgE levels. This suggests that these tests may be useful in forecasting who may be most responsive to probiotic therapy. A meta-analysis published in 2016 showed evidence that supports the use of synbiotics (combination of probiotics and prebiotics) for the treatment of AD in children age 1 year or older.[46] Finally, a spore-based probiotic has shown preliminary evidence of improving markers of leaky gut.[47] Although more study is warranted, it seems reasonable to include probiotics in a therapeutic regimen given their safety and overall health benefits.

Essential Fatty Acids

Supplementing the diet of AD patients with evening primrose, borage, or black currant oil (commercial sources of gamma-linolenic acid) may prove helpful. Several double-blind studies with evening primrose oil (typically using dosages of at least 3000 mg daily, providing 270 mg of gamma-linolenic acid) have shown benefit.[48–50] The benefits of omega-6 oils are primarily in skin barrier function. However, overall, the therapeutic results appear to be more favorable with omega-3 oil supplementation than with omega-6 oils. Several studies with evening primrose oil failed to demonstrate any therapeutic benefit over a placebo. In the largest of these studies and one of the highest in methodological quality, no benefit of evening primrose oil could be demonstrated.[51] Similarly, one study of 140 people, including 69 children, showed few beneficial effects of borage oil for AD.[52]

Dietary enrichment with "fish oil" supplements providing eicosapentaenoic (EPA) and docosahexaenoic acid (DHA) or simply eating

more fatty fish (e.g., mackerel, herring, salmon) results in significant incorporation of omega-3 fatty acids into the membrane phospholipid pools. Flaxseed oil, which contains alpha-linolenic acid, the precursor omega-3 fatty acid, may benefit patients with AD. However, because the degree of clinical improvement correlates with the increase in the concentration of DHA in serum phospholipids, and fish oils are much more effective in raising DHA levels than flaxseed oil, supplementation with EPA/DHA or increasing the consumption of cold-water fish is likely to produce better overall results in AD than flaxseed oil.[53]

Epidemiological studies have found protective associations between fish intake in pregnancy, lactation, infancy, and childhood and atopic outcomes. Similar studies of fish oil supplements have also found protective and therapeutic effects.[54]

Vitamin D

The serum concentration of 25(OH)D3 in 95 patients with AD was not statistically different from 58 control subjects. However, the frequency of bacterial skin infection was higher in patients with AD with lower 25(OH)D_3 levels, and after supplementation, both mean objective SCORAD and SCORAD index were significantly lower ($P < .05$).[55]

Vitamin E

One single-blind analysis evaluated 96 patients given either 400 international units of vitamin E or a placebo daily for 8 months. Significant improvement was reported in approximately 60% of the treatment group (compared with 2% among the placebo group), with significant reductions in serum IgE levels.[56]

The combination of vitamin D_3 1600 IU and vitamin E 600 IU daily significantly reduced SCORAD ratings.[57]

Botanical Medicines

The use of botanical medicines in AD can be generally divided into two categories: internal and external. Licorice *(Glycyrrhiza glabra)* appears to be useful in either application. Internally, licorice preparations can exert significant anti-inflammatory and antiallergic effects (see Chapter 85). These benefits are perhaps best exemplified in several double-blind studies featuring a licorice-containing Chinese herbal formula.[58] In addition to licorice, the formula contained the following:

- *Ledebouriealla seseloides*
- *Potentilla chinensis*
- *Clematis chinensis*
- *Clematis armandi*
- *Rehmania glutinosa*
- *Paeonia lactiflora*
- *Lophatherum gracile*
- *Dictamnus dasycarpus*
- *Tribulus terrestris*
- *Schizonepeta tenuifolia*

Interest in this formula by a group of researchers began after a patient with AD experienced tremendous improvement after taking a decoction prescribed by a Chinese doctor.

Several double-blind studies have confirmed this benefit. In one study, 40 adult patients with long-standing, refractory, widespread AD were randomized to receive 2 months' treatment of either the active formula or a placebo decoction, followed by a crossover to the other treatment after a 4-week washout period.[59] The treatment group demonstrated significant superiority over the placebo in clinical evaluation. In addition, of the 31 patients completing the study, 20 preferred the active formula, whereas only 4 preferred the placebo. There was also a subjective improvement in itching and sleep during the active treatment phase. No side effects were reported, although many complained about the poor palatability of the decoction.

Similar results were demonstrated in a double-blind study in children.[60] These positive preliminary studies will hopefully be followed by more extensive investigations to determine proper dosages and perhaps different forms of administration (e.g., pills, tablets, or capsules vs. decoctions).

Licorice undoubtedly plays a major role in the effectiveness of the Chinese herbal formula. At this time, until the benefits of the other components can be confirmed, it makes the most sense to base the dosage level on the level of delivered licorice.

With regard to using licorice topically, good results are likely to be obtained by using commercial preparations featuring pure glycyrrhetinic acid. Several studies have shown glycyrrhetinic acid to exert an effect similar to that of topical hydrocortisone in the treatment of eczema, contact and allergic dermatitis, and psoriasis. In one study, 9 of 12 patients with intractable eczema noted marked improvement, and 2 noted mild improvement, when an ointment containing glycyrrhetinic acid was applied topically. In another study, 93% of the patients with eczema applying glycyrrhetinic acid demonstrated improvement compared with 83% using cortisone.[61]

A proprietary topical cream of *Rheum palmatum, Scutellaria baicalensis, Cnidium monnieri,* dipotassium glycyrrhizinate, *Sanguisorba officinalis,* and *Ailanthus altissima* in a base of ceramides, hyaluronic acid, shea butter, and vitamin E has demonstrated anti-inflammatory, antiallergic, antimicrobial, antipruritic, and barrier-repair effects: 46% reduction in SCORAD in 3 weeks, equal efficacy in severe and nonsevere AD, 60% reduction in itching after 3 weeks, and 32% improvement in skin moisture level after 3 weeks (Dermatest, Germany). A clinical trial is currently in process comparing this cream with another proprietary oat-based over-the-counter (OTC) product.

Other Therapeutic Considerations

Endocrine Factors

Patients with hypothyroidism and eczema respond well to thyroid hormone supplementation.[62]

Scratching Cessation

Scratching is extremely detrimental in AD because it breaks the skin, which aids bacterial ingress and promotes barrier dysfunction and lichenification. Factors that limit itching therefore promote healing and prevent recurrence. Some behavior modification techniques have proved valuable in reducing the exacerbation of AD symptoms caused by scratching.[25]

Wet wraps are an effective barrier to scratching while also increasing hydration as well as the penetration of medication and emollients and promoting more restful sleep, and using them is simple. After applying medication and emollient, the affected areas are wrapped in warm, wet gauze or, as an alternative, 100% cotton socks with the toe portion cut off. Apply a dry layer over the wet layer, and leave it on overnight for 5 to 14 days.[63]

Bleach baths

Bleach baths (1/4 cup household bleach added to bathwater) have been shown to reduce *S. aureus* and diminish AD severity.[64]

For those patients who do not have a bathtub or prefer showering, a bleach body wash is another option. An open-label trial of 0.006% sodium hypochlorite body wash gel, left on the skin for 1 to 2 minutes before showering off, decreased *S. aureus* colonization and markedly improved symptoms and quality of life in children by 2/3 after 2 weeks of daily use.[65]

Psychological Approach

Although the mechanism of the exact relationship between stress and AD has not been fully elucidated, it has been established through both

clinical and physiological pathways that psychological stress is a significant contributor to a patient's AD disease course through its direct and indirect effects on immune response, cutaneous neuropeptide expression, and skin barrier function.[66] Emotional tension can provoke and aggravate itching in patients with AD, and according to a number of studies, patients with AD show higher levels of anxiety, hostility, and neurosis than matched controls.[66] Studies employing psychotherapy have shown promising results, with one study showing reductions in the use of corticosteroids for up to 2 years.[25]

Humor

Starting in 2001 a fascinating series of studies was done by Dr. Hajime Kimata, an allergist at Unitika Central Hospital in Uji-City, Japan. The first mention Kimata made of this therapeutic intervention was in a letter to the *Journal of the American Medical Association* in 2001.[67]

Kimata had a series of studies published over a 9-year period. In his letter, he gives credit to Norman Cousins for giving him the idea for his research. Cousins had authored a book, *Anatomy of an Illness,* published in 1979, wherein he credited his relief from the pain of ankylosing spondylitis to watching comedies on TV. In Kimata's first trial, 26 patients with AD who were all allergic to dust mites and most of whom were also allergic to cedar pollen and cat dander were studied. After going 72 hours with no medication, they underwent skin-prick tests before and after viewing *Modern Times*, a comedy starring Charlie Chaplin. The size of the resulting wheal was measured. A similar procedure was repeated before and after an 87-minute video featuring weather information. The wheal responses to dust mites, cedar pollen, and cat dander were significantly reduced after watching Chaplin, and the effect lasted for hours. Watching the weather had no effect on the wheal size.[67]

His succeeding studies built on this finding, consistently showing that humor and positive emotions ameliorated symptoms of AD.[68] In 2015 Kimata was awarded the Ig Nobel Prize for a study showing that 30 minutes of kissing with a lover or spouse behind closed doors while listening to soft music can reduce allergic reactions among atopic and allergic patients.[69]

Homeopathy

A study of 17 patients with intractable AD treated with **individualized homeopathy** showed over 50% improvement in overall impression and in their skin condition by all patients.[70]

An observational longitudinal study was conducted on 325 children (37.9%) with atopic diseases out of 857 children consecutively examined from 1998 to 2014 at the Homeopathic Clinic of Lucca in Italy: 127 children were affected by asthma, 72 by allergic rhinitis, and 126 (36%) by AD. Follow-up on AD was achieved with 104 (48.8%), and 65 (62.5%) of them reported a major improvement or resolution. Children with AD who started homeopathic treatment at less than 4.9 years of age were assessed 5 to 10 years later, and complete remission of AD was obtained in 84.2%. Children with two or three atopic diseases at the first visit were completely cured in 40% of cases.[71]

A study was conducted in a homeopathic general practice in Buenos Aires, Argentina, of 42 patients with AD spontaneously seeking homeopathic treatment. Of these patients, 21 had other atopic comorbidities, and 28 (66.7%) were moderate or severe cases. Significant differences were observed when comparing the first and last consultations in the mean percentage of affected skin area, 21.1% versus 5.5% respectively ($P = 0.002$), and in the change in the four visual analog scale (VAS) scores: area of AD, 31.1 ($P < 0.0001$); itch, 35.0 ($P < 0.0001$); general well-being, 11.1 ($P < 0.0188$); and sleep, 17.4 ($P < 0.0073$). In this study, 12 individualized homeopathic medicines were prescribed; sulfur accounted for 60% of cases with good treatment response.[72]

A third study of homeopathic treatment compared with conventional treatment of AD conducted in Berlin, Germany, was a prospective, multicenter, comparative, observational, nonrandomized rater-blinded study of 135 children (48 treated with homeopathy, 87 with conventional medicine) with mild to moderate AD. SCORAD showed no significant differences between groups at 36 months. Total costs were higher in the homeopathic versus conventional group: EUR 200.5 versus EUR 78.86 ($p = 0.005$).[73]

ENVIRONMENTAL CONSIDERATIONS

Dust Mite Exposure

In patients with dust mite sensitization and eczema, sublingual immunotherapy has shown benefit.[74] Paradoxically, lower levels of eczema have been found in children with higher levels of dust mite exposure, so reducing house dust in early infancy could increase the risk of AD.[75]

Microwave Exposure

One fascinating study of cell phone use continuously for an hour showed significant increases in the allergic response to dust and pollen in adults with eczema.[76] Microwave radiation exposure also increased plasma levels of substance P and vasoactive intestinal peptide in patients with AD. This study raises the concern that microwave radiation emitted from cell phones may actually increase sensitivity to specific allergens in some patients.

THERAPEUTIC APPROACH

Effective management requires relief from and prevention of itching while the underlying abnormalities are being treated. Barrier dysfunction must be addressed. Food allergens must be detected and controlled, phthalates should be avoided and detoxification carried out, and the presence of *H. pylori* should be determined and treated.

Diet

The patient should begin a 4-day rotation diet and eliminate all major allergens (milk, eggs, and peanuts account for the offending food in approximately 81% of cases). As the patient improves, allergens can slowly be reintroduced, and a stringent rotation diet can be modified. Cold-water fish such as wild salmon, mackerel, herring, sardine, and halibut should be included, and other animal products should be limited.

Supplements

- High-potency multiple vitamin and mineral formula
- Vitamin D dosed to achieve and maintain an optimal level of 65 ng/dL
- Vitamin E: 400 international units daily (mixed tocopherols)
- Fish oil: 1000 to 3000 mg EPA+DHA daily
- Borage oil: 1 Tbsp daily
- Probiotics: 5 to 10 billion viable *Lactobacillus acidophilus* and *Bifidobacterium bifidum* cells daily *or* a spore-based probiotic
- Modified citrus pectin to lower galectin-3 levels: 5 to 6 grams daily on empty stomach

Topical Treatment

Kamedis CALM Eczema Therapy and Eczema Wash

Patients should also try to take the following measures:

- Avoid sweating and rough-textured clothing.
- Wash clothing with mild soaps only and rinse thoroughly.
- Avoid exposure to chemical irritants and any other agent that might cause skin irritation.

Psychological Approach

It should be determined whether the patient is experiencing significant levels of anxiety, depression, or hostility. If so, he or she may be helped to resolve these problems or referred to a psychotherapist for professional assistance. Laughter from comedies and humorous films can be recommended for their salutary effect on AD.

Attention Deficit Hyperactivity Disorder

Joseph Katzinger, ND, Michael T. Murray, ND,* and *Michael R. Lyon*, MD*

OUTLINE

DIAGNOSTIC SUMMARY

- A neurodevelopmental disorder that begins in early childhood with persistence into adolescence and adulthood
- Typified by one or more symptoms of disabling inattentiveness, hyperactivity, and impulsivity
- Commonly accompanied by comorbid conditions, such as mood disorders or learning disabilities, with increased risk for multiple mental health and social difficulties

GENERAL CONSIDERATIONS

As updated in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), attention deficit hyperactivity disorder (ADHD) is defined as a condition characterized by developmentally appropriate inattention and impulsivity with or without hyperactivity. ADHD has three presentations:

Predominantly hyperactive-impulsive presentation:

- Most symptoms (six or more for children, five or more for adults) are in the hyperactivity-impulsivity categories.
- Fewer than six symptoms of inattention are present, although inattention may still be present to some degree.

Predominantly inattentive presentation:

- The majority of symptoms (six or more for children, five or more for adults) are in the inattention category and fewer than six symptoms of hyperactivity-impulsivity are present, although hyperactivity-impulsivity may still be present to some degree.
- Children with this presentation are less likely to act out or have difficulties getting along with other children. They may sit quietly, but they are not paying attention to what they are doing. Therefore the child may be overlooked, and parents and teachers may not notice that he or she has ADHD.

Combined presentation:

- Six or more symptoms (five or more for adults) of inattention and six or more symptoms of hyperactivity-impulsivity are present.

To be diagnosed with ADHD, an individual must have symptoms for 6 or more months and to a degree that is inconsistent with developmental level and that has a direct negative effect on social and academic/occupational activities. The same symptoms apply to adults as well as children, although the examples of how they manifest may be different.

Symptoms of inattention per the DSM-5 include the following:

- Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate)
- Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading)
- Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction)
- Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked)

*Previous edition contributor

- Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines)
- Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers)
- Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones)
- Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts)
- Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments)

Symptoms of hyperactivity per the DSM-5 may include the following:

- Often fidgets with or taps hands or feet or squirms in seat
- Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place)
- Often runs about or climbs in situations where it is inappropriate (Note: In adolescents or adults, may be limited to feeling restless.)
- Often unable to play or engage in leisure activities quietly
- Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for an extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with)
- Often talks excessively
- Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation)
- Often has difficulty waiting his or her turn (e.g., while waiting in line)
- Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing)

ADHD characteristics are frequently associated with difficulties in school, in both learning and behavior, as well as at work among adults. If not intensively managed, a child with ADHD will likely experience academic impairment, increased risk of injuries, and problems with self-esteem and socialization. Later in adolescence and adulthood, those with ADHD have a high risk of experiencing depression or anxiety, substance abuse and addictions, traffic accidents, financial problems, vocational underachievement, and social problems. Indeed, a 2015 large cohort of Danish individuals with ADHD found a significant increase in risk for mortality among individuals with ADHD, which remained after adjustment for related conditions, such as substance abuse disorder.[1] Nevertheless, ADHD is a condition that can be transcended, and many with ADHD have achieved a high level of personal success.

Although influenced by the region, investigator, and diagnostic criteria, ADHD has been estimated to affect approximately 6% to 7% of children and 5% of adults (for whom we have prevalence data) in the United States.[2] The worldwide prevalence is slightly less, with a 2015 meta-analysis of 41 studies and 27 countries finding an overall prevalence of 3.4%.[3] The economic cost associated with ADHD has been estimated to range from $143 billion to $266 billion per year in the United States alone.[4] Clinical observation and epidemiological surveys typically report a greater incidence in boys than girls (approximately 3–4:1), although this gap may to some degree be due to less teacher-based referrals, for whom boys' behavior is seen as more disruptive. Approximately 3.5% of children in the United States take at least one prescription drug for ADHD every day, a rate consistently higher than other Western countries.[5] Onset is usually by 3 years of age, although the diagnosis is often not made until later when the child is in school.[6]

Etiology

The behavioral and cognitive manifestations of ADHD arise from evidence associating this disorder with diminished function of polysynaptic dopaminergic circuits belonging to executive centers within the brain's prefrontal cortex.[7,8] These executive centers are largely inhibitory in nature and are responsible for impulse control and the ability to maintain sustained attention.[9]

Evidence from studies using magnetic resonance imaging (MRI), positron emission tomographic (PET) scanning, single-photon emission computed tomographic scan imaging, and electroencephalograms (EEGs) suggests that the brains of those with ADHD exhibit differences both morphologically and metabolically from normal controls, particularly with regard to the prefrontal executive centers.[10,11] Various disturbances in dopaminergic activity within these brain centers have remained the primary molecular defects implicated in ADHD, although other neurotransmitters (particularly norepinephrine) have also been incriminated. Decreased sensitivity of the dopaminergic (D4) receptor and heightened dopamine reuptake by the presynaptic dopamine transporter were both suggested to result in diminished dopaminergic activity within executive centers. More recently, task-activated functional MRI (fMRI) suggests that functional deficiencies may be more widespread throughout the brain, in multiple neuronal networks, and not just limited to executive function. For example, a meta-analysis of 55 fMRI studies found that ADHD may be better described "as a disorder underpinned by dysfunctions in multiple large-scale brain networks." This includes both hypoactivation, such as observed in the frontoparietal executive control network, putamen, and ventral attention network, as well as potentially compensatory hyperactivation in the default network and visual circuits.[12] Other areas where deficits have been found include temporal information processing and timing, speech and language, memory span, processing speed and response time variability, arousal and activation, and motor control.[13] However, all of these defects are not necessarily permanent, because as children with ADHD grow up, the brain may develop a normal level of functional activity, and the anatomical variations lessen. In addition, ADHD symptoms also tend to improve.[14]

Genetic factors play a significant role in the etiology of ADHD.[15] Twin studies suggest that ADHD has a heritability of 70% to 80% in both children and adults, and parents and siblings of those with ADHD have a five- to tenfold elevated risk themselves.[13] Differences have been identified in genes encoding for both the D2 and the D4 dopamine receptors in ADHD. Other studies have linked ADHD with genetic polymorphisms associated with increased activity of the presynaptic dopamine transporter (which would result in increased uptake of dopamine). The gene most frequently implicated in GWAS studies is CDH13, which is involved in cell adhesion and neurodevelopmental processes. However, recent analyses suggest that although up to 70% of the genetic component of ADHD may be explained by common variants, the effect of any single single-nucleotide polymorphism (SNP) or copy-number variation is very small and should be viewed as a polygenic combination, comprising both common and rare variants.[16] Other genetic factors contributing to ADHD may include inherited tendencies toward allergic states, decreased immune competence, and various genetic polymorphisms, resulting in a diminished capacity to detoxify drugs, heavy metals, and xenobiotics. In other

words, although there is little doubt that genetics are a predisposing factor, like most health conditions, environmental and dietary factors may play a significant role in how and whether these genetic factors manifest to produce ADHD in an individual.

THERAPEUTIC CONSIDERATIONS

Conventional Drugs

The role of nutritional and environmental factors as the underlying cause of ADHD has been increasingly recognized. Despite significant advances in the use of nutritional therapies for ADHD, the prevailing conventional approach to the treatment of ADHD relies almost entirely on amphetamine drugs for purely symptomatic relief. These drugs, like Ritalin (methylphenidate), Adderall (amphetamine and dextroamphetamine), Concerta (methylphenidate), and Vyvanse (lisdexamfetamine dimesylate), improve ADHD symptoms primarily by potentiating the neurotransmitter dopamine within all brain regions, including those affected in ADHD. These medications reportedly improved behavior and cognitive functioning in approximately 75% of children in formal placebo-controlled trials. However, the success of treatment when studied in actual clinical practice might be significantly lower. Furthermore, follow-up studies failed to demonstrate long-term benefits with these stimulant medications. Additionally, these drugs are associated with a high prevalence of adverse effects, such as decreased appetite, sleep problems, anxiety, and irritability. Some of the long-term effects of these drugs could be extremely detrimental to both brain function and behavior.[17–19] For example, one of the largest and longest-term studies, the Multimodal Treatment Study of Children with ADHD (MTA), found that despite initial reports of treatment success, the long-term effectiveness was more questionable, and the risk of side effects, including growth suppression in children, may have been underappreciated.[20]

Nonstimulant drugs like atomoxetine (Strattera) have been promoted as a safe alternative to parents. However, the drug has its own set of problems, including studies that showed that children and teenagers who took atomoxetine were more likely to have suicidal thoughts than children and teenagers with ADHD who did not take it.[21]

The bottom line is that every effort should be made to treat ADHD without the long-term reliance on medications.

One of the primary goals in many cases of ADHD treatment is to enhance cognitive function. Perhaps up to 50% of people with ADHD have definable learning disabilities, and most have measurable cognitive disturbances. Particularly disabling is the diminishment in nonverbal working memory exhibited by most patients with ADHD.[22,23] This feature of ADHD results in a diminished sense of time, as well as a decreased ability to hold events or tasks in the mind. Tardiness, missed appointments, procrastination, poor task planning, and failure to meet deadlines are all examples of how diminished working memory can result in serious consequences, particularly in adulthood.

ENVIRONMENTAL NEUROTOXINS

Environmental factors that contribute to the development of ADHD may begin at or even before conception. Maternal-to-fetal transport of various neurotoxins can occur readily during pregnancy. A woman who has an ongoing exposure to or a significant body burden of neurotoxic substances (e.g., heavy metals like lead and mercury, solvents, pesticides, polychlorinated biphenyls [PCBs], alcohol, or other drugs of abuse) may herself exhibit features consistent with ADHD and give birth to a child who presents with symptoms of ADHD. In such cases, it might be assumed that ADHD is inherited when it is actually acquired. Children remain susceptible to neurotoxins after birth, and some of these agents have been shown to be common among children in North America.[24,25]

Polybrominated Diphenyl Ethers

For example, exposure to polybrominated diphenyl ethers (PBDEs) is fairly common among children, and both prenatal and postnatal exposure have been associated with increases in hyperactive and aggressive behavior, as well as decreased attention and executive function, and it may be that PBDEs potentially target the prefrontal cortex.[26]

Perfluorooctane sulfonate and β-Hexachlorocyclohexane

In a large Norwegian birth cohort, early life exposure (e.g., breast milk concentrations) to perfluorooctane sulfonate (PFOS) and β-hexachlorocyclohexane (β-HCH) were each associated with nearly a twofold increase in the risk for ADHD diagnosis by a median age of 13 years.[27]

Bisphenol A

Early exposure to bisphenol A (BPA) was also found to be associated with ADHD, as found in a 2018 systematic review and meta-analysis of existing data.[28]

Maternal Drug Use

Maternal tobacco and drug use have also been associated with a higher risk of ADHD.[29–31] One study suggested that up to 25% of all behavioral disorders in children can be attributed to exposure to cigarette smoking during pregnancy.[29] In addition, long-term, low-level lead intoxication in North American children was reported to exist at an alarmingly high incidence.[25,32]

Lead

The Centers for Disease Control and Prevention estimated that about 2% of American children younger than age 6 currently meet the criteria for lead toxicity at a level that has been associated with cognitive deficits and behavioral disturbances (more than 10 ug/dL whole blood lead).[32] Low-level lead intoxication has also been associated with addictive behaviors and impulsivity, suggesting neurological changes consistent with the reward deficiency syndrome, as described earlier.[33] And recent data suggest that a cutoff of 10 ug/dL is not protective; a 2017 systematic review and meta-analysis found that even levels as low as <3 ug/dL were associated with significant increases in ADHD symptoms.[34] A recent analysis of 75 participants with ADHD also found an interaction between lead exposure and the dopamine receptor D2 receptor (DRD2) gene on frontal lobe cortical thickness, suggesting a toxin–gene interaction that affects brain morphology.[35] In keeping with these data, pilot studies demonstrated improvement in ADHD behaviors in some children with moderate elevations in blood lead levels who were treated with intravenous ethylenediaminetetraacetic acid chelation.[36]

Other Metals

In addition to lead, other toxic metals, such as mercury, cadmium, and aluminum, as well as pesticides and PCBs, are nearly ubiquitous contaminants arising from dental amalgams, food, air, and drinking water, and these agents may act synergistically to impair neurological function and development in susceptible children. The Consumer's Union of the United States conducted a large study looking at the level of human exposure to a wide range of pesticides in the U.S. food supply. In this startling report, it was demonstrated that human exposure to pesticides is far greater than ever previously estimated and that children are at particularly high risk for neurotoxic effects from regular inadvertent pesticide exposure from common foods.[37]

Organophosphate Pesticides

Quite concerning is that an analysis of National Health and Nutrition Examination Survey (NHANES) data suggests that children with levels only higher than the median for a common urinary metabolite of organophosphate pesticides (dimethyl alkylphosphate [DMAP]) have roughly twice the odds of developing ADHD as those with undetectable levels.[38] Interactions between organophosphate pesticides and genetic polymorphisms have also been observed; a study conducted in Taiwan found that not only did children with ADHD have higher levels of an organophosphate pesticide metabolite (dimethylphosphate [DMP]), but also those who had higher exposure, a polymorphism in the dopamine receptor D4 gene (DRD4), and higher levels of oxidative stress had a nearly twelvefold risk for developing ADHD.[39]

DIETARY AND LIFESTYLE FACTORS

Food Additives, Sugar, and the Feingold Hypothesis

The hypothesis that food additives can cause hyperactivity in children stemmed from the research of Benjamin Feingold, MD, and is commonly referred to as the "Feingold hypothesis." According to Feingold, many hyperactive children, perhaps 40% to 50%, are sensitive to artificial food colors, flavors, and preservatives.[40]

Feingold's claims were based on his experience with more than 1200 cases in which food additives were linked to learning and behavior disorders. Since Feingold's presentation to the American Medical Association in 1973, the role of food additives as a contributing cause of hyperactivity has been hotly debated in the scientific literature. In actuality, however, researchers focused on only 10 food dyes versus the 3000 food additives with which Feingold was concerned.

At first glance, it appears that the majority of the double-blind studies designed to test the hypothesis showed essentially negative results. However, upon closer examination of these studies and further investigation into the literature, it becomes evident that food additives do play a major role in hyperactivity.[41–43] Overwhelming evidence was produced in several of these studies.

In a more recent study, 153 3-year-old and 144 8- to 9-year-old children from the general population (in other words, the study was not conducted on children with the specific diagnosis of ADHD) were challenged with either a drink that contained sodium benzoate and an artificial food coloring mix or a placebo mix. The main outcome measure was a global hyperactivity aggregate, based on observed behaviors and ratings by teachers and parents, plus, for the 8- to 9-year-old children, a computerized test of attention. The results showed that the children given the artificial food coloring agents definitely had a statistically significant adverse reaction on hyperactivity and behavior. The results were so clear that the authors concluded that "Artificial colors or a sodium benzoate preservative (or both) in the diet result in increased hyperactivity in 3-year-old and 8/9-year-old children in the general population."[44]

It is interesting to note that although the U.S. studies were largely negative, the reports from the United Kingdom, Australia, and Canada were more supportive. Feingold contended that there is a conflict of interest on the part of the Nutrition Foundation, an organization supported by the major food manufacturers—Coca-Cola, Nabisco, General Foods, and so forth. It appears significant that the Nutrition Foundation financed most of the negative studies. The conflict of interest arises because these companies would suffer economically if food additives were found to be harmful. Other countries have significantly restricted the use of artificial food additives because of the possible harmful effects.

In looking at all of the data on the role of food additives in ADHD, the following conclusions can be made: virtually Every study (both negative and positive) demonstrated that some hyperactive children consistently react with behavioral problems when challenged by specific food additives or specific foods. Critics of the hypothesis ignore the significance of the clear (reproducible under double-blind conditions) individual results. The bottom line is that some children definitely react quite strongly to foods or food additives, warranting the exclusion of these compounds for at least 10 days to judge their significance in all cases of ADHD.

In addition to eliminating food additives, there appears to be an interrelationship between sugar consumption and artificial food dyes. One study demonstrated that destructive-aggressive and restless behavior significantly correlated with the amount of sugar consumed.[45] The higher the sugar intake, the worse the behavior. In another study, researchers performed 5-hour oral glucose tolerance tests on 261 hyperactive children, with the result that 74% displayed abnormal glucose tolerance or hypoglycemia.[46] There is also a positive side to this relationship; in 2017 *Pediatrics* published results showing not only were sugar, candy, cola, and similar dietary factors associated with a ADHD diagnosis, but lower adherence to the Mediterranean diet was associated with a risk for ADHD of over sevenfold.[47] This strongly suggests that changing dietary patterns may have a significant effect.

Individual Nutrients and Attention Deficit Hyperactivity Disorder

Essential Fatty Acids

Numerous studies have shown that children with ADHD have a measurable reduction in tissue levels of the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) compared with age-matched controls. The ratio of omega-3 to omega-6 is also likely to be lower, which may be as or more significant than omega-3 levels alone. A 2016 meta-analysis of studies that measured both omega-3 and omega-6 levels found elevated levels of omega-6/omega-3, particularly the ratio of arachidonic acid to eicosapentaenoic acid (AA/EPA).[48] Omega-3 (EPA+DHA) supplementation in ADHD has been studied extensively and is considered a sensible intervention even by many mainstream physicians. Of particular importance is the recognition that omega-3 fatty acid supplementation improves many symptoms of ADHD, including impulsive-oppositional behavior, a symptom not typically helped by the pharmaceutical treatment of ADHD.[49] A 2017 randomized trial also found that omega fatty acid supplementation had similar benefits to methylphenidate and that adding omega fatty acids to methylphenidate reduced the adverse effects of the drug.[50]

Because these omega-3 fatty acids are critical in the structure and function of brain cells, it is thought that low levels play a key role in ADHD. The nerve endings in the areas of the brain affected in ADHD should be rich in DHA because they are highly fluid and should be composed of approximately 80% DHA. DHA deficiency has also been shown to result in increased permeability of the blood–brain barrier in animal studies and is thought to play a critical role in protecting the brain from an influx of neurotoxic compounds.[51,52]

Human breast milk is also rich in DHA, and several studies suggested that formula-fed children are at twice the risk of developing ADHD as those who are breastfed.[53] The role of DHA in brain development, intelligence, and possible protection against ADHD finally led to its inclusion in many infant formulas and other foods.

Besides fatty acids, inadequate provision of other nutrients during fetal development and early childhood may also play a significant role in the development of ADHD as well as its treatment.[54,55] In addition, children with ADHD often show multiple nutrient deficiencies, highlighting the importance of broad-spectrum nutritional support. In particular, the following minerals are critical supplements in the management of ADHD.

Magnesium

Magnesium levels in serum, red blood cells, and hair were all shown to be low in the majority of children with ADHD.[56] These children also demonstrated improved behavior when administered magnesium supplements.[57]

Zinc

Lower hair and serum zinc levels were shown to frequently accompany ADHD.[58] Those children with low serum zinc were also more frequently found to have lower levels of free fatty acids, suggesting that abnormalities in fatty acid metabolism may, at least in part, result from zinc deficiency.[59] It was also shown that lower hair zinc levels correlated with a poorer response to treatment with amphetamines. Several clinical trials demonstrated the positive effects of zinc supplementation in hyperactive children.[60,61] An elevated copper/zinc ratio has also been observed.[62]

Iron

Anemia from iron deficiency is estimated to affect approximately 20% of infants, and many more are thought to have milder iron deficiencies without anemia, leaving them at risk for impairment of brain development.[63,64] Iron deficiency was found to be even much more common in children with ADHD. One study demonstrated that iron supplementation in nonanemic children with ADHD resulted in diminished ADHD symptoms within 30 days.[65] A more recent study demonstrated improvement in ADHD symptoms in children with ADHD and low iron stores.[66] A 2018 systematic review and meta-analysis found both lower ferritin levels among children with ADHD and more severe symptoms among those with iron deficiency.[67] It has also been suggested that iron deficiency may exacerbate lead exposure toxicity.

Vitamin D

Lower serum levels of vitamin D have been observed among children with ADHD compared with healthy controls.[68] An inverse association between cord vitamin D levels and ADHD in toddlers has also been observed.[69] Although clinical trials of vitamin D supplementation alone have not yet been conducted, when given as an adjunct to methylphenidate, vitamin D has been shown to improve some symptoms of ADHD.[70]

Food Allergy

There is a very strong relationship between allergies and ADHD, including food allergies.[71–75] In one study, demonstrable brainwave EEG changes occurred immediately after ingestion of a previously identified food allergy.[75] Food allergies and other allergic disorders were also associated with a higher incidence of recurrent ear infections (otitis media).[76] In turn, recurrent otitis media were associated with an increased risk of ADHD.[77] Both food allergy and ADHD were associated with sleep disturbances, which may, in turn, contribute to a worsening of ADHD symptoms. Heavy snoring and sleep apnea are particularly prevalent in allergic children and may significantly contribute to ADHD symptoms.[78,79] Studies demonstrated improved sleep in children with ADHD during a low-allergy potential (oligoantigenic) diet. Food allergy elimination or desensitization can be as effective as drug therapy in reducing ADHD symptoms.[80–84] In 2011 the *Lancet* published the results of the Impact of Nutrition on Children With ADHD (INCA) study, a randomized controlled trial conducted in the Netherlands and Belgium, and found that a strict elimination diet had a significant benefit on symptoms in 64% of children. Although immunoglobulin G (IgG) antibodies were not predictive of which foods induced symptoms, reintroduction of bothersome foods did induce symptoms, leading the authors to conclude that "dietary intervention should be considered in all children with ADHD, provided parents are willing to follow a diagnostic restricted elimination diet for a 5-week period, and provided expert supervision is available."[85]

Obstructive Sleep Apnea

It has been repeatedly demonstrated that attentional deficits are exceedingly common (95%) in both children and adults with obstructive sleep apnea (OSA).[86] Likewise, OSA is found in up to 30% of children diagnosed with ADHD, and this may be central to the etiology of their attentional problems. In children, chronic nasal or tonsillar/pharyngeal congestion is the most common etiological factor leading to OSA, although childhood obesity is also becoming a leading cause. OSA should be carefully considered in all children with ADHD, and health care providers should be familiar with the signs and symptoms suggestive of OSA as well as the local resources available for diagnosis and treatment. Children and parents will usually be unaware of the presence of OSA. However, clues such as nocturnal mouth breathing, snoring, enuresis, daytime urinary incontinence, and daytime drowsiness should strongly suggest a need to rule out OSA, usually by referring the patient for nocturnal oximetry testing or polysomnography. Because questionnaires and physical examination are relatively insensitive to pick up OSA in children, a high index of suspicion is essential. OSA results in severe sleep fragmentation and frequent hypoxic episodes, which, in turn, reduces a child's intellectual capacity, reduces attentional performance, and diminishes the child's quality of life. Children with sleep-disordered breathing should be treated. Efforts should be made to reduce nasal congestion and decrease recurrent upper respiratory infections. However, in those children with OSA who do not clearly respond to conservative measures, tonsilloadenoidectomy has been proven to have a substantial and sustainable benefit in ADHD symptoms and comorbidities. Parents need to be made aware of the substantial risks of untreated OSA versus the risks and/or benefits of this surgery.[87]

Dysbiosis, Gastrointestinal Permeability, and Intestinal Parasites

Probiotic supplementation with *Bifidobacteria* and *Lactobacilli* may be helpful in the treatment of ADHD. These organisms function as part of the first line of defense in gut immunity and have been shown to restore the altered gut permeability due to food allergies.[88,89] In addition, a stool analysis to rule out parasitical infection or altered bacterial flora appears advisable due to disturbances in gut mucosal immunity (discussed in the following). Interestingly, in a clinical trial in which 75 infants were given *Lactobacillus rhamnosus GG* or placebo during the first 6 months of life, by age 13, 17.1% of those given placebo developed either ADHD or Asperger's syndrome, whereas none in the probiotic group did. Healthy children also had higher levels of fecal *Bifidobacterium* during the first 6 months of life.[90]

IMMUNE SYSTEM IMPAIRMENT

It has been shown that subtle immune dysfunction may be a prominent problem in ADHD. Both cellular and humoral immunity were shown to be abnormal in children with ADHD compared with age-matched controls.[91] Plasma complement levels were found to be lower in children with ADHD.[92] Immune dysfunction in ADHD may be either directly inherited or may be a result of nutritional, toxicological, or atopic factors. ADHD may also be, in part, an autoimmune disorder. Antineural antibodies were found in the blood and cerebrospinal fluid in ADHD.[93,94] ADHD has been associated with a number of autoimmune conditions, including multiple sclerosis, type 1 diabetes, and inflammatory bowel disease.[95,96] Gut mucosal immunity may also be significantly impaired in ADHD, leading to increased susceptibility to gut pathogens and food allergies.

COGNITIVE-BEHAVIORAL THERAPIES

All children exhibiting symptoms suggestive of ADHD should undergo thorough neurobehavioral and cognitive assessment. Many of the features often associated with gifted children can be mistaken for symptoms of ADHD. Likewise, children with mood disorders or learning disabilities, those from abusive environments, and those who have suffered serious trauma may benefit from specific psychological or cognitive-behavioral interventions and may not respond appropriately to ADHD-specific pharmacotherapy. In addition, cognitive-behavioral therapies that can be implemented in schools and in the home environment have been shown to be efficacious in the treatment of ADHD.[97] Cognitive-behavioral therapies also appear to be as effective in older adults as they are in children.[98]

NEUROFEEDBACK

In neurofeedback (EEG biofeedback) treatment, individuals are provided with real-time feedback about their brainwave activity through electronic instrumentation. This feedback allows the subject to learn self-regulation of brainwave intensity and frequency. Measurements of brain activity in many individuals with ADHD demonstrate cortical slowing and diminished brainwave intensity in the prefrontal region and frontal lobes. Neurofeedback treatment is designed to train individuals to increase the production of brainwave patterns that reduce or eliminate this cortical slowing and thus reduce or eliminate many associated ADHD symptoms. Evidence supporting neurofeedback as an effective treatment in ADHD is accumulating, including studies showing cessation of methylphenidate (Ritalin) in children without loss of treatment effect.[99–103]

Rapid transcranial magnetic stimulation, a treatment used in many centers as a safer alternative to electroconvulsive therapy, has begun to show promise in the treatment of a variety of neuropsychiatric conditions. This treatment may hold promise in the treatment of ADHD, particularly in those children with more severe forms of the disorder, with serious comorbidities, or in those who are resistant to treatment.[104]

BOTANICAL MEDICINES

Procyanidolic Oligomers

Extracts from grape seed skin and the bark of the maritime pine such as Pycnogenol are rich sources of procyanidolic oligomers—one of the most beneficial groups of plant flavonoids. These extracts may prove useful in the treatment of ADHD due to their broad-spectrum antioxidant effects alone, because increased oxidative damage is believed to be a central factor in ADHD.

To date, four studies have been conducted in ADHD with Pycnogenol. In two of the studies, children with ADHD supplemented with Pycnogenol (1 mg/kg body weight per day) showed improved antioxidant status.[105,106] A third study not only confirmed this antioxidant effect but also showed improvements in hyperactivity.[107] In the most detailed study, 61 children with ADHD supplemented with 1 mg/kg/day Pycnogenol or placebo over 4 weeks showed that 1-month Pycnogenol administration caused a significant reduction of hyperactivity and improved attention and visual-motor coordination and concentration in children with ADHD.[108] No positive effects were found in the placebo group. These results point to an option to use grape seed or pine bark extract as a nutritional adjunct in ADHD.

Ginkgo biloba Extract

Two early pilot studies, one in children (in combination with American ginseng) and the other in adults, showed some beneficial effects attributed to supplementation with *Gingko biloba* extract.[109,110] Specifically, these studies showed improvements in inattentiveness, hyperactivity, and socialization. A more recent randomized trial found that both teacher and parent ratings improved when *Gingko* was given with methylphenidate versus methylphenidate and placebo.[111]

L-Theanine

L-theanine, an amino acid found in green tea, shows promise in improving sleep quality in children with ADHD. This amino acid is known to reduce anxiety, increase concentration, improve sleep quality, and stabilize mood without sedation.[112,113] It also improves cerebral dopaminergic activity. In a recently completed double-blind, placebo-controlled trial on L-theanine in ADHD, 90 boys with ADHD were found to have significant improvements in sleep quality as measured by nocturnal actigraphy with 400 mg L-theanine a day.[114]

THERAPEUTIC APPROACH

Many alternative and complementary therapies have been offered for the treatment of ADHD in children and adults. Some have good evidence for safety and efficacy, whereas the evidence for others is still lacking. A reasonable approach with a high probability of success will be multimodal and will address as many contributing factors as are practical. A basic workup ruling out common disorders that may manifest as ADHD is prudent because these may require specific treatments, and delay of treatment may be harmful. Celiac disease, depression, lead poisoning, sleep apnea, and visual or auditory problems are some of the problems that should be included in the differential diagnosis. Other contributory factors, such as increased intestinal permeability; food allergies or intolerances; and iron, magnesium, zinc, vitamin D, and omega-3 fatty acid deficiencies, may be assessed through laboratory testing or simply treated empirically if financial constraints prevent ordering noninsured tests.

In general, a stepwise, rational approach is often successful.

Step 1

Assisting parents in eliminating junk foods, fast foods, and food additives from the diet (especially sugary foods and beverages, white flour products, and deep-fried foods) while increasing the quantity of whole foods is an important first step. If a child consumes more whole grains, fruits, vegetables, clean protein sources, pure water, and fiber, health benefits are inevitable. In some cases, converting to a whole-foods, Mediterranean–based diet can result in marked improvements in behavior and cognitive performance. The initial adoption of a very restrictive elimination diet for at least 5 weeks, under nutritional supervision, is also likely to improve symptoms and identify problematic foods following food reintroduction. For those ready to navigate the difficulties of this diet, it may be an excellent starting point.

All sources of environmental toxin exposure need to be identified and eliminated.

Step 2

Nutritional supplementation is often helpful and usually includes a pharmaceutical-grade fish oil supplement or DHA/EPA concentrate; high-potency multivitamin/trace mineral supplement; additional calcium, magnesium, vitamin D, and zinc (additional iron is also beneficial in children and adolescents if anemia or low iron stores are documented); and potent antioxidant support (e.g., pine bark [Pycnogenol] or grape seed extract). Although there is evidence to support each of these interventions, when combined, as well as in the context of a whole-foods diet, the results are usually significant.

Step 3

Gastrointestinal rehabilitation is a concept familiar to practitioners of natural medicine. This involves therapeutic steps to reduce intestinal permeability, improve nutrient absorption, and increase the immune response to gut pathogens while diminishing hypersensitivities. A useful approach follows the mnemonic "ANT PIE" (abstain, nourish, toxins/detoxification, probiotics, identify, eliminate).

Abstain from junk foods, deep-fried foods, sugary drinks, and other foods that harm or irritate the gut, as well as unnecessary drugs or excessive alcohol.

Nourish the digestive tract with nutrients that support gut healing. Functional foods that combine low-allergy-potential protein and a number of nutrients helpful for gastrointestinal healing are readily available.

Toxins/detoxification refers to the avoidance of pesticides by eating organic foods and consuming nutrients that improve the efficiency of detoxification processes, such as L-glutamine, *N*-acetylcysteine, dietary fiber, and cruciferous vegetables. Regular exercise and stress reduction are also important parts of this step.

Probiotics are therapeutic bacteria (and some yeasts) that may improve the gastrointestinal microecology, improve immune response toward gut pathogens, reduce immune hypersensitivities, and stimulate gut repair.

Identify allergenic or intolerant foods and gut pathogens. Food allergies (type I or immediate hypersensitivity food reactions) can be identified by skin-prick testing, radioallergosorbent testing, or enzyme-linked immunosorbent assay testing for immunoglobulin-E antifood antibodies. Patients with evidence of type I hypersensitivity food allergies (e.g., postprandial swelling of the lips, urticaria, wheezing) should be referred to an allergist for definitive testing, because serious anaphylaxis could occur without proper avoidance. Delayed hypersensitivity reactions (usually type III mediated) are best identified with a properly conducted elimination test diet, followed by carefully observed reintroductions of individual food items eliminated in the test diet. IgG antifood antibodies were not found to be predictive in the INCA study.

Intestinal parasites, yeast, and pathogenic bacteria may also be identified by stool testing, *Candida* and *Helicobacter pylori* serology, breath testing, and urinary organic acids.

Eliminate foods found to be allergic or intolerant with elimination test diet. Gut pathogens, parasites, and *Candida* overgrowth may be treated.

This approach to gut rehabilitation follows a rational order that provides for optimal physiological responses to treatment. The results of following this program to its completion in children with ADHD can be quite dramatic.

Step 4

Nutraceuticals can often provide additional improvements in behavior and cognition and may be a necessary intervention earlier on if parents are pressured to submit their child to drug intervention. For example, *G. biloba* extract and/or L-theanine may provide some benefit. Cognitive-behavioral therapy should also be initiated, because it is likely to have a more sustained effect than pharmaceutical interventions.

Autism

Sidney MacDonald Baker, MD

OUTLINE

MORGAN, A NONVERBAL 5-YEAR-OLD

My new patient, Morgan, a nonverbal 5-year-old who had been diagnosed with autism, emerged from his car seat with a full bladder and worried face. After a trip to the toilet, we met outdoors for a swing test. As Morgan watched the swing support my 160-pound frame, his face shifted from worried to puzzled. I dismounted and lifted Morgan onto the generous web of small rope that formed a sturdy wood-framed seat. His mom—who had traveled with her son from Texas to Sag Harbor, New York, to consult me—was puzzled, too, that this was how our appointment began. With all the tests that Morgan had endured in the 2 years since his autism diagnosis, none had had anything to do with swings.

And this swing was a big one: suspended by a rope through a pulley 30 feet overhead then attached with an adjustable tie to an adjacent tree trunk. After drawing Morgan to the secure back of the seat, and with the swing a few steps back in its range, I let it go. Morgan's response, reflected in his mom's eyes, was grateful surprise, and soon he was embraced by the full range of the swing's trajectory. I touched the swing seat to give it a half turn and saw the expression on Morgan's face blossoming to one of pure joy. As with all such children who had taken this test over the past 25 years, it was my joy to say, "Morgan, you are a terrific swinger. You are fearless. You gave your smile to those tree branches way up there. I am proud of you." Morgan smiled and did hand stims as we walked indoors to my consultation room after he had a given me a good workout in propelling him high into the leafy world over our heads.

Morgan now knew that this doctor's visit was going to be different. We toured the adjacent rooms to help him locate himself, then settled down in my consultation room with its couch and two comfortable chairs. He ignored a big basket of toys, choosing instead to drift between where his mom was seated and the space near my chair, where he reached out to touch me after the first hour. My conversation with his mom focused first

on Morgan's strengths. I had given her a 26-page questionnaire to complete before our appointment. I had received, extracted, and contemplated her answers before the visit, sorting all of Morgan's symptom data by frequency/severity and coding all the symptoms that invited a therapeutic intervention. Page 2 focused on strengths, which is always the place to begin.

Identifying Strengths

In previous doctors' offices, Morgan had heard conversations about all the things that were wrong with him. Here, he heard his mom's elaboration of the details connecting his strengths to his medical history.

Strength	Mild	Moderate	Severe	Occasional	Frequent	Always
Wants to be liked		x				x
Sensitive to people's feelings		x				x
OK if parent leaves		x				x
Good with computer						x
Strong desire to do things						x
Especially attractive			x			
Cuddly		x			x	
Happy		x			x	
Sensitive/affectionate		x			x	
Likes to be held		x			x	
Accepts new clothes					x	
Pleasant/easy to care for					x	
Answers parent					x	
Follows instructions					x	
Pronounces words well					x	
Unusual memory					x	
Good with math					x	
Good climbing					x	
Responsible				x		
Good throwing and catching				x		
Swimming				x		
Bold, free of fear				x		
Likes to be swaddled				x		
Physically coordinated	x					

Beginning with a child's strengths lets the child, as well as the parents, know that the practitioner is paying attention to them, celebrating them, and listening to them. The child feels seen by me and might also better see him- or herself through my eyes. That was to be the theme of my relationship with Morgan and his mom: beginning with his strengths and going forward with a focus on him as an individual for every aspect of his treatment for autism.

Morgan's mom had never had a doctor take an interest in the details of her son's symptoms, only those that supported the autism label. But, as I explained to her (pausing to retell Morgan what a good job he had done on the swing), with a patient with autism, as well as with a patient with any chronic disease, it is clinically important to review *all aspects* of the patient's health. It is with these specific details that the functional medical doctor and the family can make joint decisions about options for treatment. The entire symptom checklist I use for all in-depth consultations can be found in Chapter 137, Let the Data Speak, of this book.

Let the Data Speak

Morgan's treatment plan was built on the previously described data enriched by his mother's narrative as recorded in her completion of the "Chronological History Form." The following six excerpts exemplify the value of such a format:

1–2 months. Breastfeeding well established. Healthy growth. Colicky baby. Poor sleeping—Perhaps 3 hours per night total. Great eye contact. Coos. Responsive. Smiles.

Lifting head. Tends to cry when placed on tummy.

7–8 months. Razzing. First hand clap. Getting into crawling stance. Sits "mostly unsupported," using pillows.

Immunizations (DPT and Hib1)—"Got a fever and felt lousy for a week."

13–14 months.

11/20/09 Immunizations. MMR, HepA, pneumococcal, conjugate vaccine. "Sick for days." Seems like it was about a week of sickness. Fever, crying, fatigue, no appetite.

December—Starts to shake head "no" and say "na-na"

Mouths word "up" to be picked up. Doesn't say it again. Very high activity level. Poor attention. Not gaining enough new skills; development seems to be at a standstill.

19–20 months.

Morgan says, "Dive me dat!" Heard once and not again.

Extreme hyperactivity. Very intense sensory seeking. Running back and forth, throwing body against the walls. Either understimulated or overstimulated—never at stasis.

Toe walking. Flapping.

25–26 months.

11/3/2010—Autism diagnosis.

December: Establishing therapies. Home program. Starts making progress.

Dec. 2010—The whole family is ill. Morgan is "sick for 2 weeks." Loses weight. Refusing all foods except bacon, waffles, and noodles. Morgan is "not vocalizing, quiet and unhappy."

We start ABA. Rapid improvement.

45–46 months.

July—Eliminate casein. Easy adjustment.

Headaches stop completely. Constipation improves within 1 to 2 days. 2 weeks later, eliminated gluten. No noticeable changes.

Visits to developmental pediatrician and allergist/immunologist. Concerns: pale, bloated belly, constipation, inflamed ring around anus, allergic shiners, seasonal allergies that seem to last all year, repeated pink eye and upper respiratory infections. Recommendations are not helpful or have no impact.

I start digestive enzymes. It relieves the constipation, but his stools become poorly formed; mushy.

Now he has intermittent diarrhea/mushy stools and constipation.

Treatment Plan

Morgan's treatment plan at the time of our first consultation was initialed at a clinic specializing in autism and included the following:

Diets	Doing now?	Very Good	Good	No Response	Bad	Very Bad	Don't Know	Negative, Then Good	Comments:
Gluten-free	x						x		
Casein-free	x	x							
Yeast-free	x	x							
Specific carbohydrate diet	x	x							

Therapies	Taking now?	Very Good	Good	No Response	Bad	Very Bad	Don't Know	Negative, Then Good	Comments:
Lovaas	x	x							
Occupational therapy			x						
Speech therapy	x			x					

Medication or Supplement (please mark the response with lowercase x's	Taking now?	Very Good	Good	No Response	Bad	Very Bad	Don't Know	Negative, Then Good	Comments:
Digestive enzymes	x		x						
Probiotics	x						x		
B6 and magnesium	x						x		
Folic acid	x						x		
Melatonin		x							Sleeps well presently
Multivitamin, high potency	x						x		
Vitamin B_3 (niacin)	x						x		
Vitamin B_6	x						x		
Magnesium	x			x					
DHA-rich oils	x		x						
EPA-rich oils	x		x						
Cod liver oil	x		x						
Flax oil	x						x		

Morgan was a boy with many strengths, of which one was a very well-organized and bright mom. His symptoms, laboratory work, and response to previous treatment justified optimism in his prognosis. As rich as has been my experience in predicting treatment outcome, picking the winners remains an uncertain task in which positive response to previous treatments counts higher than other variables. The fact of his long list of symptoms of neuromuscular irritability, despite supplementation with magnesium, was disconcerting, although perhaps explained by bowel issue that would have limited his magnesium tolerance.[1]

Restore the Gut

Actionable findings from laboratory tests previously ordered at an autism clinic near his home were as follows:

Stool: *Dientamoeba fragilis* trophozoites, the growth of a non-*Candida* yeast, and *Rhodotorula* species.

Blood: Nutritional profile showed unmet needs for B vitamins, vitamins A and E, and alpha-tocopherol.

Plan:

1. Treat the amoebic infection with trimethoprim-Sulfamethoxazole and paromomycin as a red herring in his autism spectrum.
2. Cover the antimicrobials with an antifungal—he was already on *Saccharomyces boulardii.*

After a hiatus for treatment by his local physician for a question of strep versus fifth disease, Morgan responded dramatically to immune restoration treatment via probiotics (discussed later in the chapter), as his mother reported:

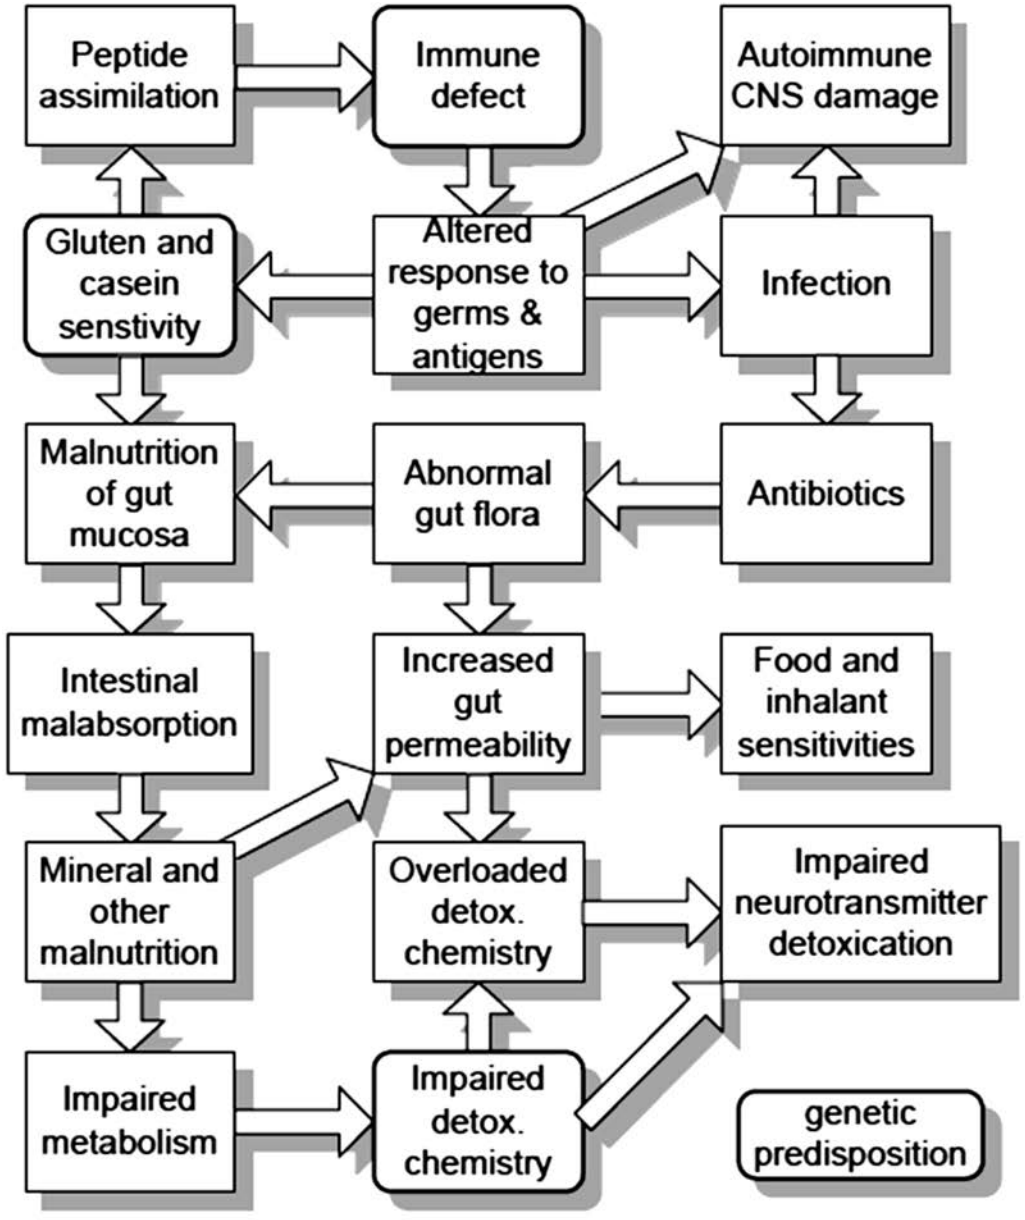
> *Huge improvement in overall immune functioning! Morgan has not been ill at all this summer. He attended 4 separate summer camps (each camp had attendance of 15–20 4-year-olds) and did not become ill! Previously attendance in these activities would result in*

bacterial and viral infections that would essentially negate his ability to attend. He has NEVER been able to tolerate that level of exposure! He has been at school for 3 weeks and has not become ill. Additionally, his seasonal and mold allergies have been very mild.

The immune restoration treatment has not produced significant improvements in symptoms such as weakness in his hands, poor fine motor, balance, and attention. Stimming remains.

Restore Immune Balance

Various supplements were on Morgan's plan, but the turning point came with the addition of helminthic therapy in the form of *Hymenolepis diminuta* cysticercoids, after which all of his autism symptoms cleared. He has since emerged as a brilliant and articulate. His mom recently updated me on his progress: "The school recently had a guest speaker, children's author and Newbery Medal winner Jack Gantos. Morgan was the darling of the event when he answered all of the prized author's questions with innocent humor and unique perspective. His teacher said he was totally engaged by the author and 'on.' The school is slowly recognizing that the strange, socioeconomically disadvantaged, disheveled-looking autistic child that managed somehow to transfer into their exclusive school is actually a benefit to their campus, as he may someday pull up their standardized test scores."



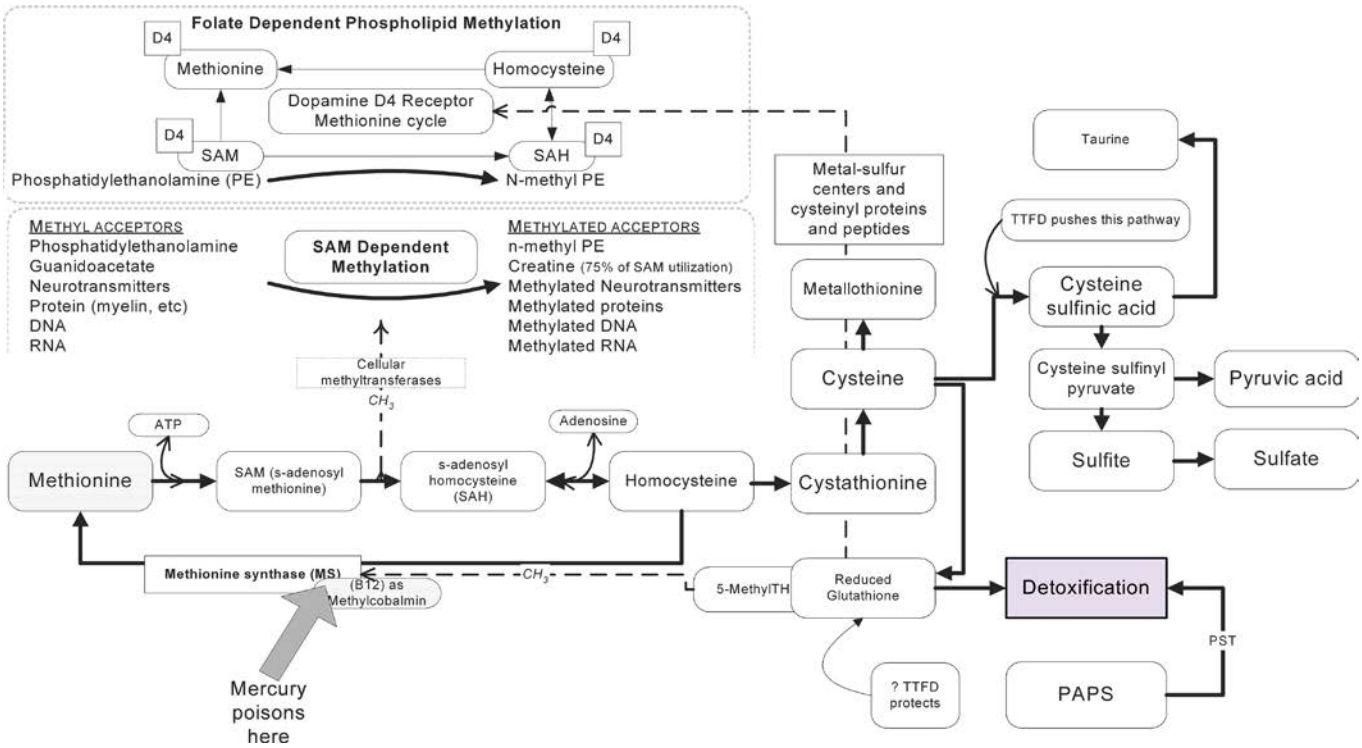
A model for relationships among "alternative approaches to autism spectrum problems

A Historical Perspective for a Comprehensive Model

Morgan's story is typical of the many children for whom the word *restoration* is the key to understanding a therapeutic strategy designed to evoke Nature's strong impulse toward healing by meeting special unmet needs, and/or eliminating toxins, allergens, and microorganisms. A consensus among 30 scientists, practitioners, and parents was formed in 1995 when Bernard Rimland, PhD; Jon Pangborn, PhD; and I organized a meeting in Dallas, Texas, in which the spirit among attendees from diverse backgrounds was to find common ground. The accompanying diagram summarized the landscape of biochemistry, toxicology, and immunology that could, we agreed, help organize thinking for each of us as we pursued our various efforts to seek actionable options for individual children affected by autism. Now, more than two decades later, our vision has been vindicated by research findings and the kinds of clinical outcomes illustrated by Morgan's response to treatment.

Our meeting took place three decades after the publication of Dr. Rimland's book challenging the medical view that had been current since the 1940s that autism was due to cold mothering.[2] That challenge unfolded when genetic research was fed by the reality that everything is genetic, as indicated by the "genetic predisposition" in the lower righthand corner of the diagram that evolved during 3 days of brainstorming. What was missed in the enthusiasm of advocates of the genetic etiology of autism was the impossibility of a genetic epidemic. As the prevalence of autism rose dramatically in the past two decades, those of us who were at that meeting and came up with the boxes in our diagram felt increasingly justified by our portrayal of the arrows. They give a clear impression that we are dealing with a *system,* which is a different reality an *entity*. Read the appendix by Crookshank in Ogden and Richards's linguistic classic, *The Meaning of Meaning* (Harcourt, Brace Jovanovich, 1959). It presents a serious concern that the medical profession's failure to make distinctions among names, ideas, and things will lead to increasing problems for the medical profession as the burden shifts from acute illnesses to chronic disease.

Conventional medical practitioners seemed incapable of avoiding the language and thinking about autism as if it were an entity that causes symptom until the word *spectrum* entered our citadel like the Trojan horse into Troy. Using the word *spectrum* combined with autism brought a simplicity to thinking about children with the defining symptoms in behavior, speech, and movement that opened our minds to the full picture of symptoms that drew attention to immune and digestive disruptions. For parents, this shift gave rise to a dispiriting feeling as the diagnostic label lost the implication that "we know what it is" and became one of being lost in a poorly defined space.

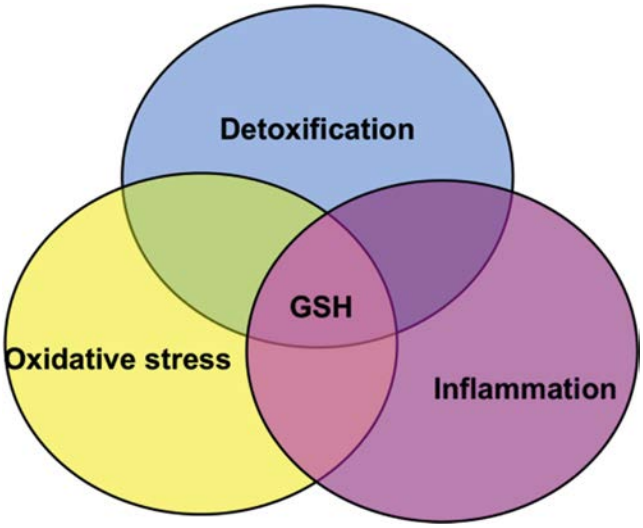


Definition of that space came as our original meeting in Dallas in 1995 gave rise to an organization to which Dr. Rimland gave the name Defeat Autism Now! (DAN!). Keen to meet again, we were able to afford future meetings by inviting an audience of parents, professionals, and scientist to come, listen, and participate. Richard Deth, PhD, of Tufts University pointed us to Jill James, PhD, of the University of Arkansas to add deep insight into problems of oxidative stress and the particular burdens of certain toxins (lead, mercury) on the chemistry in which glutathione was the threatened moiety in a vicious biochemical cycle breakable only by large doses of such nutrients as methylcobalamin and methyl folate. Here is the chart that Drs. Deth and James helped me draw. More biochemists and immunologists have since come on board and stayed as the Autism Research Institute's role as a meeting organizer shifted back to support of research and a new entity, the Medical Academy for Pediatric Special Needs, inherited the role of training physicians in the biochemistry, toxicology, and immunology that provide the basis for medical management of individual children on the autism spectrum.

Dan Rossignol, MD, has maintained his leadership role in the teaching program and in collaboration with Richard Frye, MD/PhD, published a stream of papers offering validation of the common sense of the approaches outlined in this chapter as well as peer-reviewed research supporting their scientific basis.

Readers who have a strong affiliation with the Institute for Functional Medicine (IFM) will recognize in this chapter a strong influence shared by IFM, DAN!, and MAPS. IFM did not sponsor a meeting focused on children's health until 2017, and as of this writing, the future of such a focus is uncertain.

The DAN! and MAPS path to discovery of effective treatment options has yielded dramatic clinical response in the children under the care of physicians who have been trained in the commonsense application of dietary and medical interventions aimed at finding in each individual child those elements in diet, supplementation, and natural and pharmaceutical medicine that evoke Nature's buoyant impulse toward healing. Going back to 1967, a registry kept by the Autism Research Institute (ARI) under the leadership of Dr. Rimland and Steven Edelson, PhD, recorded ratings of pharmaceuticals, nutritional supplements, and dietary measures and has yielded a treasure trove that should be examined by readers of this chapter.[3] It offers the clinician a detailed picture of the failure of conventional pill-for-an-ill practice and strong support for natural remedies plus antifungal medicines.



Dr. Rossignol's literature review cited herein is an invaluable resource, but ARI's presentation of good, neutral, and bad responses to various treatments given to children in the autism spectrum offers, on a single page, a clear message that will shorten the learning curve of any practitioner who may feel intimidated when crossing the bridge to the seemingly unfamiliar landscape of the autism spectrum. Once there, it will become clear to the explorer that the territory is not some exotic colony beyond the margins of mainstream medicine. On the contrary, autism is simply the core of pathology found in the most vulnerable members of our culture who are exposed to the stressors relating to micro- and commensal organisms, detoxification, and oxidative stress. After our DAN! group had welcomed new participants, the accompanying diagram began to coalesce around a theme that was to match that of the evolving understanding about all chronic illness and support a view of treatment options that is more of a guide than a shopping list. The diagram could be replaced in our current way of thinking by a single sentence: "While some would say that 'everything is autoimmune until proven otherwise' reading the chapters in this book written by world leaders in autoimmunity brings one to the conclusion that everything after all is infectious until proven otherwise (including autoimmune diseases)."[4] I believe that to be the most important sentence written in the field of chronic illness in my five decades as a doctor. Its author, Dr. Yehuda Shoenfeld, embraces the decisions we clinicians make every day and the way we speak with our patients and colleagues about options for the prevention and treatment of chronic illness. The language spoken by those who care and are cared for in contemporary culture is full of particularities. These items are embodied in words such as "disease entities" that preserve an ancient mythology that is kept alive in the classification of disease. Our system for naming illnesses wrongly guides our thinking about concepts by modeling them on the Linnaean categorization of live or once-living entities. How can we escape the muddle embodied in the confusion of concepts with entities that is so deeply engrained in the way we name and blame diseases as if they are things that cause symptoms?

CAUSES OF COMPLEX DISEASE

Loss of Immune Tolerance

Dr. Yehuda Shoenfeld's statement guides us to grasp that, whatever name we give it, the cause of chronic illness is the loss of immune tolerance. If everything we see in the realm of chronic illness is a manifestation of the loss of immune tolerance, then restoration of immune tolerance is the goal we strive to achieve. Nowhere more so than in the autism spectrum do we find so rich a set of symptoms presenting the ways sensitivity can be expressed in the human. Nowhere more so than in the autism spectrum do we discover resources for the recovery of immune tolerance that comes with the answer to a conceptually simple question: Does this individual have a special unmet need to get, avoid, or be rid of something, which, if taken care of, would favor Nature's buoyant impulse toward healing?

The word *spectrum* came into contemporary medical parlance as did the Greeks' horse into Troy, giving medical professionals a secure metaphor while parents were deprived of the (false) security of knowing the precise name of the "thing" that is causing their affected child's problems. Autism's history is full of cruelty, starting with a consensus formed in the mid-20th century that children who could not learn speech and were devastated by odd postures and behaviors and troubled by hypersensitivity to noise, touch, smell, taste, and bright lights were this way because of care given by "refrigerator mothers."

As second-year medical students at Yale in 1962, we were rarely shown movies, perhaps considering the risk of sleep. We witnessed two films at the Child Study Center. In one, the dignified doctor explained to the parents of a child with autism that it was his mother's fault. In another, a developmentally impaired child's parents were cautioned to "not look for answers." We students were told that it would be unlikely that we'd ever see an autistic child, rare as was that disease. I had seen but not grasped institutionalized individuals during my internship's rotation in the Southbury Training School. My first contact with an autistic child was when the fist of a speechless 14-year-old resident of another institution shattered the bridge of my glasses with a stroke to my nose. The precision and force of that hit produced in me the afterthought that he was saying to me, "You are looking into me with your ophthalmoscope, but you are not seeing **me**." I was struck and resolved to learn from other children I would meet.

One was referred to me by a former patient in a prepaid healthcare plan where I practiced for 7 years leading up to my directorship of the Gesell Institute of Child Development. This child of my patient's neighbor had developed a roaring case of eczema after a course of antibiotics. Could I see the child for the minute needed to cover a

prescription for nystatin? I agreed, saw the child's skin in a quick visit, and called in the script, and 6 weeks later, my former patient reported that the eczema was cured, and so was the child's autism. It was the dawn of my understanding that, within Dr. Yehuda Shoenfeld's model, the proliferation of yeasts gave a stimulus in which skin inflammation resulted in a case of mistaken identity in which immune defenses against yeasts targeted the child's skin as they had also been doing all along to her senses.

Is autism a matter of autoimmunity where yeasts are the exclusive trigger to an inflammatory response that affects the brain? No, but such a consideration deserves priority among all diagnostic and treatment considerations. Is autism the exclusive manifestation of the loss of immune tolerance evidenced by the increase of chronic illness in our population? No, but the increase in attention deficit disorder, arthritis, asthma, autism spectrum disorder, autoimmune disorders, developmental/learning disorders, cancer, cardiovascular problems, cerebral palsy, cystic fibrosis, diabetes, epilepsy, food allergies, obesity, respiratory allergies, sickle cell anemia, and spina bifida is more likely to have one cause than different causes for different diseases.

Unity of Disease Causes

The perception of unity in diseases with diverse presentations is easy if we notice that all living things share the same fundamental challenges to their health: bugs, toxins, and fire. In more technical language, these threats have to do with the following:

- Our interaction with internal and external predatory and commensal organisms
- Detoxification and ridding of our own metabolic end-products and environmental toxins
- Oxidative stress as expressed in the protection from being burned by our own metabolic fire

The appealing odor of the essential oils of plants supports the belief that the ancient substances offer themselves to us for our use as they have for plants in the noted three domains since the dawn of life. This textbook does not have an independent chapter discussing essential oils, which are known to many readers who value their role in healing. I will only add here that the marketplace, as I have found it, suffers from the same enthusiasm as contaminates thinking in both conventional and natural medicine: an enchantment with complexity. Purveyors of essential oils tend to multiply the options beyond the capacity of beginners and fail to promote the fact that a dozen or so such oils will do to cover the bases for which these oils were evolved in plants long before so-called higher organisms evolved. These oils addressed the same problems that have existed for living organisms since our planet became oxygenated and referred to in the previous list as bugs, toxins, and fire. A selection of a dozen or so oils may be used therapeutically by patients willing to read and seek advice on how to select the ones that together cover the three bases. The fact that essential oils, being low-molecular-weight lipids, pass through the skin and may travel from the bottom of a person's feet to the brain in 20 minutes is especially important in the context of knowing that any contaminants of such oils may join them it that passage. Thus shopping for oils must be guided by a need to ensure documentation of purity.

The simplicity of the challenges to health of bugs, toxins, and fire argues for a corresponding simplicity in considering the options for all individuals with chronic illness.

The word *special* inserts itself in the thinking—as stated previously—needed to solve the mystery of a person's illness. The term *special needs* has been around for a long time in the delivery of social and educational services for children and adults. Natural medicine's focus is treating not the disease but the individual, where "special needs" applies to therapeutic options. We begin in our consideration of each child's options with the one question—about unmet special needs to get, avoid, or be rid of items—that will favor healing. The answers to such a question come from the patient's narrative, the implication of certain symptoms, laboratory testing, and thumbs testing, defined as the introduction of a therapeutic trial in which a positive result generates a thumbs-up, a negative response generates a thumbs-down, a mixed response generates one thumb up and one down, and no response generates thumbs-sideways. Of all the tests in my toolbox, the thumbs test is the most easily explained and interpreted by patients and parents.

Shifting Thinking

The attachment of the word *spectrum* to autism reveals a new way of thinking in medicine and that is compatible with that of naturopathic medicine. The word *spectrum* joins affected children more loosely than a designation of a disease name. It was introduced in medical writing in 1985[5] but did not enter common lay and medical parlance until late in the 1990s. The word may be applied to all diseases, but its use belongs exclusively to autism in the sense that referring to someone as being on or "in the spectrum" is universally understood as "autistic."[6] A spectrum is a continuum: both wide and deep. It is a metaphor embracing various features of different individuals. The traditional medical way of speaking and thinking about a disease used the word *entity* and carried the thought of something "well defined" by a limited number of symptoms or laboratory tests.

Shifting from "entity" to "spectrum" directs thinking away from the selection of a treatment for *this disease* to tailoring treatment for *this individual*. Failure to understand the implication of this shift creates misunderstandings among doctors and patients. The confusion starts with the implication that a disease is a thing. Diseases are not things but ideas we form about people grouped by similar symptoms and laboratory tests. The danger in this confusion is neglect of the fundamental scientific principle in biology—and medicine—that each person is unique and that the individual, not the disease, is the proper target of treatment.

Understanding that autism spectrum disorder happens to an individual with manifestations on a spectrum of severity allows us to better understand chronic disease and other challenges to human health in the modern age. As different as conditions such as Alzheimer's and autism may look to specialized practitioners, they may be much more similar than we think: the manifestation of environmental, social, and epigenetic conditions I will discuss herein that are compromising human immunity and brain function.

AUTISM SPECTRUM DISORDERS

The Troubling Rise in Prevalence

Autism spectrum disorder (ASD) is an umbrella term given to a wide variety of developmental brain disorders that affect behavior, sociability, and communication. The typical presentation of ASD includes an inability to make eye contact, limited to no social interaction with others, inflexibility, and repetitive behaviors, including hand flapping, various movements called stimming, and repetitive play. The severity of symptoms in those identified as being on the autism spectrum is highly variable. Some children diagnosed with autism, like Morgan before treatment, are highly relational and enjoy social interaction. Others disappear completely into their own world and find social interaction impossible. The common denominator is that those diagnosed with ASD are presenting with behavioral and immunological dysfunction.

In 2014 the Centers for Disease Control and Prevention (CDC) estimated that ASD affected 1 in 45 children. In 2015 the estimate

was 1 in 43 children. The most current number of children diagnosed with ASD, released by the CDC in November 2017, is that 1 in every 36 children is on the spectrum.[7] Three times more boys than girls are affected. That ratio was four to one for many years and, as I reported in 2014,[8] it dropped suddenly in 2013 in the wake of a year when the girls' symptom data were more dispersed, suggesting that an increase in the variance of the data points to instability in the biological system—the autism spectrum—that must surely be environmental.

Doctors trained in the 1980s or earlier, as I was, were told in medical school that it would be unlikely they would ever encounter more than one or two people with autism over the course of their entire career. Now autism has become so prevalent that primary care doctors, particularly pediatricians and family physicians, often have several patients with ASD. ASD is so common, in fact, that the American Academy of Pediatrics recommends that every child be routinely screened for autism. The standard screening is the Modified Checklist for Autism in Toddlers (M-CHAT), usually administered between 16 and 30 months. Early screening is primarily recommended because of the benefits of early intervention in lessening the severity of symptoms. When delays are found on M-CHAT or clinically, steps must be taken to support optimal biochemistry, as discussed later in this chapter, and stop toxic exposures that may be harming a child's brain functions.

Although functional medical practitioners are unequivocal that autism rates have skyrocketed for reasons that cannot be contributed solely to genetics or epigenetics, there continues to be debate in the mainstream medical community about whether the rise in autism is due to a real increase in numbers or simply to better diagnosis. Work done by Stanford-educated atmospheric research scientist Cynthia Nevison, PhD, puts that debate to bed. Nevison's systematic comparison of temporal trends in autism prevalence in the United States revealed that between 75% and 80% of the tracked increase in autism is due to actual increase, whereas 20% to 25% may be attributed to changing diagnostic criteria.[9]

Etiology of Autism

We practitioners should not be misled from considering the environmental causes of ASD in an individual patient when we hear the constant refrain from conventional medicine that the "cause of autism is unknown." We should, moreover, take the lessons we learn from the many children who recover completely from having been autistic to become brilliant and talented individuals.

That said, it is true that we do not have a clear picture of autism's chain of causation. We know it is not caused by refrigerator mothers. We know that the autism we are seeing in the current epidemic does not have a genetic origin in the usual sense. We know that there is a viral shadow over the landscape of many children's stories and laboratory tests, with a particular focus on the measles vaccine virus derived from the measles, mumps, and rubella (MMR) immunization. Whereas the conventional medical doctor is adamant that we do not know what causes autism (therefore making it impossible to avoid as well as to treat), the functional medical practitioner understands that the cause of brain and immune dysfunction that falls under the umbrella term ASD is multifactorial and may be found in a given individual. The likely environmental triggers of autism include are discussed next.

Toxin Exposure and Autism Spectrum Disorders

Although the cause of ASD is still unclear, the role of environmental toxicants in increasing the risk for this disorder has been repeatedly shown. For example, insurance claim data covering one third of the U.S. population was reviewed to see if there was an association with known toxicant-induced disorders and ASD. Congenital malformations of the reproductive system, known to be environmentally induced, were used as a surrogate for environmental toxicant exposures. It was found that males with congenital reproductive malformations were 283% more likely to also have the diagnosis of ASD. A study of 192 twins was done to determine the roles of genetics and environment on the development of ASD.[10] These researchers found that environmental factors carried 55% of the etiological weight, whereas genetics only accounted for 37%.

Maternal exposure to environmental chemicals and body burden has also been associated. Mothers with chemical sensitivity were three times more likely to have a child with autism and 2.3 times more likely to have a child with attention deficit hyperactivity disorder (ADHD). The risk of being a parent of a child diagnosed with ASD is increased by a factor of 7.3 for occupational exposure to lacquers, 4.7 for varnish, 2.7 for xylene, 3.1 for solvents, and 6.9 for asphalt.[11] A study in San Francisco revealed that women occupationally exposed to toxicants have a significantly higher risk of having a child with ASD.[12] Women exposed to disinfectants at work were 4 times more likely to have a child on the spectrum, and those exposed to exhaust and combustion by-products were 12 times more likely.

The presence of low-molecular-weight phthalate metabolites in a mother's urine during her third trimester of pregnancy has been significantly correlated to the child having greater problems with social cognition, social awareness, and social communications by the age of 7.[13] In a Swedish study that followed families over a 5-year period and focused on the home environment and health, the researchers found a connection between vinyl flooring and the diagnosis of autism, Asperger's, and Tourette's syndromes.[14] In addition to increased rates of these diagnoses in children whose parents had vinyl flooring in the bedroom, risk was also associated with parental smoking, condensation on the windows, and reduced ventilation in the home.

Between 2010 and 2015, several articles were published on the relationship between air pollution and ASD. The first was a case-control study with 383 children with ASD and 2829 control children who had speech and language impairment from North Carolina and West Virginia.[15] Exposures to ambient levels of metals, particulates, and volatile organic compounds were assessed via pollutant data on the area where the child's parents lived during pregnancy. Significant associations were found between ASD risk and exposure to the polycyclic aromatic hydrocarbon quinolone (odds ratio [OR] 1.4), styrene (OR 1.8), and methylene chloride (OR 1.4). A group of 284 children with ASD in the San Francisco Bay area was compared with over 600 neurologically normal children to see if there was any difference in air pollutant exposures between the two groups.[16] The researchers found that children living in the San Francisco Bay area with higher levels of atmospheric mercury were 92% more likely to have been diagnosed with ASD. Areas with the highest vinyl chloride levels increase ASD risk by 75%, high cadmium levels by 54%, trichloroethylene by 47%, nickel by 46%, and diesel exhaust by 44%. Another study in California found that children with ASD were far more likely to be living in areas with high vehicular exhaust.[17] During the first year of life, exposure to either nitrogen dioxide (NO_2), particulate matter (PM)2.5, or PM10 all more than doubled the child's risk of developing ASD. In a large cohort of over 49,000 Taiwanese children, those with the highest exposure to NO_2 had a 340% increased risk of developing ASD.[18] In addition to the increased risk from NO_2, each increase of 10 ppb in ambient ozone increased ASD risk by 54%, and each 10-ppb increase in carbon monoxide (CO) levels increased the risk of autism by 37%.

Toxic Exposures During Gestation

Toxic exposures during gestation, especially exposure to prenatal ultrasound,[19] acetaminophen, and endocrine disruptors, have been

implicated in autism. The fact that autism affects at least three times as many males as females raises the possibility that the timing of prenatal exposure through disruption of the embryonic development, which follows a different hormonal course in boys versus girls, could play a role.

Pre- and Postnatal Exposure to Acetaminophen in Combination With Oxidative Stress

An exhaustive literature review by a team of researchers from Harvard and Duke Universities found that one contributing factor in the increased prevalence of autism is increased exposure to acetaminophen, which, in the presence of inflammation and oxidative stress, becomes neurotoxic to infants.[20] It blocks glutathione synthesis, further jeopardizing an individual with a detoxification pathway that is overloaded or compromised by other toxins.

Overexposure to Aluminum

Intracellular aluminum in autism brain tissue has been identified as a causative factor in ASD.[21] Mechanisms by which the human brain is exposed to potentially toxic amounts of aluminum include the synergistic effect of multiple aluminum-containing vaccinations given simultaneously and aluminum in medications such as parenteral nutrition[22] and vitamin K given to neonates, as well as via personal hygiene products and ingestion.[23] In addition, many water supplies and foods are contaminated with aluminum.

A Depleted Microbiome

Overuse of antibiotics during pregnancy and infancy, along with dietary deficiencies, excessive hygiene, and inadequate exposure to soil and other microbes, has resulted in an unhealthy microbiome for many. The antibiotic effect translates directly to consideration of the overgrowth of yeast and other fungi.

Toxic Metal Poisoning in Infancy

Lead and mercury interfere with our body's principal detoxification pathway, creating a vicious cycle.[24]

Loss and Restoration of Immune Tolerance

ASD, like all chronic illness, involves a loss of immune tolerance. If everything we see in the realm of chronic illness is a manifestation of the loss of immune tolerance, then the restoration of immune tolerance is the goal we strive to achieve.

A THREE-STEP PROCESS FOR CARING FOR CHILDREN WITH ASD

Step 1: Listen. There are many ways of listening. Listening begins with hearing the patient or the parent voice the child's story, in which the strengths, symptoms, life events, and previous responses to treatment and dietary intervention are the key elements. No other medical condition is more demanding or richer than the autism spectrum in terms of the details of these elements for presenting options for treatment. A system for coding the actionable implication of symptoms is described in Chapter 137, Let the Data Speak, of this book.

One way of gathering the patient's story of strengths, symptoms, changes, treatment responses, exposures, and life events is a checklist, and the other is a free-form aid for simply listing everything that describes how your patient feels, looks, and acts. Each has its merits. Neither is easy, but no one is better than the patient or the parent at getting it done. Just as one has to endure the pain of a needle to gather information from the blood, one has to exercise patience to get the full picture of a person's health.

Having that picture will reward you in two ways. First, the picture is full of messages about treatment options. Second, when the data are organized properly, they provide a means for helping the parent and the patient with autism see through the physician's eyes. How many times have I asked a patient how things are going and have been told that the stimming and toe walking have not changed? When I raise the question of what has happened with the hand scratching, constipation, and sleep problems, I may get a surprised reaction, "Oh, I forgot about those symptoms!" When the absence of those symptoms is noted and celebrated, families feel a sense of progress that helps support decisions about next steps.

Step 2: Test. Next come various signals from laboratory tests—looking at the body, as well as the blood, urine, stool, saliva, and spinal fluid, with various devices for picturing the shape, movements, and function of tissues and organs that are hidden from view. Finally, as we begin our tailoring, we observe what happens after each step in "trying on" treatments.

Step 3: Try and Evaluate. Most interventions should be considered tests until a positive response turns them into a treatment based on feedback from the patient and/or the laboratory. Healing can be felt and observed and sometimes confirmed by changes in laboratory tests, and in some laboratory tests, such as measures of heavy metals provoked by chelators such as ethylene diamine tetra-acetic acid (EDTA) and dimercaptosuccinic acid (DMSA), a clinical response to the test material may convey as strong of a message as the laboratory result. Beyond that, every treatment is what I call a "thumbs test": a way to ask the body how it feels in response to a change. Every illness, including ASD, is a signal to change. Once a change has been made, there is no more persuasive evidence than what the body tells us as to the value of that change. We can try on various treatments and evaluate their effectiveness by reading the patient before us as opposed to rigorously following a given protocol.

Tailoring Treatment to Fit Individuals

The conventional medical approach posits that autism cannot be successfully cured, only that the symptoms can be managed. The functional/natural/integrative medical approach posits that actionable treatment options exist to help with *tailoring* treatments to fit *individuals* on the autism spectrum, and that with careful tailoring, many children diagnosed with ASD can improve so much as to lose their diagnoses. The fit is best determined by scrupulous attention.

Imagine tailoring a suit of clothing. You try it on and then make adjustments to suit the individual until you have a good fit. A good fit does not mean attempting to suppress symptoms only. A good fit means taking action to favor Nature's strong impulse toward healing.

To achieve such a fit requires discovering and dealing with unmet needs, avoiding triggers, and detoxifying the body if necessary. Unmet needs include nutrients (vitamins, minerals, fatty acids, amino acids, and accessory nutritional factors), light, and rhythmic integration. Triggers include germs, allergens, and toxic exposures. If triggers are present in the body, detoxification will be a seminal step in healing. Toxins may be elementary (e.g., lead and mercury), synthetic (e.g., pesticides), or poisons made by living things such as plants and germs. Once we start thinking this way, the treatment process switches from being the old-fashioned "doctor knows best" and "do what the doctor says" to a different approach: "listen to the patient" and "work together."

TREATMENT

Step 1

In my practice, for years I have avoided doing a large set of laboratory tests before seeing the patient. It saves money, and the interventions I

may begin may produce benefits that will affect laboratory tests, thus making them invalid by the time a commonsense treatment option has been engaged. Toward the end of an initial visit, I demonstrate the injection of a dose 64.5 mcg/kg that will be repeated by the parent once every 3 days from methylcobalamin solution 25 mg/mL into a child's upper outer buttock, violating the prohibition of that location because the slow absorption in buttock fat reduces the benign but, to parents, curious appearance of pink urine resulting from renal overflow. A full explication by Jim Neubrander, MD, of the use of methyl B_{12} can be found on his website.[25]

Step 2

My next step is to find the dose of magnesium that achieves bowel tolerance. It is a precondition to all other interventions. Magnesium supplementation is free of any risk except in patients with poor renal function. Magnesium citrate is my top choice for a diagnostic trial of supplementation. The idea is to take it in escalating doses, starting in a range of 100 to 200 mg in an adult and 50 to 100 mg in a child, to fine "bowel tolerance"—that is, the point of bowel frequency and looseness that is a bit too much, and then back down a bit.

Magnesium taurate is another option for patients with very light-colored stools. Many forms of magnesium citrate capsules are available, and of course, magnesium citrate solution is available as a cathartic—used for "bowel prep" before lower bowel endoscopy or surgery. The dose of approximately 4000 mg found in such preparations in the 6- to 10-oz bottles sold at pharmacies gives a good indication of the general safety of oral magnesium supplementation. Very few individuals with unmet needs for magnesium cannot tolerate an oral dose that would be needed for a therapeutic trial. If so, they can apply magnesium cream (CALM is a brand found in most health food stores) liberally to smooth skin at bedtime. CALM comes as a powder for making a solution for children who do not swallow pills.

The idea with all of these options is to start with a low dose, usually first in the evening, and then increase by adding a dose in the morning, then more in the evening, then more in the morning, and so on until you reach "bowel tolerance" as signaled by loose bowel movements (BMs). At that point, you may back off to a dose that is associated with symptom relief and comfortable bowels.

Children with autism have an increased incidence of constipation and other gastrointestinal disorders.[26] Establishing a dose of magnesium at bowel tolerance provides a way of dealing with constipation. Most importantly, it lets us see improvement in neuromuscular irritability symptoms and allows us to expect the alleviation of other, less noticeable problems that are solved by meeting magnesium needs. These symptoms of neuromuscular irritability are described in Chapter 137, Let the Data Speak. Keep in mind, therefore, that as important as magnesium is in correcting "uptight" symptoms, those symptoms are not the only target of magnesium supplementation. Magnesium, with its partner pyridoxal 5 phosphate, is a cofactor in dozens of steps in every aspect of body chemistry. Many of these processes are relatively silent compared with those related to tension in the nerves and muscles. With that principle in mind, you may ask why I am so fixated on treating neuromuscular irritability instead of "treating autism." Removing a pebble from your shoe is not just for your foot but also for the journey.

Because various kinds of magnesium (magnesium sulfate) and high doses (4000 mg) of magnesium citrate are used as cathartics, patients and practitioners get confused into thinking that magnesium is just a temporary treatment for the constipation and fail to understand that people who have been under—and remain under—stress may have an ongoing need for magnesium supplementation that is magnified by the restricted diet common in many autistic kids.

Step 3

Once bowel tolerance has been achieved for magnesium with at least one reliable BM per day, the next step is a thumbs test with *Saccharomyces boulardii* to be given in escalating doses with activated charcoal as needed to quench the Herxheimer reaction (a die-off reaction, also called Herx, explained herein) symptoms that confirm the suspicion of a yeast problem that is nearly always indicated by answers on the questionnaire and a history of antibiotics.

Children with autism have a problem moving their tongues. We see in the many children who recover that they knew all the words, and some children teach us, in the midst of a sudden recovery, that they can go from very limited to fluid speech in a few days. What's going on when that happens? The research and review of contemporary science by Woody McGinnis, MD, brought the interactions among the midbrain and its far reaches in the gut and the higher brain to the attention of the autism community. We now understand that substances in the gut pass through the bloodstream and affect or touch the midbrain. This touch is based on the midbrain's ancient job of "tasting" the blood for signals that are needed to regulate automatic body functions shared by all animals.

In recent history, humans have experienced changes in diet, enormous increases in exposure to novel toxins and antibiotics, and the disappearance of beneficial gut organisms. These changes result in new signals coming from the gut to the midbrain. These signals cause confusion and result in damage to the automatic movements of organs of digestion, including the tongue and the gut. In humans, the tongue does double duty as an organ of digestion and speech. Both of these can be impaired when the autonomic nervous system is affected. Nonverbal children diagnosed with ASD have impaired function in the midbrain. The conventional medical approach is to treat the symptoms by intensive therapy with a speech pathologist. The consensus among professionals is that speech therapy works for children. It provides benefits that would not be obtained without that intervention.

Although early behavioral intervention can be helpful, the functional physician understands that detoxification takes precedence over speech therapy to get to the root causes of this autonomic dysfunction. I have found that successfully treating yeast overgrowth in nonverbal children with ASD is the key to resolving this autonomic problem. Morgan's story is a case in point. As the result of being on high doses of antifungal medication, Morgan went from having no speech to being a highly articulate, precocious talker over the course of just a few months.

Just recently, I treated a 4-year-old boy who was deep in the autism spectrum with very little speech. After seeing him respond to *S. boulardii* with a big Herx reaction relieved by activated charcoal, I uncovered that he had a significant yeast overgrowth meriting a change to trials of pharmaceutical antifungals. I decided to change to a pharmaceutical to go after the yeasts that persisted in showing up in his MOAT test from Great Plains Lab, where indications of *Aspergillus* turned up with elevation of 5-hydroxymethyl-2-fuoic. Watching to be sure his aspartate aminotransferase (AST) and alanine aminotransferase (ALT) stayed level, I increased his dose of Sporanox to 600 mg per day: three times the adult dose. This increase was done in tortuous steps of Herx reactions and wonderful breakthroughs in which we saw a new boy emerging. After getting to 600 mg, my patient came to his mom and said, "Mommy, I am all better now." In his new school (where they didn't know he had been diagnosed with ASD), his language ability was tested to be at the 6-year-old level. As an experienced solo practitioner, I have the leeway to be guided by a decision process in which the stakes are very high, the risk is tolerable, and the odds seemed pretty good. As the work of Dr. McGinnis and this case illustrate, a leaky midbrain can let in toxins that tie up a patient's tongue and adjacent parts of the nervous system.

Saccharomyces boulardii, Herx, and Activated Charcoal

Why do I move forward in this description without having first addressed changes in diet, which we agree are a foundation to nearly all natural medical interventions? Because asking parents of a child in the autism spectrum to make serious dietary changes—if they have not already started a gluten-free diet—is like asking them to convert to a different religion. Whether it has to do with introducing solid foods to babies in the villages of Chad, Africa, well before they are weaned at, say, age 2 or requesting a cattle rancher to go vegan, asking people to change the dietary habits of a child with serious sensory issues is an obstacle to be avoided even at the cost of perfection. Of course, we will soon move toward dietary changes that might ideally be good to have done at the beginning. To ask for it up-front as a sort of precondition to engaging in "treatments" in the form of thumbs testing is a challenge that is, I think, unnecessarily overburdening to families.

Saccharomyces (sugar fungus) is the genus name of common yeasts such as *Saccharomyces cerevisiae* (baker's and brewer's yeast). *Saccharomyces boulardii* is a closely related yeast whose exact classification and distinction from *Saccharomyces cerevisiae* are debated but that clinically acts as if it kills off pathogenic yeast and supports the development of normal gut flora. Taking *S. boulardii* may cause three main initial results (intense initial aggravation of symptoms typically due to Herx, nothing happens all, or marked benefit) that can be expected with any antifungal, except that the intensity of the Herx may be more than with any other antifungal. Charcoal (see box) is the answer to such a Herx and usually quenches it to make it stop or become tolerable. Apart from Herx reactions, this microbial supplement has no toxicity. It resides in the gut, where it joins the other flora until shortly after discontinuation and then disappears. A stool culture may grow out a yeast identified by the laboratory as *S. cerevisiae* because the laboratory cannot distinguish between these two strains.

Activated Charcoal—A Panacea

Parents who have witnessed the dramatic effects of charcoal in quenching a die-off reaction taught me years ago that it is helpful in many situations that, however mysterious, have no apparent relationship to a die-off reaction. We all have seen kids plunge into the depths of a really bad day of volatile moods, dominant among which are irritability and depression but could include all dysfunctional manifestations. In these situations, charcoal is a kind of panacea. The harm in using it every day is that it interferes with the absorption of nutrients from food, supplements, or medicine. If it is taken on a stomach that has been empty for an hour or will stay empty for an hour (20 minutes in a pinch), one need not worry about negative effects from up to 15 doses per week.

The *S. boulardii* dosage can be increased safely to multiples of the original dose to explore the possibility of overcoming partial resistance of the targeted fungus. The option of switching to other "systemic" antifungals, such as terbinafine (Lamisil), ketoconazole (Nizoral), itraconazole (Sporanox), and fluconazole (Diflucan), is remarkably safe but cannot compete with the complete safety of *S. boulardii*.

As I have emphasized, this trial should not be undertaken without first achieving control of constipation, usually with magnesium citrate capsules (150 mg) or CALM powder or liquid, such as is found in 10-oz bottles, provided as a cathartic but can be portioned out to be taken "to bowel tolerance" just short of risking an embarrassing urgency of BMs. As that dose is approached, the idea is to back off until reliable daily BMs are achieved with a frequency of at least once, preferably twice or three times.

When yeasts are killed by *S. boulardii*, they burst open, releasing their toxins in larger measure than when they are alive. The resulting mischief (the Herx reaction) may consist of the very symptoms that are the target of the diagnostic trial. Herx reactions may result in new symptoms of any kind and are occasionally quite disconcerting, but not harmful, and can usually be managed by taking activated charcoal. It comes as a 500-mg fine black powder, preferably refined from coconut. Its capacity to absorb poisons of all kinds is astonishing, as is its effectiveness.

Activated charcoal absorbs not only the targeted toxins but just about anything else it encounters, including medications, supplements, and nutrients. It is intended only for temporary use—as, for example, to get through a few days of Herx. An interval of at least 30 minutes should separate it (before or after) from medications, supplements, and food so that it neither absorbs medication and supplements nor is absorbed by food. It will impart a greenish-black hue to the stool and may be constipating, necessitating a sometimes-substantial hike in the dose of magnesium to keep toxins from lagging in their trip to the toilet. Observation of the time taken from the first dose until its appearance in the toilet gives a rough idea of one's "transit time," which should be about 12 hours from eating a food until its waste products appear in the toilet.

Activated charcoal should be recommended only if Herx symptoms emerge. Even if such symptoms are mild—or perhaps especially so—charcoal's effect in reversing symptoms helps to document that what your patient is experiencing is, in fact, probably a Herx reaction. I say "probably" because charcoal works for just about everything. Individuals—especially the parents of children who have been through Herx with the benefit of charcoal's dramatic neutralization of negative symptoms—find that charcoal can alleviate a wide variety of symptoms, such as malaise, hyperactivity, fatigue, headache, allergic reactions, and so forth, when taken occasionally as needed. It is not, as stated previously, for routine use.

It was 1831. In front of his distinguished colleagues at the French Academy of Medicine, Professor Touery drank a lethal dose of strychnine and lived to tell the tale. He had combined the deadly poison with activated charcoal. http://www.emedicinehealth.com/activated_charcoal/article_em.htm

S. boulardii. Klaire Labs (Reno, Nevada) now provides *S. boulardii* in powder form to facilitate the high doses that I recommend as needed to be able to walk away from a diagnostic trial with a strong conviction that it was given a fair trial. It is gratifying to hear from a patient or parent who has been skeptical of giving a high dose and struggling through the Herx reactions and charcoal and reports a sudden change to a dramatic success. The doses can be given the morning and evening because we are simply feeding a colony of temporarily commensal organisms that really know how to kill their cousins—a bit like the model of steps taken in a crime family. Uncomfortable Herx symptoms can be managed with 500 to 2000 mg of charcoal up to 5 times in 24 hours. A small amount of frozen grape juice concentrate thawed to a liquid provides a dark-colored, intensely sweet vehicle that may get charcoal past the vigilant senses of a child.

For some patients, the trial of *S. boulardii* is sufficient to control a yeast problem without any risk beyond the Herx reactions, which stop when the critical dose is achieved. At the very least, the trial of *S. boulardii* is sufficient to prove the existence of a yeast problem that may then be confronted with more careful dietary methods or a trial of systemic antifungal drugs or natural medicines.

The space given to magnesium and antifungal medicines and helminthic therapy (discussed in the following section) represents the

priority claimed in the implication of Dr. Yehuda Shoenfeld's point to the effect that all chronic illness is autoimmune. Of all the treatments that make up the toolkit for helping children in the spectrum recover, the ones that worked for Morgan represent a very good place to start.

Once all these diagnostic steps are in place, I have the following tests done, along with others that may be called for based on responses to the steps:
Zinc (*International Classification of Diseases* [ICD-10] code E60)
Ferritin (ICD-10 code V78.0)
Carnitine, (ICD-10 code E71.40)
Vitamin D_3 (ICD-10 code E55.9)
Vitamin A (ICD-10 code E56.9)
Beta-carotene (ICD-10 code E50.9)
Serum AST and ALT (ICD-10 code R94.6)
Thyroid-stimulating hormone (TSH) 244.9 (ICD-10 E03.9)
Complete blood count (CBC) with differential (ICD-10 D64.9)
Cortisol morning and evening (ICD-10 code E27.40)
Testosterone (ICD-10 code E27.40)
Dehydroepiandrosterone (DHEA) (ICD-10 code E27.40)
Pregnenolone (ICD-10 code E27.40)
Amino acid profile (ICD-10 code E72.9)
Lipid profile (ICD-10 code Z13.220)

The next step will usually be a trial of helminthic therapy, for which 6 biweekly doses are sufficient to judge efficacy for the *Hymenolepis diminuta* cysticercoids (HDC). Human and pig whipworm, human hookworm, and *Trichuis suis* ova (TSO) are other options available in a currently existing informal market. HDCs are supplied internationally by Biomerestoraton.com with a preservative. I provide HDCs shipped overnight with freezer packs by FedEx to recipients in the United States in a consultative context with referring practitioners. Other than allergy desensitization methods, antifungals and helminths are two effective options for the restoration of immune tolerance. This is not to say that the restoration of immune tolerance is not a function of healing provoked by many applications of the healing arts. In my experience with patients with severe chronic illness in forms that are as explicit as alopecia or autoimmune thyroiditis, these two interventions stand above all other treatment options.

Helminthic Therapy

HDCs are an organism native to the gut—part of the families of microorganisms that are essential to human health. The use of what is generally called "helminthic therapies" is not widely known. The popular view of "worms" is guided by experience with pinworms as well as by false claims that many individuals with chronic illness suffer from resident helminths. The functional medical practitioner needs to understand, however, that an absence of helminths is a major driver in autoimmune disorders, and reintroducing helminths into the human body is an essential component of the successful treatment of ASD and other chronic diseases.

Background: 10,000 years ago, our 200th great-grandmother was inventing agriculture while primitive men were out hunting and gathering. A beetle and a rat were watching Grandma planting seeds that were to become grain. The beetle said, "These humans are so cool! They are doing this for us." Ever since, the grain supplies of our planet have been host to grain beetles and rats whose parts and poops we consume safely and unaware. The transient, lively presence of HDCs in our digestive tracts restores immune tolerance that is present in populations living the old-fashioned ways whose microbiome naturally includes helminths.

Grain Beetle

Other organisms have also coevolved with us to live peacefully in our digestive tracts, and we humans have paid a high price for losing them. As a Peace Corps Volunteer in Chad in the 1960s, I took care of large numbers of Africans who were mostly fit and healthy, although sometimes afflicted with trauma or fumigating infections. The Chadian patterns of health and disease looked very different from Europeans'. We never saw an African living the old-fashioned way who had *any* allergies, autoimmune diseases, gallstones, appendicitis, or any of the kinds of skin or cardiovascular diseases so common among Americans.

Forty years later, researchers have established that these contrasting patterns of health are related to the absence in the digestive tract of Americans and Europeans of various organisms that were common among people living in less hygienic conditions. It is now uncontested that the rise in the prevalence of allergic and autoimmune diseases in Europe and America is due to the absence in our digestive system of organisms that have been regarded as parasitical. Without beneficial worms (symbionts), an underutilized immune system will attack itself. The phrase "loss of immune tolerance" applies to those of us who, during recent generations, have collectively suffered the absence of various sorts of worms. As a result, we suffer a lack of tolerance (allergy) to mold, pollens, dust, foods, and our own tissues (autoimmunity).

Tolerance is the treasure of all complex systems: social, political, mechanical, and biological. Its partner is diversity. As the organisms inhabiting the human digestive tract have become less diverse, the tolerance of the immune system has decreased, which is another contributing factor in the rise of ASD, as well as other autoimmune and allergic problems in those of us who have enjoyed the benefits of toilets and clean water. By introducing any of several options (human hookworms, pig whipworm eggs [TSO], or HDCs), the immune system regains tolerance so that inflammation in different tissues in different people is healed.

Helminth therapy for ASD: My experience with TSO and HDCs over the past decade is rich in cases with patients with all sorts of autoimmune and allergic problems. Given the high stakes involved in chronic illness and reasonable odds of success with Primobiotic use and the absence of significant risk, a trial of six doses at 2-week intervals is an option worthy of consideration to treat ASD. HDCs are, at first, a test in which we seek a result indicated by thumbs up, down, or sideways before deciding about continuing.

Primobiotics are not the treatment for any specific symptom of ASD. They are, like other probiotics, an option for all individuals with chronic illness to weigh by considering the BROCS, which are described later in this chapter. In that consideration, we often tend to overlook the stakes when focusing on the odds. That omission may occur even when the cost is tolerable, the potential benefit is great, and the risk is close to zero, as it is with the use of HDCs. When the stakes are high, as they are with any chronic illness, the odds of success with any proposed treatment may be less decisive than the stakes.

Complications: About one in a hundred patients acquires a rat tapeworm, which presents no significant risk and is expelled after a

dose of Biltricide (praziquantel). We have found that patients who have an initial puzzling mixture of positive and negative responses often have yeast problems that have not been treated with sufficiently aggressive therapy, including restriction of sugar intake.

Patients respond well to visiting the question of an inadequately addressed yeast problem. Response to HDCs is more robust and less confusing when such measures are taken into consideration.

Contraindications: Immunosuppressive drugs, systemic steroids, anesthesia, antiparasitic medicines, and antimetabolites. Helminth therapy depends on the participation of an active immune system.

Probiotics: Patients must be told to look at the label of any probiotics and discontinue those that specify any organisms with the name *Lactobacillus* or that begin with the abbreviation "L." or "l.," as in *L. acidophilus*. Primobiotics will work in the presence of such probiotics, but they work better without them. *Lactobacilli* that are the agents of fermentation in yogurt and kefir and other fermented foods are not a problem when these foods are consumed. Other probiotics are okay. Options for *Lactobacillus*-free probiotics from Klaire Laboratory include Ther-Biotic Factor 4 and BioSpora.

It usually takes only a matter of weeks, during which a small number (between 5 and 30) of HDCs can restore tolerance in a person's immune system to produce a large benefit, with a risk that is close to zero. A placebo-controlled double-blind study, conducted by Joel Weinstock, MD, and his colleagues, showed that pig whipworm resulted in dramatic improvements in 44.8% of those receiving the therapy, compared with 17.4% for those who took the placebo. No patient suffered adverse effects.[27]

Chelation

When chelation first appeared as a treatment for autism among pioneering doctors in the autism community in 2000, my original reaction was profound skepticism. I soon learned that I had been wrong, not only from my own patients' results with it but also from the data collected by the ARI.[28] Of all the treatments that were monitored by the ARI's parent reporting project, EDTA and DMSA chelation was not only the one with the highest score for positive/negative results, but it also climbed the ratings within a couple of years from its inclusion in the reporting module in 2001.

At an annual meeting of the DAN! think tank, I asked the physician attendees to raise their hands if they had seen positive responses to EDTA and DMSA that occurred so soon after the beginning of their administration, creating a strong impression of efficacy based on a mechanism other than heavy metal removal. Note that the latter mechanism was not to take place as monitored by serial 6-hour urine testing over months of treatment.

James Adams reported that children receiving just one dose of DMSA had positive responses comparable to those who were treated with multiple doses.[29] There appears, in other words, to be two separate features of the heavy metal/chelation picture. First, there is good evidence[30] pointing to a goal of minimizing lead and mercury levels to as low a level as can be achieved. The Lanphear paper responded to findings in a study of lead toxicity in the Boston study showing that children's cognitive testing had no significant improvement when blood levels were reduced from above 45 to below 25 ug/dL. Lanphear's review showed that cognitive health improved only when lead levels were brought below 10 ug/dL and improved more so between 5 and 0 than between 10 and 5. These data put us in a position in which maximizing the removal of heavy metals is justified to the point of continuing chelation until no further lowering can be achieved with additional bouts of chelation on a biweekly schedule. Here we find a disconcerting gap between the data used to drive public policy and what we use for children under our care, in whom the Lanphear's data oblige us to treat for maximum effect as measured by urinary output from an EDTA/DMSA chelation.

EDTA and DMSA are chelating medicines that bind to heavy metals and other toxins and send them out in the urine. They can be swallowed, injected, or given by suppository. I prefer to use suppositories, which provide very good absorption and results.

Both medications can be used for testing and for treatment. EDTA and DMSA are each "strong" in ways that make for a good partnership. I find in my patients that a 500-mg suppository of EDTA will pull a substantial amount of mercury and lead into the urine, and then, if followed 6 to 7 hours later with a DMSA suppository, another—sometimes larger—amount of mercury and lead comes out in the next 6 to 7 hours. The partnership of the two aligns with the observation that EDTA, while cleaning, tends to throw up some "dust" consisting of mercury and lead that would best be captured before it can settle back down in the body.

Whether you go by the ARI data showing parental evaluations bringing chelation to the top of treatment ratings or by the exquisite study by Lanphear et al., measuring children's body burden of heavy metals with an EDTA and DMSA loading test and following through with biweekly—allowing the body burden to equilibrate—chelation is the gold standard. Various protocols are in use for heavy metal detoxification. However, when I ask families who have done such protocols, I find that they have no objective test results that document the start, course, and end of the treatment.

Now we come to the second feature of the heavy metal/chelation picture. There was a consensus, referred to previously, that EDTA and DMSA often produce benefits for patients with ASD with an immediate timing that is consistent with a mechanism other than the necessarily slow process of heavy metal removal. And James Adams's report of sustained clinical improvement after just one chelation further suggests that there is something odd going on in this clinical landscape. Be that as it may, we are obliged to take very seriously the fact that we are living in an environment that exposes children to a burden of toxins and that the children on the autism spectrum have measurable weaknesses in detoxification.

Elevated Body Burden of Lead, Mercury, and Other Neurotoxins

Chelating agents are used to test for the body burden of lead and mercury and other neurotoxic chemicals. That burden is inside cells. Neither a blood level nor urine level will provide an accurate view of the starting point for considering further chelation unless the burden is high. Careful studies of lead poisoning have demonstrated that the improvement in key measures of health and behavior does not begin to occur until the blood levels of lead in the blood are below what has until recently been considered safe: 10 ug/dL. When lead levels drop from 5 to 0, the improvement in cognitive function is markedly better than in the range from 10 to 5. In the context of this international pooled analysis, "better" meant something quite different from what the scientists and intuition would predict. Most of us would expect that as the burden of lead gets closer to zero, smaller increments of improvement would occur—sort of like the law of diminishing returns, which says, for example, that continuing to add fertilizer to your lawn reaches a point where each handful produces much less of an effect than previous handfuls. In the case of removing lead, one might expect the rate of improvement to diminish as zero is approached.

Lanphear's study has shown that as one gets closer to zero, the positive effect is the highest.[31] For the child with ASD with a high body burden of lead, it is worth the effort to pursue a target of as close to zero as can be achieved, as long as it is done safely. To do so means that

one has to assess the size of the problem and then track progress over time to see the rate of improvement and find the point at which further chelation produces no further improvement in not blood but urine concentrations after a challenge with DMSA.

Testing for heavy metal burden may include blood levels to start with but not without giving a test dose of DMSA to see how much lead, mercury, and so forth will appear in the urine over the next 6 hours.

DMSA Suppository Loading Test

The Doctor's Data Lab is used for toxic metal testing. The protocol recommended here is different from the standard challenge testing protocol.

On three consecutive nights, the patient is administered 500-mg DMSA suppositories. On the first night at bedtime, administer one suppository. Nothing more is required until the second night at bedtime. On the second night, right after the bladder is emptied, administer the second DMSA suppository and begin a 6-hour urine collection—that means all urine passed during and including any produced at the 6-hour mark. If sleep continues a little beyond 6 hours, that's okay, but the collection must not exceed 7 hours. Repeat the same procedure on the third night.

The reason for doing three nights' collection is that the peak excretion of heavy metals tends to occur after the second or third night's dose of DMSA. The reason for doing the collection at night is that nighttime is the phase of the circadian cycle when detoxification is most active. When the levels of excretion are initially high, the discrepancy between nights 2 and 3 may be quite wide. With ongoing treatment after the initial tests, the gap should diminish and obviate the need for the double collection. In the early phases, a single measurement—instead of having the average of two—may bring a less reliable picture of the trend. A trend is very helpful in predicting the overall duration.

For a child, the trauma of suppositories may be alleviated/prevented by instructing the parent to do the following:

a. Place a hand mirror on the floor and invite the child to squat over it so as to get a good view of the anus.
b. "This is the hole where your poops come out. We call it your "____"
c. Explain that sometimes the doctor finds it better to put medicine in there, especially when the medicine is smelly.
d. Offer a whiff of the suppository. "See how smelly this is? It would not be fun to swallow it, would it?"
e. "Putting the suppository into your anus feels funny—like pooping backward—but it does not hurt."

For the treatment phase, the same routine is followed for the three nights every 2 weeks.

RESTORATION

Morgan's story illustrates the two steps that I have witnessed since 1977 and 2007, respectively, to beckon the word *restoration* into our efforts to promote Nature's buoyant impulse toward healing. First was a diagnostic trial of *S. boulardii* and the sequence of antifungal pharmaceuticals in search of the best fit, and finally was helminthic therapy, which was the dramatic final step in supporting Nature's job. A third approach to promoting tolerance is embodied in various methods to achieve desensitization. It was in the medical family of clinical ecology—later to become environmental medicine—that I learned the side of my medical paradigm that has to do with avoiding allergens and toxins or ridding them from our environment, and that continues to be part of my toolkit, minus the methods for "neutralization" that I practiced for many years and admire in the hands of colleagues who can restore tolerance by those methods. The more I learned about finding out what my patients were sensitive to, the more I became curious about *why* they were sensitive. The what and why lists are short, and yeast and mutualistic organisms turn out to be the major factors in the loss of immune tolerance. The list cautions against the danger of being blinded by the obvious to the point of ignoring other causes of sensitivity.

What Sensitive To?	Why Sensitive?
Food	Unmet needs[a]
Inhalants (dust, dander, mold)	Bad digestion
Microorganisms	Bad flora, esp. yeast
Chemicals	Toxins (Al, Hg, Pb, and novel chemicals)
	Adrenal insufficiency
	Invasive life events

[a]Essential nutrients, accessory nutrients, light, love, rhythmic integration, mutualistic organisms.
From Baker, SM. *Detoxification and Healing.* New York: McGraw-Hill; 2003.

Diet

For ASD, a diet free of sugars and starches is absolutely critical. Whether it comes in the form of Dr. Natasha Campbell-McBride's gut and psychology syndrome diet (GAPS); the specific carbohydrate diet (SCD), which is based on the work of Sidney Hass, MD; the diet more recently presented in Dr. David Perlmutter's book *Grain Brain;* the paleo diet, popularized by Loren Cordain, PhD; or the super immunity diet presented by Joel Fuhrman MD, the common feature of diets that can help resolve many of the symptoms of autism, including self-injurious behavior (which I discuss in more detail in the following discussion), is the restriction of carbohydrates. Disagreements about what is the right diet for everyone have been debated publicly and have produced confusion in all of us for the past half century, but a consensus has finally emerged. Dr. Mark Hyman's 2018 book *FOOD: What the Heck Should I Eat?* provides a commonsense standard.

A healthy diet to treat ASD:

1. Must consist of real, whole, fresh organic foods
2. Must be free of refined sugars
3. Must be gluten-free
4. Must be low in casein and soy (casein and soy are better off avoided.)
5. Must consist of a diversity of foods

One of the greatest strengths in children with autism is an iron will, which makes it difficult for families affected by autism to implement new diets. Children on the autism spectrum also have problems with midbrain regulation of the muscles of chewing, swallowing, digesting, and pooping, making those functions more problematic for them than for neurotypical children.

Mainstream medicine posits that there are no "proven" treatments for autism. Granted, there are a few drugs that are "approved" for the symptoms of children with autism. For instance, risperidone and aripiprazole are both antipsychotics approved by the U.S. Food and Drug Administration (FDA) to treat irritability caused by ASD. The natural medical doctor's job is not to find the cure for "autism" but to find out what works for the individual patient. If we want to find out if a given dietary intervention, supplement, or other treatment works for one particular child, we can put it to the thumbs test.

Implement dietary changes for at least 6 weeks. Parents, teachers, grandparents, and practitioners who are unable to change a child's diet are passing up the most potent therapy we have, a therapy that is certainly better and often more effective than all the drugs. Understanding that should mobilize families to prove the point for themselves.

Eliminating sugar, restricting carbohydrates, and eating a diet of real foods are the first steps to resolving self-injurious behavior and other symptoms of autism that are often exacerbated by food additives,[32] pesticide and herbicide residues, and other contaminants. A diet free of gluten and casein should be implemented at the beginning of any effort to make a therapeutic plan for a child on the autism spectrum. No other step is more demanding of parental understanding of the following aspects of dietary changes:

A. Background of reasoning and science and the experience of countless physicians and parents
B. Potential for producing an immediate and very dramatic breakthrough
C. Need from support from an experienced diet counselor and/or parent

The Yeast Problem

In the children I have treated who have recovered from autism to become not just normal but usually gifted with various cognitive talents, a yeast problem has been an important factor in all such children, so naturally I feel that this consideration is high on the list of options for testing and treatment. Symptoms, such as those discussed Chapter 137, Let the Data Speak, are a good guide to patient selection, but no child should be deprived of a diagnostic trial of a dietary thumbs test. I describe it here as a matter of protocol, with the understanding that many new patients on the autism spectrum come to us on very restricted diets with little latitude for experimentation until measures beyond the basics (gluten-, casein-, and sugar-free) can be implemented. The following may fit situations in which the patient's diet is so yeasty as to perhaps be an obstacle to further thinking. Otherwise, the following information may be a resource to share with parents as a glimpse down the path that will begin with less resistance and more focus. Keep in mind that the population of patients on the spectrum share a profound sensitivity expressed in the domains of the nervous and immune systems. The word *senses,* as in touch, taste, vision, hearing, and olfaction, has the same function as does the immune system in terms of receiving, remembering, and responding to environmental stimuli. In other words, the immune system and this aspect of the central nervous system are a functional unit. As such, it is not surprising to find that children on the spectrum have allergic, autoimmune, and sensory issues that gather under the term *loss of tolerance.* Food is obviously one environmental stimulus that engages the senses and immune system in challenging ways. By that token, the avoidance of a bothersome food can, in some instances—such as gluten—bring about marvelous changes in a matter of days. But let's focus here on yeasts.

Yeasts and other molds are the only organisms to be found in the air we breathe, in food (e.g., on the surfaces of fruits and as used for leavening and fermenting), as well as being members of our microflora, where they are subject to overgrowth from the consumption of antibiotics and sugars. Even milk can have fairly large amounts of yeast in it. Our relationship with them crosses the boundaries among commensal, infectious, and allergic interactions. When the latter case is put under scrutiny, various tests can indicate sensitivity, and the most precise test in terms of establishing pathological sensitivity is strict avoidance followed by a challenge. Extreme sensitivity to molds and yeasts found in food requires strict yeast/mold avoidance for at least 5 days, followed by a challenge to implicate symptoms that have cleared and then been provoked.

Usually, a simplified yeast-/mold-free diet is sufficient to make this point. Many foods consumed nowadays are heavily yeasty or moldy, and avoidance of these is often enough to establish the relationship between sensitivity to yeast/mold and various symptoms, which may include craving bread, vinegar, and sugar. A simplified yeast- and mold-free diet focuses on avoiding the yeasty substances normally found in a healthy diet, including the following, which may be put in a handout for your patients.

Leavened foods: Breads, bagels, pastries, pretzels, crackers, pizza dough, and rolls are usually made with yeast as leavening. Biscuits, muffins, and soda bread, as well as waffles, pancakes, and some cookies made with baking soda or baking powder, are allowed. "Essene" bread is made with sprouted grain, and no yeasts or baking powder/soda is used. Baked goods made with baking soda or baking powder are permitted on a yeast-free diet.

For the yeast-sensitive person, sourdough bread offers no advantage, and even when sourdough bread is labeled "yeast-free," it should not be considered so from the standpoint of people avoiding yeasts and molds.

Dairy products: Cheese is a product fermented from a variety of molds and bacteria. Some of these are quite distantly related to the family of molds referred to as yeasts, and some yeast-sensitive people can eat even quite strong cheeses without difficulty. During the yeast avoidance that is designed to detect yeast sensitivity, all cheeses should be avoided. Milk products known as "processed" are usually prepared with a substance called rennet. Artificial types of rennet are derived from mold products and, therefore, are not safe for the person trying to avoid yeast. Other milk products such as cottage cheese and sour cream may be made by adding vinegars or lactic acid to milk and are, therefore, "yeasty." Yogurt is fermented milk, and the germ used to make yogurt is a *Lactobacillus* or *Acidophilus* species. These bacteria are healthy, normal inhabitants of the human intestinal tract and vagina and are not related to yeasts or molds that are pathogenic. Yogurt without fruit can be consumed by people who are yeast-sensitive even though the milk itself, as mentioned, may have some yeast in it.

Juices: The juices of all fruits and berries contain yeasts that came from their skin. Ciders, apple juices, commercial frozen or reconstituted orange juices, and the juices of berries have an impressive content of yeasts and can be extremely troublesome for yeast-sensitive people. During the trial avoidance of yeasts, then, juices must be avoided. For the treatment of ASD, juices should be avoided anyway because of their glycemic index.

Dried fruits, condiments, and sauces: Most sauces and condiments are made with some vinegar or other products of fermentation as well as sugars. This includes salad dressings, barbecue sauce, tomato sauce, soy sauce, miso, tamari sauce, mincemeat, horseradish, sauerkraut, pickles, and olives. Dried fruits themselves are, of course, very "yeasty" because the drying process generally reduces the whole fruit to a small size while the surface yeast has had a chance to proliferate during drying. Salad dressing can be made with oil, lemon juice (in place of vinegar), and some spices.

Mushrooms: Mushrooms, which are fungi, are the product of molds that live in a lacy network underground and periodically push up a mushroom as part of their reproductive processes. The mushroom itself is relatively unrelated to yeasts, and some yeast-sensitive people can eat mushrooms. During a trial avoidance of molds and yeasts, mushrooms should be avoided. The same applies to truffles.

Sugar and Carbohydrates: Some yeast-sensitive people have a lot of trouble with carbohydrates of any kind, and for most, the consumption of refined sugar is bothersome. Anyone going to the trouble of removing yeast is well advised to eliminate refined carbohydrates, such as sugars, white rice, and white flour.

The following yeast-free diet outline addresses only the yeast question, not gluten, casein, or other issues.

Dairy Products

Permitted: butter, margarine, mozzarella cheese, feta, milk (cow or goat), yogurt (plain)

Not permitted: yogurt with fruit, aged cheeses, processed cheeses (which are often made with an artificial rennet derived from fungi)

Cereals/Grains

Permitted: soda bread, cakes, waffles, pancakes, popovers, cookies, biscuits, barley, corn, oatmeal, grits, rice, pasta (check label), amaranth, buckwheat, quinoa

Not permitted: bread, sourdough bread (except that made with *Lactobacillus* culture), rolls, breakfast cereals, crackers (check label), nongrains

Meat, Poultry

All permitted (preferably organic to avoid antibiotics)

Vegetables

Permitted: all fresh vegetables, tofu (fresh), legumes (beans)

Not permitted: mushrooms, olives, capers, tempeh

Fruits

Permitted: pineapple, avocado, banana, any fruit you can peel, but no fruit juice

Not permitted: berries, melons (they are not yeasty but tend to cross-react for people with mold allergy), prunes, dates, figs, raisins, cherries, commercial juices (concentrate, premium, in cans, in bottles)

Nuts

Permitted: almonds, almond butter, cashew, cashew butter, walnut, brazil, macadamia, filbert, pistachio, pecan, chestnut, water chestnut

Not permitted: peanut, peanut butter

Oils

All oils are **permitted.**

Beverages

Permitted: herb teas, mineral water, soda water, artificial sweeteners (but they are not good for you)

Not permitted: fruit juice

Miscellaneous

Permitted: English mustard (made without vinegar), salad dressing made with oil and lemon juice

Not permitted: catsup, mayonnaise, French mustard (made with vinegar), salad dressing made with vinegar, **sweets,** Chinese food (admittedly a broad and tempting category, but in general, Chinese food is poorly tolerated by yeast-sensitive individuals)

Artificial Sweeteners Implicated in Brain Dysfunction

Richard Wurtman, MD, and John Fernstrom, PhD, neurologists at the Massachusetts Institute of Technology, have pointed to aspartame's potential interference with neurotransmitter function.[33] The vigilant practitioner occasionally finds patients whose symptoms are relieved by abstinence from aspartame. The first sip of a diet soda tells the brain, "here comes sugar," raising metabolic expectations and mobilizing vital processes. The brain tells the body to get the insulin because sugar is on its way. Insulin levels begin to rise, only to find that what has been imbibed is empty of the calories the insulin is there to manage. It is as if you made a date for dinner, told your friend to order for you, and then failed to show up. The insulin grabs whatever real sugar is available and pushes it into the cells. This causes blood sugar to drop, providing a truthful signal to the brain that the body needs sugar. This cycle is the real roller coaster behind the artificial sweetener story and the mechanism behind the diet soda habit that I see in so many patients. Artificial sweeteners are all "bad" in the sense that they compromise the metabolism, fooling the body's chemistry with a false promise that calories are about to arrive. For thousands of years, our species has used sweet taste as a perfect test for what is good to eat. Refined sugar is, strictly speaking, an artificial sweetener because in its pure form it was unknown in the human. But it is not, at least, duplicitous at the cellular level.

Dietary Tests

Start with all the additives. If a food has a label with anything but the name of the food on it, then do not give that food during the time when the diet test is taking place. Sensitivity is the issue. The test of avoidance to see if a person may experience a positive change that may take as little as 5 days, after which the avoidance may be followed with a confirmatory challenge. If the results are equivocal, repeat avoidance testing is required to make sure that a suspect food deserves avoidance, considering that we wish to avoid diets that verge on being too limiting. Rarely, the avoidance of a food may require as long as 3 weeks to be confirmatory. Such is the case with gluten. The research of Alissio Fasano, MD, shows that gluten opens the tight junctions in almost everyone. An elimination diet serving as a test should put gluten near the top of the list and be given more than the 5-day minimum for such tests.

Oxalates. Susan Owens was an early member of the DAN! movement. She has developed a website (http://www.lowoxalate.info) and a Facebook group (Trying_Low_Oxalates) with more than 15,000 members. Her work has benefited vast numbers of people who have been able to untangle the complexities of oxalates for their benefit in confronting a variety of vexing clinical problems. I encourage you and your patients to become informed and make use of her efforts in ways that, I must say, have not been fully grasped and appreciated by the DAN! movement.

Foods rich in oxalate, such as the spinach, kale, Swiss chard, and arugula found in the green smoothies that have been popularized as a way of "cleaning up" the diet, can be harmful in large quantities. The complexities of oxalate are increased by the role of oxalate-producing bacteria and yeasts that are part of our microbiome. Quirks in our own biochemistry add to the total production. This biochemistry is fueled by the consumption of foods with amino acids that convert to oxalate. In addition, dietary calcium and oxalate have interactions that result in a paradox. A high-oxalate food, spinach, reduces calcium absorption even though spinach is a good source of calcium. The oxalate binds calcium in the gut and prevents its absorption so that the calcium oxalate ends up in the toilet. Thus calcium (and magnesium) supplements lower oxalate absorption. In body fluids—destined to pass through the kidneys to become urine—calcium and oxalate combine to form kidney stones (if citrate levels in the urine are insufficient to solubilize the supersaturated calcium oxalate solution). One must consume the calcium with the meal to bind the oxalates in the gut and allow them to be excreted in the feces. Consuming the calcium between meals, however, can increase oxalate stone formation because binding will take place after absorption.

Oxalate crystals can accumulate in many tissues, including the brain. Oxalate accumulation figures in chronic fatigue syndrome, and oxalate crystals in the urine can be irritants that cause vulvar pain that can be misdiagnosed as infectious or hormonal. A family history of kidney stones, vulvar pain, fibromyalgia, and even stroke or cardiovascular disease may alert you to the need to look for oxalate issues in a child with ASD. A rich source of information on the subject of oxalates is available at Susan's website and Facebook address.

A change in diet is not the only way to evaluate. Arguably the most informative test to have done in a child on the autism spectrum—or for that matter, with any mysterious chronic illness—is a measure of

urinary organic acids. This test was first provided by Andy Braille, PhD, and Richard Lord, PhD, at Metametrix and is now available from Great Plains Laboratory and Genova Diagnostics. Testing for the key organic acids—produced not by the patient but by the fungal flora of the patient's microbiome—is a very useful clinical tool.

Urinary Organic Acids

William Shaw, PhD, at Great Plains Laboratory has continued to develop testing that reveals the presence of some of the key germs that produce compounds that are closely associated with toxic and immunological damage in children on the autism spectrum. The test not only allows documentation of yeast and other fungi, *Clostridia,* and other harmful microorganisms but also provides a way of tracking progress when it comes to treatment. The urinary organic acid test reveals other features of the metabolic "fire" and many aspects of our biochemistry, including energy production. The urine organic acid test is the most valuable among all that take a biochemical inventory leading to actionable options for safe intervention.

BROCS TEST FOR ANY PROPOSED MEDICAL TREATMENT FOR ASD

B stands for benefit, in which the doctor and patient share.
R stands for risk, in which the doctor's part is called liability.
O stands for odds, or the probability of the desired benefit.
C stands for cost, as in the expenditure of time and resources.
S stands for stakes, shared variably by the doctor and patient.

These considerations apply to choices confronting doctors and patients when trying to help a patient severely affected by ASD. When weighing the options for treatment, we may keep in mind that nearly all chronic illnesses have to do with the loss of immune tolerance. Once we accept that proposition, then the question of tailoring the treatment to a particular individual is simplified when we consider that the individual, not the disease, is the target of treatment. How do we know which people will be cured or benefited or will be nonresponders? We do not know. That's where the idea of a safe therapeutic trial comes in. Indeed, it's the only way to find out.

If you have explored the terrain of thumbs testing, methyl B_{12} injection, magnesium to bowel tolerance, yeasty dysbiosis, helminthic therapy, and heavy metal testing and chelation and seen the benefits of a sugar-, casein-, gluten-free organic diet, you will have reached an altitude where the view will offer various options as your thumbs embrace a view of responsiveness. If antifungal approaches have yielded Herx reactions and some improvement, I suggest an effort to engage with a high dose of Sporanox with monitoring of AST and ALT in case it returns a sudden miracle, such as I have seen. This is the time to weigh the BROCS.

The menu of choices will differ depending on whether you have a responder or not. The order of the following tests and treatments will depend on the view past your thumbs, which includes the following options:

1. **Induction of glutathione and its partners in dealing with oxidative stress.** At the 2016 Institute for Functional Medicine Meeting, Albena Dinkova-Kostova, PhD, from Dr. Paul Talay's team at Johns Hopkins, and Eleanor Rogan, PhD, revealed the path to raising glutathione levels by inducing them as well as estrogen quinone hydroxylase and other agents for the protection of DNA, RNA, and other vital players that need to hang on to their electrons. Broccoli sprout extract has since been through various steps to produce its ideal in the form of Avmacol.
2. **Induction of NRF2 and NRF1 with Protandim.** Because it is sold in a multilevel marketing mode, I am not sure how to handle this recommendation. You can email Erin at katepande@yahoo.com. I have done my homework on it, and so has David Perlmutter. Get microbial organic acids testing (MOAT) and MYCOTOX testing from Great Plains Laboratory. Whether you know already or not, these data will help you answer the key question in the antifungal sphere, "Have we done everything we can for this patient?"
3. **Antiviral therapy.** The immune system of autistic children tends to be both weakened and defensive. So-called thymus helper 1 (Th1) immunity is down, and thymus helper 2 (Th2) is up. The most helpful image to illustrate this situation is an unbalanced see-saw. The low end corresponds to mechanisms that deal with viruses, fungi, and cancer cells: all foes with which we humans have nothing but unfriendly encounters. The high end represents an enhanced activity of the immune system's branch offices that deal with more complex defensive decisions regarding food, bacteria, and other foreign agents (antigens), among which are friends, foes, and cases of mistaken identity giving rise to allergy and autoimmunity. The see-saw is an unbalanced Th1–Th2 relationship.

Th1 cells are the important cellular participants in defensive activities of the immune system. Th2 refers to immunity derived from antibodies, which are sticky proteins made specifically against everything internal and external that you encounter in life; these serve to label and handle foods, germs, toxins, and so forth.

Viral or fungal infections lower Th1 immunity. Low Th1 immunity leads to difficulty in resisting viral and fungal infections. Here is another vicious cycle in which it is hard to tell which came first: the infection or the lowered cellular immunity. We know that measles vaccine virus has been isolated from the biopsied gut lymphoid tissue of a number of the autistic children in whom it was tested. Did this virus cause the lowered Th1, or did the virus take hold because Th1 immunity was already lowered—perhaps from the effects of antibiotics or overvaccination or both?

When we find evidence of viral infection—including the isolation of measles vaccine virus from gut lymph nodes as well as spinal fluid—then the cause-versus-effect dilemma becomes secondary to therapeutic considerations, which are especially confusing in kids who may have severe symptoms of autism but seem to get sick less frequently than their neurotypical siblings and neighbors. Those kids may not be getting sick because their immune systems are activated by already being sick.

Jaquelyn McCandless, MD, has shown that low-dose naltrexone raises Th1 and is an antiviral, not because it kills viruses but because it rebalances immune function by other means. Dr. McCandless presented evidence that low-dose naltrexone (LDN) can help children with autism, but not without some caveats. I refer practitioners to the latest edition of Dr. McCandless's *Children With Starving Brains: A Medical Treatment Guide for Autism Spectrum Disorder,* published just before her untimely death in 2014.

Ridding children of the persisting presence of harmful viruses can be a helpful treatment, but we do not know if the apparent effectiveness of "antiviral" treatments stems from their antiviral properties or results from a different mechanism. The benefits of LDN have been demonstrated in AIDS, so the hope regarding the immunological benefits of LDN is well founded. The benefits of other antiviral treatments, such as acyclovir (Zovirax) and related medicines (e.g., Valtrex), may stem from the fact they combat viruses belonging to the large family of herpes viruses. These drugs also lower levels of adenosine in the body (see the diagram to find adenosine at the tip of the curved arrow between SAH and homocysteine).

The diagram shows the effect of the antiviral Acyclovir on adenosine levels. It is what Dr. McCandless cited in her book tying the antiviral drug effects to the same with LDN. Its levels are, in turn, also affected by the interplay between dietary gluten and the enzyme DPP-IV that digests gluten and also functions as a regulatory protein (CD26) in the immune system.

OTHER CONSIDERATIONS IN TREATING ASD

Taurine

Notice that taurine is at the end of the line in the previous diagram. With that in mind, here is Edward's story. This 8-year-old patient with ASD had light-colored stools. Edward came to see me with his mother and grandmother. I explained to the family how bile cuts dietary fat in the body much the same way that soap cuts grease when we wash dishes. Formed in the liver during the night, bile descends to the gallbladder to await the need for digesting (breaking up, cutting, dissolving) dietary fat in the morning. Instead of lard, which is used with a mineral in soap, the liver uses cholesterol to make bile. Instead of a caustic mineral such as potash (potassium carbonate), taurine steps forward, pretending successfully to be a mineral, and joins with cholesterol to make the bile that helps digests fat. If taurine is in short supply, cholesterol has no partner and is left in the gallbladder to form gallstones, which are not rocks but pebbles of hard cholesterol.

After I explained all this, we decided to start Edward on a trial of taurine at a dose of 1000 mg in the evening to see if it would darken his stools and help his itchy skin and digestive issues. Mind you, taurine has other very important roles in biochemistry, not the least of which is the quenching of the ring of hypochlorite (bleach). Macrophages use taurine to protect themselves from the bleach they use to kill ingested microorganisms. If Edward's stools would darken (not a long shot), it would reveal that his previous shortage of taurine had been giving him trouble with bile.

Two months later, Edward's family returned. Edward's grandmother announced that she took taurine and her gallbladder pain stopped immediately. An angry skin condition she had suffered from for decades cleared up. For years she had visited dermatologists who had confidently diagnosed eczema without being able to make the link to a special sensitivity to chlorine that resolved with her use of taurine. Meanwhile, Edward's stools had darkened as the taurine supplement satisfied his needs in bile formation, cleared his itchy skin, and presumably in the several other, more silent ways that taurine plays its role of pretending to be a mineral in his body's chemistry.

I have seen taurine supplementation result in lasting health benefits like these in my practice more times than I can count. Do you ask each patient the color of his or her stool?

Gene Variants DQB1 and DRB1

I was asked to testify in a divorce case in a state with a law that mandates immunization to the hilt. The judge was, moreover, noted for her anti-anti-vax position. The affluent husband insisted on catch-up immunization for his two boys, one of whom was on the spectrum and seemed to have gotten there after immunization during infancy. The boys tested positive for DQB1 and DRB1 alleles. Individuals with DQB1 and DRB1 mutations are at significant risk of having a serious negative reaction to vaccines with aluminum as an adjuvant. The test can be ordered from the laboratory with a request for "Please do: HLA-DR/DQ Low Resolution Typing, CPT Code 81375, Includes DRB1, DQB1." A small percentage of individuals with different variants (alleles) of the DQB1 and DRB1 families of genes react to the aluminum that is used in the vaccines. The reaction may take the form of many different autoimmune conditions and can produce lifelong disability and continued risk with further exposure to aluminum, such as is found in baking powders and buffered aspirin. The risk may be as low as 1 in 100. If you were invited to take a flight on an airplane with a 1 in 100 risk of crashing, would you do so? Would you consider taking such a flight once, 10 times, 50 times? You get the point. No one knowing the odds and with one of the DQB1 or DRB1 markers would allow vaccination with an aluminum-containing vaccine. At least 75 scientific peer-reviewed articles support this recent research. The public health and commercial entities with an interest in this research have not made a public response, which is, indeed, one that will be difficult to manage in terms of the overall risk/benefit with regard to mass immunization. The literature on this is covered in Dr. Shoenfeld's book.[34]

The judge returned from a brief recess, and the case was decided in the mother's (and children's) favor. If the question of vaccines comes up, I'd say the BROCS strongly indicate having these variants tested. Although the public has become increasingly aware of methylenetetrahydrofolate reductase (MTHFR) variants, when it comes to genetic testing, DQB1 and DRB1 testing may be more important.

Electroconvulsive Therapy

Let's go to a darker part of this landscape, where we find nonresponders. I had a patient who seemed to respond to just about everything for a few days and then went back to breaking everything in his house, including his parents' hearts. Brett grew to well over 6 feet tall and weighed 500 pounds. He had lost 300 pounds in the past couple of years, but that's about the only good thing that has happened for him in the 26 years I have known him. He can, at times, be cheerful, but the injuries he has self-inflicted and delivered to his caretakers have been repetitive tragedies. I met Dr. Lee E. Wachtel, medical director of the Behavioral Unit at the Johns Hopkins School of Medicine in Baltimore, MD, and learned about electroconvulsive therapy (ECT) for a similar patient. With the right technique, Dr. Wachtel explained, ECT could be transformative.

Dr. Wachtel published the first report of the use of ECT in an 8-year-old child. "Self-injury included slapping and punching his head as well as banging his head on his knees and shoulders, with daily rates averaging 109.3 attempts hourly based on 24-h data collection."[39]

During the 5 years since the onset of his self-injury, 17 psychotropic drugs had failed to provide relief, and 2 of them (sertraline and fluoxetine) made him worse. Only clomipramine and fluphenazine led to small reductions in self-injury. The following interventions failed: "behavioral assessments and interventions including, but not limited to multiple functional analyses, antecedent analyses, preference assessments, reinforcement-based interventions (i.e., functional communication training, differential reinforcement procedures, noncontingent reinforcement), response reduction procedures (i.e., brief physical holds, contingent application of helmet), and bilateral arm restraints and protective equipment (i.e., padding)." The ECT resulted in a profound reduction in the rates of self-injurious behavior.[35]

Brett lived a thousand miles away, but miraculously, a kindly psychiatrist who was simply making rounds when Brett was hospitalized for a leg he broke on a trampoline peeked into his room as a courtesy. He knew about Dr. Wachtel's protocol and managed to carry it out, and Brett had a year of respite. Then the kindly doctor moved far away, and the nuances of how to tailor the ECT to Brett went with him. The only other treatment that worked for Brett to calm his violent episodes and uncontrollable rages has been cannabis. Now that cannabis has become legal in his state, it is doing a pretty good job. Cannabis may prove of medicinal benefit for many patients with ASD in the coming years.

If your patient's life is controlled by self-injurious behavior, ECT may be a reasonable intervention. A consultation with a neurologist is helpful.

Fasting

Dr. Wachtel's reports of the use of ECT compared with the results of psychotropic drugs, as mentioned previously, certainly make the drugs seem of limited effect in extreme cases. Given that ECT itself is an extreme measure, I wonder whether extreme dietary interventions might first deserve more serious consideration. The model of extremity in dietary matters is fasting. Many children have been reported to calm down and or be relieved of various severe symptoms during abstinence from food. Preparation for radiological examinations and surgery and loss of appetite during acute illness are widely recognized as having transient beneficial effects. Although many of the children I have treated have followed restricted diets (e.g., sugar, gluten, casein, yeast), none has done so in ways that would seem therapeutic in the broader sense. Many with gastrointestinal problems have been found to tolerate only a few foods (e.g., chicken, rice, squash) while continuing to suffer from symptoms that are barely controlled by diet. Fasting, on the other hand, requires complete abstinence from food. It is a practice with a long history in human experience and a recent upsurge of interest in its medical benefits. I believe that the resistance to the notion of fasting in children may be overcome by the comparative danger of some of the symptoms many children endure without relief when using other interventions. Just as Dr. Wachtel was the first to try the extreme measure of ECT for an 8-year-old, another researcher or practitioner will try fasting a child with uncontrolled, continuous self-injurious behavior.

Supervised fasting has been a foundational protocol in the natural hygiene and naturopathic medicine traditions. Trevor Salloum, ND, first wrote the first modern, scientific chapter on fasting almost three decades ago for this book. This chapter has since been extensively updated by Alan Goldhammer, DC (see Chapter 37, Fasting, and supporting Appendix).

Several sources are of value to any practitioner who wishes to learn about fasting. The classic reference was written by early naturopath Herbert Shelton, ND: *Fasting Can Save Your Life.* Trevor Salloum, ND, wrote *Fasting: Signs and Symptoms: A Clinical Guide* for consumers. *Fasting: The Ultimate Diet* by Alan Cott, MD, is a fascinating little book by one of the pioneers of orthomolecular psychiatry. In no other concept or practice did I feel as misinformed as I was for decades on the subject of fasting. I made a sudden turnaround when biochemist T. Colin Campbell, PhD, told me the personal story of his cure by fasting from a condition for which he had consulted a top neurologist. The neurologist told him he would be dead in 6 months from his progressive disease. He consulted another top neurologist, who offered the opinion that he would commit suicide in 6 months. It goes to show the value that can sometimes come from a second opinion! As it turned out, Dr. Campbell undertook a medically supervised fast, and his health was completely restored.

Unmet Needs for Calcium Connected to Self-Injurious Behaviors

Mary Coleman, MD, a lone pioneer in autism research at the academic level in the 1970s, visited my office in the 1990s and told me about an association between eye-poking and unmet needs for calcium. She had a patient who poked incessantly at his eyes. His mom had consulted Dr. Coleman about the eye-poking, and Dr. Coleman asked her to collect a 24-hour urine specimen that was needed to document what Dr. Coleman thought would be a problem of unmet needs for calcium—leading to eye-poking in some autistic children. Twenty-four-hour urine collections in any child are a challenge, and especially so in children who are not toilet trained and have many uncontrolled, hyperactive behaviors.

The boy's mother was unable to collect the urine, and the boy poked out his own eye. Returning to consult Dr. Coleman after this tragic event, the mom found a way to collect the urine, which revealed the suspected low calcium level. The boy was started on a calcium supplement and stopped poking his other eye, saving his vision.

I was haunted by this story and spoke of it again in 2014 with Dr. Coleman. She pointed out the value of the urine test for calibrating calcium intake to the patient's need. I asked whether the level at which eye-poking stopped could be found by simply trying an escalating dosage regimen without urine collection. She said yes. I asked her what she believed was the root cause of eye-poking. One boy in Dr. Coleman's practice who was able to explain, once he became verbal, said that his eye-poking had been a response to an intense itching behind the eye.

Many children seem to prefer pain to itching, and I have seen patients with ASD injure their skin by scratching it raw. Sometimes a self-inflicted pain, such as wrist biting, may change the intensity of another pain in the body. The father of one of my wrist-biting patients told me of his own need to press hard on his eyes to blunt the pain of severe migraine. We must keep in mind that various self-injurious behaviors may be pain substitutions.

These examples illustrate that self-injurious behavior is likely *done for a reason*. Once the practitioner understands that self-injurious behaviors may be motivated by sensory challenges such as incessant itching or extreme pain, our own motivation to get to the bottom of the behavior is magnified. When confronted with any mysterious repetitive behavior, consider that remedies such as calcium supplementation may, in some individuals, also have benefits beyond the specific indications that I have described. To find out if such a treatment works, try it on the individual patient and let the results speak for themselves. Take into consideration the risk, probabilities, potential benefits, and the stakes. When the stakes are high, as in self-injurious behavior, a decision to give a safe treatment—such as calcium supplementation in the form of calcium citrate—can be reasonable even if the probability of success seems low. The dose would range from 1 to 6 g daily over a few weeks, depending on body weight.

Lithium

Head pain (e.g., cluster headaches) has been shown to be responsive to a form of lithium.[36,40,41] Lithium has many medicinal uses in low doses (5–100 mg of lithium orotate), as well as in high doses (900–1200 mg of lithium carbonate). Low-dose lithium is found in some well water because the wells draw from natural water tables, which can contain a generous concentration of lithium salts. Several comparative studies reveal a lower prevalence of anxiety and hyperactivity in consumers of such water compared with people living in low-lithium areas.[37] Low-dose lithium may also help with anxiety in the child with ASD. In a nonverbal individual practicing self-injurious behavior that may be indicative of underlying severe pain, a trial of lithium is simply common sense.

Testosterone

A mild form of congenital adrenal hyperplasia may be spotted by aggressive or hyperactive behavior accompanied by elevated testosterone levels. This is best handled not by suppressing testosterone levels but by recognizing the underlying adrenal problem of underproduction of cortisol so that the pituitary's stimulation evokes production of what the adrenals are able to produce: androgens. Subreplacement doses of hydrocortisone are the logical answer to a problem that must be considered when seeing aggressive behavior in patients with ASD.

Zinc

White spots on the fingernails and stretch marks in various parts of the skin are indications not seen in younger children with unmet needs for zinc. A serum zinc level is, therefore, an important part of blood screening. The consensus in a meeting of trace element researchers that I attended years ago was that the cutoff in displaying laboratory zinc test results should be ignored in favor of accepting a level of at least above 80 ug/dL.

Cholesterol

See the Great Plains Laboratory's website for an excellent body of information on the question of low cholesterol levels and their treatment with Sonic Cholesterol. While you are there, order William Shaw's excellent autism book's most recent edition. Only because of the availability of that guide do I have the leeway to focus here on subjects with which I am particularly familiar without having to pretend omniscience.

Thiamine Tetrahydrofurfuryl Disulfide

Thiamine tetrahydrofurfuryl disulfide (TTFD) was first identified by Derrick Lonsdale, MD, a professor and head of a department at the Cleveland Clinic. He retired in 1982 to open a private office to focus on the care of individual children, as contrasted with the study of diseases. Dr. Lonsdale brought his deep understanding of biochemistry to the ARI's meetings and introduced us to the potential of TTFD, a "fatty" form of vitamin B_1 (thiamine), to be of benefit to some children on the autism spectrum. My experience with it has shown that its potential in different children has a wide range. The effects of its use are dazzling in some children, although no prior testing will pick the winners. Here is the protocol I have used with remarkable success in many children. A 21-day trial is a reasonable thumbs test.

A. **Apply TTFD cream, 0.5 mL (½ mL), on a patch of skin at bedtime.** Instruct your patient to choose a location (e.g., the lower legs and feet) that is easily washed the next morning, to remove the skunky/garlicky odor that may form there. **Reapply it in the morning** if there will be no social problems arising from having a kid smell like a skunk. Otherwise, wait until later in the day when out of the public nose and then **apply the second daily dose**, repeating it at bedtime. Afternoon and evening doses can be separated by only a couple of hours.

B. **After 3 days, apply ½ mL topical reduced glutathione twice daily to another part of the skin.** Reduced glutathione (often abbreviated GSH) is the body's main detoxifying "usher" that combines with various toxic molecules that need to be taken from the body. Note whether the odor increases consequent to the reduced glutathione. In some instances, the odor will be barely perceptible until the addition of the reduced glutathione. The enhancement of the odor on the skin after the application of GSH provides persuasive evidence that the GSH gets on board through the skin and forms a detoxifying partnership with TTFD.

C. **After 3 days of that combination, add 0.5 mL twice daily of topical alpha-lipoic acid,** which is another sulfur-containing molecule and is a partner of vitamin B_1 in key steps in chemistry in addition to having a role in detoxification that is exemplified by its use in treating, for example, mushroom poisoning. The enhancement of odor with alpha-lipoic acid provides evidence for its partnership in the process we are trying to achieve.

D. **Keep up all three creams/gels for at least 1 month and observe any improvement in symptoms.** If a rash develops at the site of the application, add the following two supplements: molybdenum 300 mcg daily, biotin 1 mg daily. If the rash does not resolve, discontinue. It may be preferable to start the molybdenum and biotin when starting the TTFD. This idea is based on the experience of a child who went off TTFD and GSH for a bad rash, waited for the rash to go away, started the molybdenum and biotin, and got a report from school of marked cognitive and behavioral improvement before she had restarted the TTFD and GSH—which, this time, were not associated with any rash. If hyperactivity occurs, try activated charcoal, approximately 500 mg four times daily, to quench it. If the hyperactivity persists, stop the treatment.

Postscript about TTFD and GSH creams: We do not know yet whether the role of TTFD in helping kids with autism resolve their symptoms has to do with heavy metal detoxification directly, for which there is some evidence (mercury in the urine), or with energy metabolism, where it plays a very crucial role. Considering that detoxification is the most energy-demanding part of chemistry (other than growth in children), it may not make that much difference, or it may be some of each. We do not know the exact nature (beyond membership in the family of sulfur-bearing molecules called mercaptans) of the compounds that appear on the skin, and it is speculative to consider that mercury is brought out by that route. The smell on the fingers of a person applying TTFD and GSH represents the same phenomenon.

Both TTFD and GSH have important roles in the body's synthetic chemistry (construction), so the benefits associated with their intended use in detoxification (sanitation) may be attributable to the multiple jobs TTFD, lipoic acid, and GSH have in energy metabolism and the making of new molecules.

OTHER LABORATORY TESTING

Complete Blood Count and Comprehensive Metabolic Panel

The CBC and comprehensive metabolic (CMP) tests are the bedrock of traditional medicine and are necessary to rule out the failure of basic body functions and organs—bone marrow, liver, kidneys—but they are generally of little value until pathology has substantially progressed. Platelet count stands out in many autistic children as a key indicator of inflammation and, as such, is useful for tracking progress. The red blood cell indices, measuring their average size and volume as MCH, MCHC, and MCV, are of interest because large red blood cells (high MCV) occur with a deficiency of vitamin B_{12} and/or folic acid. Children who are very responsive overall to high doses of B_{12} and folic acid may not reflect that special need with the elevated levels of MCV (i.e., large red blood cells) that go with deficiency of these two vitamins. Thus the CBC's indices are of often of little value for tracking the benefits of B_{12} and folate supplementation. A low MCV—typical of iron deficiency (and certain inherited abnormalities of red blood cell size)—is, however, a solid indicator that will increase with correction by iron supplementation.

Thyroid

Hypothyroidism can mimic some symptoms of autism and impair development. TSH can check for this problem. The problem with thyroid testing is the so-called "reference range." It is a "normal" but not necessarily healthy range and may certainly not reflect the optimal level

for a given individual. Endocrinologist disagree, but experts will say that a TSH of close to 1 is normal. That means that a level of above 1, which will include most tests done on children, leaves some doubt about the question at hand, namely whether the patient would benefit from a supplement of either iodine or thyroid hormone. In an adult, such a question is quite easily resolved by a thumbs test—a trial of escalating thyroid supplementation over a period of 3 to 6 weeks. An adult can reliably report changes in body warmth and energy. It is a tricky problem in children, and given that thyroid problems are reaching epidemic levels and have a serious but often subtle implication for child development, it must be confronted thoughtfully by practitioners.

Iron

Low iron can cause attention deficient problems and has also linked to lowered IQ. Many physicians believe that a low red blood cell count, hemoglobin level, or hematocrit (anemia) is a reliable indicator of iron deficiency, and they do not measure serum ferritin, which is the only good indicator of iron status. Serum iron levels are not reliable because iron is withdrawn from circulation under conditions of stress (infection), so a low serum iron becomes a false indicator of deficiency. Iron supplements may be constipating and may be resisted by parents coping with a child who already has such problems. Iron supplementation must be recommended with magnesium, if at all.

Ammonia and Lactic Acid

The accuracy of blood ammonia level testing depends on the blood being drawn in the laboratory where the test is performed to avoid any delay.

This testing may determine whether mitochondrial dysfunction, associated with low energy production and hypotonia, exists. Mitochondrial dysfunction may be treatable with coenzyme Q_{10} and L-carnitine supplementation.

Cholesterol

There is a subset of children with ASD who have low cholesterol levels and benefit from supplementation. A cholesterol count of less than 145 mg/dL has been shown to be detrimental, increasing defiance and irritability in neurotypical children. Cholesterol is needed to synthesize steroid hormones (estrogen, testosterone, cortisol) and to make bile. Conventional medical doctors continue to perpetuate the idea that cholesterol is detrimental, but in patients with ASD, low cholesterol can be problematic. Supplementation with cholesterol may be in order.

Urinary and Stool Measures

Urinary porphyrin concentrations can reflect increased heavy metal or pesticide levels in the kidney and are markers of the metal burden in the body.

Urinary neopterin is a marker of inflammation and tends to reflect autoimmunity in some children with autism. Elevated neopterin often predicts positive responses to anti-inflammatory treatments.

Urinary oxidized DNA and RNA are markers of oxidative stress inside the cell,[26] and children with elevated levels often have improvements with antioxidants.

Urinary isoprostane is a marker of oxidative stress outside the cell.[26] Again, antioxidants can be helpful when this is elevated.

Urinary pyrroles. A condition called pyroluria may also underlie some cases of autism. Pyroluria, or pyrrole disorder, was described by Carl Pfeiffer, MD, in his 1976 book *Mental and Elemental Nutrients.* William Walsh, PhD, a biochemist who has continued Pfeiffer's work, explains that this quirk in biochemistry, also known as the mauve factor, is a common feature of behavioral and emotional disorders. It is detectable as a purple metabolite in the urine on testing paper. Children with pyroluria are severely deficient in zinc, vitamin B_6, and arachidonic acid (an omega-6 fatty acid). Walsh explains further: "certain pyrroles called kryptopyrroles (literally, 'hidden pyrroles') bind with B_6, then zinc to deplete the body's supply. Common symptoms include explosive temper, mood swings, poor short-term memory, and frequent infections. These patients are easily identified by their inability to tan, poor dream recall, abnormal fat distribution, and sensitivity to light and sound. The decisive laboratory test is analysis for kryptopyrroles (the 'mauve factor') in urine."[38]

The treatment for pyroluria includes zinc and B_6 supplements (P5P if unresponsive), along with omega-6 essential fatty acids.

Stool testing can check for the presence of inflammation, dysbiosis (increased levels of yeast and abnormal bacteria), digestion, and absorption.

Omega-6 and Omega-3 Fatty Acids

The omega-6 and omega-3 families of molecules are distinctive in human chemistry. The human body can make dozens of them, with two noteworthy exceptions. One exception is a member of the so-called omega-6 family, and the other is the source of all the members of the omega-3 family. These fatty acids are needed for making not only the flexible membrane that encloses each of the 10 billion cells in the body but also the messenger molecules that these cells use to communicate with one another. Linolenic acid (LA) and alpha-linolenic acid (ALA) must come from dietary sources. They are essential in two ways. We cannot make them, and we cannot live without them. Getting LA from the diet is not usually a problem; it is well distributed in food. ALA is more difficult. It is found only in flax oil (edible linseed oil 40% ALA), walnut oil (10%), and soy that is grown in northern climates (10%).

When I was a child, there was no such thing as vegetable oil. We had Crisco, olive oil, and butter. Not until the 1940s were large steel presses invented for extracting vegetable oils from various seeds, such as corn. This provided consumers with cheap, easily distributed cooking fats. The traces of ALA found in such oils were removed from the vegetable oils that became widely available in grocery stores because ALA quickly becomes rancid, which limits its shelf life. The result is that our food supply is short on the very one element that we must get from our diet.

Signs of unmet needs for essential fatty acids (EFAs) include dull and dry skin, dandruff, unmanageable hair, and brittle or fraying nails. The abundance of television ads to rectify these problems testify to an epidemic of EFA deficits in those living in modern industrial cultures. Blood testing readily documents such deficits. The appearance of the skin, hair, and nails is sufficient to drive a decision to supplement with omega-3 oils such as flax, fish, or krill oil.

When a child with ASD shows the previously noted symptoms, I recommend daily omega-3 supplementation given in the morning, which is the best time for the body to absorb and metabolize it. The dosage is 1 teaspoon per year of life per day. So a 2-year-old would be given 2 teaspoons in the morning.

Delta-6 desaturase deficiency: The nutritional/biochemical problem that causes unmet needs for omega-6 fatty acids is common. The essential dietary source of the oils in the omega-6 family are "regular" vegetable oils. The first step in the synthesis of downstream members of the family is the insertion of a double bond into the sixth C-C bond from the delta end of the 16-carbon structure of the essential fatty acid molecule. Delta-6-desaturase deficiency worsens with age; alcohol consumption; sugar consumption; saturated fat consumption; and deficiencies of Mg, Zn, B_3. It is common in patients with eczema, multiple sclerosis, hypertension, premenstrual syndrome, hyperactivity, and autoimmune problems. It can be treated by giving primrose, borage, or black currant seed oils, which are sources of fatty acids that help the body better synthesize omega-6s. These should not be routinely prescribed but may be tried in cases where a deficiency in delta-6 desaturase is suspected.

METHYLATION

It is important for the functional practitioner to understand how methylation, methyl-B_{12}, and most of the other nutrients work in the autism spectrum. The same nutrients, interestingly, are relevant to all chronic illnesses as well as to aging. Why? Because medical treatments aimed at individuals—rather than disease—are based on fundamentals of biochemistry that are shared by all of us.

SAM: Recall that taurine, which is like an amino acid but plays roles on stage for minerals, is at the last stop in the previous diagram. Look at the upper right-hand corner of the diagram. There he is—glad that you recognize him as he gets off the bus. See how he has been transformed on a trip that started all the way on the left-hand side of the diagram as methionine?

Now follow the arrows that start with methionine and notice that adenosine triphosphate (ATP) gets into the game with methionine and becomes s-adenosyl methionine (SAM). SAM, under the trademark "SAMe," is used as a treatment for osteoarthritis, depression, ADHD, and a buildup of bile in the gall bladder, as is taurine. SAMe may be effective in doses ranging from 400 to 1200 mg daily in divided doses. It has been used for patients with Alzheimer's disease, pain, migraine, and bursitis, so it provides a good example of a remedy that may be useful for certain individuals and does not have the same effect in certain diseases.

Follow the arrow that goes upward as SAM goes to work as the distributor of CH_3 in the long list of methylations that hovers over the first part of our bus route. Creatine, the stuff you can find in big jars in the health food store where muscle-builders go for "energy," is indeed a molecule that is a crucial player in energy transfer in the body and certainly works to give some people more energy (see Chapter 139, Sports Nutrition, for a more complete discussion). The restlessness that may be a side effect from taking SAMe may be minimized by starting with a low dose and increasing slowly. SAM's role in methylation (adding CH_3) in the chemistry of neurotransmitters, proteins, RNA, and DNA strongly makes it a reasonable supplement to use in treating autism, especially considering that it is safe and has a much lower chance of producing negative effects than pharmaceutical medications. Unfortunately, my experience with it is that, although worth a try, it does not often fulfill the hopes we attach to it based on its place in biochemistry.

SAH: S-adenosyl homocysteine (SAH) is what is left after the CH_3 leaves. Then adenosine gets off the bus. Adenosine is, as mentioned previously, mischievous when it accumulates. High levels promote inflammation, and that effect may be seen as what happens when the high adenosine level creates a stoppage on SAM. Recall that adenosine levels are decreased by the antiviral medication acyclovir.

Homocysteine: As we arrive at homocysteine, we have already found relevance in the diagram to treatment with SAMe, creatine, antiviral medications, and a gluten-free diet. Now we arrive at a crisis point in the bus trip. Methionine has lost a CH_3, and adenosine has come and gone, leaving a very hot, sticky molecule called homocysteine. I say sticky because its sulfur atom is very exposed. Sulfur is both stinky and sticky. The odor of sulfur that appears when you strike a match is distinctive in that it sticks to the fecal odors that you may wish to cancel before leaving the toilet. Homocysteine is hot in the sense that it is like an ingot in the blacksmith's tongs. It is ready to be fashioned into something useful, but it cannot be simply put down and kept around without the risk of damage. The crisis involves the choice of what to do with homocysteine: quench it, returning it to its original state as methionine, or send it further along the bus route.

Quenching is not a simple as the blacksmith cooling an ingot with water. Homocysteine must get a methyl group put back on. That process is depicted in the diagram where the dashed line with a CH_3 in it catches up with the U-turn that homocysteine has made. The CH_3 gets on board right at the point of the arrow showing mercury poisoning the process.

Mercury is only one of many toxins that can impair the crucial step of remethylation of homocysteine (quenching the valuable but dangerous ingot). This step and its investigation by Richard Deth, PhD, are of interest in understanding the pathology of ASD and other conditions. Does the vulnerability of this step to various environmental toxins explain its importance in the autism spectrum? Or is the special complexity of the remethylation process—involving a very delicate dance engaging vitamin B_{12}, 5-methyl-tetrahydrofolate, homocysteine, and SAM—the source of its vulnerability? Both factors are probably at work, but the bottom line is that this step deserves our attention in all efforts to treat autism. Those efforts include the following:

- **Injections of high doses of methyl-B_{12}.** This was described previously and is mentioned here to emphasize the point that the injections are not to correct a deficiency but to bring a strong force to bear on a step that needs a good (safe) kick to get it working. That's why oral doses are not able to do the job.
- **Oral doses of folinic acid.** Again, not to correct a deficiency but to ensure sufficient amounts for that kind of folic acid that is needed for a task that is not shown on the diagram.
- **Methylenetetrahydrofolate reductase (MTHFR).** An enzyme is a large molecule that embraces small ones so that the small ones join or come apart. Enzymes are named in ways that reveal their function and end in *-ase.* Then scientists abbreviate them to letters such as MTHFR that give them an important sound.

MTHFR is indeed important. This enzyme converts a molecule called 5,10-methylenetetrahydrofolate to a molecule called 5-methyltetrahydrofolate. To oxidize a molecule means to steal its electron. So reduction means to give it an electron. That's what it takes to get homocysteine to take the U-turn back to methionine. That's the gift that requires several contributors, among which MTHFR is a major player.

The code MTHFR refers to the gene that provides the instructions for making this big molecule, in whose embrace a major part of homocysteine's return trip takes place. Mutations (malformation of the gene) of the MTHFR gene occur with varied prevalence in different ethnic/racial groups and range from 1 in 10 to 1 in 5 individuals in most groups. The list of medical conditions and diseases for which 1 of 40 different mutations is a risk factor includes everything from heart attacks to cancer, depression, and schizophrenia. The good news is that supplementation of various activated folics is the preventive measure and/or remedy for all of them. Testing for MTHFR mutations has become a common medical practice. Many patients who consult me have found out that their child with ASD has an MTHFR mutation. What it means, really, is that they need supplementation with methyl folate, and if they do so, their risk factors are normalized. It need not be a subject for grief or drama in the realm of genetics. Methyl folate is at the heart of the biochemistry that was previously referred to in terms of the contribution of Dr. James and Dr. Deth. Look at the chart of methylation and see where mercury does its dirty work.

GLUTATHIONE

Oral administration: The problem with oral administration is that GSH is disassembled in the digestive tract and needs to be reassembled in the liver and then disassembled for export to other parts of the body. GSH is very sticky, so sending it around intact is problematic. Oral GSH can be very effective. I used oral GSH to cure long-standing inflammation of the eyes in a patient who had seen many doctors and tried many other remedies. The induction of GSH with glucoraphanin (Avmacol) is more efficient.

Transdermal and intravenous administration: Transdermal preparations and intravenous administration are usually more effective than oral glutathione administration. There is a way of "packaging" GSH inside membranes, like the ones that enclose every cell in the body. These membranes are made of fat (lipid) molecules. These travel through the lymph ducts from the intestine up through the chest and are delivered directly into a vein under the left collarbone. They stay in the circulation, giving the serum a milky appearance that lasts for a few hours before it is absorbed by body tissues. GSH packaged in microscopical fat balls, called liposomes, takes advantage of this distribution of ingested fat to distribute GSH.

Induction of GSH is the top choice in terms of safety, cost, and long-term efficacy.

CONCLUSION

We are in the midst of an epidemic of inflammatory disease with environmental causes. Autism is probably the most malignant, and research on its origins has been delayed by mistaken searches for genetics while it became clear that such could simply not be the case. We continue to hear that "the cause" has not been found so that a cure must await further research. We who are on the front lines of functional medicine must do our best to learn from each other as we treat each individual patient, case by case, and find ways of supporting Nature's strong impulse toward healing. We must tailor our treatments to the needs of each individual patient while heeding the experience of our peers on the familiar landscape of detoxification, microbes, and oxidative stress. Morgan's mom's report on the way his school now values his gifts is a testimony to what a determined parent and clinician can do together to lessen symptoms and even cure autism spectrum disorders.

Bacterial Sinusitis

Michael T. Murray, ND,* and *Elaine Roe, MD*

OUTLINE

DIAGNOSTIC SUMMARY

- History of acute viral respiratory infection, dental infection, or nasal allergy
- Purulent nasal discharge
- Nasal obstruction; facial pain, pressure, and fullness; or both
- Worsening of symptoms after initial improvement if less than 10 days' duration, or no reduction in symptoms if more than 10 days' duration
- Transillumination showing opaque sinus
- Chronic infection, often producing no symptoms other than mild postnasal discharge, a musty odor, or a nonproductive cough

GENERAL CONSIDERATIONS

The most common predisposing factor in acute bacterial sinusitis, defined as a symptomatic inflammation of the paranasal sinuses and nasal cavity, is a viral upper respiratory infection. Allergic rhinitis and other factors that interfere with normal protective mechanisms, including asthma and exposure to cigarette smoke, may precede the viral infection and therefore are the more likely predisposing factors. Any factor that induces edema of the mucous membranes may result in obstruction of meatal drainage. The transudate that is produced serves as a suitable medium for bacterial overgrowth, with the most common pathogens in adults being *Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,* and *Staphylococcus aureus.*[1,2]

Although up to 90% of adults with a viral upper respiratory tract infection have concurrent viral sinusitis, only 0.5% to 2.0% will progress to acute bacterial sinusitis. The diagnosis of acute bacterial sinusitis cannot be made with any one sign or symptom, such as fever or pain, and radiographic evidence cannot adequately distinguish between viral and bacterial sinusitis. An algorithm has been suggested for the diagnosis in which the following three conditions must be present: (1) purulent nasal discharge; (2) nasal obstruction or facial pain, pressure, or fullness, or both; (3) if the duration is less than 10 days, there is a worsening of symptoms after an initial improvement, *or* if more than 10 days, the symptoms are not decreasing.[3] The diagnosis is made similarly in children but also allows for a severe onset, characterized by a temperature of greater than or equal to 39°C/102.2°F and purulent nasal discharge for at least 3 consecutive days.[4]

In chronic bacterial sinusitis, an allergic background is commonly present, and in 10% to 12% of cases of chronic maxillary sinusitis, there is an underlying dental infection.[5]

Although vasoconstrictors and antihistamines cause transient relief, their chronic use is contraindicated because there is usually a reflex reaction after continual administration.

Cigarette smokers should be advised to quit smoking. Secondhand exposure is also a contributing factor.

THERAPEUTIC CONSIDERATIONS

Antibiotics

Although antibiotic therapy is the dominant treatment for acute and chronic bacterial sinusitis, it is of limited value.[6] A detailed analysis to determine the evidence for the effectiveness of antibiotic treatment in acute maxillary sinusitis in adults by assessing the methodological quality of placebo-controlled, double-blind, randomized trials concluded: "The effectiveness of antibiotic treatment in acute maxillary sinusitis in a general practice population is not based sufficiently on evidence."[7] In 2018 a Cochrane review of more than 15 trials and 3000 healthy adult participants found that only 5 to 11 more people per 100 with acute rhinosinusitis would be cured faster if they received antibiotics instead of either placebo or no treatment. Additionally, although imaging results or specific clinical symptoms may somewhat improve the cure rates with antibiotics, the very low incidence of serious complications and the high rate of adverse events led the authors to conclude "there is no place for antibiotics for people with uncomplicated acute rhinosinusitis."[8] Nonetheless, in severe or unresponsive cases, antibiotics may be appropriate, and most reviews have focused on acute sinusitis that is not strictly defined as having a bacterial etiology. In a Cochrane review, it was shown that although 80% of participants treated without antibiotics improved within 2 weeks, antibiotics had a small treatment effect in patients with uncomplicated acute sinusitis in a primary care setting with symptoms for more than 7 days (this longer duration of symptoms

* Previous edition contributor

supports a diagnosis of bacterial sinusitis). Newer, more potent antibiotics (e.g., lactam antibiotics) appear to be more effective than penicillin, amoxicillin, and other less potent antibiotics.[9] Amoxicillin and amoxicillin-clavulanate are considered first-line antibiotics. Topical antibiotics via nasal irrigation may also be used.

In children, it is also questionable that antimicrobial therapy is of significant benefit for uncomplicated sinusitis.[10] Overuse of antibiotics in children with sinusitis or otitis media is a growing concern because it is leading to antibiotic-resistant strains of bacterial pathogens. Antibiotics are currently used in 82% of children with acute sinusitis, although the majority of these infections would likely resolve on their own.[11] However, when controlled for symptoms that suggest a diagnosis of acute *bacterial* sinusitis, antibiotics are associated with a higher cure rate (50% vs. 14%) and lower treatment failure (14% vs. 68%) than placebo.[12]

In chronic sinusitis, antibiotics are also of little or no benefit.[13] Clearly, the most rational approach seems to be to address the underlying cause of chronic sinusitis (e.g., respiratory or food allergens) along with providing supportive therapy (e.g., saline nasal sprays, immune-enhancing herbs, natural decongestants).

Allergy

Studies indicate that most patients with chronic sinusitis, perhaps as many as 84%, have allergies.[14,15] Patients with chronic sinusitis should be aggressively screened for environmental and food allergies. Environmental control requires the elimination of dust mites (warm-water washing at a temperature of least 58°C), use of air-filtering vacuum cleaners, installation of an air cleaner with a high-efficiency particulate air filter, and whatever methods are necessary to maintain the humidity under 50%. Some particularly sensitive patients may need to have all pets removed, along with carpeting and featherbedding.[16]

Mucolytics

Airway mucociliary clearance depends on the properties and volume of secreted mucus, ciliary function, and mucociliary interactions. In chronic sinusitis, mucus viscoelasticity is higher than the optimal values for mucociliary clearance. Mucolytic agents such as *N*-acetylcysteine (NAC) and proteolytic enzymes can reduce viscoelasticity and promote mucociliary clearance.[17]

NAC is the most commonly used mucolytic agent. The free sulfhydryl group of NAC interacts with the disulfide bonds of mucus glycoproteins, thereby breaking the protein network into less viscous strands. Although NAC is often used as a 10% solution by dilution with saline, sodium bicarbonate, and sterile water, it can also be used orally for sinusitis, and it has been shown to be effective for chronic bronchitis.[18]

Proteolytic enzymes may break down complex proteins at the site of inflammation, exert some antimicrobial effects, or act directly on the naked peptide region of mucus glycoproteins. Trypsin, chymotrypsin, *Serratia* peptidase, bromelain, and streptokinase are the proteolytic enzymes that can break down mucus glycoproteins and other proteins when they are administered topically. When *Serratia* peptidase was given at a dose of 30 mg/day for 4 weeks to patients with chronic sinusitis, it significantly reduced the viscosity but not the elasticity of nasal mucus.[19]

It has been reported that the ratio of the viscosity to the elasticity is an important determinant of mucociliary transport. When *Serratia* peptidase was administered at the same dose to patients with chronic bronchitis, it significantly increased mucociliary clearance.[20] A multicenter, double-blind, placebo-controlled study of 193 subjects suffering from various acute or chronic ear, nose, or throat disorders, including sinusitis, demonstrated a greater efficacy and rapid action of the peptidase against all the symptoms examined.[21] Orally administered bromelain has also shown benefit in the treatment of chronic sinusitis.[22] A small study among children with acute sinusitis found that treatment with bromelain alone resulted in faster recovery than when combined with standard therapies or with standard therapy alone.[23]

Nasal Saline

Intranasal saline irrigation improves sinusitis symptoms by washing away secretions, allergens, and irritants. A 2015 Cochrane review found that although existing trials have been too small and had a high risk of bias, nasal saline therapy may have possible benefit for upper respiratory tract infections.[24] Among individuals with frequent sinusitis, it has also been shown to improve symptoms and sinus-related quality of life while reducing the need for medication.[25]

Nasal Steroids

Inhaled glucocorticoids may be of use in acute sinusitis and are commonly used in chronic sinusitis.[26] A 2013 review of four studies and nearly 2000 adults and children with acute sinusitis found that intranasal steroids were associated with a greater likelihood of resolution or improvement versus placebo (relative risk [RR] 1.11).[27]

Pelargonium sidoides (South African Geranium)

Extracts from the rhizomes and tubers of *Pelargonium sidoides* have been shown to exert a number of beneficial effects in upper respiratory tract infections, particularly acute bronchitis, an indication for which it is an approved drug in Germany (see Chapter 155, Bronchitis and Pneumonia). *P. sidoides* has demonstrated immune-enhancing effects as well as antibacterial and antiviral effects and the ability to prevent adhesion of bacteria to epithelial cells.[28] In one double-blind, placebo-controlled trial, 103 patients with acute rhinosinusitis of presumably bacterial origin were given an ethanolic extract of *P. sidoides* (EPs 7630) or matching placebo at a dose of 3 mL three times daily for a maximum 22 days.[29] The mean decrease in the Sinusitis Severity Score was 5.5 points in the EPs 7630 group compared with 2.5 points in the placebo group, a difference of 3.0 points. This result was confirmed by all secondary parameters, indicating a more favorable course and a faster recovery in the EPs 7630 group.

THERAPEUTIC APPROACH

In acute sinusitis, the immediate therapeutic goals are to reestablish drainage and clear the acute infection. Various measures can be used: local application of heat, local use of volatile oils and botanicals with antibacterial properties, and immune system support (see Chapter 136).

Because chronic bacterial sinusitis is often secondary to allergy, long-term control depends on isolation and elimination of the food or airborne allergens and correction of the underlying problem that allowed the allergy to develop. During the acute phase, the elimination of common food allergens (milk, wheat, eggs, citrus, corn, and peanuts) is indicated until a more definitive diagnosis can be made.

Local applications of heat have been shown to be effective in alleviating both the short- and long-term symptoms of allergic rhinitis.[30]

Supplements

- Vitamin C: 500 mg three times a day
- Bioflavonoids: 1000 mg/day
- Vitamin A: 5000 IU/day or beta-carotene (but only if single-nucleotide polymorphisms [SNPs] are checked to rule out those who do not convert beta-carotene to actual vitamin A): 25,000 IU/day
- NAC: 200 mg three times a day

Serratia Peptidase or Bromelain

- *Serratia* peptidase (enteric coated): 50 mg three times a day between meals
- Bromelain (1200–1800 MCU): 250 mg three times a day

Botanicals

Echinacea sp.

- Dried root (or as tea): 0.5 to 1 g
- Freeze-dried plant: 325 to 650 mg
- Juice of aerial portion of *Echinacea purpurea* stabilized in 22% ethanol: 2 to 3 mL
- Tincture (1:5): 2 to 4 mL (½–1 tsp)
- Fluid extract (1:1): 2 to 4 mL (½–1 tsp)
- Solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150 to 300 mg

Hydrastis canadensis

The dosage should be based on berberine content. Because there is a wide range of quality in goldenseal preparations, standardized extracts are recommended. Three-times-a-day dosages follow:

- Dried root or as infusion (tea): 2 to 4 g
- Tincture (1:5): 6 to 12 mL (1.5–3 tsp)
- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp)
- Solid (powdered dry) extract (4:1 or 8%–12% alkaloid content): 250 to 500 mg

Pelargonium sidoides

Dosage recommendations for EPs 7630 or equivalent preparation:

- Adults: 3 mL three times a day or two 20-mg tablets three times a day for up to 14 days
- Children: ages 7 to 12 years, 30 drops (1.5 mL) three times a day; age 6 years or less, 10 drops (0.5 mL) three times a day

Local Treatment

- Intranasal douche with saline water or *Hydrastis* tea
- Swabbing of passages with oil of bitter orange
- Menthol or eucalyptus packs over sinuses (care should be taken to avoid irritation)

Physical Therapy

- Local applications of hot packs
- Diathermy: 30 minutes (discontinue if pain increases without drainage)

Benign Prostatic Hyperplasia

Geovanni Espinosa, ND, LAc, IFMCP, CNS, and *Ralph Esposito, ND, LAc*

OUTLINE

DIAGNOSTIC SUMMARY

- Symptoms of bladder outlet obstruction (progressive urinary frequency, urgency and nocturia, hesitancy, and intermittency with reduced force and caliber of urine)
- Enlarged, nontender prostate
- Uremia with prolonged obstruction

GENERAL CONSIDERATIONS

Benign prostatic hyperplasia (BPH) is the fourth most common diagnosis in older men.[1] More than 50% of men over age 50 years are affected, and 90% of men will have an enlarged prostate by the time they are 80 years old. Progression to urinary retention may occur, with an accompanying risk of recurrent urinary tract infections, bladder calculi, and occasionally renal insufficiency. Management options for BPH include exercise, low-fat diet, supplementary medications, minimally invasive therapies, and prostate surgery.

The most common symptoms of BPH are lower urinary tract symptoms (LUTS), such as frequent urination, urgency to urinate, nocturia, weak urinary stream, incomplete bladder emptying, straining to void, and an intermittent stream. A patient may have multiple symptoms but be bothered primarily by one. Prostate cancer, bladder cancer, overactive bladder, urinary tract infections, prostatitis, urethral stricture, and bladder stones can also cause LUTS and must be ruled out before a diagnosis of BPH is made.[2]

Risk Factors

Abdominal obesity and genetic factors appear to be the main risk factors for the development of BPH, which appears to run in families. If one or more first-degree relatives are affected, an individual is at greater risk of developing this disorder.[1,3] Waist size, body mass index, and increases in body weight appear to increase the volume of the prostate gland.[4]

Hormones and Benign Prostatic Hyperplasia

The role of androgens in the development of prostate enlargement is evident, owing to the fact that BPH does not develop in men who have been castrated before puberty and therefore have greatly depleted levels of circulating androgens. Furthermore, in men with BPH, medical or surgical castration has been shown to lead to a reduction in prostate volume.[5]

For testosterone to have any effect on the prostate, it must be converted to dihydrotestosterone (DHT) by the enzyme 5-alpha-reductase.[6] DHT has twice as great an effect on the prostate as testosterone.[7]

Although testosterone levels decline with age, the concentration of DHT remains constant in both younger and older men, even with a low serum level.[5] Circulating DHT, by virtue of its low serum plasma concentration and tight binding to plasma proteins, is of diminished importance as a circulating androgen affecting prostate growth.[8]

However, much of the latest research has questioned the medical paradigm of testosterone as a cause for BPH. In fact, two recent review papers have found no correlation between testosterone replacement therapy and worsening LUTS or BPH.[9,10] It has been proposed that testosterone may be protective against BPH. Several studies have shown improvement or no change in the International Prostate Symptom Score (IPSS), transrectal ultrasound (TRUS) prostate volume, LUTS, and maximum flow rate in men on testosterone replacement.[9] It is suspected that the mechanism is multifactorial. Low testosterone levels are a risk factor for metabolic syndrome, which can lead to autonomic hypertonicity, chronic pelvic inflammation, and lower nitric oxide (NO) levels. Low NO levels worsen bladder detrusor activity and cause urethral contractions, thus worsening BPH. Interestingly, testosterone improves NO levels, thus displaying the protective impact of testosterone on LUTS.

Most of the research on BPH and its pharmaceutical treatment has focused on modulating DHT by inhibiting the enzyme 5-alpha-reductase. Other intriguing and accumulating research has illustrated the effects of estrogen or, more importantly, the estrogen:testosterone ratio in aging men and its effects on BPH.

In animal models, estrogen has shown molecular changes in the prostate of the aging dog.[11] The evidence is less clear in humans. Estrogens in the male are predominantly the products of peripheral aromatization of testicular and adrenal androgens.[12] Although the testicular and adrenal production of androgens declines with aging, levels of total plasma estradiol do not decline. In fact, estradiol remains relatively constant or even increases with age in men. This increase has been attributed to increased aromatase activity in the aging male, who often also has an increased accumulation of body fat. Fat cells contain aromatase, an enzyme that converts certain androgens to estrogen. The resulting disproportion in the estrogen:testosterone ratio may increase up to 40% in some men.[13]

By limiting aromatase or inhibiting the binding of estrogen to prostate cells, it may be possible to reduce BPH or slow its progression. Yet as we are now discovering, the interplay of androgens, testosterone and DHT metabolites, estrogens, and their respective receptors is intricately involved in the growth of prostatic tissue. DHT has gained a reputation for being problematic and the cause for BPH; however, 3-beta-diol and 3-alpha-diol, two DHT metabolites, may affect prostate growth via their binding activity of estrogen receptor (ER)-alpha and ER-beta.[14] ER-alpha induces prostatic stromal proliferation, whereas ER-beta induces apoptosis in luminal, basal, and stromal BPH cells.[15] Interestingly 3-beta-diol binds to ER-beta, reducing prostatic growth, and has been inversely correlated with IPSS.[14] ER-alpha is upregulated in BPH, along with aromatase, resulting in increased estrogens and ER-alpha, subsequently worsening BPH.[16] These findings suggest there is a unique interplay between androgens, estrogens, and their respective metabolites and receptors. It may not be fair to indict one single hormone as a causal factor for BPH, instead requiring consideration of the complete hormonal milieu.

Metabolic Syndrome as a Risk Factor

Metabolic syndrome (MetS) is a cluster of conditions including abdominal obesity, impaired glycemia, hypertension, hypertriglyceridemia, low high-density lipoprotein (HDL), and hyperlipidemia.[17] It is very well known that together, these conditions increase the risk of type 2 diabetes and cardiovascular disease.[18] However, what is less apparent but is certainly a health concern for men is the risk associated with MetS and BPH/LUTS.[19]

There is a significant body of evidence suggesting there is a strong clinical association between BPH and MetS.[20–22] Not only has the correlation between the two been very well established in the literature, but MetS has also been correlated with the severity of LUTS[21] and increased prostatic growth[17] and is a predictor of the clinical progression of BPH.[23] BPH/LUTS is also positively associated with the number of MetS components, with the research showing an increased risk of experiencing an IPSS of greater than 7, a total prostate volume of greater than or equal to 30cc, and a postvoid residual (PVR) of greater than or equal to 50 mL with an increasing number of MetS abnormalities.[20] This suggests that the more components of MetS a man experiences, the more likely he is to experience BPH/LUTS.

With lack of exercise also being a significant risk factor for LUTS[24] together with MetS, it would be prudent for practitioners to address MetS as an underlying cause of BPH and LUTS in older men.

Toxins as Risk Factors

Endocrine-disrupting chemicals (EDCs) are defined as exogenous agents that interfere with the synthesis, secretion, transport, metabolism, binding action, or elimination of natural blood-borne hormones that are present in the body and are responsible for homeostasis, reproduction, and developmental process. EDCs include the biologically persistent organochlorine compounds (chlorinated pesticides and polychlorinated biphenyls [PCBs] and dioxins) and brominated flame retardants (PBDE), as well as nonpersistent plastics (bisphenol A), plasticizers (phthalates), organophosphate pesticides, fungicides, and herbicides.

It is well established that steroidal hormones (testosterone and estrogen) increase the risk of BPH, and cytochrome P450 (CYP) enzymes, especially CYP1A1, CYP1B1, and CYP17, metabolize these hormones. Thus functional polymorphisms in these genes and exposure to EDCs may further increase BPH risk. A study of 100 subjects with newly diagnosed BPH and 100 age-matched healthy male controls evaluated this potential risk.[25] Levels of p,p′-DDE and Endosulfan-α were found to be significantly higher among subjects with BPH compared with controls, and CYP17 polymorphism was observed to be significantly associated with subjects with BPH compared with controls, indicating that these factors may be important risk factors for BPH.

Although cadmium is a known antagonist of zinc and increases the activity of 5-alpha-reductase, its concentration in the prostate and its effects are unclear. Several studies have produced conflicting results.[26,27] An epidemiological study from India examined the association of cadmium (Cd) and lead (Pb) in the pathophysiology and progression BPH in 116 patients with the condition.[28] Prostatic acid phosphatase activity, prostate-specific antigen, maximum urinary flow rate, and redox status of BPH patients were correlated with Cd and Pb contents in the prostate. Increased levels of lipid peroxidase, a marker of oxidative damage, and increased glutathione peroxidase, thought to be via a compensatory action, are the possible mechanism as to which Cd contributes to prostatic hyperplasia.

Bisphenol A (BPA) has been shown to exert endocrine-disrupting effects on reproduction, development, metabolism, and cancer in humans, and findings in animal studies have linked BPA with BPH. In BPA-treated rats, the weight of the ventral prostate significantly increased, with a corresponding depletion of the antioxidant defense system and an increase in oxidative stress in epididymal sperm.[29] An additional rodent study induced BPH with testosterone and then treated the rats with BPA (10, 30, or 90 μg/kg daily), 17β-estradiol (50.0 μg/kg daily), or vehicle for 4 weeks. Rats treated with low-dose BPA (10 μg/kg) had a significant increase in relative prostate weight, and for prostate lobes, BPA 10μg/kg/day significantly increased the relative weight of the ventral prostate as well as the weight and relative weight of the dorsolateral prostate.[30]

DIAGNOSTIC CONSIDERATIONS

International Prostate Symptom Score

A useful subjective assessment tool for BPH patients is the IPSS. The IPSS is a modification of the American Urological Association (AUA) Symptom Index, adding a single question assessing the quality-of-life or bother score based on the patient's perception of the problem. The IPSS is a questionnaire that assesses the degree of LUTS and the quality of life of patients with BPH.

Patients can fill out the IPSS form before their examinations, but as little as possible interference from the health care provider and personnel is recommended (Fig. 154.1). A score of 7 or less is considered mildly symptomatic, 8 to 19 points is considered moderate, and a score of 20 to 35 points is considered severely symptomatic. Both the AUA index and IPSS questionnaire—although not specific for BPH, prostate volume, urinary flow rate, PRV, or bladder outlet obstruction—have been validated and are sensitive enough to be used in evaluating symptoms and selecting treatment.[31]

A good physical examination should include a digital rectal examination (DRE) to determine the approximate consistency and shape of the patient's prostate and abnormalities suggestive of prostate cancer,

International Prostate Symptom Score (I-PSS)

Patient Name: _____ **Date of birth:** _____ **Date completed** _____

In the past month:	Not at all	Less than 1 in 5 times	Less than half the time	About half the time	More than half the time	Almost always	Your score
1. Incomplete emptying How often have you had the sensation of not emptying your bladder?	0	1	2	3	4	5	
2. Frequency How often have you had to urinate less than every two hours?	0	1	2	3	4	5	
3. Intermittency How often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. Urgency How often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Weak stream How often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Straining How often have you had to strain to start urination?	0	1	2	3	4	5	
	None	**1 Time**	**2 Times**	**3 Times**	**4 Times**	**5 Times**	
7. Nocturia How many times did you typically get up at night to urinate?	0	1	2	3	4	5

Quality of life due to urinary symptoms	Delighted	Pleased	Mostly satisfied	Mixed	Mostly dissatisfied	Unhappy	Terrible
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	**0**	**1**	**2**	**3**	**4**	**5**	**6**

Fig. 154.1 International Prostate Symptom Score (IPSS) questionnaire. (From Bope E, Kellerman R, Rkel, R. *Conn's current therapy 2011*. Philadelphia: Saunders; 2011. International Prostate Symptom Score [IPSS] questionnaire, available from the Urological Sciences Research Foundation at http://www.usrf.org/questionnaires/UA_SymptomScore.html. Accessed September 26, 2011. Used with permission.)

BPH, or prostatitis. The approximate size of the prostate can be determined with a DRE; however, inadvertent misestimations can be made even by physicians who are highly experienced. Prostate size can be determined most accurately by a TRUS or magnetic resonance imaging (MRI).

Urine and Blood Tests

Patients with suspected BPH should undergo dipstick urinalysis testing or microscopical urinalysis to screen for infection and hematuria, proteinuria, pyuria, glycosuria, and ketonuria. If a urine dipstick is positive, a urine culture may be necessary to determine whether the patient's LUTS are independent of BPH.

Prostate-Specific Antigen

Because the symptoms of BPH and prostate cancer can be similar, measurement of prostate-specific antigen (PSA) is often used to differentiate BPH from prostate cancer. Recent studies show there are high levels of false-positive and false-negative PSA test results; therefore the benefits and risks of the test should be discussed with the patient. PSA testing is one of the tools used to assess for prostate cancer and its severity, along with imaging, PSA density, staging, and Gleason score. This remains a controversial test, however, owing to its lack of specificity, which can lead to the overdiagnosis and overtreatment of indolent prostate cancers.[32,33] One European study showed that it takes 1 of 48 men treated for prostate cancer to be saved from prostate cancer death

over a 10-year period, yet the conversation comparing the benefits versus harms of PSA screening in overall survival is still largely debated in the medical society.[32,34]

PSA and BPH

PSA is a glycoprotein secreted by the glands of the prostate; it is released in the serum with disruption of normal prostatic tissue due to prostate cancer, inflammation, BPH, or trauma.

Finasteride (5-mg dose) and dutasteride (0.5-mg dose), both of which are 5-alpha-reductase inhibitors used for the treatment of BPH and male-pattern baldness (1-mg dose of finasteride), will lower PSA levels by approximately 50% regardless of the dose.[35] Ejaculation and DRE have been reported to increase PSA levels, but studies have shown the effects to be variable or insignificant.[36,37] Prostate biopsy, however, will usually cause a substantial elevation of PSA levels. Therefore, after biopsy, PSA testing should be postponed for at least 3 to 6 weeks.[38,39] Although an elevated level indicates prostate cancer in about 90% of cases, it must be kept in mind that midrange elevations in PSA can be caused by BPH and that in some instances, there may be prostate cancer without an elevation of PSA levels. One approach to distinguish the two conditions when PSA is elevated is to measure the ratio of free to total PSA: more free PSA (fPSA) than complexed PSA suggests BPH rather than prostate cancer. A ratio of around 20% or greater for fPSA is considered more likely to represent BPH than cancer.[40] The 4K score, an algorithm utilizing total PSA, fPSA, intact PSA, and hK2, is being integrated into medical practices because it has the highest level of evidence of its ability to identify aggressive prostate cancer before biopsy.[41]

PSA density (PSAD) can be used to differentiate between prostate cancer and BPH in men with PSAs between 4 and 10 ng/mL and normal DRE results. PSAD should be higher in men with prostate cancer than in those with benign disease because cancer causes a greater elevation in PSA per prostate volume in comparison with BPH. To determine PSAD, the patient's PSA can be divided by prostate volume (as determined by a TRUS examination). Studies show that a PSAD greater than 0.15 may mean a higher risk of prostate cancer. A lower PSAD would likely indicate that the patient has BPH. This method should not conclusively determine whether a patient has BPH or prostate cancer, but it can be one piece of the puzzle.[42]

THERAPEUTIC CONSIDERATIONS

Left untreated, BPH eventually obstructs the bladder outlet, leading to the retention of urine and eventual kidney damage. Because this situation is potentially life-threatening, proper surgical treatment is crucial. Surgery may also be indicated in patients who have failed medical therapy or have recurrent infections, hematuria, or renal insufficiency. In the past, medical treatment involved a procedure called transurethral resection of the prostate (TURP). Because this surgery is associated with the risk of considerable morbidity (sexual dysfunction, incontinence, and bleeding)[43] and often makes matters worse, it should be avoided unless absolutely necessary. Surgical procedures that use thermal microwaves or a laser to reduce hyperplastic tissue are also available. Generally, these newer procedures are less expensive than TURP and have fewer complications, although subsequent therapies are often required.[44] Green-light therapy or photoselective vaporization of the prostate is a newer option that has similar outcomes to TURP, with a reduced risk of bleeding.[45]

Lifestyle/Exercise

There is an inverse association between physical activity[22] and BPH and a positive association between abdominal obesity and BPH.[44] In fact, sedentary men are at higher risk of LUTS/BPH, with even nonsedentary activities such as field work and casual walking proving to be protective against BPH.[46]

The ingestion of more calories may encourage abdominal obesity and sympathetic nervous system activity, both of which can increase the risk of BPH. Increased sympathetic activity, which is the "fight-or-flight" arm of the autonomic nervous system, may cause the prostate's smooth muscle to contract, resulting in a worsening of LUTS. Furthermore, hyperinsulinemia and insulin resistance caused by increased caloric ingestion, especially of high sugar content, may further complicate BPH/LUTS via a hypersympathetic response, thus resulting in constriction of the internal urethral sphincter.[46–48] However, a higher caloric intake does not seem to increase BPH risk when accompanied by increased physical activity.[49]

It is thus possible that physical activity may serve a threefold purpose:

It may increase blood flow to the area, allowing the body to remove wastes efficiently.

It can decrease the sympathetic stress responses, thus relaxing prostatic tissue.

It can reduce excess abdominal weight, which increases overall lower body pressure, thus relaxing the prostate/rectal region and improving blood flow into and out of the area.

Dietary and Nutritional Factors

Diet appears to play a critical role in the health of the prostate. Diets high in overall fat (not specific to the type of fat) are associated with an increased risk of BPH, as are diets high in red meat (whether conventional meats were used in comparison with the grass-fed kind is unknown). Conversely, according to a recent large randomized trial, diets high in protein and vegetables are associated with a decreased risk.[44] A special emphasis should be considered for onions, garlic, and other *Allium* plants because higher intakes of these foods have been found to be associated with a decreased BPH risk.[50]

It is particularly important to avoid pesticides, increase fruit consumption,[51] increase the intake of zinc and essential fatty acids, decrease coffee consumption,[52] decrease butter consumption, avoid margarine,[51] and keep cholesterol levels below 200 mg/dL. A moderate intake of alcohol can possibly benefit BPH but make LUTS worse.[53]

High-Protein Diet

The research evaluating protein intake and BPH is mixed. Some evidence shows that a high-protein diet (total calories: 44% protein, 35% carbohydrate, 21% fat) can inhibit 5-alpha-reductase, whereas a low-protein diet (10% protein, 70% carbohydrate, and 20% fat) may stimulate the enzyme.[54] On the other hand, an 8-year study of 3523 men with BPH found that total protein intake is positively associated with BPH, with the association being slightly stronger for animal protein intake than vegetable protein.[44] A study of Chinese farmers also revealed a correlation between a higher intake of animal protein and the incidence of BPH (91.1% in those eating diets high in animal protein vs. 11.8% in those not eating animal protein).[55]

A possible theoretical reason why high protein intake may not be helpful relates to a greater osmolar load, which may influence urinary output and thus impose an undue extra burden on an already taxed system.[7] Therefore we recommend against ingesting excess animal protein as a means to increase total protein intake. Instead, high-quality, plant-derived protein and protein from cold-water fish in moderate amounts is probably a reasonable recommendation until we know more about the relationship between protein intake and BPH.

Zinc

Studies conducted in the 1970s showed that zinc supplementation reduced the size of the prostate and the symptomatology of BPH in the majority of patients.[56] A more recent randomized trial comprising 4770 participants indicates a possible protective role of zinc against BPH. In that investigation, BPH was assessed over 7 years and defined in terms of medical or surgical treatment or repeated elevation (above 14) on the IPSS questionnaire. Diet, alcohol, and the use of supplements were assessed via a food frequency questionnaire. Higher zinc intake was associated with a significantly reduced risk for BPH.[49] The mechanism probably involves zinc's ability to inhibit 5-alpha-reductase[57] and/or its ability to inhibit prolactin.[58] Prolactin has been shown to increase the uptake of testosterone by the prostate, thereby leading to increased levels of DHT by providing additional substrate.[59]

Alcohol

Although only beer raises prolactin levels, higher alcohol intake may be associated with BPH. In a 17-year study of 6581 men in Hawaii, it was noted that an alcohol intake of at least 25 ounces per month was directly correlated with the diagnosis of BPH.[60]

The association was most significant for beer, wine, and sake and less so for distilled spirits. Most other recent studies confirm a protective effect of alcohol with regard to BPH when consumption is kept under three alcoholic beverages daily because anything above this amount may increase obstructive and irritative LUTS in men.[43,61,62]

Amino Acids

The combination of glycine, alanine, and glutamic acid (in the form of two 6-grain capsules administered three times daily for 2 weeks and one capsule three times daily thereafter) has been shown in several studies to relieve many BPH symptoms. In a controlled study of 45 men, nocturia was relieved or reduced in 95%, urgency was reduced in 81%, frequency was reduced in 73%, and delayed micturition was alleviated in 70%.[63] These results have also been reported in other controlled studies.[64] The mechanism of action is unknown but is likely related to the amino acids acting as inhibitory neurotransmitters and reducing the feeling of a full bladder. In other words, amino acid therapy is only palliative.

Cholesterol

The association among cholesterol, BPH, and LUTS is mixed. High levels of serum lipids have been associated with cardiovascular disease and include elevated serum low-density lipoprotein (LDL) cholesterol, decreased serum HDL cholesterol, and increased serum triglycerides. In the case of BPH, however, as described by Parsons, no positive association has been shown for cholesterol.[65] In fact, hyperinsulinemia with hyperlipidemia and low HDL are risk factors for prostatic inflammation and BPH.[47]

Beta-Sitosterol

Beta-sitosterol is one of several plant sterols (cholesterol is the main animal sterol) found in almost all plants. High levels are found in rice bran, wheat germ, corn oil, and soybeans; peanuts and their products—such as peanut oil, peanut butter, and peanut flour; and *Serenoa repens,* avocados, pumpkin seed, *Pygeum africanum,* and cashew fruit. The ability of beta-sitosterol and other phytosterols to lower cholesterol has been well documented.[66] Beta-sitosterol has also been shown to improve BPH. One double-blind study comprised 200 men receiving beta-sitosterol (20 mg) or placebo three times daily.[67] The beta-sitosterol group experienced an increase in maximum urinary flow rate from a baseline of 9.9 to 15.2 mL/s and a decrease in mean residual urinary volume of 30.4 from 65.8 mL.

In yet another study, 177 patients with benign prostate enlargement were randomized.[68] Patients received 130 mg of beta-sitosterol each day and were monitored for over 6 months. Measurements of the IPSS, urinary flow, and residual urine in the bladder after voiding were recorded. On average, urinary flow values increased by 4.5 mL/s, whereas residual urine volumes decreased by a substantial 33.5 mL. The IPSS showed a statistically significant improvement.[68]

Furthermore, a large systematic review analyzing 519 men among four randomized, placebo-controlled trials found that beta-sitosterol, although it did not reduce prostate volume, did improve urinary flow measures via IPSS, urodynamic measure, mean urine flow, residual urine volume, and nocturia.[69]

Vitamin D

Krystal and colleagues showed that vitamin D supplementation was associated with a reduced risk of BPH, but the dosage was imprecise. The association in this 4770-subject trial was observed only among men who used both multivitamins and single vitamin D supplements. There were no associations of supplement use with BPH risk, with the exception of a trend toward decreased BPH risk with increased intake of supplemental vitamin D.[49] Although this study lacked data on the frequency, dose, and duration of vitamin D use, the results are intriguing enough to support further research addressing whether high-dose supplementation will have any benefit for BPH. Numerous studies have shown that vitamin D_3 may have protective effects against prostate cancer.[70]

The mechanism of vitamin D's favorable effect on BPH is by attaching this molecule to vitamin D receptors on the prostate and bladder and inhibiting prostate growth, lowering excessive contractility, and reducing inflammation.[71]

Lycopene

Commonly found in watermelon and tomatoes, lycopene is a carotenoid known for its strong antioxidative effects. Levels in the prostate appear inversely correlated with disorders. However, controlled intervention trials, although promising, have been small and typically in conjunction with other interventions, such as the botanical medicines discussed in the next section.

Botanical Medicines

Botanical medicines in the treatment of BPH have been a popular recommendation in Europe for decades.[72] The chance of clinical success with any of the botanical treatments of BPH appears to be determined by the degree of obstruction, as indicated by the volume of residual urine. For levels of less than 50 mL, the results are usually excellent. For levels between 50 and 100 mL, the results are usually quite good. With residual urine levels between 100 and 150 mL, it will be tougher to produce a significant improvement within the customary 4- to 6-week period. If the volume of residual urine is greater than 150 mL, saw palmetto extract and other botanical medicines alone are unlikely to produce any significant improvement.

Serenoa repens (Saw Palmetto)

The liposterolic extract of the fruit of the saw palmetto palm tree (also known as *Sabal serrulata*), native to Florida, has been shown to significantly improve the signs and symptoms of BPH in numerous clinical studies (see Chapter 112). The mechanism of action is related to inhibition of DHT binding to both the cytosolic and nuclear androgen receptors, inhibition of 5-alpha-reductase, and interference with intraprostatic estrogen receptors. Owing to these effects, the results of most randomized trials have been excellent. Systematic literature reviews and meta-analyses of clinical trials report excellent results using

Serenoa, comparing quite favorably with those of finasteride (Proscar) and tamsulosin (Flomax) in terms of efficacy but with a better side-effect profile. It appears that the effect of *Serenoa* extract is most obvious in the early stages of BPH (i.e., in cases of mild to moderate hypertrophy) because the clinical research has clearly shown that roughly 90% of men with mild to moderate BPH experience improvement in symptoms during the first 4 to 6 weeks after starting *Serenoa* extract (320 mg per day of the liposterolic extract). However, it is likely that *Serenoa* extract may show little if any clinical benefit in more advanced cases of BPH. Chapter 112 offers a complete discussion of the pharmacology of *Serenoa.*

Furthermore, although *Serenoa* is often very effective on its own, better results may be achieved by combining *Urtica dioca* root extract (discussed herein) with *Serenoa* extract. One double-blind study involving 431 patients found this combination to produce clinical benefit equal to that of finasteride.[73] In a more recent long-term study, the efficacy and tolerability of this combination was investigated in elderly male patients suffering from LUTS caused by BPH.[74] In total, 257 patients were randomized to treatment with the combination (320 mg of *Serenoa* and 240 mg of *Urtica* extracts per day) or placebo. A 24-week double-blind treatment was followed by an open control period of 24 weeks, during which all patients were given the *Serenoa* and *Urtica* combination. Patients treated with the botanical combination exhibited a substantially greater reduction in total IPSS after 24 weeks of double-blind treatment than did patients in the placebo group. This applied to obstructive as well as to irritative symptoms and to patients with moderate symptoms as well as those with severe symptoms at baseline. Patients randomized to placebo showed a marked improvement in LUTS (as measured by the IPSS) after being switched to the botanical combination. Like the extract of *Serenoa, Urtica* extract appears to interact with the binding of DHT to cytosolic and nuclear receptors.[75] In vitro studies also show that lignans found in *Urtica* may modulate hormonal effects because of their affinity for sex hormone–binding globulin.[74] Although earlier studies have shown promising results, a large recent Cochrane review suggests that the benefits of *Serenoa,* even at high doses, may be best utilized as a combination therapy. Studies have shown benefits when combined with *Urtica,* as described previously, but also with selenium and lycopene. The combination of selenium, lycopene, and *S. repens* shows improved IPSS and urinary function tests.[76]

Furthermore, this same Cochrane review claims *Serenoa* alone was no better than placebo but also that it was equally as effective as tamsulosin in reducing IPSS scores.[77] This thus raises the question, if *Serenoa* is no better than placebo but equal to tamsulosin, then is either no better than placebo?

Cernilton

Cernilton, an extract of rye-grass flower pollen, has been used to treat prostatitis and BPH in Europe for more than 35 years.[78] It has been shown to be quite effective in several double-blind clinical studies in the treatment of BPH,[79,80] where the overall success rate is about 70%.[81] Patients who respond typically experience less nocturia and diurnal frequency (a reduction of about 70%) as well as significant reductions in residual urine volume.[73] The extract has been shown to exert some anti-inflammatory action and to produce a contractile effect on the bladder while simultaneously relaxing the urethra. In addition, Cernilton contains a substance that inhibits the growth of prostate cells.[75]

In one study, the clinical efficacy of Cernilton in the treatment of symptomatic BPH was examined over a 1-year period.[79] Seventy-nine men averaging 68 years of age (range 62–89) with a mean baseline prostatic volume of 33.2 cm^2 were given 63 mg Cernilton pollen extract twice daily for 12 weeks. As a result, their average urinary maximum flow rate increased from 5.1 to 6 mL/s. The average flow rate increased from 9.3 to 11 mL/s. Residual urine volume decreased from 54.2 mL to less than 30 mL. Clinical efficacy, based on symptoms, was as follows:
Urgency or discomfort: improved by 76.9%
Dysuria: improved by 71.4%
Nocturia: improved by 56.8%
Incomplete emptying: improved by 66.2%
Prolonged voiding: improved by 64.1%
Delayed voiding: improved by 62.2%
Intermittency: improved by 60.6%
Postvoid dribbling: improved by 42.7%

Overall, 85% of the test subjects experienced benefit: 11% reporting "excellent," 39% "good," 35% "satisfactory," and 15% "poor" results.

A summary review of two placebo-controlled studies, two comparative trials (both lasting 12–24 weeks), and three double-blind studies of 444 men showed that although Cernilton did not improve urinary flow rates, residual volume, or prostate size compared with placebo or the comparative study agents, it did improve self-rated urinary symptom scores and reduced nocturia compared with placebo and an amino acid mixture.[75] Clearly, more long-term studies of Cernilton need to be conducted to elucidate the terms of its usefulness as an alternative or adjunct to *Serenoa.*

Last, a study by Preuss and associates illustrates the potential value of a combination of nutrients used for BPH. In this randomized trial, 144 subjects were randomized to Cernilton, saw palmetto, beta-sitosterol, vitamin E, or placebo. After 3 months, the combination group had significantly less nocturia, frequency, and overall BPH symptoms, without any adverse side effects.[82]

Ganoderma lucidum

Of the many medicinal mushrooms utilized in naturopathic medicine, *Ganoderma lucidium* has shown the most promise in improving BPH symptoms and LUTS in older men. This medical mushroom has been shown to inhibit 5-alpha-reductase in the ventral prostate of rats.[83] Two follow-up randomized, placebo-controlled trials tested the use of *G. lucidum* in adult men with LUTS. The primary outcomes assessed for changes in the IPSS. The two studies exhibited a significant reduction in IPSS using 6 mg daily of *G. lucidum.*[84,85] There was no added benefit at doses of 60 mg, suggesting a higher dose is not necessary to reduce LUTS.[84]

Interestingly, no changes were noted in quality-of-life scores, peak urinary flow, mean urinary flow, residual urine, prostate volume, serum PSA, or testosterone levels.[84,85] This would suggest that the benefits observed from *Ganoderma* are not dependent on the ability to inhibit 5-alpha-reductase, as was seen in earlier animal trials. This is significant because reductions in PSA and the inhibition of androgen and DHT receptors in the prostate may affect screening for BPH and prostate cancer. Therefore supplementing with *Ganoderma* may improve symptoms and still allow for proper PSA screening and monitoring.

Vaccinium macrocarpon

Vaccinium macrocarpon, better known as cranberry fruit, has been popularized for its use in urinary tract infections. However, the use of this fruit has also shown promise in the management of LUTS and BPH in men. Two studies have assessed the efficacy of *Vaccinium* extract in improving the IPSS and quality-of-life scores, along with clinical parameters such as PSA, PVR, average urinary flow rate (Q ave), and maximum urinary flow rate (Q max). Findings from both studies suggest that *Vaccinium* improves the IPSS, along with significantly improving urinary parameters such as Q max, Q ave, and

PVR.[86,87] One of the studies assessed the benefits of PSA reduction, showing this fruit was able to reduce PSA in men with histologically confirmed nonbacterial chronic prostatitis.[86] Possible mechanisms, although unclear, suggest *V. macrocarpon* improves detrusor contraction and activation, improves the micturition reflex, reduces inflammation, and possibly improves the dynamic and static prostatic components of voiding.[86,87]

Pygeum africanum

The bark of *Pygeum africanum,* an evergreen tree native to Africa, has historically been used in the treatment of urinary tract disorders. The major active components of the bark are fat-soluble sterols and fatty acids. Virtually all of the research on *Pygeum* has featured a *Pygeum* extract standardized to contain 14% triterpenes, including beta-sitosterol and 0.5% n-docosanol. This extract has been extensively studied in both experimental animals and humans in clinical trials (see Chapter 107). A study on rat prostatic cells suggests that the therapeutic effect of *Pygeum* may be due in part to the inhibition of growth factors epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), and insulin-like growth factor I (IGF-I), which are responsible for prostatic overgrowth.[88] Additional possible benefits of *Pygeum* have been suspected to be due to its ability to inactivate androgen receptors, inhibit cellular proliferation, and reduce inflammation.[89–91]

Numerous clinical trials with more than 600 patients have shown *Pygeum* extract to be effective in reducing the symptoms and clinical signs of BPH, especially in early cases.[92] However, in a double-blind study that compared *Pygeum* extract with extract of saw palmetto, the latter produced a greater reduction of symptoms and was better tolerated.[93] In addition, the effects on objective parameters, especially urine flow rate and residual urine content, were better in the clinical studies with saw palmetto. However, there may be circumstances in which *Pygeum* is more effective than saw palmetto. For example, saw palmetto has not been shown to produce some of *Pygeum*'s effects on prostate secretion. Of course, the two extracts have somewhat overlapping mechanisms of action and can be used in combination.

Urtica dioica (Stinging Nettle)

Extracts of the root of *Urtica dioica* have also been shown to be effective in the treatment of BPH. Three double-blind studies have shown it to be more effective than a placebo.[94,95] The most recent study, conducted in Iran, was a 6-month double-blind, placebo-controlled, randomized, partial crossover, comparative trial of *Urtica* with placebo in 620 patients.[96] Both groups continued the medication up to 18 months, and only those who continued the therapy had favorable results. No side effects were identified in either group.

THERAPEUTIC APPROACH

Therapeutic goals for BPH are aimed at the following goals:
Normalize prostate nutrient levels.
Restore steroid hormones to normal levels.
Inhibit excessive conversion of testosterone to DHT.
Inhibit DHT-receptor binding.
Reduce inflammation.
Eliminate excess estradiol production.
Limit promoters of the hyperplastic process (e.g., prolactin).

Severe BPH resulting in significant acute urinary retention may require catheterization for relief; a sufficiently advanced case may not respond rapidly enough to therapy and may require the short-term use of an alpha$_1$ antagonist by itself or combined with a 5-alpha-reductase medication or surgical intervention.

Lifestyle

Patients should exercise, between four to six times a week, and properly stretch the prostate/urogenital area to increase blood flow.

Diet

Initially, the diet should be higher in vegetable protein, low in carbohydrates, low in animal fats, and high in unsaturated oils. After the patient responds, a less strict whole-foods, balanced approach can be used. The patient should limit alcohol and coffee intake; avoid drug-, pesticide- and hormone-contaminated foods; and limit cholesterol-rich foods. Soy foods should be used regularly.[97]

Supplements

Zinc: 30 to 45 mg/day (picolinate preferred, maximum of 6 months; reduce dosage to 15–30 mg/day after 6 months; consider monitoring copper status in long-term therapy)
Glycine: 200 mg/day
Glutamic acid: 200 mg/day
Alanine: 200 mg/day
Vitamin D3: 2000 to 5000 IU/day

Botanicals

Liposterolic extract of saw palmetto *(S. repens)* (standardized at 85%–95% fatty acids and sterols): 160 mg two times a day
Flower pollen extract (e.g., Cernilton): 63 mg two to three times a day
P. africanum extract (14% triterpene content): 50 to 100 mg/day
U. dioica extract: 120 to 150 mg two times a day
Beta-sitosterol: 60 to 130 mg/day

Bronchitis and Pneumonia

John Nowicki, ND, and *Michael T. Murray*, ND*

OUTLINE

GENERAL CONSIDERATIONS

The respiratory system is the primary interface for inhaled compounds and the center for gas exchange in the body. Alveoli are tiny, balloon-shaped structures that allow the rapid exchange of oxygen and carbon dioxide between the lungs and pulmonary capillaries (Fig. 155.1). For gas exchange to occur, the molecules must be capable of traversing three structures: the alveolar epithelium, the interstitial space, and the capillary endothelium. If ventilation is reduced because of lung disease, or perfusion is decreased through small-vessel vasculitis, lung function is impaired. In addition, inhalation of foreign particles or infection can cause inflammation and mucus production, which may act as potential barriers to gas exchange if these secretions are found on the respiratory surfaces.

The airway distal to the larynx is normally sterile owing to several protective mechanisms, both mechanical and humoral. The mucus-covered ciliated epithelium that lines the lower respiratory tract propels sputum to the larger bronchi and trachea, evoking the cough reflex. The respiratory secretions contain substances that exert nonspecific antimicrobial actions: alpha$_1$ antitrypsin, lysozyme, and lactoferrin. At the level of the alveoli, potent defense mechanisms are present, including alveolar macrophages, a rich vasculature capable of rapidly delivering lymphocytes and granulocytes, and an efficient lymphatic drainage network.

Bronchitis is inflammation of the mucous membranes that line the bronchi, the airways that carry air to and from the lungs. Pneumonia is inflammation of lung tissue caused by a bacterial, viral, or fungal infection in one or both lungs accompanied by infiltration and inflammation of the alveoli. Both acute bronchitis and pneumonia are characterized by the development of a cough with or without the production of sputum.

Acute bronchitis often occurs during the course of an acute viral illness such as the common cold or influenza. Viruses cause about 90% of cases of acute bronchitis. Chronic bronchitis is one type of chronic obstructive pulmonary disease (COPD) and is characterized by recurrent episodes of bronchitis for at least 3 months over 2 or more consecutive years. In chronic bronchitis, innate immune cells, including macrophages and neutrophils, increase the levels of airway inflammation through the excessive secretion of cytokines and chemokines that recruit and activate other immune cells and release tissue-destructive proteases.[1] Several pulmonary toxicants have been found to be associated with chronic bronchitis, including particulate matter (i.e., air pollution), organic dusts (e.g., grain, hay, animal by-products, microorganisms), silicates, gases (e.g., nitrous oxides, methane, ozone), mycotoxins, pesticides, and metals (e.g., arsenic, cadmium,

* Previous edition contributor

lead). Cigarette smoking is the major risk factor for COPD and continues to be one of the leading causes of cigarette smoke–related death worldwide.[2]

Although pneumonia may appear in healthy individuals, it is usually seen in those who are immune compromised, particularly drug and alcohol abusers. The growing population of those with chronic lung diseases and other debilitating illnesses and a history of the use of respiratory therapy, immunosuppressive drugs, and other such technologies has contributed to the further increase of nosocomial and opportunistic pneumonias, which have high mortality rates. Acute pneumonia is the seventh-leading cause of death in the United States.[3] It is particularly dangerous in the elderly.

In healthy individuals, pneumonia most often follows an insult to the host defense mechanisms: viral infection (especially influenza), cigarette smoke and other noxious fumes, impairment of consciousness (which depresses the gag reflex, allowing aspiration), neoplasms, and hospitalization (Table 155.1). In immunocompetent, nonelderly adults, cigarette smoking is the strongest independent risk factor for invasive pneumococcal disease.[4]

DIAGNOSTIC SUMMARY

Bronchitis

The diagnosis of acute bronchitis is usually made by ruling out other causes of an acute cough—such as pneumonia, the common cold, acute asthma, or an exacerbation of chronic obstructive pulmonary disease (Fig. 155.2).

TABLE 155.1 Etiologies of Common Pneumonias

Type	Percentage
Viral (influenza)	20 (3)
Mycoplasmal	10–20
Bacterial	12
Bacterial superimposed on viral	6
Chlamydia	10
Unknown cause (Legionnaires' disease, toxic)	38

Data from Branch WT Jr. *Office practice of medicine*. Philadelphia: Saunders; 1982: 57–76.

In patients with the presumed diagnosis of acute bronchitis, viral cultures, serological assays, and sputum analyses should not be routinely performed because the responsible organism is rarely identified in clinical practice.

In patients with acute cough and sputum production suggestive of acute bronchitis, the absence of the following findings reduces the likelihood of pneumonia sufficiently to eliminate the need for a chest radiograph: (1) heart rate greater than 100 beats per minute; (2) respiratory rate greater than 24 breaths per minute; (3) oral body temperature above 38°C; and (4) chest examination findings of focal consolidation, egophony, or fremitus.

Pneumonia

The diagnosis of pneumonia is usually made by physical examination and confirmed by a chest x-ray. Common physical examination findings include:

- Rales (a bubbling or crackling sound)—Rales on one side of the chest and rales heard while the patient is lying down are strongly suggestive of pneumonia.
- Rhonchi (abnormal rumblings indicating the presence of thick fluid)
- Percussion—A dull thud instead of a healthy hollow, drum-like sound indicates certain conditions that suggest pneumonia, including:
  - Consolidation (a condition in which the lung becomes firm and inelastic)
  - Pleural effusion (fluid buildup in the space between the lungs and the surrounding lining)

Examination of the sputum suggestive of infection includes the presence of blood; a positive Gram stain; and thick, opaque, yellow-, green-, or brown-colored sputum. Sputum culture and sensitivity are not always helpful in identifying the cause of pneumonia due to contamination of the sample with throat or mouth bacteria.

A urine test (Binax NOW, Binax Inc., Scarborough, Maine) can detect *Streptococcus pneumonia* or *Legionella pneumophila* antigens within 15 minutes. It may identify up to 77% of pneumonia cases and may rule out the infection in 98% of patients who do not have *S. pneumoniae*. However, the test is not very useful in diagnosing *S. pneumoniae* as a cause of pneumonia in children because the organism is common in this population with or without pneumonia. *L. pneumophila* is the bacterium that causes Legionnaires' disease, a severe form of pneumonia.

A chest x-ray is nearly always taken to confirm a diagnosis of pneumonia, but a positive result is not necessary to make the clinical diagnosis. A positive chest x-ray for pneumonia may reveal lung infiltrates or complications of pneumonia such as pleural effusions.

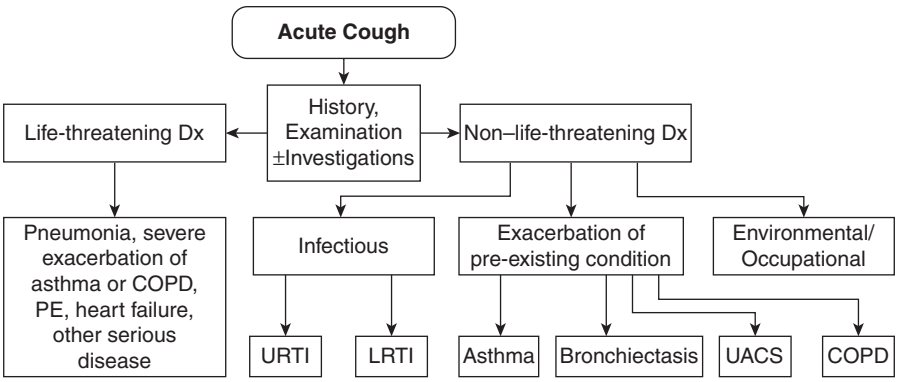

Fig. 155.2 Algorithm for assessment of acute cough in patients 15 or more years of age. *COPD,* Chronic obstructive pulmonary disease; *LRTI,* lower respiratory tract infection; *UACS,* upper airway cough syndrome; *URTI,* upper respiratory tract infection. Special Considerations With Pneumonia

There are more than 100 types of bacteria, viruses, and fungi known to cause bronchitis or pneumonia. The three most common forms of pneumonia are viral, mycoplasmal, and pneumococcal.

Viral pneumonia. Viral pneumonia is most often caused by one of several viruses: adenovirus, influenza, parainfluenza, and respiratory syncytial virus. Viral pneumonia is responsible for about 30% of pneumonia cases and may develop as a complication of viral upper respiratory infections. Immunocompromised individuals are at risk for more serious viral pneumonia. Antibiotics are of no value in treating viral pneumonia unless a secondary bacterial infection develops.

Clinical summary for viral pneumonia.

- People who are at risk for more serious viral pneumonia are often immunocompromised.
- Antibiotics are of no value in viral pneumonia.
- Symptoms of viral pneumonia often begin slowly and may not be severe at first.
- The most common symptoms of viral pneumonia are as follows:
  - Cough (some patients with pneumonia may cough up mucus or even bloody mucus)
  - Fever, which may be mild or high
  - Shaking chills
  - Shortness of breath (may only occur when on merely climbing stairs)

Mycoplasmal pneumonia. *Mycoplasma* is a genus of bacteria that lack cell walls. Mycoplasmal pneumonia is caused by the bacterium *Mycoplasma pneumoniae.* Various studies suggest that *M. pneumoniae* is responsible for 15% to 50% of all cases of pneumonia in adults and even more than those in school-age children. It is often referred to as "walking pneumonia" because symptoms tend to be milder than pneumonia caused by other organisms. *M. pneumoniae* infections are one of the most common etiologies of community-acquired pneumonia (CAP). Antibiotics are usually not necessary but may speed recovery. Effective classes of antibiotics that may be effective against *M. pneumoniae* include macrolides, quinolones, and tetracyclines.

Clinical summary for mycoplasmal pneumonia.

- Most commonly occurs in children or young adults
- Insidious onset over several days
- Nonproductive cough, minimal physical findings, temperature generally less than 102°F
- Headache and malaise are common early symptoms
- White blood cell count is normal or slightly elevated
- X-ray pattern is patchy or inhomogeneous

Pneumococcal pneumonia. Pneumococcal pneumonia (due to *S. pneumoniae*) is the most common bacterial pneumonia and the most common cause of pneumonia requiring hospitalization. Careful clinical judgment is necessary in determining the severity of the disease and the status of the patient's immune system because it is often necessary to administer antibiotics or to refer for hospitalization, especially for elderly or immunocompromised patients.

Unfortunately, most reports show an increase in resistance rates to antibiotic therapy and an increase in the proportion of highly resistant strains.[5–7] In two multinational studies, the worldwide prevalence of penicillin- and macrolide-resistant *S. pneumoniae* ranged from 18% to 22% and from 24% to 31%, respectively.[8,9] Given this information, it is important to consider natural treatments in cases resistant to antibiotics or as an adjunctive treatment to strengthen the immune response and increase the therapeutic effect.

Clinical summary for pneumococcal pneumonia.

- Pneumonia is usually preceded by upper respiratory tract infection.
- There is a sudden onset of shaking, chills, fever, and chest pain.
- Sputum is pinkish or blood-specked at first, then becomes rusty at the height of the infection, and finally becomes yellow and mucopurulent during resolution.
- Gram-positive diplococci are present in the sputum smear.
- A rapid urine test (Binax NOW) for *S. pneumoniae* antigens is positive.
- Initially, chest excursion is diminished on the involved side, breath sounds are suppressed, and fine inspiratory rales are heard.
- Later, classic signs of consolidation appear (bronchial breathing, crepitant rales, dullness).
- Leukocytosis is present.
- Radiograph shows lobar or segmental consolidation.

THERAPEUTIC CONSIDERATIONS

The basic approach in the treatment of bronchitis and pneumonia is to use an expectorant, mucolytic, and immune-supportive nutrients. Although antibiotics are of limited value in acute bronchitis, they certainly play a role in treating pneumonia.

Expectorants

Botanical expectorants have a long history of use in bronchitis and pneumonia. Because impaired cough reflexes have been thought to play a role in recurrent bronchitis and pneumonia,[10] it seems reasonable that these botanicals would be useful in helping relieve this condition and preventing recurrences. Botanical expectorants act to increase the quantity, decrease the viscosity, and promote expulsion of the secretions of the respiratory mucous membranes. Many also have antibacterial and antiviral activity. Some expectorants are also antitussives; however, *Lobelia inflata,* a commonly used expectorant, helps promote the cough reflex.[11] Therefore *Lobelia* may be more effective at clearing the lungs than other expectorants when the cough is productive. Other commonly used expectorants include *Glycyrrhiza glabra* (licorice), *Pelargonium sidoides* (South African geranium), *Hedera helix* (ivy), and wild cherry bark.

Pelargonium sidoides (South African Geranium)

P. sidoides is a medicinal plant in the geranium family that is native to South Africa. *Umckaloaba,* its common name, is a close approximation of the word in the Zulu language that means "severe cough" and is a testimony to its effect in bronchitis. The plant has an intricate grouping of thick dark-red rhizomes and tubers underground that allows it to withstand the frequent grass fires in its habitat. Extracts from the rhizomes and tubers have been shown to exert a number of effects beneficial in upper respiratory tract infections, particularly bronchitis. Most of the research has been conducted using an ethanolic extract known as EPs 7630 (also marketed as Umcka), and it is an approved drug for the treatment of acute bronchitis in Germany. It is produced using 11% ethanol to yield a drug/extract ratio of 1:8 to 10. The primary active ingredients include highly oxygenated coumarins (e.g., umckalin) and polyphenolic compounds.[12]

Research with EPs 7630 shows that it exerts a three-pronged approach in acute bronchitis: (1) it enhances immune function; (2) it has some antimicrobial effects, including antimycobacterial[13] and antiviral activity,[14] and appears to inhibit the attachment of bacteria, viruses, and perhaps other organisms to mucous membranes of the respiratory tract[12]; and (3) it acts as an expectorant.[12] These effects are mediated by the activation of macrophages (with the involvement of cytokine interferon-gamma) and the consequent increase in the production of nitric oxide (NO) (Fig. 155.3). Regarding its antiviral effects, EPs 7630, at concentrations up to 100 mcg/mL, interfered with

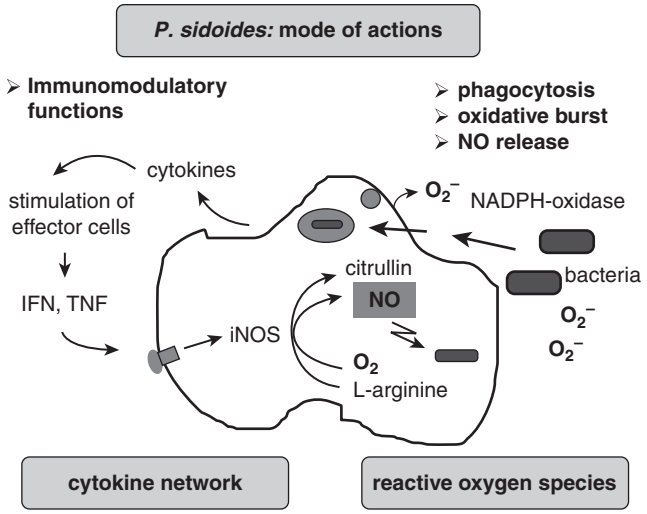

Fig. 155.3 Illustration of cytotoxic defense mechanisms of activated macrophages induced by the root extract of *Pelargonium sidoides*. (From Kolodziej H. Antimicrobial, antiviral, and immunomodulatory activity studies of *Pelargonium sidoides* 9Eps 7630) in the context of health promotion. Pharmaceuticals (Basel). 2011;4[10]:1295–1314. PubMed PMID: 27721327.)

the replication of seasonal influenza A virus strains (H1N1, H3N2), respiratory syncytial virus, human coronavirus, parainfluenza virus, and coxsackievirus but did not affect replication of highly pathogenic avian influenza A virus (H5N1), adenovirus, or rhinovirus.[14]

A 2008 meta-analysis of four randomized clinical trials (RCTs) of EPs 7630 comprising 1647 patients with acute bronchitis supports its safety and efficacy in acute bronchitis.[15] Inclusion criteria required patients to have been diagnosed with acute bronchitis within 48 hours and that they should not have received antibiotic therapy and had no obvious contraindications to therapy. The primary outcome or review of efficacy for most of the trials involved changes in the Bronchitis Severity Score (BSS), which includes the symptoms of coughing, expectoration, chest pain, dyspnea, and wheezing from baseline versus after 7 days of treatment. Included in this review was a double-blind placebo-controlled study in 468 adults with recent onset of acute bronchitis who were given either placebo or EPs 7630 for 1 week. The results showed a significantly greater improvement in symptoms in the treatment group compared with the placebo group. On average, participants who received the real treatment were able to return to work 2 days earlier than those given placebo. In another included study, 742 children with acute bronchitis showed a drop of at least 80% in the severity of component symptoms of the BSS within 2 weeks of therapy, and over 88% of the treating physicians rated the performance as "successful."

In 2018 a review of eight RCTs found that the early administration of EPs 7630 not only reduced the severity of symptoms resulting from infection of the airways but also preponed the start of symptom improvement, with a reduction of illness duration and an earlier resumption of usual activities in the affected patients.[16]

Additional studies provide evidence of the safety and efficacy of EPs 7630 in acute bronchitis as well as further insight on dosage. In one study, 406 patients with acute bronchitis were randomly assigned to one of four parallel treatment groups—10-mg EPs 7630 tablets three times a day (30-mg group), 20-mg EPs 7630 tablets three times a day (60-mg group), 30-mg EPs 7630 tablets three times a day (90-mg group), or placebo three times a day (control group)—for a treatment period of 7 days.[17] The primary endpoint was the change in the total BSS score from baseline to day 7. Between day 0 and day 7, the mean BSS score decreased by 2.7 (control group), 4.3 (30-mg group), 6.1 (60-mg group), and 6.3 (90-mg group), respectively. These results indicated that the 20-mg tablets of EPs 7630 taken three times daily constitute the optimal dose. Similar results were seen in a study of 400 children with acute bronchitis using the same dosage assessment.[18]

In another study, 200 children with acute bronchitis were randomized to receive either EPs 7630 in liquid form or placebo for 7 consecutive days.[19] Dosage was based on age: from ages 1 to 6 years, 10 drops three times daily; from ages 6 to 12 years, 20 drops three times daily; and from ages 12 to 18 years, 30 drops three times daily. From baseline to day 7, the mean BSS score improved significantly more for EPs 7630 compared with placebo (3.4 vs. 1.2 points). On day 7, secondary measures of treatment outcome were significantly better, satisfaction with treatment more pronounced, onset of effect faster, and time of bed rest shorter compared with placebo.

In clinical studies with umcka in more than 2500 adults and children, adverse events occurred on par with a placebo and mainly consisted of mild gastrointestinal complaints and skin rashes. There were no known drug interactions.[12]

Hedera helix (Ivy)

In Europe, herbal preparations containing extracts from the leaves of ivy enjoy great popularity for the relief of cough as well as asthma. In 2007 more than 80% of herbal expectorants prescribed in Germany comprised ivy extract and amounted to nearly 2 million prescriptions nationwide. Ivy leaf contains saponins that show expectorant, mucolytic, spasmolytic, bronchodilatory, and antibacterial effects. The mucolytic and expectorant action of ivy is based on indirect β_2-adrenergic effects, and this action is due to the saponins α-hederin and hederacoside C, the latter of which is metabolized to α-hederin when ingested. The indirect effect is that α-hederin inhibits the intracellular uptake of β_2 receptors and leads to an increased β_2-adrenergic response of the cell.[20]

Ivy is often used as a monopreparation, with very good safety, compliance, and efficacy ratings from postmarketing surveillance studies in both acute and chronic bronchitis.[21,22]

A randomized, placebo-controlled, double-blind trial was conducted to assess the efficacy and safety of ivy leaves cough liquid in the treatment of 181 adult patients with acute cough. [23] Participants were treated with either ivy leaves cough liquid containing EA 575 or with placebo three times a day for 1 week. The evaluation of the visual analogue scale (VAS), BSS, and Verbal Category Descriptive (VCD) score revealed that subjects treated with ivy leaves cough liquid showed statistically significant and clinically relevant reductions in cough severity, severity of symptoms associated with cough, and bronchitis compared with the placebo group. In addition, an early onset of efficacy was observed: significant reductions of cough severity were detected within 48 hours after the first intake. Treatment advantage was observed at all following visits and even 7 days after the end of treatment compared with placebo.

One double-blind study in acute bronchitis used a combination of ivy and thyme (*Thymus vulgaris*).[24] The 361 patients with acute bronchitis and 10 or more coughing fits during the day, onset of bronchial mucus production with impaired ability to cough up at a maximum of 2 days before recruitment, and a BSS score of greater than or equal to 5 points were randomly assigned to an 11-day treatment (5.4 mL three times daily) with either thyme–ivy combination syrup or placebo syrup. The mean reduction in coughing fits on days 7 to 9 relative to baseline was 68.7% under the thyme–ivy combination compared with 47.6% under the placebo. In the thyme–ivy combination group, a 50% reduction in coughing fits from baseline was

reached 2 days earlier compared with the placebo group. The symptoms of acute bronchitis (BSS) improved rapidly in both groups, but the regression of symptoms was faster, and the responder rates compared with placebo were higher at visit 2 (83.0% vs. 53.9%) and visit 3 (96.2% vs. 74.7%) under the treatment of the thyme–ivy combination. Treatment was well tolerated, with no difference in the frequency or severity of side effects between the thyme–ivy combination and placebo groups.

Mucolytics

A mucolytic agent should be used to improve the quality of the mucus secretions so as to promote expectoration. Guaifenesin (also known as glycerol guiacolate) is a derivative of a compound originally isolated from beech wood. Guaifenesin is an approved over-the-counter expectorant and mucolytic. Alternatives include N-acetylcysteine and bromelain.

N-Acetylcysteine

N-acetylcysteine (NAC) has an extensive history of use as a mucolytic in the treatment of acute and chronic lung conditions. It directly splits the sulfur linkages of mucoproteins, thereby reducing the viscosity of bronchial and lung secretions. As a result, it improves bronchial and lung function, reduces cough, and improves oxygen saturation in the blood.

NAC is helpful in all lung and respiratory tract disorders, especially chronic bronchitis and COPD. A detailed analysis of 39 trials concluded that oral NAC reduces the risk of exacerbations (severe worsening) and improves symptoms in patients with chronic bronchitis compared with placebo.

In addition to its effects as a mucolytic, NAC increases the synthesis of glutathione, a major antioxidant for the entire respiratory tract and lungs. The typical dosage for NAC is 200 mg three times daily.

Bromelain

Bromelain is a useful adjunctive therapy for bronchitis and pneumonia owing to its fibrinolytic, anti-inflammatory, and mucolytic actions as well as enhancement of antibiotic absorption.[25] Bromelain's mucolytic activity is responsible for its effectiveness in respiratory tract diseases, including pneumonia, bronchitis, and sinusitis.[26]

IMMUNE AND BARRIER FUNCTION SUPPORT

Vitamin C

In the early part of the 20th century, before the advent of effective antibiotics, many controlled and uncontrolled studies demonstrated the efficacy of large doses of vitamin C in bronchitis and pneumonia but only when they were started on the first or second day of infection.[27] If administered later, vitamin C tended only to lessen the severity of the disease. Researchers also demonstrated that in pneumonia, white blood cells take up large amounts of vitamin C.

The value of vitamin C supplementation in elderly patients with pneumonia was demonstrated in a double-blind study of 57 elderly patients hospitalized for severe acute bronchitis and pneumonia.[28] The patients were given either 200 mg/day of vitamin C or a placebo. Patients were assessed by clinical and laboratory methods (vitamin C levels in the plasma, white blood cells, and platelets; sedimentation rates; and white blood cell counts and differential). Patients receiving vitamin C demonstrated substantially increased vitamin C levels in all tissues, even in the presence of an acute respiratory infection. Using a clinical scoring system based on major symptoms of respiratory infections, results indicated that the patients receiving the vitamin C fared significantly better than those on placebo. The benefit of vitamin C was most obvious in patients with the most severe illness, many of whom had low plasma and white blood cell levels of vitamin C on admission.

Vitamin A

Vitamin A supplementation appears to be of value, especially in children with measles. This may be because of the increased rate of excretion of vitamin A found during severe infections such as pneumonia. One study evaluated 29 patients with pneumonia and sepsis and found that their mean excretion rate of vitamin A was 0.78 mmol/day. Subjects with fever excreted significantly more retinol than did those without fever. A remarkable 34% of the patients excreted more than 1.75 mmol/day of retinol, which is equivalent to 50% of the U.S. recommended daily allowance.[29]

This may be particularly important for children. A randomized, double-blind trial of 189 children with measles (average age 10 months) in South Africa evaluated the efficacy of vitamin A in reducing complications. Providing 400,000 IU (120 mg of retinyl palmitate), one-half on admission and one-half a day later, reduced the death rate by more than 50% and the duration of pneumonia, diarrhea, and hospital stay by 33%.[30]

However, another study did not show any benefit from vitamin A supplementation. The difference may be due to the lower dose (100,000 IU) used in the second study or that vitamin A was not limited to children with pneumonia as a complication of measles, a condition known to also decrease vitamin A levels.[31]

Evidence also indicates there are positive results using vitamin A concomitantly with zinc supplementation. One study of 2482 children aged 6 months to 3 years revealed that those children given initial high doses of vitamin A followed by 4 months of elemental zinc (10 mg/day for infants and 20 mg/day for children older than 1 year) brought about a reduced incidence of pneumonia, which was not seen in the group given only vitamin A.[32]

Vitamin E

Patients with influenza complicated by pneumonia experience a sharp rise in lipid peroxidation (LPO) products, especially those who are seriously ill. Administration of α-tocopherol promotes a significant decrease in the levels of lipid peroxidation products and a more benign clinical course.[33]

Garlic

Allium sativum (garlic) has exhibited a broad spectrum of antibiotic activity against both gram-positive and gram-negative bacteria.[34] In vitro studies have demonstrated garlic to be an effective antibacterial agent against *S. pneumoniae*.[35] Therefore its use should be considered in cases of antibiotic resistance or as an adjunct to antibiotic therapy. Alternatively, berberine-containing plants like *Hydrastis canadensis* (goldenseal) may be helpful.

Bottle Blowing and Salt Pipes

A Swedish study was carried out with 145 adults hospitalized for community-acquired pneumonia.[36] These patients were divided into three groups. Group A was given early mobilization with no breathing-associated exercises, group B was instructed to sit up and take 20 deep breaths 10 times daily, and group C was instructed to sit up and blow bubbles in a bottle containing 10 mL water through a plastic tube 20 times on 10 occasions daily. In this study, length of hospitalization was significantly modified in groups B and C: group A patients were hospitalized for a mean of 5.3 days, group B for 4.6 days, and group C for only 3.9 days. The number of days with fever was lowest in the bottle-blowing group. It should be noted that early mobilization itself is known to significantly decrease hospital stays in pneumonia patients.[37] Despite the positive clinical results, C-reactive protein levels, peak expiratory flow, and vital capacity were not significantly affected.

Although it is not completely understood why the patients who performed bottle blowing had shorter hospital stays, it seems that the changes in respiratory pressure associated with this exercise may be involved in providing an environment for more efficient bacterial clearance. Another study also found decreased impairment of pulmonary function and an increase in total lung capacity in patients who had undergone coronary artery bypass.[38] This modality or another similar activity, like playing a wind instrument, may well prove useful as a means of decreasing the frequency and duration of respiratory events in patients who are vulnerable to respiratory infections like pneumonia.

An alternative to bubble blowing is the use of a salt pipe. These pipes are inhaler-type devices containing tiny salt particles said to ease breathing. The practice originated in central Europe, where individuals with respiratory complaints would spend time in salt caves or mines to help relieve their breathing problems.

THERAPEUTIC APPROACH

As previously mentioned, the basic approach is to use an expectorant, mucolytic, and immune-supportive nutrients to help resolve the condition. Some general physical modalities and measures that may be helpful include the following:

- Diathermy to chest and back: 30 min/day
- Mustard poultice: once/day
- Lymphatic massage: three times a day
- Postural drainage: three times a day
- Bottle-blowing therapy: blowing bubbles in a bottle containing 10 mL water through a plastic tube 20 times on 10 occasions a day
- Getting plenty of rest
- Drinking enough liquids
- Using a humidifier

Expectorants

Choose one or more of the following:

Lobelia inflata

- Dried herb: 50 to 200 mg three times a day
- Tincture: 10 to 20 drops three times a day
- Fluid extract: 8 to 10 drops three times a day

Glycyrrhiza glabra

- Powdered root: 1 to 2 g three times a day
- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp) three times a day
- Solid (dry-powdered) extract (4:1): 250 to 500 mg three times a day

Pelargonium sidoides

Dosage recommendations for EPs 7630 or equivalent preparation are as follows:

Adults: 1.5 mL three times a day or 20-mg tablets three times a day for up to 14 days

Children: age 7 to 12 years, 20 drops (1 mL) three times a day; age 6 years or less, 10 drops (0.5 mL) three times a day

Hedera helix

Ivy leaf is available primarily in tincture and fluid extract forms and the dry powdered extract in capsules and tablets. Based on clinical studies, the daily dosages are to deliver the following equivalent to dried herbal substance: 1 to 5 years: 150 mg; 6 to 12 years: 210 mg; above 12 years: 420 mg. Therefore the typical dosage for adults and children over 12 years of age for a 4:1 dried powdered extract is 100 mg daily.

Mucolytics

Choose one or more of the following.

Guaifenesin

Adults and children 12 years of age and older: 200 to 400 mg every 4 hours. It is inadvisable to take more than 2400 mg in a 24-hour period.

The dosage for children age 6 to 11 years is 100 to 200 mg every 4 hours and no more than 1200 mg in a 24-hour period. For children age 2 to 5 years, 50 to 100 mg every 4 hours and no more than 600 mg in 24 hours. Guaifenesin is not recommended for children under 2 years of age.

N-Acetylcysteine

- 200 mg three times a day

Bromelain (1200–1800 Milk Clotting Units [MCU])

- 500 to 750 mg three times a day between meals

Supplements

- Vitamin A: 50,000 IU/day for 1 week or beta-carotene 200,000 IU/day (Note: Vitamin A should not be used in menstruating women owing to possible teratogenic effects.)
- Vitamin C: 500 mg every 2 hours
- Vitamin E: 200 IU/day
- Choose one of the following:
  Bioflavonoids (mixed citrus): 1000 mg/day
  Grape seed *(Vitis vinifera)* extract (95% procyanidolic oligomers) 150 to 300 mg/day
  Pine bark extract *(Pinus pinaster)* 150 to 300 mg/day
- Zinc: 30 mg/day

Additional Recommendations for Pneumococcal Pneumonia

Choose one or both of the following.

Garlic

A commercial garlic product should provide a daily dose equal to at least 4000 mg of fresh garlic, which translates to at least 10 mg alliin or a total allicin potential of 4000 mcg (see Chapter 50, *Allium cepa*).

Hydrastis canadensis

Given berberine's broad-spectrum antimicrobial activity and immune-enhancing effects, berberine-containing plants are an important consideration. The dosage should be based on berberine content. Because of the wide range of quality in goldenseal preparations, standardized extracts are recommended. The following dosages are intended to be given three times daily:

- Dried root or as an infusion (tea): 2 to 4 g
- Tincture (1:5): 6 to 12 mL (1.5–3 tsp)
- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp)
- Solid (powdered dry) extract (4:1 or 8%–12% alkaloid content): 250 to 500 mg

Carpal Tunnel Syndrome

Terry M. Elder, DC, and *Robert M. Martinez*, DC, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Insidious onset of numbness and tingling, primarily in the first three fingers, often bilaterally
- Pain over the palmar surface of the wrist, which may extend proximally up to the forearm or shoulder
- Pain often worse at night that may wake the patient
- Positive Tinel's and Phalen's signs
- Neurodiagnostic testing showing altered nerve conduction of the median nerve at the carpal tunnel

GENERAL CONSIDERATIONS

Carpal tunnel syndrome (CTS) involves compression of the median nerve in the carpal tunnel. Sensory impairment occurs in the first three digits and the lateral one half of the fourth digit of the hand. Pain may be felt in the palm, anterior wrist, forearm, and proximally to the shoulder. Loss of fine motor skills and strength in abduction and opposition of the thumb may develop. Atrophy of the opponens pollicis muscle may occur.[1]

Anatomy of the Carpal Tunnel

The floor and sides of the carpal tunnel are formed by the carpal bones; the roof is formed by the flexor retinaculum. The median nerve lies between the flexor retinaculum and the finger flexors and pollicus longus tendons and their tenosynovium (Fig. 156.1). The flexor retinaculum acts to prevent bowstringing of the flexor tendons. When the flexors contract, especially with the wrist in flexion, the tendons in the carpal tunnel compress the median nerve between the tenosynovium and the flexor retinaculum.

Etiology

Most cases of CTS are considered idiopathic. It should be noted that the term *idiopathic* in the medical literature does not include any mention of mechanical dysfunction or its subsequent neurological consequences. Nonspecific flexor tenosynovitis has been reported as the most common cause of CTS. The most common histological findings in CTS are noninflammatory synovial fibrosis[2] and vascular proliferation. Conceptually, it helps to think of factors that cause the canal to get smaller or factors that cause the contents to swell.

Causes of CTS include the following[3]:

- Increased volume of canal contents/edema (nonspecific flexor tenosynovitis, obesity, pregnancy, oral contraceptives)
- Trauma (fracture, repetitive wrist flexion)
- Aberrant anatomy (cysts, lipomas, arthritic spurs)
- Infections (septic arthritis, Lyme disease)
- Metabolic conditions (diabetes, hypothyroidism)
- Inflammatory conditions (rheumatoid arthritis, gout, connective tissue disease)

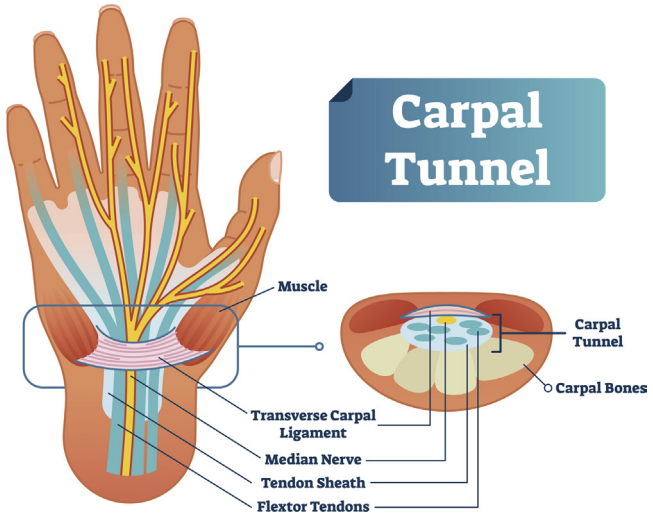

Fig. 156.1 The carpal tunnel is a passageway through which nine flexor tendons and the median nerve pass to supply function, feeling, and movement to the thumb, index, middle, and half of the ring finger. (VectorMine/iStock.com.)

* Previous edition contributor

Risk Factors and Frequency of Occurrence

CTS most often occurs after age 30, and women are affected three times as often as men.[4] Repetitive strain injury (RSI) from light-duty work as a cause of CTS is not well supported by the current literature.[5] However, a study of 501 participants, 156 of whom were diagnosed with CTS, showed the following risk factors: repetitive activities with a flexed or extended wrist, hysterectomy without oophorectomy, and menopausal women who had their last menstrual period 6 to 12 months earlier.[6] Others report an increased incidence of CTS due to pregnancy, hypothyroidism, diabetes, and recent menopause.[7]

Although uncommon, acute carpal tunnel syndrome has been reported after anticoagulation therapy.[8] Complications appear to be secondary to intraneural hemorrhage of the median nerve. In addition, features of CTS, predominantly sensory peripheral polyneuropathy, were found in 18% of individuals with lifetime low-level exposures to drifts containing organophosphate pesticides.[9]

DIAGNOSTIC CONSIDERATIONS

There is no single reference standard for diagnosis of the syndrome; a combination of symptoms, signs, and tests should be used to characterize the disorder.[1]

History

CTS typically has an insidious onset of intermittent tingling or numbness, often bilaterally, of the first three fingers and the lateral one half of the fourth digit. Symptoms are frequently worse at night, often waking the patient. As the condition progresses, loss of fine motor skills and loss of grip strength, with "things slipping from my fingers," are commonly reported. Relief is gained from shaking the affected hand or hands. Katz and Stirrat[10] developed a self-administered hand diagram test that has an 80% sensitivity and a 90% specificity for CTS. Loss of finger dexterity and atrophy are late complaints.

Physical Examination

Examination may show decreased sensation over the distribution of the median nerve to sharp, light touch and vibration (128-Hz tuning fork). Surprisingly, many patients are not able to localize the symptoms to the median distribution and feel that the whole hand is involved, which may be due to autonomic nerve involvement. Tingling in the distribution of the median nerve produced by tapping on the wrist crease (positive Tinel's sign), tingling in the distribution of the median nerve produced by holding the wrist in forced flexion for 60 to 90 seconds (Phalen's test), or tingling produced by forcibly extending the wrist and applying pressure over the median nerve (reverse Phalen's test) are signs of CTS. Early on, the perceived loss of strength may be due to loss of sensory feedback, not loss of strength. Manual muscle tests may elicit weakness of the LOAF muscles—the muscles innervated by the median nerve in the hand: **l**umbricals first and second, **o**pponens pollicus, **a**bductor pollicus, and **f**lexor pollicis brevis. As CTS advances, atrophy of the thenar eminence and weakness of the thumb abductor muscle may develop.

Other Diagnostic Tests

The carpal compression test, in which the examiner exerts direct compression with the thumbs over the patient's carpal tunnel for 30 seconds and reproduces the symptoms, was reported as having 89% sensitivity and 96% specificity when performed with the Durkan gauge.[11] Other studies have not reproduced these findings but have reported that "Tinel's, Phalen's, Reverse Phalen's, and carpal tunnel compression tests are more sensitive, as well as being specific tests for the diagnosis of tenosynovitis of the flexor muscles of the hand, rather than being specific tests for CTS."[12,13] Weakness of the thumb abductor muscle is a strong indication to order neurophysiological testing (nerve conduction studies [NCSs] and/or electromyography). In CTS, NCSs may show motor and sensory latencies across the wrist.

Magnetic resonance imaging (MRI) and high-definition ultrasound imaging can measure the dimensions of the carpal tunnel and size of the median nerve, but these tests are expensive and not needed in uncomplicated CTS.

DIFFERENTIAL DIAGNOSIS

When the clinical picture is not clear, other sources of paresthesia should be considered, such as compression of the brachial plexus in the thoracic outlet, impingement of the median nerve under the pronator teres muscle, and entrapment of either the radial or ulnar nerves. The initial presentation of complex regional pain syndrome (reflex sympathetic dystrophy) may appear to be CTS.

THERAPEUTIC CONSIDERATIONS

Many patients report spontaneous recovery from CTS. CTS from pregnancy most often is self-resolving. The waxing and waning symptoms of CTS can give a false sense of success from conservative treatment. The cost of conservative care in persistent CTS may be greater than a carpal tunnel release when performed as an office procedure.[14] In cases of progressive neurological deficit and pain, an open release procedure may be the best choice of treatment.[15] In the Netherlands, only open procedures are compensated by the state plan because of their high rate of success and low rate of complications. Unless the surgeon has good skills, the more expensive endoscopic procedures have poorer outcomes.[16]

Physical Medicine

Splinting

Initially, the most recommended treatment is 4 weeks in a neutral wrist splint worn full time, which provides better results than night-only splinting, but night-only splinting has higher compliance. Splinting is most effective when it is started within 3 months of the onset of CTS. Specialized splints have not been proven more effective than a good-quality, well-fitted, off-the-shelf splint.[17,18] Splinting should not be done after carpal tunnel release.[19]

Therapeutic Ultrasound

Ultrasound (US) therapy for 2 weeks is generally not beneficial, but one trial showed significant symptom improvement from US (1 MHz, 1.0 W/cm^2, pulse 1:4, 15 minutes per session) after 20 sessions over 7 weeks that was maintained at 6 months.[20] The cost of 15 to 20 sessions of US treatment may be prohibitive.

Yoga and Stretching

One small preliminary study described 10 yoga poses held for 30 seconds, each followed by 10 to 15 minutes of relaxation, that resulted in significantly reduced pain and increased grip strength persisting for more than 8 weeks.[21]

Tests recording carpal tunnel pressure showed a significant rise in pressure with wrist flexion, wrist extension, making a fist, holding objects, and isolated isometric flexion of a finger against resistance. But after 1 minute of specific stretching–loading exercises, intratunnel pressures dropped to normal levels and remained normal for more than 15 minutes.[22]

Manual Manipulation

Studies of manipulation show benefits from soft tissue and joint mobilization of the forearm, wrist, and hand but not from spinal manipulation alone.

A case report of manipulative treatment to the cervical spine, right elbow, and right wrist performed three times per week for 4 weeks reported improved grip strength; both Tinel's and Phalen's tests became negative, and NCSs improved.[23]

In 1993 Sucher[24] described the treatment of four patients with myofascial release and self-stretching techniques performed three to five times daily. Posttreatment comparison MRI demonstrated increased dimensions in the carpal tunnel, and NCSs showed a reduction in distal latencies or an increase in motor response amplitudes. Nerve and tendon gliding exercise produced no changes in Phalen's test, Tinel's test, or NCSs but reduced the number of reported surgeries.[25]

Low-Level Laser Therapy

One small (N = 11) randomized, double-blind, placebo-controlled crossover trial studied low-level laser therapy (LLLT) combined with microcurrent transcutaneous electrical nerve stimulation (TENS).[26] Eleven patients with mild to moderate symptoms of CTS who had failed to improve with standard medical or surgical treatment were treated with real or sham local applications of LLLT and microcurrent for 3 to 4 weeks. After treatment, there was a significant improvement in scores on the McGill Pain Questionnaire, sensory and motor latency scores with electromyography (EMG), and Tinel's and Phalen's tests; these improvements were not found after sham treatment.

Hydrotherapy

An anecdotal naturopathic treatment to relieve CTS pain is immersing the wrist and hand in hot water for 3 minutes, then immersing in cold water for 30 seconds, repeated three to five times once or twice a day. It is important to ensure that the hot-water immersion is deeper than the cold.

Acupuncture

A randomized controlled study comparing prednisolone (20 mg for 2 weeks, then 10 mg for 2 weeks) to eight sessions of acupuncture over 4 weeks showed acupuncture to be effective in symptom control, but acupuncture decreased distal motor latency, and prednisolone did not.[27]

One acupuncture study with the puncture of PC-7 and PC-6 on the affected side demonstrated a positive response in 35 of 36 patients (14 of whom were previously treated unsuccessfully with surgery).[28]

Ergonomics

There is insufficient epidemiological evidence that computer work causes CTS.[4] Other studies have not demonstrated that work practices (other than high-force work, like that done by meatpackers) have a direct influence on CTS.[29]

Nutrition

Vitamin B Supplementation

The increased incidence of CTS since its initial description by Phalen in 1950 parallels the increased presence of pyridoxine antimetabolites (hydrazine dyes, isoniazid, hydralazine, dopamine, penicillamine, and oral contraceptives) in the environment as well as the intake of excessive protein.

Ellis and coworkers[30–32] demonstrated the efficacy of vitamin B_6 supplementation for CTS with 50 mg initially and increased to 200 to 300 mg. An even greater effect was seen when vitamins B_6 and B_2 were given together, possibly as a result of riboflavin-dependent enzymes, which convert pyridoxine to pyridoxal 5′-phosphate. Two randomized controlled trials suggest that vitamin B_6 is no better than placebo; however, given its safety profile, vitamin B_6 can be considered in the treatment of CTS.[33,34] Failure of vitamin B_6 supplementation to relieve CTS could be due to a lack of riboflavin or a genetic defect that does not allow sufficient levels of vitamin B_6 to be converted to the active P5P form.

Medications

Steroid injection proximal to the carpal tunnel provides relief for up to 8 weeks, but 50% of those receiving the steroid injection require surgery within a year. Oral prednisolone (20 mg for 2 weeks, then 10 mg for 2 weeks) provides short-term relief over 8 weeks. Nonsteroidal anti-inflammatory drugs and diuretics were found to provide no reduction in symptoms and should *not* be used because of their potential side effects.[35]

No studies were found evaluating the use of the "natural" anti-inflammatory medications (bromelain, curcumin, *Boswellia,* various oils). Remedies that address noninflammatory synovial fibrosis[2] and vascular proliferation would theoretically be beneficial.

Surgery

Surgery for CTS should not be considered before 6 months of more conservative treatment, but "In general, the management is surgery for persistent (not resolving after 1 year) or deteriorating (worsening clinically plus or minus deterioration on nerve conduction studies) CTS." Surgery should not be delayed beyond 3 years. Open carpal tunnel release surgery is one of the most commonly performed outpatient surgeries and is less expensive than endoscopic procedures. The abstract in the review of the Cochrane Library[36] reports no difference in long-term results between the procedures, but pain is reduced during the first 2 weeks after endoscopic surgery compared with open procedures. Surgery with early mobilization,[19] surgery with oral homeopathic *Arnica* and topical *Arnica* ointment,[37] and surgery with controlled cold therapy[38] all showed benefits over surgery alone.

THERAPEUTIC APPROACH FOR MILD/MODERATE IDIOPATHIC CARPAL TUNNEL SYNDROME

Approximately 50% of patients will improve spontaneously. Identify and reduce causes of strain and vibration, and prevent repeated trauma.

Physical Medicine

Regular wrist stretching, yoga, and exercises. The key to these exercises is performing them several times daily and "breaking up" activities that are strenuous and repetitive. Nerve/tendon gliding may be helpful.

Splint. For moderate persistent CTS, full-time splinting in neutral is recommended. Splinting is less effective if it is not started within 3 months of onset or if the splints are only worn at night.

Acupuncture. PC-7 and PC-6 on the affected side should be needled. Laser acupuncture can be considered.

Manipulation/deep-tissue mobilization. Manipulation for CTS can be very effective if a comprehensive manipulation protocol is utilized. In the short term, manipulation of the distal radial ulnar expansion/gapping and the "opponens roll maneuver" (Kaltenborn) to increase the length of the transverse carpal ligament are very effective. Some musculoskeletal etiological factors must be considered to understand the effectiveness of manipulation procedures.

The distal radioulnar joint is functionally a homologue of the ankle mortice joint. During the late midstance phase of gait with full dorsiflexion, the tibia and the fibula have to separate due to the width of the talus. A joint restriction that prevents this from happening causes an adaptation that leads to looser (hypermobile) tarsal joints and a pronated foot. The same process occurs in the wrist. During dorsiflexion of the wrist, the radius and ulna must also separate to accommodate the shape of the carpals.

A joint restriction that does not allow for this separation or gapping also leads to hypermobile carpal joints that are the support structure for the carpal tunnel. The mechanical support for the carpal tunnel fails, leading to the collapse of the roof of the carpal tunnel, which is the transverse carpal ligament. The transverse carpal ligament mechanically rests on the median nerve, which leads to the symptoms of CTS. It should also be noted that if atrophy is prevalent during CTS examination, there is a high probability that the median nerve axon distal to the tunnel has undergone Wallerian degeneration (the axon has died). Any treatment modality at this point requires that the axon must regrow to reinnervate the distal structures. This regrowth process could take a minimum of 2 to 3 months, and the first sensation that would return would be pain. This, I believe, is why many research studies fail to show significant effectiveness in the treatment of CTS.

In addition to the previously mentioned treatment protocols, a comprehensive treatment must also include the entire upper extremity, the upper thoracic spine, and the lower cervical spine. In her editorial, a second commentary on "Multifocal Neuropathy: Expanding the Scope of Double Crush Syndrome," Catherine Curtin, MD, uses a new term called *multifocal neuropathy*. The double-crush theory as theorized by Upton and McComas in *Lancet* in 1973 stated that a peripheral nerve may only develop symptomology if there is more than one compression site along the length of the entire nerve. Curtin stated that treatment should include metabolic, postural, and secondary entrapments for effective treatment to occur. One omission that has led to much controversy and misunderstanding concerning the double-crush theory or the new term *multifocal neuropathy* is mechanical traction of the nerve. All studies and articles have focused on entrapment or compression and fail to recognize the effect of mechanical traction on nervous tissue, which could cause continuous firing of pain fibers. As noted in Curtin's editorial, postural changes should be a part of any CTS treatment.

Manipulation and postural exercise would be the best treatment to effect this change. A review of the *National University of Health Sciences (NUHS) Postgraduate Neuroanatomy Study Guide* (National University of Health Sciences, Lombard, IL), reveals that the C5, C6, and C7 nerve roots; first rib; scalenes; pectoralis minor; three different sites at the elbow; and the carpal tunnel (10 sites) can all be affected by compression, entrapment, or mechanical nerve traction. Therefore effective carpal treatment should include all the tissues and joints along the path of the median nerve.

Contrast hydrotherapy. Immerse for 3 minutes in hot water followed by a 30-second immersion in cold water three to five times daily. Heat alone is contraindicated.

Diet

All sources of hydrazines should be avoided.

All foods containing yellow dyes should be avoided.

Daily protein intake should be limited to a maximum of 0.75 g/kg body weight.

Supplements

- Pyridoxine: 50 to 200 mg/day: administer in divided dosages of 25 to 50 mg two to four times a day
- If no response to pyridoxine, pyridoxal 5′-phosphate: 10 mg two to four times a day
- Riboflavin: 5 to 10 mg/day

Celiac Disease

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- A chronic intestinal malabsorption disorder caused by an intolerance to gluten
- Bulky, pale, frothy, foul-smelling, greasy stools with increased fecal fat
- Weight loss and signs of multiple vitamin and mineral deficiencies
- Increased levels of serum antiendomysium and/or transglutaminase antibodies
- Diagnosis confirmed by jejunal biopsy

GENERAL CONSIDERATIONS

Celiac disease, also known as nontropical sprue, gluten-sensitive enteropathy, or celiac sprue, is characterized by malabsorption and an abnormal small intestinal structure that reverts to normal on the removal of dietary gluten. The protein gluten and its polypeptide derivative gliadin are found primarily in wheat, barley, and rye grains. Symptoms most commonly appear during the first 3 years of life, after cereals are introduced into the diet. A second peak incidence occurs during the third decade, and although celiac disease is often thought of as a disease diagnosed early in life, more diagnoses are made in adulthood than in childhood.[1] It is not unusual for individuals to experience symptoms for 4.5 to 9 years before a confirmed diagnosis. A screening of more than 13,000 individuals found that those with digestive complaints such as constipation, diarrhea, and/or abdominal pain had a 1:56 chance of having celiac disease, a risk increase of more than twofold that of the general population.[2]

The prevalence of celiac disease has increased dramatically, and this is not solely because of increased detection. Until a few decades ago, celiac disease was believed to be relatively rare (approximately 1 case in 5000 within the United States). Now, however, celiac disease is thought to affect approximately 1% of most populations and approximately 3 million people in the United States. Gluten sensitivity has become quite common, and the incidence continues to increase. Interestingly, the amount of wheat consumed today is far less than the amount consumed in the 19th century. The average American consumed 225 pounds of wheat flour per person in 1880 versus 132.5 pounds of wheat flour per person in 2011.[3] However, celiac disease remains largely undiagnosed.[4,5] Undetected celiac disease carries with it increased mortality, indicating that widespread screening may be economically justified.

Chemistry of Grain Proteins

Gluten, a major component of the wheat endosperm, is composed of gliadins and glutenins. Only the gliadin portion has been demonstrated to activate celiac disease. In rye, barley, and oats, the proteins that appear to activate the disease are termed secalins, hordeins, and avenins, respectively, and prolamines collectively. Cereal grains belong to the family *Gramineae.* The closer a grain's taxonomic relationship to wheat, the greater is its ability to activate celiac disease. Rice and corn, two grains that do not appear to activate celiac disease, are further removed taxonomically from wheat. The taxonomic relationship of the grains is shown in Fig. 157.1.

Gliadins are single polypeptide chains that range in molecular weight from 30,000 to 75,000, with a high glutamine and proline content. There are at least 50 toxic epitopes (i.e., antigenic determinants) in gluten peptides exerting cytotoxic, immunomodulatory, and gut-permeating activities. Gliadins have been divided into four major electrophoretic fractions: alpha-, beta-, gamma-, and omega-gliadin, and are distinguished based on their amino acid sequences. Alpha-gliadin is believed to be the fraction most capable of activating celiac disease, although beta- and gamma-gliadin are also capable of doing so. Omega-gliadin does not appear to activate the disease, although it has the highest content of glutamine and proline. As seen in Fig. 157.2, each of the various peptide sequences in α-gliadin has different toxic activities: cytotoxic, immunomodulatory, zonulin release, and interleukin (IL)-8 release. Gliadin that has been subjected to complete hydrolysis does not activate celiac disease in susceptible individuals.[6]

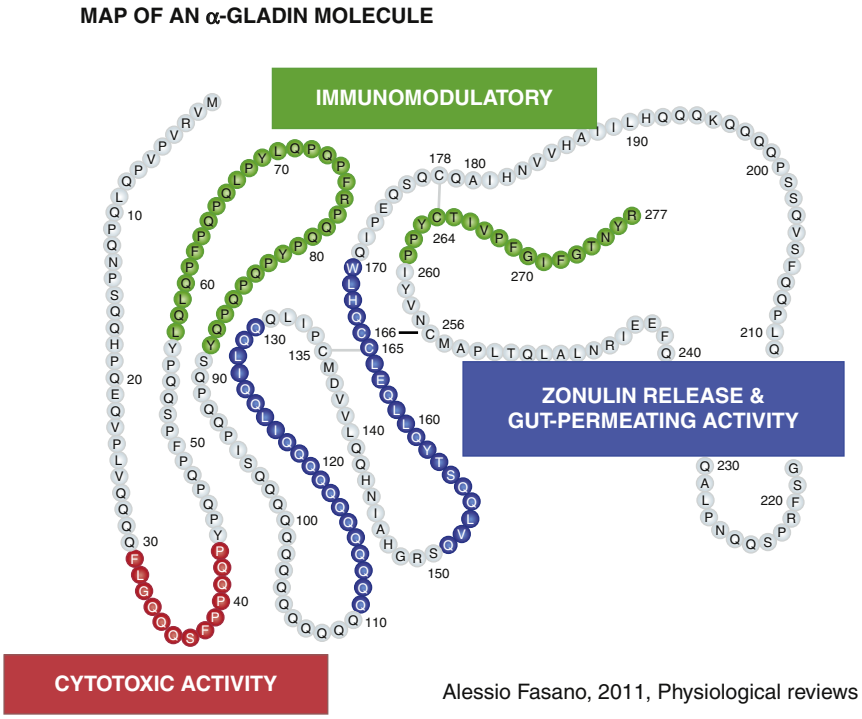

Fig. 157.2 Map of a molecule.

Zonulin

Zonulin is a protein modulator of intercellular tight junctions. It has been shown to induce a significant and reversible increase in gastroduodenal and small intestinal permeability and is involved in tolerance/immune response balance. The hybridization of wheat to dramatically increase gluten (gliadin) content and its overconsumption, multiple times a day, every day, in the typical diet, chronically disrupts this tolerance/immune response balance. Zonulin release is stimulated by contact with gliadin (alpha-gliadin is the most effective). The enterocytes that release zonulin occur in the jejunum and distal ileum but not in the colon. When exposed to gliadin, zonulin receptor-positive IEC6 and Caco2 cells release zonulin, leading to the rearrangement of the cell cytoskeleton, loss of occluding-ZO1 protein–protein interaction, and increased intestinal permeability to macromolecules.[7] Chemokine receptor CXCR3 is the receptor for specific gliadin peptides that cause zonulin release and a subsequent increase in intestinal permeability (Fig. 157.3). In vitro research with chemokine receptor CXCR3 transfectants found that several peptides, especially 33-mer, from gliadin bind to the receptor. Zonulin and CXCR3 are overexpressed in the intestinal mucosa of patients with celiac disease and autoimmune disease.

Human zonulin was discovered to be prehaptoglobin-2 (pre-HP2) and was known in earlier research as an "inactive" precursor for HP2. Haptoglobin, identified as a marker of inflammation several decades ago, is an α2–globulin found in human plasma at a concentration of 82 to 236 mg/dL. It is an acute-phase plasma protein whose primary role appears to be to bind the free hemoglobin released when erythrocytes are damaged, thus decreasing the oxidative damage of the freed iron. It is composed of four polypeptide chains: two α chains and two β chains connected by disulfide bridges. Human haptoglobin occurs primarily as three major phenotypes: HP1-1, HP2-1, and HP2-2. The phenotypes are differentiated by the presence of an α1 chain (HP1-1) or an α2 chain (HP2-2) with a combination of α1 and α2 chains distinguishing HP2-1.

Gliadin causes the release of zonulin in the 80% of the population with HP2. Although HP1-1 has a much lower chance of an immunological reaction, the probability is still not zero. There is growing recognition of the nonimmunological reaction to wheat, which is identified as nonceliac gluten sensitivity (NCGS). Table 157.1 provides an estimate of the percentage of the North American population in each haptoglobin category, along with clinical responses and clinical

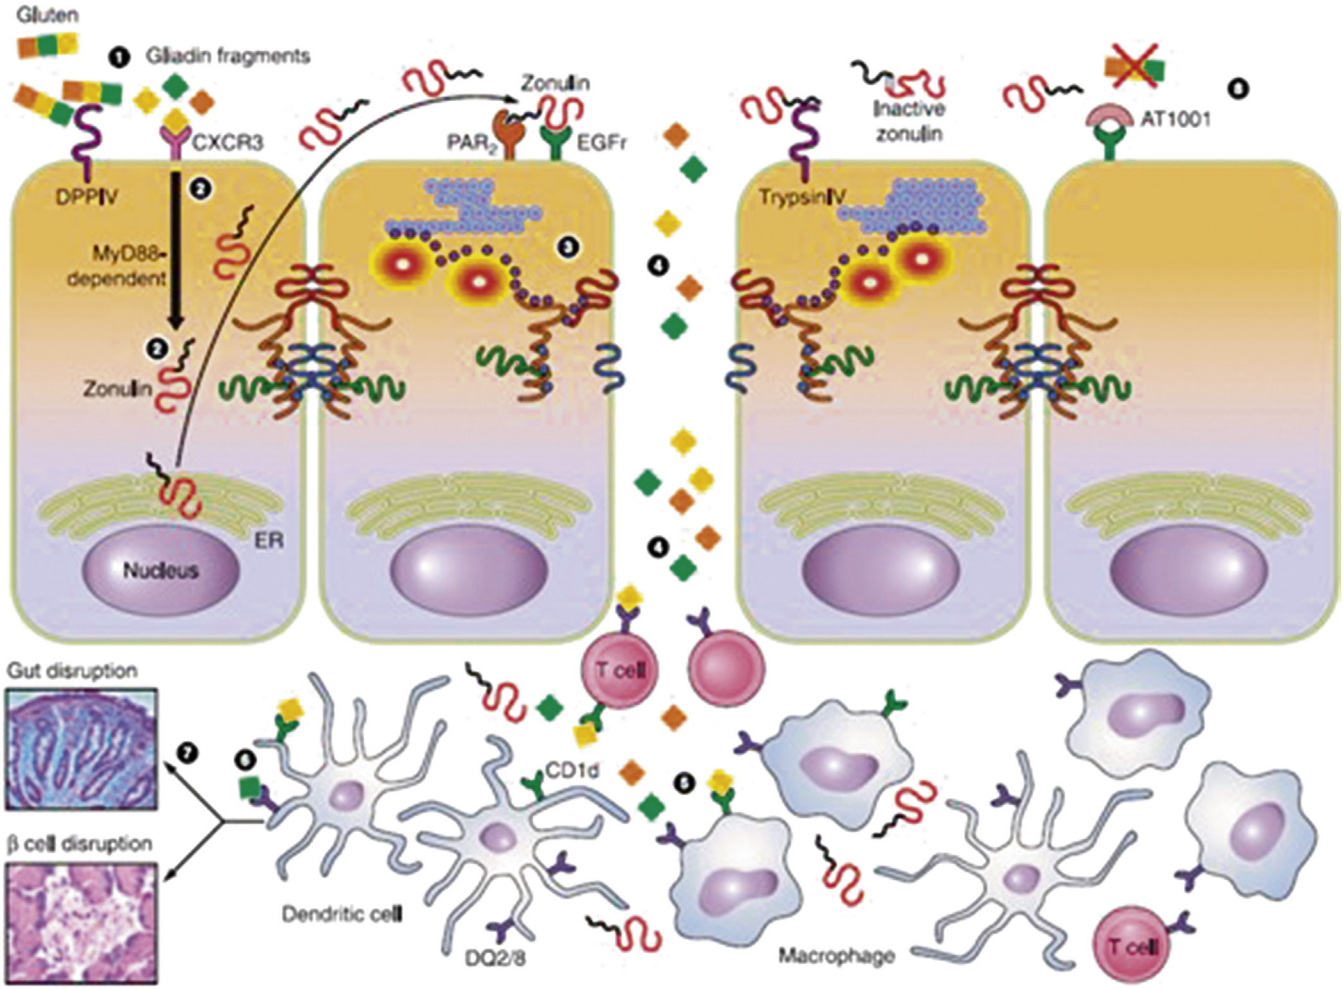

Fig. 157.3 Gliadin release of zonulin to open tight junctions and activate immune system. (From Lammers KM, Lu R, Brownley J, et al. Gliadin induces an increase in intestinal permeability and zonulin release by binding to the chemokine receptor CXCR3. *Gastroent*. 2008 Jul;135[1]:194–204.)

TABLE 157.1 Summary of Clinical Responses to Wheat and Clinical Recommendations

Response to Wheat	% Pop.	Characteristics	Intervention
Safe	34%	HP1-1; no grain antibodies	None needed
Inconsistent, dose-dependent response (some research is labeling severe form nonceliac gluten sensitivity [NCGS])	43%	HP2-1; low to elevated blood zonulin	Limit wheat, rye, barley; optimize protein digestion; reseed with *Bifidobacteria* and other healthy gut bacteria.
Immune reactions to grains	15%	Antibodies to some grain proteins	Avoid all grains.
Celiac disease	3%	HP2-1 or HP2-2; elevated antibodies to gliadin; HLA-DQ2 or DQ8	Strictly avoid wheat, rye, barley; may need to avoid other grains as well.
Autoimmune disease	5%	HP2-1 or HP2-2; elevated antiself antibodies	Strictly avoid all allergens.

HLA, Human leukocyte antigen.

recommendations. Although this may be inconsistent with "official" numbers, considering the significant underdiagnosis of these conditions, the research suggests this is an accurate reflection of actual occurrence.

Pathogenesis

Celiac disease appears to have a genetic etiology because it is associated with specific human leukocyte antigen (HLA) molecules—HLA-DQ2 in 95% of patients and DQ8 in the remainder. These gene loci are believed to be linked to the immunological recognition of antigens and specific T-cell–regulated immune responses.

Various hypotheses have been proposed to explain the pathogenesis of celiac disease. Currently, the most likely relates to abnormalities in the immune response rather than some "toxic" property of gliadin. Sensitization to gliadin occurs both in humoral and cell-mediated immunity, and it appears that T-cell dysfunction is the main factor responsible for the enteropathy.[6] A number of circulating antibodies that are specific for celiac disease, particularly antiendomysial antibody

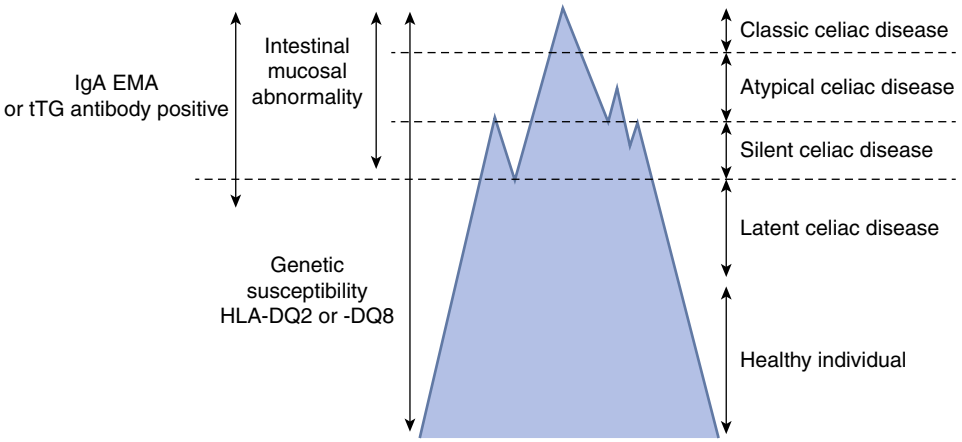

Fig. 157.4 The spectrum of celiac disease. (Feldman M, Friedman LS, Brandt LJ. Sleisenger and Fordtran's gastrointestinal and liver disease e-book: pathophysiology, diagnosis, management. 2010. https://clinicalgate.com/celiac-disease-and-refractory-celiac-disease/#f0010.)

(AEA), have been identified. These serological markers have been used successfully to screen patients and to estimate the true prevalence of celiac disease in the general population. The discovery that tissue transglutaminase (tTG) is the autoantigen for AEA led to the development of an improved enzyme-linked assay using recombinant tTG, which has been shown to be highly sensitive and specific for celiac disease. Tissue transglutaminase is a ubiquitous, predominantly cytoplasmic enzyme that can be released extracellularly, particularly in response to tissue wounding and stress. The observation that anti-tTG antibody titers fall and can become undetectable during a gluten-free diet suggests that tTG–gliadin complexes stimulate gluten-specific T cells to induce anti-tTG antibody production. T and B cells likely recognize different parts of this antigen complex, with T cells reacting to the smaller gliadin peptides and B cells responding to the larger tTG enzyme.[6]

Interestingly, breastfeeding appears to have a prophylactic effect, and breastfed babies have a decreased risk of developing celiac disease.[8,9] The reduced risk of celiac disease was even more pronounced in infants who continued to be breastfed after dietary gluten was introduced. Not surprisingly, the risk of celiac disease was greater when gluten was introduced in the diet in large amounts than when introduced in small or medium amounts. The early introduction of cow's milk is also believed to be a major etiological factor.[10] Research in the past few years has clearly indicated that breastfeeding and delayed administration of cow's milk and cereal grains are primary preventive steps that can greatly reduce the risk of the development of celiac disease.

CLINICAL ASPECTS

The histological lesions of celiac disease are often indistinguishable from changes caused by tropical sprue, food allergy, diffuse intestinal lymphoma, and viral gastroenteritis. Furthermore, celiac disease often leads to the development of multiple food allergies; disaccharidase deficiency, causing lactose intolerance; and increased intestinal permeability.[11] Improving nutritional status, even something as simple as taking a multiple B vitamin, appears to produce significant improvement in quality of life in patients with celiac disease. In one double-blind study, 65 patients with celiac disease who were on a strict gluten-free diet for several years were randomized to a daily dose of 0.8 mg folic acid, 0.5 mg cyanocobalamin, and 3 mg pyridoxine or placebo for 6 months.[12] After vitamin supplementation, homocysteine levels dropped a median of 34%, accompanied by a significant improvement in well-being, notably anxiety and depressed mood.

Celiac disease exhibits a range of clinical presentations (Fig. 157.4). Atypical celiac disease involves gluten-sensitive enteropathy that manifests only as extraintestinal signs and symptoms such as short stature, anemia, and osteoporosis. Silent celiac disease also involves fully expressed gluten enteropathy, but patients are asymptomatic, and the diagnosis is typically discovered after serological testing. A combination of serological, genetic, and histological data has led to the identification of latent celiac disease (normal-villus architecture on a gluten-containing diet but have had or will have gluten-sensitive villus atrophy) as well as potential celiac disease (elevated gluten antibodies but negative intestinal biopsy).

Associated Conditions

Perhaps the most significant condition associated with celiac disease is an early death. A landmark study looked at almost 30,000 patients between 1969 and 2008 and examined deaths in four groups: those with full-blown celiac disease, those with inflammation of the intestine but not full-blown celiac disease, those with latent celiac disease or gluten sensitivity, and a control group with no evidence of celiac disease or gluten sensitivity.[13] The findings were significant: compared with the control group, there was a 39% increased risk of death in those with celiac disease, 72% increased risk in those with gut inflammation related to gluten, and 35% increased risk in those with gluten sensitivity but no celiac disease.

A review article lists 55 health conditions linked to celiac disease and gluten sensitivity, including irritable bowel disease, inflammatory bowel disease, anemia, migraines, epilepsy, fatigue, canker sores, osteoporosis, rheumatoid arthritis, lupus, multiple sclerosis, and almost all other autoimmune diseases.[14] Thyroid abnormalities, insulin-dependent diabetes mellitus, psychiatric disturbances (including schizophrenia), dermatitis herpetiformis, and urticaria have also been linked to gluten intolerance.[1] A more ominous association is the increased risk for malignant neoplasms seen in celiac patients, especially for non-Hodgkin's lymphoma.[15] The hypothesis that gluten is a contributing factor in some cases of schizophrenia is substantiated by epidemiological, clinical, and experimental studies.[16–19] Pepsin hydrolysates of wheat gluten have demonstrated opioid activity. This activity is believed to be the factor responsible for the association between wheat consumption and schizophrenia. Gluten sensitivity has also been weakly linked to mood scores, cognitive impairment, and autism.[20–22]

The effects of gut inflammation associated with altered permeability are not restricted to the digestive system. For example, animal models of type 1 diabetes have shown that intestinal permeability, with

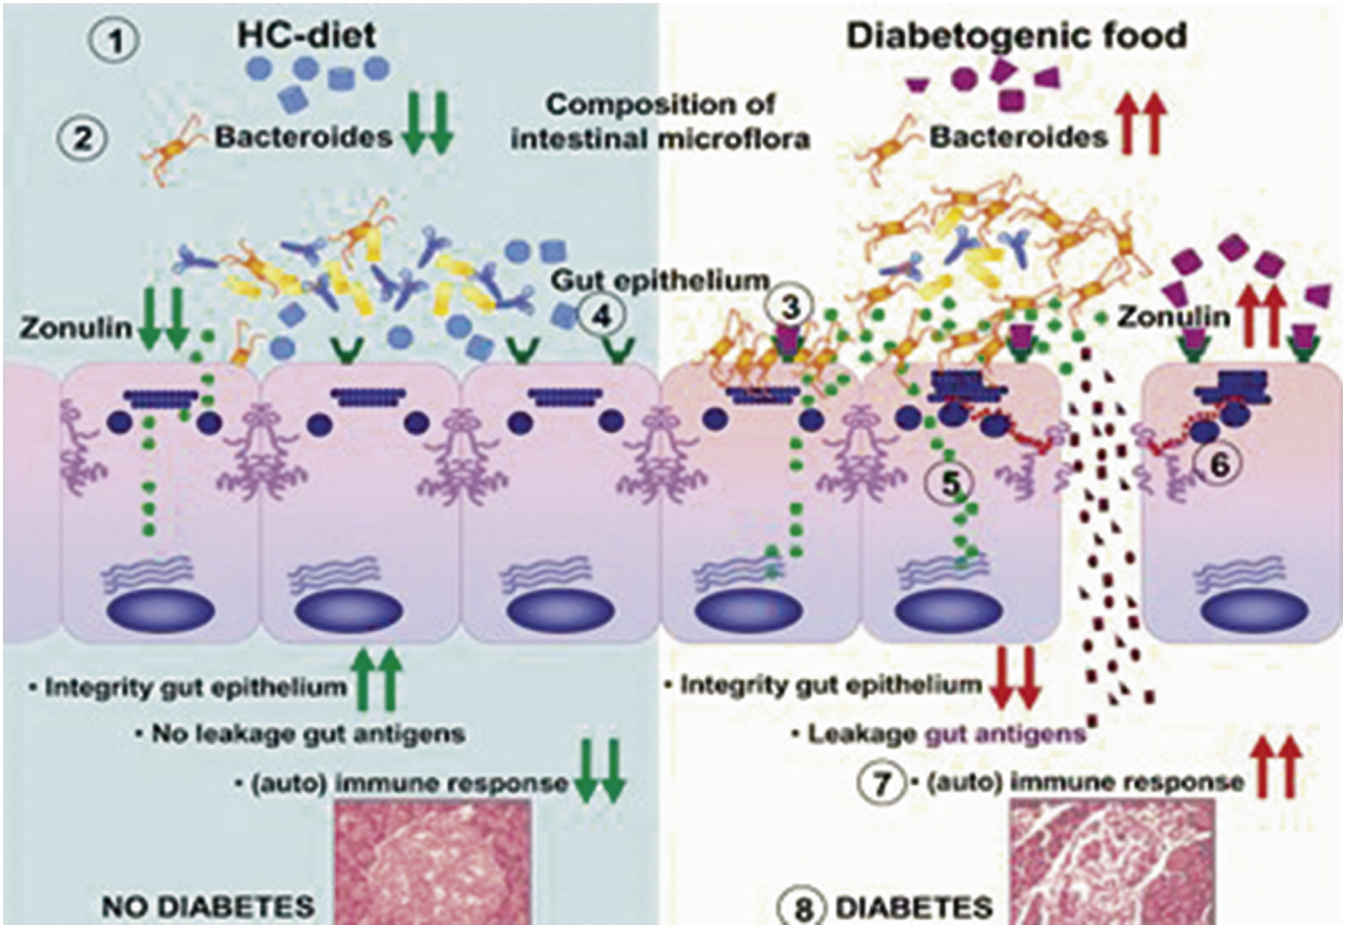

Fig. 157.5 Diet affects the composition of the intestinal microflora, and gluten interaction influences diabetes development. (From Visser J, Rozing J, Sapone A, et al. Tight junctions, intestinal permeability, and autoimmunity: celiac disease and type 1 diabetes paradigms. *Ann NY Acad Sci.* 2009 May;1165:195–205.)

resultant inflammation, plays a role in the autoimmune destruction of pancreatic islet cells. There appears to be a link between antibodies to Glo-3a (a wheat-related protein), zonulin up-regulation, and islet cell autoimmunity in children at increased risk for type 1 diabetes.[23] In individuals who went on to develop type 1 diabetes, elevated serum zonulin was detected in 70% of subjects during the pre–type 1 diabetes phase and preceded the onset of disease by 3.5 ± 0.9 years.[24] Increased lactulose permeability (with normal mannitol) appears to precede the detectable clinical onset of disease, suggesting that the small intestine participates in the pathogenesis of the disease. The composition of the gut microbiota combined with gluten intake affects intestinal integrity, which affects the development of diabetes (Fig. 157.5).

Zonulin is also associated with the development and/or progression of chronic inflammatory lung and neurological disease. The blockade of zonulin reduces the severity of acute lung injury by reducing capillary leak, diminishing the accumulation of polymorphonuclear leukocytes (PMNs) in the interstitial and alveolar components, and attenuating levels of proinflammatory mediators.[25] There is some evidence that the expression of zonulin correlates with the aggressiveness of gliomas and may indicate the degree of disturbance of the blood-brain barrier and the walls of the blood vessels.[26]

DIAGNOSIS

As an initial screening for celiac disease, serological tests are an excellent starting point, and they may be followed by a biopsy of the small intestine for a definitive diagnosis. Before the introduction of highly sensitive and specific serological markers, endoscopy with jejunal biopsy was the definitive diagnostic procedure. To fully understand a patient's response to gluten, the key laboratory tests are haptoglobin type, serum zonulin, HLA type, antibodies to wheat proteins, and antiself antibodies. Of these serological markers, the test for human antitissue transglutaminase antibodies (IgA anti-tTG) is the most widely used, primarily owing to a lower cost compared with antiendomysium (IgA EMA) and a greater sensitivity compared with antigliadin antibodies (AGAs). IgA EMA can detect celiac disease with a sensitivity and specificity of 90% and 99%, respectively. Anti-tTG also has a high sensitivity (99%) and specificity (>90%) for identifying celiac disease. An equivocal result on tTG testing should be followed by IgA EMA. With IgA EMA testing, it is recommended that a total serum IgA level be checked in parallel because celiac patients with IgA deficiency may be unable to produce the antibodies on which these tests depend, leading to a false-negative result.

Genetic tests for HLA-DQ2 and DQ8 have poor positive predictive value but are considered up to 100% sensitive and are therefore able to assist in ruling out celiac disease. The progression of an immunological reaction to gliadin to autoimmune disease appears to be dependent on several factors, especially HLA class.

Endoscopy/gastroscopy and biopsy should still be performed if clinically warranted.

THERAPEUTIC CONSIDERATIONS

Diet

Once the diagnosis has been established, a gluten-free diet is indicated. This diet should not contain any wheat, rye, barley, triticale, or oats. Species falling in the genus *Triticum* are almost certain to be harmful to gliadin-sensitive patients. Although the hybridization of wheat to higher concentrations of gluten has clearly aggravated the problem, this does not mean that so-called "ancient" wheats are safe for those who react to gliadin. *Triticum spelta* (spelt or spelta), *Triticum polonicum* (Polish wheat or kamut), and *Triticum monococcum* (einkorn or small spelt) still contain gliadin and must also be avoided. They may be acceptable in modest dosages for those who are wheat intolerant but do not react immunologically. Buckwheat and millet are often excluded as well. Although buckwheat is not in the grass family, and millet appears to be more closely related to rice and corn, buckwheat and millet contain prolamines with similar antigenic activity to the alpha-gliadin of wheat.

In addition, other foods should be rotated, and milk and milk products should be eliminated until the patient's intestinal structure and function return to normal.

Patient Response

Usually, clinical improvement will be apparent within a few days or weeks (30% respond within 3 days, another 50% within 1 month, and 10% within another month). However, 10% of patients respond only after 24 to 36 months of gluten avoidance.[1]

If the patient does not appear to respond, the following should be considered:

- The diagnosis is incorrect.
- The patient is not adhering to the diet or is being exposed to hidden sources of gliadin.
- There is an associated disease or complication, such as zinc deficiency.

The U.S. Food and Drug Administration (FDA) has strict criteria and labeling requirements for food manufacturers to label a food "gluten-free." However, even with this assurance, it seems that many people on a gluten-free diet are ingesting enough gluten in their diets to cause issues. Eating as little as 10 mg of gluten is enough to cause issues in some especially sensitive individuals, whereas most patients with celiac disease can tolerate up to 100 mg per day. A detailed analysis to determine the amount of gluten consumed by measuring the level of gluten in the stool and urine in people with celiac disease and those without celiac disease who were following a gluten-free diet.[27] The results showed that the average inadvertent exposure to gluten by people with celiac disease on a gluten-free diet was estimated to be between 150 and 400 mg/d using the stool test and between 300 and 400 mg/d using the urine test. These results indicate that patients with celiac disease, as well as those with gluten sensitivity or intolerance, should be on a gluten-digesting enzyme (discussed later in the chapter) as well as a gluten-free diet. Clinical trials with gluten-digesting enzymes combined with a gluten-free diet show a statistically significant, dose-dependent reduction in the severity and frequency of symptoms as well as improved intestinal biopsy results in patients with mild to moderate celiac disease.

Multivitamin/multimineral supplementation in patients with celiac disease appears indicated. In addition to treating any underlying deficiency, supplementation provides the necessary cofactors for growth and repair. OCTN2, the specific carnitine receptor, has been found in intestinal cells and is decreased in patients with celiac disease compared with normal subjects. A randomized, double-blind-versus-placebo parallel study evaluated the effect of L-carnitine treatment on fatigue in adult patients with celiac disease.[28] The results showed that fatigue was significantly reduced in the L-carnitine group, and because L-carnitine is involved in muscle energy production, its decreased absorption due to OCTN2 reduction might explain muscular symptoms in patients with celiac disease. Other potential nutritional deficiencies include iron, zinc, calcium, copper, fat-soluble vitamins, and dietary fiber. Celiac disease is refractive to dietary therapy if an underlying zinc deficiency is present.[29]

SUPPLEMENTS

Pancreatic Enzymes

Low fecal elastase-1, a marker for pancreatic insufficiency, is common among individuals with celiac disease. Even when following a gluten-free diet, celiac patients with chronic diarrhea are likely to have low fecal elastase.

The effect of pancreatic enzyme substitution therapy in the 2 months after the initial diagnosis of celiac disease (gluten enteropathy) was investigated in one double-blind study. The study sought to clarify the benefit of pancreatic enzyme therapy because previous studies had shown pancreatic insufficiency in 8% to 30% of patients with celiac disease. In this study, patients followed a gluten-free diet, the standard treatment for celiac disease, and received either two capsules of pancreatic enzymes with each meal (6–10 capsules a day with each capsule containing lipase 5000 IU, amylase 2900 IU, and protease 330 IU) or two placebo capsules with meals. Complete nutritional and anthropomorphic evaluations were conducted at days 0, 30, and 60. Results indicated that pancreatic enzyme supplementation enhances the clinical benefit of a gluten-free diet during the first 30 days but does not provide any greater benefit than the placebo after 60 days. These results support the use of pancreatic enzyme preparations in the first 30 days after a diagnosis of celiac disease[30] (see Chapter 100 for a complete discussion).

Alternatively, a superior choice to pancreatic enzymes is enzyme preparations containing glutenases. A mixture of two gluten-specific recombinant proteases (Latiglutenase) that degrades gluten proteins into small, physiologically irrelevant fragments has been shown to mitigate gluten-induced intestinal mucosal injury as well as effect symptomatic improvements in clinical trials, and it is particularly effective in patients with celiac disease who remain seropositive despite a gluten-free diet; however, this preparation is not currently available commercially.[27] Two options with confirmed glutenase activity are available: prolyl endopeptidase from genetically modified *Aspergillus niger* (AN-PEP) and dipeptidyl peptidase IV (DPP-IV) from *Aspergillus oryzae.* Of the two, AN-PEP is the most effective in degrading gluten more completely, including the immunogenic epitopes.[31] (See Chapter 95 for a comprehensive discussion.) DPP-IV targets both gliadin and casein (milk protein) and is resistant to breakdown by other digestive enzymes. DPP-IV is thought to be one of the key enzymes responsible for the digestion of these proteins and is known to be found in lower amounts in the intestinal mucosa of individuals with celiac disease and also to have an inverse correlation with the level of mucosal damage among those with as well as without celiac disease. The lower the DPP-IV, the more significant the damage to the intestinal lining. Preparations containing DPP-IV are often recommended to safeguard against any hidden sources of gluten. They are not a substitution for a gluten-free diet.[32]

THERAPEUTIC APPROACH

The therapeutic approach is straightforward: eliminate all sources of gliadin (see Appendix 6), eliminate dairy products initially, correct

underlying nutritional deficiencies, treat any associated conditions, and determine and eliminate all food allergens. If the patient does not begin to respond within 1 month, reconsider the diagnosis and search for hidden sources of gliadin.

The discovery of the zonulin pathway enables an opportunity for both diagnostic and therapeutic applications to be developed. The strategy to facilitate repair of the damaged intestinal mucosa involves three steps: (1) stop the damage by avoiding known gastrointestinal toxins, (2) reestablish a healthy microbial flora, and (3) stimulate regeneration. In addition, reestablishing the zonulin-dependent intestinal barrier function may provide a mechanism by which processes such as autoimmune disease, inflammatory conditions, and neoplastic disorders may be halted in their development and possibly reversed.

There is interesting evidence supporting the use of the zonulin inhibitor AT1001 in the prevention of autoimmune diseases such as type 1 diabetes and celiac disease. Pretreatment with AT1001 has been shown to prevent the loss of intestinal barrier function, the appearance of auto-antibodies, and the onset of disease and protected against the insult of pancreatic islets and, therefore, of the insulitis responsible for the onset of T1D.[33] The protective effects of AT1001 were also demonstrated in a small study of 20 patients on a gluten-free diet randomized to a 3-day AT1001 treatment (12 mg once daily) or placebo with a 2.5-g oral gluten challenge on the second day.[34] In the placebo group, a significant 70% increase in intestinal permeability was observed after gluten challenge compared with no changes in permeability in the AT1001-treated group. In addition, AT1001 has been shown to reduce proinflammatory cytokine production and gastrointestinal symptoms in patients with celiac disease exposed to gluten.[35] The maintenance of a strict gluten-free diet is difficult in the United States because of the ubiquitous distribution of gliadin and other activators of celiac disease in processed foods. Patients must be encouraged to read labels carefully to avoid hidden sources of gliadin, as it is found in some brands of soy sauce, modified food starch, ice cream, soup, beer, wine, vodka, whiskey, and malt. Patients should also be encouraged to consult resources for patient education and information on gluten-free recipes. Supplemental glutenases may be helpful to offset a low level of inadvertent gluten ingestion but are not a substitute for a gluten-free diet.

Cervical Dysplasia

Angela Sadlon, ND, and *Michael T. Murray*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Abnormal Papanicolaou (Pap) smears (atypical squamous cells of undetermined significance [ASC-US]; low-grade squamous intraepithelial lesions [LGSILs]; high-grade squamous intraepithelial lesions [HGSILs])
- Human papillomavirus (HPV) testing for the presence of high-risk strains
- Colposcopy, endocervical curettage, cervical biopsies

Since the Bethesda System of reporting was first established in 1988, it has been revised several times. The current U.S. cervical disease management guidelines were last updated in 2012 and include the recommended frequency of Pap smear testing and algorithms for managing high-risk HPV strains, ASC-US, atypical cells for which high-grade lesions cannot be ruled out (ASC-H), LGSILs, and HGSILs.[1–3] Recommendations for HPV testing and cytology testing and the combination of the two, HPV vaccinations, colposcopy and biopsies, follow-up cytology testing, and colposcopy based on abnormal results are complex and often change. Guidelines differ depending on the patient's age, history of previous abnormal cytology testing, pregnancy status, previous exposure to diethylstilbestrol, immunosuppression status (e.g., kidney transplants), human immunodeficiency virus (HIV) status, and hysterectomy for benign indications and prior history of cervical intraepithelial neoplasia (CIN). It is recommended that the clinician consult the latest available guidelines for screening and evaluation with colposcopy, biopsy, and follow-up testing from the American College of Obstetricians and Gynecologists, the American Cancer Society, and/or the U.S. Preventive Services Task Force.

A possible future risk factor not included in the current guidelines is the patient's ethnicity. Although more studies are needed, there seem to be racial differences in the time it takes for progression (e.g., ASC-US to LSIL) or regression (e.g., LSIL to ASC-US) to occur. A 10-year study[4] of 5472 women (self-reporting as either white, black, Asian, or Hispanic), all with the same access to health care and follow-ups, showed that blacks had the slowest progression rate from ASC-US to HSIL (expected time = 28.1 months) and the slowest regression rate from HSIL to ASC-US (expected time = 49 months) without intervention. Conversely, Hispanics had the fastest progression rate (expected time = 17.6 months) as well as the fastest regression rate (expected time = 27.6 months). The rates for whites were approximately 21 months for progression and 36 months for regression, and those for Asians were approximately 24.5 months for progression and 41 months for regression. Although the causes of these observations are still considered unknown, the authors proposed a biological explanation that HPV-16 sequence variations (e.g., E6 hybridization, African 1 or 2 variants, Asian variants, Hispanic variants) may be an influencing factor.[4] If there proves to be reproducible evidence of racial differences, the treatment options presented to the patient may vary based on that race's speed of progression. It may also help guide the length of natural therapy, showing a possibility that Hispanics may expect to have a shorter therapeutic protocol for regression, whereas blacks may expect to have a longer therapeutic protocol.

Currently, HPV is identified with tissue collection during a Pap smear, either as a default if the Pap smear is abnormal or as ordered by the physician. For greater than a decade, research has been testing other, less invasive ways to detect HPV.[5–10] Menstrual pads with a filter, allowing the blood to be collected and tested, seem to show the most promise. The accuracy of menstrual blood in comparison with cervical sampling for HPV ranged from 67% to 100% for sensitivity and 86% to 99% for specificity.[5–7,9,10] However, in one study, the specificity was as low as 45.5%.[10]

GENERAL CONSIDERATIONS

Cervical dysplasia is generally regarded as a precancerous lesion with risk factors similar to those of cervical cancer.[11] Therefore this discussion focuses on the following lifestyle and nutritional factors that appear to be cofactors in the development and progression of cervical dysplasias and ultimately cervical cancer[11,12]:

- Early age of first intercourse
- Multiple sex partners (in heterosexual women without barrier contraception)
- Other infectious agents (*Chlamydia,* herpesvirus)
- History of genital warts

*Previous edition contributor

- Immunosuppression (HIV, transplant patient, chronic corticosteroid therapy, chemotherapy)
- Smoking
- Oral contraceptive use
- Pregnancy
- Many nutritional factors

RISK FACTORS (TABLE 158.1)

Human Papillomavirus

Papillomaviruses are small DNA viruses around 50 to 55 nm. They are nonenveloped viruses. Papillomaviruses are found in not just humans but also cats, rabbits, and nonhuman primates. Papillomaviruses have an affinity for skin and mucous membranes (genitals, mouth, larynx, and esophagus). The DNA specifics of papillomavirus are summarized in Leto's 2011 review article.[13]

The human papillomavirus can be classified into cutaneous, mucosal, cutaneous and/or mucosal, and cutaneous associated with epidermodysplasia verruciformis.[13] For the purpose of this section, only the mucosal will be discussed. There are 40 HPV mucosal types ranging in number from 6 to 114. High-risk types 16 and 18 are found approximately 70% of the time in cervical cancer and 50% of the time in CIN3.[13] Other high-risk HPV types include 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73, and 82.[13–15] There are four types that are possibly high risk: 26, 53, 67, and 70.[15] And there are 12 low-risk types for carcinogenesis: 6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, and CP6108.[14,15] Women can be infected with more than one type of HPV, and the highest incidence of this is with younger women at the peak of their sexual activity or women with an impaired immune response.[14,15]

TABLE 158.1 Risk Factors in Cervical Dysplasia/Cancer[a]

Risk Factor	Relative Risk
Smoking (10+ cigarettes/day)	3.06
Multiple sex partners (2–5)	3.46
First intercourse before age 18	2.76
Deficient dietary β-carotene (<5000 IU/day)	2.813
Deficient dietary vitamin C (<30 mg/day)	6.716

[a]The actual values for the absolute risk of the various risk factors are as yet somewhat controversial. The numbers listed here represent the author's summarization of the literature. These risks are not linearly additive because they are usually closely related; more extensive multivariant analysis will be necessary to determine the actual relative risk of each.

According to a 1999 study, 99.7% of cervical cancer is associated with long-term persistent HPV infection (usually HPV type 16 or 18), which is easily transmitted by genital-to-genital contact.[16] The time from exposure to the appearance of a lesion or an abnormal Pap smear can range from a few weeks to decades (Fig. 158.1).

The Centers for Disease Control and Prevention (CDC) reports that nearly 80 million Americans are currently infected with HPV. About 14 million people in the United States become infected each year.[17] For most people (9 out of 10), the HPV infections will resolve without intervention within 2 years.[3,17] This suggests that the host immunity is able to defend against the development of clinical disease and that HPV infections are often transient and result in minor manifestations such as ASC-US. For other individuals, especially women, HPV results in a clinical expression to which the host immune response has not been able to respond effectively. The result is clinical disease that can include flat or raised genital warts; cervical, vaginal, vulvar, or perianal dysplasias; or progression to invasive cancers of the same site.[17] The first step in the development of dysplasias or invasive cancers is viral entry. A complex interaction of host immunity, viral load, viral type, and host susceptibility determines the natural course of the disease.

Histological Considerations

The principal reservoir of HPV is the moist mucosa and the cutaneous epithelial tissue in adjacent areas. Ninety-five percent of cervical dysplasias and cancers originate in the squamocolumnar junction of the cervical os.[11] In adolescence, glandular epithelium covers much of the exocervix, but as adolescence progresses, the columnar epithelium is gradually replaced by squamous cells. This actively growing area seems to be more susceptible to multiple insults and HPV, probably because of the metaplastic nature of the conversion process and the inflammatory process of metaplasia.

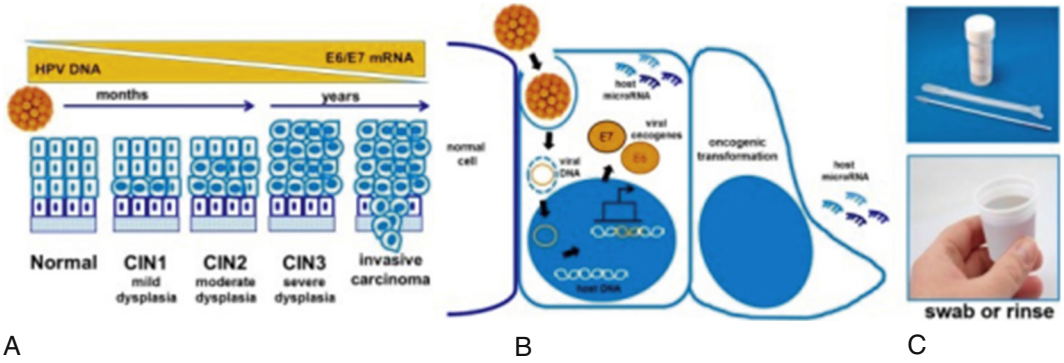

Fig. 158.1 Timeline of cervical cancer progression. (a) Human papillomavirus (HPV) infects the basal cells of the cervical epithelium *(dark blue)* exposed by wounding, leading to cytological abnormalities. Expression of viral oncogenes E6/E7 accompanies malignant transformation. (b) HPV infection pathway. After viral entry, viral replication is synchronous with host cellular DNA replication. Integrated and episomal viral DNA produce E6 and E7 oncoproteins. E6 targets p53 for degradation and prevents apoptosis, whereas E7 inactivates retinoblastoma (Rb) tumor suppressors, promoting cell-cycle progression. The end result of these processes is cellular transformation. HPV infection also alters the transcription of host microRNAs. (c) Samples for detection of HPV E6/E7 mRNA or host microRNA. *CIN,* Cervical intraepithelial neoplasia. (Shah SS, Senapti S, Klacsmann F, Miller DL, Johnson JJ, Chang HC, Stack MS. Current technologies and recent developments for screening of HPV-associated cervical and oropharyngeal cancers. *Cancers* (Basel). 2016;8[9]:pii: E85. PubMed PMID: 27618102.)

Sexual Transmission

Early age at first intercourse, multiple sexual contacts without the use of condoms, or both are associated with an increased risk of cervical dysplasia/carcinoma.[11,12] From this and other evidence, it has been suggested that cervical cancer is a sexually transmitted disease in the sense that the implicated infectious agent, HPV, is easily transmitted by genital-to-genital contact. Because the time from exposure to the appearance of a lesion can range from weeks to decades, it is almost impossible to identify individuals who transmit the virus.[17]

Genital-to-oral transmission is suggested to be possible owing to the detection of HPV types 6, 11, and 16 in some oropharyngeal cancers, but oral HPV lesions are in fact rare. Nonsexual exposure to the virus may occur from examination tables, doorknobs, tanning beds, and other inanimate objects, but it is difficult to document and prove.

Other infectious agents such as herpes simplex, *Chlamydia,* and HIV may serve as cofactors for HPV. These agents may alter cervical immunity, contribute to inflammation, facilitate entry of HPV into the basal cells, accelerate the replication of HPV in the host cell nucleus, and coexist with HPV infection.

Smoking

A significant risk factor for cervical cancer and cervical dysplasia is cigarette smoking: smokers have an approximately threefold increased incidence compared with nonsmokers (one study[18] showed the increase to be as high as seventeenfold in women ages 20–29).[18–21] Several hypotheses have been proposed to explain this association:

- Smoking may depress immune function, allowing a sexually transmitted agent to promote abnormal cellular development, leading to the onset of cervical dysplasia.
- Smoking induces vitamin C deficiency, and vitamin C levels are significantly depressed in smokers.[22]
- Cervical cells may concentrate nicotine.
- There may be unrecognized associations between smoking and sexual behavior.[18–21]

Oral Contraceptives

Earlier studies suggested that the use of oral contraceptives (OCs) increased the risk of cervical neoplasia, both the invasive and precancerous types. More recent studies controlled for sexual history have not confirmed this association. Three large, well-controlled studies looked at invasive cervical cancer and OC use and did not find statistically significant associations compared with women who never used OCs.[23–25] There was no overall change in the risk of invasive cervical cancer; however, one of the three studies[23] found a modestly increased risk in long-term users of OCs. The other two studies failed to find a significantly increased risk of invasive cervical cancer even with long-term OC use. Two other studies assessed OC use and the risk of cervical dysplasia, and neither found any statistically significant associations.[26,27]

A more disturbing aspect is that OC use has been associated with an increased incidence of adenocarcinoma, a rare cancer of the cervix. This is a less common variant of squamous cervical cancer. It appears that the incidence of this disease has increased over the past several decades, whereas the incidence of invasive squamous cervical cancer has decreased since the OC pill was introduced. Two studies found a modest but statistically significant increased risk of invasive cervical adenocarcinoma in women who had used OCs for more than 12 years.[24,28]

OCs are known to potentiate the adverse effects of cigarette smoking and to decrease the levels of numerous nutrients, including vitamins C, B_6, and B_{12} as well as folic acid, riboflavin, and zinc.[29]

Toxicant Exposure

A study evaluating the effect of depleted uranium weapons used in the Balkan war on the incidence of cervical intraepithelial neoplasia (CIN) found that the incidence of precancerous lesions of the cervix in areas near the borders of former Yugoslavia may be influenced by environmental factors such as exposure to depleted uranium due to the bombings.[30] Compared with histologically normal tissues, endometrial cancer, hyperplasia, and CIN revealed significantly increased levels of toxic metals (Cd and Pb), an altered status of Cu and Mn, and an elevated Cu:Zn ratio.[31]

Xenoestrogens are environmental estrogens that have endocrine effects, acting as both estrogen agonists and antagonists. In human cervical cancer cells (HeLa cells), dichlorodiphenyltrichloroethane (DDT) variably but significantly suppressed bcl-2 protein expression.[32] DDT has also been shown to mimic estradiol stimulation of breast cancer cells. However, these results should be interpreted with caution, because in vitro effects cannot be reliably extrapolated to chronic, low-dose exposure in vivo effects.

THERAPEUTIC CONSIDERATIONS

A follow-up Pap test is used to determine what course of action is needed. Many cases of mild cervical dysplasia (ASC-US, LSILs) will go away spontaneously. The median time required for progression from cervical dysplasia to carcinoma in situ ranges from 86 months for LSIL to 12 months for HSIL. In LSIL, the natural approaches provided in this chapter can be followed with a follow-up Pap smear and colposcopy at 3 months. If colposcopy finds abnormal tissue, endocervical curettage may be appropriate. Prescribing a patient diagnosed with HSIL a colposcopy with endocervical curettage is recommended.

Dietary Factors

Numerous nutritional factors have been implicated as cofactors in the development of cervical dysplasia. Although many single nutrients may play a significant role (particularly beta-carotene and retinoids, folate, pyridoxine, and vitamin C), it is important to recognize that a large proportion (67%) of patients with cervical cancer have multiple nutrient deficiencies or abnormal anthropometric measurements. Significant abnormalities have been found in height-to-weight ratios, triceps skin-fold thickness, midarm muscle circumference, serum albumin levels, total iron-binding capacity, hemoglobin levels, creatinine height index, prothrombin time, and lymphocyte count. Many other patients have marginal but "normal" nutritional status as determined by these cursory evaluations,[33] suggesting that multiple nutrient deficiencies are probably the rule rather than the exception.

Vitamin assessment by biochemical evaluation (plasma and red cell folate; serum beta-carotene; vitamins A, B_{12}, and C; erythrocyte transketolase for thiamine determination; erythrocyte glutathione reductase for riboflavin determination; and erythrocyte aspartate transaminase for pyridoxine determination) in patients with untreated cervical cancer shows that at least one abnormal vitamin level was present in 67% of patients, whereas 38% displayed multiple abnormal parameters.[34]

There is a correlation between elevated total plasma homocysteine levels (>9.12 mumol/L) and cervical dysplasia.[35] Because homocysteine levels are influenced by folate status, this may be an indirect way to determine whether there may be a folate deficiency.

General dietary factors are also important. A high fat intake has been associated with an increased risk for cervical cancer, whereas a diet rich in fruits and vegetables is believed to offer significant protection against carcinogenesis, probably owing to the higher intake of fiber, beta-carotene, and vitamin C.[20] Total serum carotene and tocopherol levels and their association with dietary intakes and the risk of newly diagnosed CIN and invasive cervical cancer were evaluated in a case-control study in Brazil.[36] Increasing concentrations of serum

lycopene were negatively associated with CIN 1, CIN 3, and cervical cancer. Increasing concentrations of serum alpha and gamma tocopherols and higher dietary intakes of dark green and deep yellow vegetables/fruits were associated with nearly 50% decreased risk of CIN 3. In another case-control study, 239 women with squamous cell carcinoma of the cervix from the tumor registry in Buffalo, New York, completed a questionnaire, whereby researchers investigated the relationships between intakes of selected dietary nutrients and food groups and risk of cervical cancer.[37] Significant reductions in risk of cervical cancer of approximately 40% to 60% were observed for women in the highest versus the lowest tertiles of dietary fiber, vitamin C, vitamin E, vitamin A, α-carotene, beta-carotene, lutein, and folate.

A 2003 study also suggests a lower antioxidant status (in this case coenzyme Q_{10} [CoQ_{10}] and tocopherols) was seen in patients with various grades of CIN and cervical cancer compared with controls.[38]

Nutritional Supplements

Several key individual supplements are discussed later, but a combination of products may work best. One study showed that multiple vitamin and mineral formulas, vitamins A and E, and calcium were significantly associated with a lower risk of cervical cancer and a lower HPV viral load.[39] The study enrolled 1096 women between the ages of 18 and 65 and included 328 HPV-positive women, 166 controls, 90 women with CIN 1, and 72 women with CIN 2 or 3. Multiple vitamins and minerals, vitamins A and E, and calcium were significantly associated with a lower risk of CIN 2 or 3. The patients who took the multiple vitamins and minerals had a lower HPV viral load and a significantly decreased frequency of CIN 1.

Vitamin A and Beta-Carotene

A minor association appears to exist between dietary retinoids and the risk of cervical cancer or dysplasia as well as a strong inverse correlation between beta-carotene intake and the risk of cervical cancer or dysplasia.[40–43] Although only 6% of patients with untreated cervical cancer have below-normal serum vitamin A levels, 38% have stage-related abnormal levels of beta-carotene.[34] Low serum beta-carotene levels are associated with a threefold greater risk for severe dysplasia,[42] and serum vitamin A and beta-carotene levels were found to be significantly lower in patients with cervical dysplasia than in a control group (54 vs. 104 mg/dL for vitamin A and 21.3 vs. 13.9 mcg/dL for beta-carotene).[44,45] However, the serum levels of retinoic acid (vitamin A) may not be reflective of the cellular levels of retinoic acid,[46,47] meaning even if the serum retinoic acid level is normal, it may still be low in the cervical tissue.

Response rates to intervention with carotenoids have been inconsistent. In a double-blind, randomized, placebo-controlled trial composed of more than 100 women who used either 30 mg/day of beta-carotene or placebo,[48] cervical biopsies were performed before treatment and after 6 and 24 months. Persistence of CIN 3 resulted in the patient's removal from the study. Of the 124 women included, 21 were not randomized because they moved, became pregnant, or voluntarily withdrew or the pathological review of their initial cervical biopsies did not confirm CIN 2 or 3. Of the remaining 103 women, 33 experienced lesion regression, 45 had persistent or progressive disease, and 25 women did not complete the study and were considered nonresponders.

The overall regression rate (32%) was similar between the beta-carotene and placebo arms and when stratified for CIN grade. HPV typing of 99 women showed that 77% were HPV positive and 23% HPV negative at enrollment. HPV-positive lesions were subdivided into indeterminate-, low-, and high-risk categories. The response rate was highest for women with no HPV detected (61%), lower for those ranked at indeterminate or low risk (30%), and lowest for those classified at high risk (18%). In conclusion, beta-carotene did not enhance the regression of high-grade CIN, especially in HPV-positive subjects.[48]

Other intervention studies also fared poorly for beta-carotene:

- No difference in regression of CIN 1 lesions after 12 months with 30 mg of beta-carotene daily versus placebo[49]
- No regression of CIN lesions with 10 mg/day of beta-carotene versus placebo[50]
- After 9 months, lower regression rates of CIN 1 to 3 with 30 mg/day beta-carotene versus placebo[51]
- Slightly increased progression of ASCUS and CIN 1 with 30 mg/day of beta-carotene versus no treatment[52]

However, naturopathically, carotenoids and retinols can offer several types of protection. They improve the integrity and function of the epithelial tissues, regulate cellular differentiation, provide antioxidant properties, and enhance immune system function (see Chapter 136).[47]

In an HPV-immortalized human ectocervical epithelial cell line, retinoids downregulated the cell proliferative activity of epidermal growth factor receptor (EGFR) expression.[53]

Topical vitamin A was used in a study of 301 women who received either four consecutive 24-hour applications (using a collagen sponge in a cervical cap) of retinoid or placebo followed by two more applications at 3 and 6 months. Retinoic acid increased the complete regression rate of moderate dysplasia from 27% in the placebo group to 43% in the treatment group. The women with severe cervical dysplasia did not improve.[54] In a University of Arizona study, vitamin A was delivered to 20 women via a cervical cap. In 10 of 20 women, cervical dysplasia completely disappeared. Of the 10 patients with a complete response, 5 had mild dysplasia, and 5 had moderate dysplasia.[55] There were too few patients with severe dysplasia to be evaluated.

Vitamin A suppositories have also been used as part of a multifactorial treatment plan using oral folic acid, vitamin C, and carotenes with topical vitamin A suppositories and herbal vitamin suppositories. Other patients with more severe disease were treated with a topical "escharotic treatment." This study of atypia, mild, moderate, and severe dysplasia and carcinoma in situ comprised 43 women.[56,57] Of these, 38 returned to a normal disease-free state, 3 had partial improvements, 2 stayed the same, and none progressed to a more severe state of dysplasia during the course of the natural treatment protocol.

Newer research has illuminated a possible biochemical explanation for the improvements seen with retinoic acid and abnormal cervical cells.[46,47] An enzyme that metabolizes retinoic acid (CYP26A1) was expressed in LSIL, HSIL, and cervical cancer. It was not present in normal cervical epithelium. The authors theorized that the overexpression of CYP26A1 in the cervix may contribute to the development and progression of cervical cell abnormalities.[46,47]

It seems that vitamin A, instead of beta-carotenes, may be a better recommendation for cervical dysplasia. With vitamin A (retinyl palmitate), it is important to watch for symptoms of excess, with the first usually being a low-grade headache. If this occurs, the vitamin A dosage should be lowered or discontinued. As a reminder, vitamin A dosages in excess of 10,000 IU/d are not considered safe during pregnancy.

Vitamin C

A significant decrease in vitamin C intake and plasma levels occurs in patients with cervical dysplasia, and it has been documented that inadequate vitamin C intake is an independent risk factor for the development of premalignant cervical disease and carcinoma in situ.[43,58,59] Vitamin C is known to do the following[29]:

- Act as an antioxidant
- Strengthen and maintain normal epithelial integrity
- Improve wound healing

- Enhance immune function
- Inhibit carcinogen formation

Folate

Low folate levels are implicated in many cases of cervical dysplasia, although this link is less now with the widespread folic acid fortification of the food supply. When cervical cells lack folate, they become "macrocytic" in the same way as red blood cells (RBCs). Cervical cytological abnormalities related to folate deficiency precede hematologic abnormalities by many weeks.[60,61] Before fortification of the food supply with folic acid, it was the most common vitamin deficiency in the world and was especially common in women who were pregnant or taking oral contraceptives (OCs).[61,62] It is possible that many abnormal cytological smears in the past reflected folate deficiency rather than "true" dysplasia.[52,54,61]

Even with food fortification, folate is still a factor in many cases of cervical dysplasia. This observation is particularly applicable to patients taking OCs. It has been hypothesized that OCs induce a localized interference with folate metabolism, and although serum levels may be increased, tissue levels at end-organ targets, such as the cervix, may be deficient.[63,64] This is consistent with the observation that tissue status as measured by erythrocyte folate is typically decreased (especially in those with cervical dysplasia), whereas serum levels may be normal or even increased.[65] OCs are believed to induce the synthesis of a macromolecule that inhibits folate uptake by cells. In controlled clinical studies in women with cervical dysplasia taking OCs, folic acid supplementation (10 mg/day) has resulted in the improvement or normalization of Pap smears.[63,66,67] Regression rates for patients with untreated cervical dysplasia are typically 1.3% for mild and 0% for moderate dysplasia. When patients were treated with folic acid, the regression-to-normal rate, as determined by colposcopy/biopsy examination, was observed to be 20% in one study,[67] 63.7% in another,[66] and 100% in another.[63] Furthermore, the progression rate of cervical dysplasia in untreated patients is typically 16% at 4 months, a figure matched in the placebo group in one study, whereas the folate-supplemented group had a 0% progression rate.[64] These figures were achieved despite the fact that the women remained on OCs.

Lower folate status has been shown to enhance the effect of the other risk factors for cervical dysplasia. For example, low RBC folate appears to be a major risk factor for HPV infection of the cervix.[66–68] In particular, higher circulating concentrations of folate are independently associated with a lower likelihood of becoming positive for high-risk human papillomaviruses (HR-HPVs) and of having a persistent HR-HPV infection and a greater risk for HSIL.

Vitamin B_{12} supplementation should always accompany folate supplementation to rule out the possibility that the latter may be masking an underlying vitamin B_{12} deficiency. In addition, women with higher concentrations of plasma folate who also had sufficient plasma vitamin B_{12} had 70% lower odds of being diagnosed with cervical dysplasia.[69]

Pyridoxine

Vitamin B_6 status, as determined by erythrocyte transaminase, is decreased in one third of patients with cervical cancer.[70] Decreased pyridoxine status would have a significant effect on the metabolism of estrogens and tryptophan while also impairing the immune response.

Selenium

Low selenium levels in the diet and blood have been reported to be significantly lower in patients with cervical dysplasia. In one study, significantly lower selenium and zinc levels were found in both HSIL and cervical cancer patients compared with the control group. The activity of the selenium-containing antioxidant enzyme glutathione peroxidase was significantly lower in the patients with HSIL or cancer than with the control group, and total antioxidant ability decreased from the control group to those with CIN to those with cancer. Increased glutathione peroxidase activity resulting from increased selenium intake is believed to be the factor responsible for selenium's anticarcinogenic effect, although other factors may be of equal significance.[71]

A 2002 study did not find a correlation with serum selenium (67.5–185.0 ng/mL) levels and a relationship to invasive cervical cancer in 227 invasive cases, 127 in-situ cases, and 526 controls.[72]

Copper:Zinc Ratio, Zinc, and Retinol

An increase in the serum copper:zinc ratio is a nonspecific reaction to inflammation or malignancy. In a study involving gynecological cancer, it was suggested that the serum copper:zinc ratio "is clinically of utmost importance, since it constitutes a tool with which to establish the extent of the cancer."[73] A ratio above 1.95 indicated malignancy in 90% of the patients in that study. Elevated ratios are also seen in various conditions, including the following:

- OC use
- Pregnancy
- Acute and chronic infections
- Chronic liver disease
- Inflammatory conditions

Therefore the serum copper:zinc ratio should not be used to predict malignancy in patients with these conditions. A decrease in available zinc may explain why retinol-binding protein was either absent or undetectable in 80% of dysplastic tissue samples compared with 23.5% in normal tissue. A large study of 206 women found an inverse relationship between serum levels of both retinol and zinc and the incidence of cervical dysplasia.[74]

Indole-3-Carbinol/Diindolylmethane

Indole-3-carbinol (I3C) is a phytochemical found in vegetables of the cabbage family. It is converted in the stomach to several compounds, including diindolylmethane (DIM). I3C and DIM are antioxidants and potent stimulators of natural detoxifying enzymes in the body. Studies have shown that increasing the intake of vegetables of the cabbage family or taking I3C or DIM as a dietary supplement significantly increases the conversion of estrogen from cancer-producing forms to nontoxic breakdown products.[75,76] The body breaks down estrogen in several ways. It can be converted into a substance called 16-α-hydroxyestrone, a compound that promotes estrogen-dependent cancer. Another method of breakdown produces 2-hydroxyestrone, which does not stimulate cancer cells. Women with HSIL have altered estrogen metabolism, with a higher level of 16-α hydroxyestrone and fewer 2-hydroxyestrogen metabolites than normal.[77]

Given the ability of I3C or DIM to improve estrogen metabolism and possibly exert anti-HPV activity, these agents are very good candidates in the treatment of cervical dysplasia.[76] Preliminary studies are very encouraging. In one double-blind, placebo-controlled study of 30 women with HSIL (biopsy-proved CIN 2 or 3), the women were given either 200 or 400 mg of I3C or a placebo for 12 weeks.[77] In 4 of 8 patients in the group who took 200 mg per day of I3C and 4 of 9 in the 400-mg group, there was complete regression of their severe dysplasia, compared with none of the placebo group. HPV was detected in 7 of 10 placebo patients, in 7 of 8 in the 200 mg/day group, and in 8 of 9 in the 400 mg/day group.

DIM was used in another study of 64 patients with HSIL (biopsy-proved CIN 2 or 3) who were scheduled for loop electrosurgical excision procedure (LEEP). The patients were randomized 2:1 to receive DIM at approximately 2 mg/kg/day for 12 weeks or placebo.

Although there was no statistically significant difference in any outcome between the DIM and placebo groups, the overall results with DIM showed an improved Pap smear in 49% (22 out of 45), with either a less severe abnormality or normal result. Colposcopy also improved in 25 subjects in the DIM group (56%).[78]

Botanical Medicines

Green Tea

Constituents of green tea, namely polyphenol E and epigallocatechin-3-gallate (EGCG), have been effective against HPV-infected cervical cells and lesions in both laboratory and clinical studies. Green tea appears to induce apoptosis of HPV-infected cervical cells and also to arrest cell cycles, modify gene expression, and inhibit tumor formation.[79,80]

A clinical study confirmed these findings in patients through the use of either topical application via a green tea polyphenol ointment and/or oral ingestion of a green tea polyphenol capsule or an EGCG capsule. All treatment groups improved more than the placebo group (50%–75% vs. 10%), but those given the topical treatment improved most significantly.[80]

Coriolus Versicolor

The *Coriolus versicolor* mushroom has a mucopolysaccharide and polysaccharide protein complex that composes its cell wall. These complexes are high in beta-glucans. Studies done with mucopolysaccharides indicate many beneficial health benefits, such as anticarcinogenic, immune-modulating, antimicrobial, and anti-inflammatory effects, to name a few.[81] There have been at least three studies on *C. versicolor* and HPV.[82–84] Unfortunately, no further details can be provided because the studies are all in Bulgarian. However, the Bogdanova study[82] used *Coriolus* to study the ability to reverse the early stages of cervical cancer and reduce the risk factors of recurring HPV virus.

Miscellaneous Considerations

Vaginal Depletion Pack

The vaginal depletion pack (or "vag pack") has a long history of effective use by naturopathic and eclectic physicians in the treatment of cervical dysplasia. Although its mechanism of action has not yet been elucidated, it is thought to work by promoting the sloughing of the superficial cervical cells, particularly those that are abnormal. It is effective as part of a multifactorial nutritional and topical treatment approach.[56,57] (See Appendix 14 for a complete description of this technique.)

Escharotic Treatment

The escharotic treatment is a topical herbal cryotherapy treatment of the cervix used to remove abnormal cells. It involves the use of zinc chloride mixed with *Sanguinaria canadensis,* a botanical. A full description of this protocol is given in Appendix 2. The escharotic treatment is especially indicated for CIN 2 and CIN 3, both HGSILs, but only when a satisfactory colposcopy has been performed by a clinician. In addition, the use of the escharotic treatment, rather than a LEEP or conization, must fall within the guidelines outlined under "Therapeutic Approach." The escharotic treatment is best implemented twice a week, with 2 full days between treatments. The zinc chloride solution must be made by a compounding pharmacy as a prescription item.

A 2009 case report involved a 20-year-old female with CIN 2, 3 who refused conventional recommendation and instead received escharotic treatment twice weekly for 5 weeks and oral vitamins and botanicals. She had a complete reversal of the diagnosis at her 4-month and 10-month check-ups. She was followed for 5 years and remained negative for abnormal Pap smears.[85]A case report involving a 28-year-old female with CIN 3 who followed the same escharotic treatment protocol (as the 2009 case report) had similar results.[86]

THERAPEUTIC APPROACH

Treatment of cervical dysplasia requires proper monitoring and coordination of care if one practitioner is doing the workup with colposcopy/biopsies and another is proceeding with natural or integrated treatment approaches. The basic approach is to eliminate all factors known to be associated with cervical dysplasia and to optimize the patient's nutritional status. In particular, smoking and OC use are eliminated, and the patient follows the supplementation program listed here.

The guidelines provide further insight into the appropriate medical care of cervical dysplasia.

A. Criteria for Naturopathic Protocol
   1. ASC-US
   2. ASC-US with documented HPV
   3. ASC-H: endocervical curettage is negative or positive with a satisfactory colposcopy.
   4. Low-grade squamous intraepithelial neoplasia: endocervical curettage is negative, with a satisfactory colposcopy.
   5. High-grade squamous intraepithelial neoplasia: endocervical curettage is negative, with a satisfactory colposcopy.
   6. ASC-H: endocervical curettage is positive, with a satisfactory colposcopy, but either the patient is at low risk for more serious disease, has a low-risk type of HPV, or even if the patient does not have low-risk HPV, the natural treatment protocol may be recommended at the discretion of the practitioner.
   7. Low-grade squamous intraepithelial neoplasia: endocervical curettage is positive, with a satisfactory colposcopy, but either the patient is at low risk for more serious disease or has a low-risk type of HPV or the practitioner may recommend the natural treatment protocol at his or her discretion.
   8. High-grade squamous intraepithelial neoplasia: endocervical curettage is positive, with a satisfactory colposcopy, but the patient is at low risk, or even if not, the natural treatment protocol may be recommended at the discretion of the practitioner and considered carefully after colposcopy, biopsies, and careful evaluation.
   9. It is possible to treat carcinoma in situ in select cases, but this is definitely a judgment call and should be considered very carefully after colposcopy, biopsies, and careful follow-up.

B. Referrals for Colposcopy With Biopsies
   1. ASC-US if HPV DNA testing is positive for high-risk HPV; if no HPV testing is done, then the Pap test should be repeated twice at 4- to 6-month intervals. If HPV typing is negative for high-risk types, then the Pap test should be repeated in 12 months.
   2. ASC-H
   3. Low-grade squamous intraepithelial lesions
   4. High-grade squamous intraepithelial lesions
   5. Atypical glandular cells of undetermined significance (AGUS); endometrial biopsy is needed as well.
   6. Adenocarcinoma in situ (AIS): endometrial biopsy is needed as well.
   7. Pap smear diagnosis of microinvasion or frank invasion
   8. Endometrial cells present in a postmenopausal woman; also calls for an endometrial biopsy even if the cells are benign.

9. A patient who may not follow through with the recommended follow-up Pap smear after an abnormal Pap result
10. Visible unknown cervical lesion regardless of the Pap smear test result
11. Initial examination of a DES daughter
12. Unexplained or persistent cervical bleeding
13. Vulvar condyloma with abnormal Pap test result
14. To be used for follow-up after treatment plan is completed, especially in high-grade squamous intraepithelial lesions

C. Referrals for Conization or LEEP
1. Pap test results show more than one grade of dysplasia different from that seen on colposcopy or reported on in the biopsy.
2. Biopsy shows squamous intraepithelial lesions with three to four quadrants involved.
3. Unsatisfactory colposcopy with any degree of squamous intraepithelial lesions on biopsy
4. The patient may not be a good candidate for ongoing treatment and the closer follow-up required by alternative treatments.
5. No improvement in pathology with the initial naturopathic plan or repeated alternate plan
6. If AGUS is found on the Pap test and no disease is detected on colposcopy, biopsies and endocervical curettage are indicated.
7. If AIS is found on the Pap test and no disease is detected on colposcopy, biopsies and endocervical curettage are indicated.

D. At the Discretion of the Practitioner and Patient
1. Positive endocervical curettage with any degree of squamous intraepithelial lesions. A more assertive approach is recommended.
2. High-risk patients: the last Pap test more than 1 year previous, a history of genital warts, a history of cervical dysplasia, smokers, multiple sex partners with lack of safe-sex practices. In these cases, a more proactive and assertive approach is recommended.

E. Referral for Probable Hysterectomy
1. Microinvasive cervical cancer
2. Frank invasive cervical cancer
3. Adenocarcinoma

Diet

Increase fruits and vegetables, especially those yellow and orange in color. A general immune-supportive diet is considered prudent—high in fiber, vegetables, fruits, nuts, and seeds; low in fat and saturated fat.

Nutritional Supplements

- High-potency multiple vitamin and mineral formula
- Folate or methyltetrahydrofolate: 10 mg/day for 3 months, then 2.5 mg/day for 1 year
- Vitamin B_{12} (methylcobalamin): 1 mg/day
- Retinyl palmitate: 50,000 IU/day for 1 month, then decrease to 15 to 25,000 IU/day until repeat testing is normal. Refer to the previous section on vitamin A for cautions.
- Vitamin C: 1 to 3 g/day for 3 to 12 months
- Vitamin E: 200 IU/day for 3 to 12 months
- Selenium: 200 to 400 mcg/day for 3 to 12 months
- Zinc: 20 to 30 mg/day for 3 to 12 months
- Choose one of the following:
  - I3C: 200 to 400 mg/day for 3 months
  - DIM: 2.2 mg per kg body weight/day

Botanical Medicines

- Green tea extract (>90% total polyphenol content): 150 to 300 mg/day for 3 to 12 months

Sample Treatment Protocols

Atypical Cells of Undetermined Significance

- Topical
  Week 1: Insert vitamin A suppository every night for 6 nights.
  Week 2: Insert herbal vaginal suppository every night for 6 nights.
  Week 3: Repeat vitamin A.
  Week 4: Repeat herbal.
  Weeks 5 to 12: Insert green tea suppository 2 nights a week.
- Supplementation as previously noted for a minimum of 3 months

Low-Grade Squamous Intraepithelial Lesions

- Topical
  Week 1: Insert vitamin A suppository every night for 6 nights.
  Insert vag pack suppository on night 7.
  Week 2: Insert herbal suppository every night for 6 nights.
  Insert vag pack suppository on night 7.
  Week 3: Repeat vitamin A.
  Insert vag pack suppository on night 7.
  Week 4: Repeat herbal suppository.
  Insert vag pack suppository on night 7.
  Weeks 5 to 12: insert green tea suppository twice a week.
- Supplementation as previously noted for a minimum of 3 months

High-Grade Squamous Intraepithelial Lesions

- Topical
  Escharotic treatment twice a week for 5 weeks
  The last treatment is followed by 1 month of suppository routine as in LGSIL, then a green tea suppository twice a week for weeks 5 through 12.
- Supplementation as previously noted for a minimum of 3 months

Chronic Candidiasis

Michael T. Murray, ND

OUTLINE

GENERAL CONSIDERATIONS

In the past 30 years, overgrowth in the gastrointestinal (GI) tract of the usually benign yeast *Candida albicans* has become increasingly recognized as a complex medical syndrome known as chronic candidiasis, or the yeast syndrome (Fig. 159.1).[1,2] Specifically, the overgrowth of *C. albicans* is believed to cause a wide variety of symptoms in virtually every system of the body, with the GI, genitourinary, endocrine, nervous, and immune systems being most susceptible.[3]

Although chronic candidiasis has been clinically defined for a long time, it was not until Orion Truss published *The Missing Diagnosis* and William Crook published *The Yeast Connection* that the public and many physicians became aware of the magnitude of the problem.[1,2]

Normally, *C. albicans* lives harmoniously in the inner creases and crevices of the digestive tract (and vaginal tract in women). However, when this yeast overgrows, immune system mechanisms are depleted, or when the normal lining of the intestinal tract is damaged, the body can absorb yeast cells, particles of yeast cells, and various toxins.[3] As a result, there may be significant disruption of body processes, resulting in the development of the "yeast syndrome."

Women are eight times more likely to experience candidiasis compared with men, likely the result of estrogen, oral contraceptive use, and the higher number of prescriptions for antibiotics (Box 159.1).[4] Fatigue, allergies, immune system malfunction, depression, chemical sensitivities, and digestive disturbances are some of the symptoms patients with the yeast syndrome may experience.[3]

Causal Factors

Chronic candidiasis is a classic example of a multifactorial condition (Box 159.2). Therefore the most effective treatment involves addressing and correcting the factors that predispose to *C. albicans* overgrowth and includes much more than killing the yeast with antifungal agents, whether synthetic or natural.

Antibiotics

Prolonged antibiotic use is believed to be the most important factor in the development of chronic candidiasis. Antibiotics, through the elimination of the normal intestinal bacteria that prevent yeast overgrowth and suppression of the immune system, strongly promote the overgrowth of *Candida.*

Syndromes Related to the Yeast Syndrome

Small intestinal bacterial overgrowth (SIBO) and the leaky gut syndrome are often associated with *C. albicans* overgrowth and may produce identical symptoms to the yeast syndrome. For further discussion of small intestinal bacterial overgrowth and leaky gut syndrome, see Chapters 9 and 19.

DIAGNOSIS

Questionnaire

One of the most useful screening methods for determining the likelihood of yeast-related illness is a comprehensive questionnaire (see Appendix 1).

Diagnosis of the yeast syndrome is primarily based on clinical judgment from a detailed medical history and patient questionnaire. In addition, laboratory techniques such as stool cultures for *C. albicans* and measurement of antibody levels to *C. albicans* or *C. albicans* antigens in the blood may aid in the diagnosis and can be used to confirm the diagnosis.

Comprehensive Digestive Stool Analysis

Rather than simply culture a stool sample for the presence of *C. albicans,* the comprehensive digestive stool analysis (CDSA) is more clinically useful (discussed in detail in Chapter 28). This battery of integrated diagnostic laboratory tests evaluates digestion, intestinal function, intestinal environment, and absorption by carefully examining the stool. It is a useful tool in determining

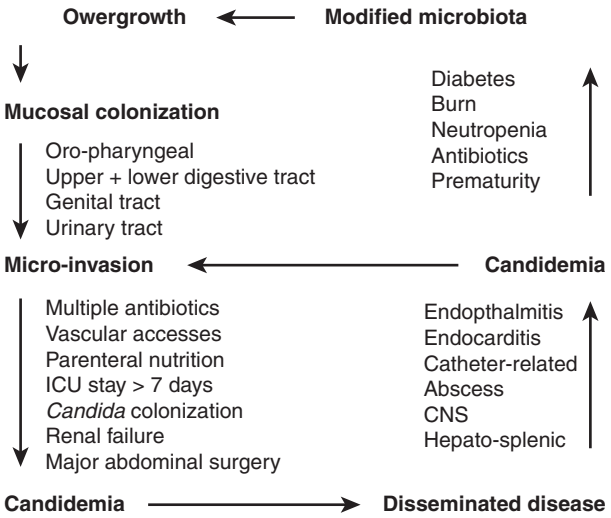

Fig. 159.1 Pathophysiology of chronic candidiasis. (From Eggimann P, Bille J, Marchetti O. Diagnosis of invasive candidiasis in the ICU. *Ann Intensive Care.* 2011;1:37. PubMed PMID: 21906271.)

the digestive disturbance that is likely to be the underlying factor responsible for *C. albicans* overgrowth. In addition, the CDSA may determine that the symptoms are not related to *C. albicans* overgrowth but, rather, to conditions such as SIBO and/or the leaky gut syndrome.

Antibody and Antigen Levels

Another laboratory method to confirm the presence of *C. albicans* overgrowth is measuring the level of antibodies to *Candida* or the level of antigens in the blood.[3,5] Although these tests are rarely necessary, some patients and physicians may desire confirmation that *C. albicans* is a responsible factor in the patient's health equation. In this situation, blood studies can be helpful and may also be used as a way of monitoring therapy.

THERAPEUTIC CONSIDERATIONS

A comprehensive approach is more effective in treating chronic candidiasis than simply trying to kill *C. albicans* with a drug or natural anti–*C. albicans* agent. Drugs like nystatin, ketoconazole, and Diflucan, as well as various natural anti–*C. albicans* agents, rarely produce significant long-term results because they fail to address the underlying factors that promote *C. albicans* overgrowth. In many cases, it is useful to try to eradicate *C. albicans* from the system, preferably with the help of natural anti–*C. albicans* therapies such as timed-release caprylic acid preparations, enteric-coated volatile oil preparations, or fresh garlic preparations. A follow-up stool culture and *C. albicans* antigen determination will confirm if the *C. albicans* has been eliminated. If *C. albicans* has been eradicated but symptoms persist, the symptoms are unrelated to an overgrowth of *C. albicans* and may be caused by SIBO. In this scenario, pancreatic enzymes and berberine-containing plants like goldenseal can be helpful.

Diet

A number of dietary factors appear to promote the overgrowth of *C. albicans.* The most important factors are a high intake of sugar, milk and other dairy products, foods containing a high content of yeast or mold, and food allergies/sensitivities.

BOX 159.1 Typical Chronic Candidiasis Patient Profile

Sex: Female

Age: 15 to 50 years

General Symptoms
- Chronic fatigue
- Loss of energy
- General malaise
- Decreased libido

Gastrointestinal Symptoms
- Thrush
- Bloating, gas
- Intestinal cramps
- Rectal itching
- Altered bowel function

Genitourinary System Complaints
- Vaginal yeast infection
- Frequent bladder infections
- Endocrine system complaints
- Primarily menstrual complaints

Nervous System Complaints
- Depression
- Irritability
- Inability to concentrate

Immune System Complaints
- Allergies
- Chemical sensitivities
- Low immune function

History
- Chronic vaginal yeast infections
- Chronic antibiotic use for infections or acne
- Oral birth control usage
- Oral steroid hormone usage

Associated Conditions
- Premenstrual syndrome
- Sensitivity to foods, chemicals, and other allergens
- Endocrine disturbances
- Eczema
- Psoriasis
- Irritable bowel syndrome

Other
- Craving for foods rich in carbohydrates or yeast

BOX 159.2 Predisposing Factors to *Candida albicans* Overgrowth

- Decreased digestive secretions
- Dietary factors
- Impaired immunity
- Nutrient deficiency
- Drugs (particularly antibiotics)
- Impaired liver function
- Underlying disease states
- Altered bowel flora
- Prolonged antibiotic use

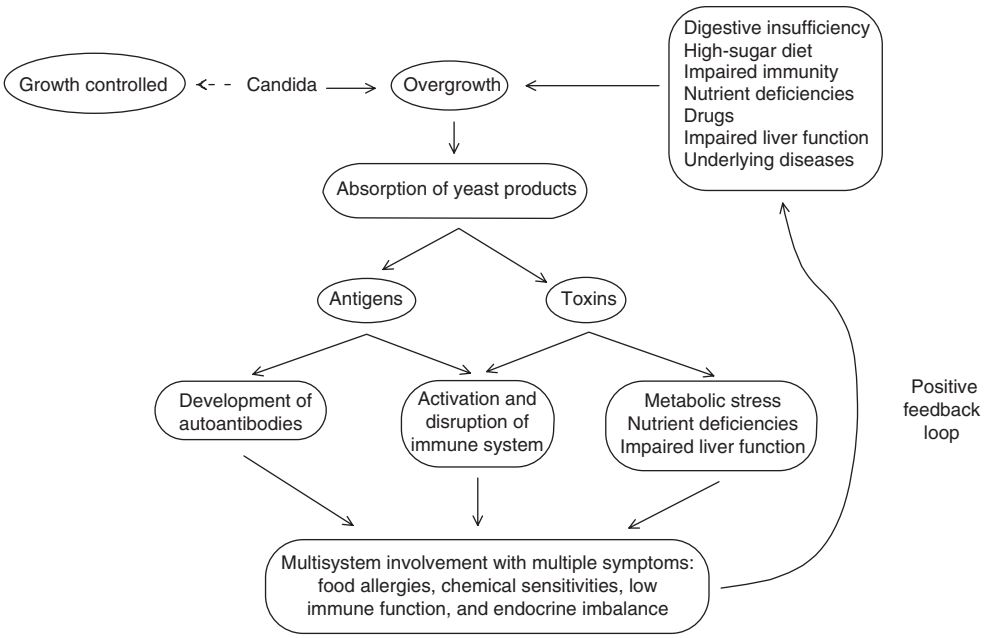

Fig. 159.2 The vicious cycle of chronic candidiasis.

Sugar

Sugar is the chief nutrient of *C. albicans*. It is well accepted that restriction of sugar intake is a necessity in the treatment of chronic candidiasis. Most patients do well by avoiding refined sugar and large amounts of honey, maple syrup, and fruit juice.[1–4]

Milk and Other Dairy Products

Several reasons to restrict or eliminate the intake of milk in patients with chronic candidiasis include the following:

- High lactose content promotes the overgrowth of *Candida*.
- Cow's milk and dairy products are some of the most frequent food allergens.
- Milk may contain trace levels of antibiotics, which can further disrupt the GI bacterial flora and promote *Candida* overgrowth.[1–4]

Mold- and Yeast-Containing Foods

Many experts recommend that individuals with chronic candidiasis avoid foods with a high content of yeast or mold, including alcoholic beverages, cheeses, dried fruits, and peanuts. Although many patients with chronic candidiasis may be able to tolerate these foods, it is best to eliminate these foods from the diet until the situation is resolved.[1–4]

Food Allergies

Food allergies are another common finding in patients with the yeast syndrome.[3] Enzyme-linked immunosorbent assay tests, which determine both immunoglobulin E– and immunoglobulin G–mediated food allergies, are often helpful in identifying food allergies.

Hypochlorhydria

Gastric hydrochloric acid, pancreatic enzymes, and bile all inhibit the overgrowth of *C. albicans* and prevent its penetration into the absorptive surfaces of the small intestine. Decreased secretion of any of these important digestive components can lead to overgrowth of *C. albicans* in the GI tract. Therefore the restoration of normal digestive secretions through the use of supplemental hydrochloric acid, pancreatic enzymes, and substances that promote bile flow is critical in the treatment of chronic candidiasis. The CDSA can provide valuable information in identifying which factor is most important.

People on antiulcer drugs, such as Tagamet (cimetidine) and Zantac (ranitidine), often develop *C. albicans* overgrowth in the stomach.[6] This occurrence highlights the importance of hydrochloric acid in the prevention of *C. albicans* overgrowth. Restoring proper levels of gastric acid with supplemental hydrochloric acid is often useful in chronic candidiasis.

Pancreatic enzymes can also be useful in the treatment of chronic candidiasis. As well as being necessary for protein digestion, proteases are responsible for keeping the small intestine free from parasites (including bacteria, yeast, protozoa, and intestinal worms).[7,8] A lack of proteases or other digestive secretions greatly increases an individual's risk of having an intestinal infection, including chronic *C. albicans* infections of the GI tract.

Enhancing Immunity

Recurrent or chronic infections, including chronic candidiasis, are characterized by a depressed immune system. The cycle of chronic candidiasis makes it difficult for individuals to overcome the condition (Fig. 159.2); a compromised immune system leads to infection, and infection leads to damage of the immune system, further weakening resistance.

The importance of a healthy immune system in protecting against *C. albicans* overgrowth is well known by physicians who work with patients having acquired immunodeficiency syndrome (AIDS) or those who may be taking immunosuppressive medications. The occurrence of *C. albicans* overgrowth in these conditions provides considerable evidence that improving immune function is essential in resolving chronic candidiasis.

In addition, patients with chronic candidiasis often have other chronic infections, likely secondary to a weakened immune system. Typically, this depression of immune function is related to decreased thymus function, primarily presenting as depressed cell-mediated immunity. Although expensive laboratory tests can document this depression, a history of repeated viral infections (including the common cold), outbreaks of cold sores or genital herpes, and prostatic (men) or vaginal (women) infections provides enough evidence to support reduced immune function.

BOX 159.3 Triggers to Impaired Immunity in Candidiasis

- Antibiotic use
- Corticosteroid use
- Other drugs that suppress the immune system
- Nutrient deficiency
- Food allergies
- High-sugar diet
- Stress

Causes of Depressed Immune Function in Candidiasis

Regarding the immune system, a triggering event such as antibiotic use or nutrient deficiency (Box 159.3) can lead to immune suppression, allowing *C. albicans* to overgrow and become more firmly entrenched in the lining of the GI tract. Once the organism attaches itself to the intestinal cells, it competes with the cell and ultimately the entire body for nutrition—potentially robbing the body of vital nutrients. In addition, *C. albicans* secretes a large number of mycotoxins and antigens and is referred to as a "polyantigenic" organism because more than 79 distinct antigens have been identified.[9,10]

Restoring Proper Immune Function

Restoring proper immune function requires a comprehensive approach involving lifestyle, stress management, exercise, diet, nutritional supplementation, glandular therapy, and the use of plant-based medicines.

Perhaps the most effective intervention in reestablishing a healthy immune system is employing measures designed to improve thymus function. Oral candidiasis occurs in roughly 90% of HIV-positive individuals, and the clinical remission of oral candidiasis has been shown to be critically dependent on T-cell function.[11,12] Presumably, improving thymus-mediated immunity is also critical in the remission of chronic candidiasis. Promoting optimal thymus gland activity involves the following:

- Prevention of thymic involution or shrinkage by ensuring adequate dietary intake of antioxidant nutrients, such as carotenes, vitamin C, vitamin E, zinc, and selenium
- The use of nutrients that are required in the manufacture or action of thymic hormones

Promoting Detoxification

Patients with chronic candidiasis may exhibit multiple chemical sensitivities and allergies, indicating that detoxification reactions are stressed. Therefore their liver function must be supported. When the liver is even slightly damaged by chemical toxins, immune function is severely compromised. Improving the health of the liver and promoting detoxification may be one of the most critical factors in the successful treatment of candidiasis.

The immune system–suppressing effect of nonviral liver damage has been repeatedly demonstrated in experimental animal studies and human studies. For example, when the liver of a rat is damaged by a chemical toxin, immune function is severely hindered.[13] Liver injury is also linked to *C. albicans* overgrowth, as evident in studies of mice demonstrating that when the liver is even slightly damaged, *C. albicans* runs rampant through the body.[14]

A rational approach to aiding the body's detoxification involves the following:

- A diet focused on fresh fruits and vegetables, whole grains, legumes, nuts, and seeds
- A healthy lifestyle, including avoiding alcohol and exercising regularly

BOX 159.4 Indications of the Need for Detoxification

- More than 20 lb overweight
- Diabetes
- Presence of gallstones
- History of heavy alcohol use
- Psoriasis
- Natural and synthetic steroid hormone use
  - Anabolic steroids
  - Estrogens
  - Oral contraceptives
- High exposure to certain chemicals or drugs
  - Cleaning solvents
  - Pesticides
  - Antibiotics
  - Diuretics
  - Nonsteroidal anti-inflammatory drugs
  - Thyroid hormone
  - History of viral hepatitis

- A high-potency multiple vitamin and mineral supplement
- Lipotropic formulas and silymarin to protect the liver and enhance liver function
- A 3-day fast at the change of each season

If any of the factors in Box 159.4 apply to the patient, enhancing detoxification is a major therapeutic goal.

Lipotropic Factors

The nutrients choline, betaine, and methionine are often beneficial in enhancing liver function and detoxification reactions. These compounds, referred to as lipotropic agents, promote the flow of fat and bile to and from the liver. In essence, they produce a "decongesting" effect on the liver and promote improved liver function and fat metabolism. Formulas containing lipotropic agents are useful in enhancing detoxification reactions and other liver functions. Lipotropic formulas have been used for a wide variety of conditions, including a number of liver disorders such as hepatitis, cirrhosis, and chemical-induced liver disease. The daily dosage should be 1000 mg of choline and 1000 mg of methionine or cysteine, or both.

Lipotropic formulas appear to increase the levels of two important liver substances: S-adenosyl-methionine, the major lipotropic compound in the liver, and glutathione, one of the major detoxifying compounds in the liver.[15,16]

Promoting Elimination

A diet that focuses on high-fiber plant foods should be sufficient to promote proper elimination by supplying an ample amount of dietary fiber. If additional support is needed, fiber formulas can be prescribed. These formulas are composed of natural plant fibers derived from psyllium seed, kelp, agar, pectin, and plant gums like karaya and guar. Alternatively, fibers can be purified semisynthetic polysaccharides like methylcellulose and carboxymethylcellulose sodium. Psyllium-containing laxatives are the most popular and usually the most effective. Fiber formulas most closely approximate the natural mechanism that promotes a bowel movement. In the treatment of candidiasis, 3 to 5 g of soluble fiber at bedtime should be recommended, especially if antiyeast therapies are employed, to ensure that dead yeast cells are excreted and not absorbed.

Probiotics

Intestinal flora plays a major role in the health of the host, especially in the battle against GI tract infection.[17,18] Intestinal flora is intimately involved in the host's nutritional status and affects immune system function, cholesterol metabolism, carcinogenesis, and aging. Although probiotic supplements such as *Lactobacillus acidophilus* and *Bacterium bifidum* can be used to promote overall good health, the four primary uses related to chronic candidiasis are the promotion of a proper intestinal environment, postantibiotic therapy, vaginal yeast infections, and urinary tract infections.

The dosage of a commercial probiotic supplement is based on the number of live organisms. The ingestion of 5 to 10 billion viable *L. acidophilus* or *B. bifidum* cells daily is a sufficient dosage for most people. Amounts exceeding these may induce mild GI disturbances, whereas smaller amounts may not be able to colonize the GI tract.

See Chapters 104 and 105 for a more comprehensive discussion of these useful agents.

Natural Antiyeast Agents

A number of natural agents have proven activity against *C. albicans.* Rather than relying on these agents as a primary therapy, it is important to address the factors that predispose one to chronic candidiasis, especially a lack of either hydrochloric acid or pancreatic enzymes. The five natural agents recommended against *C. albicans* are as follows:

- Caprylic acid
- Berberine-containing plants
- Garlic
- Enteric-coated volatile oil preparations
- *Propolis*

Most patients can achieve benefits from the natural agents described rather than the use of pharmaceuticals. Antiyeast therapy can produce a die-off (Herxheimer) reaction due to the rapid killing of the organism and subsequent absorption of large quantities of yeast toxins, cell particles, and antigens. The Herxheimer reaction refers to a worsening of symptoms as a result of this die-off. The Herxheimer reaction can be minimized by the following means:

- Following the dietary recommendations for a minimum of 2 weeks before taking an antiyeast agent
- Supporting the liver
- Starting any antiyeast medications in low doses and gradually increasing dosages over 1 month to achieve full therapeutic dosage

Caprylic Acid

Caprylic acid is a naturally occurring fatty acid that has been reported to be an effective antifungal compound in the treatment of candidiasis.[19,20] Because caprylic acid is readily absorbed in the intestines, it is necessary to take timed-release or enteric-coated caprylic acid formulas to allow for gradual release throughout the entire intestinal tract.[21] The standard dose for these delayed-release preparations is 1000 to 2000 mg with meals.

Chitosan

Chitosan is a natural polysaccharide derived from the outer skeleton of shellfish composed of β-linked D-glucosamine and N-acetyl-D-glucosamine. It is used in the treatment of obesity, high cholesterol, and Crohn's disease. In addition, a randomized, single-blind, clinical trial investigated the antifungal effects of low-molecular-weight chitosan solution on *C. albicans* in denture stomatitis in comparison with nystatin suspension.[22] After 2 weeks of treatment, the chitosan solution significantly decreased the erythematous surface area, burning sensation, and time required for clinical improvement, making it a promising candidate for use as an antifungal mouthwash.

Berberine-Containing Plants

Berberine-containing plants include goldenseal *(Hydrastis canadensis),* barberry *(Berberis vulgaris),* Oregon grape *(Berberis aquifolium),* and goldthread *(Coptis chinensis).* Berberine, an alkaloid, has been extensively studied in both experimental and clinical settings for its antibiotic activity. Berberine exhibits a broad spectrum of antibiotic activity, having shown antibiotic activity against bacteria, protozoa, and fungi, including *C. albicans.*[23–29] Berberine's action in inhibiting *C. albicans,* as well as pathogenic bacteria, prevents the overgrowth of yeast, which is a common side effect of antibiotic use.

Diarrhea is a common symptom in patients with chronic candidiasis. Berberine has shown remarkable antidiarrheal activity in even the most severe cases. Positive clinical results have been shown with berberine in relieving diarrhea in cases of cholera, amebiasis, giardiasis, and other causes of acute GI infection (e.g., *Escherichia coli, Shigella, Salmonella,* and *Klebsiella*) and may also relieve the diarrhea seen in patients with chronic candidiasis.[30–36]

The dosage of any berberine-containing plant should be based on berberine content. Because there is a wide range of quality in goldenseal preparations, standardized extracts are preferred. Three-times-a-day dosages are as follows:

- Dried root or infusion (tea), 2 to 4 g
- Tincture (1:5), 6 to 12 mL (1.5–3 tsp)
- Fluid extract (1:1), 2 to 4 mL (0.5–1 tsp)
- Solid (powdered dry) extract (4:1 or 8%–12% alkaloid content), 250 to 500 mg

Note that the dosage recommendations for berberine would be 25 to 50 mg three times daily or a daily dose of up to 150 mg. This dosage is consistent with the dosage range in the positive clinical studies in patients with GI infections. For children, a dosage based on body weight is appropriate. The daily dose would be the equivalent of 5 to 10 mg of berberine/kg (2.2 lb) body weight.

Berberine and berberine-containing plants are generally nontoxic at the recommended dosages. However, berberine-containing plants are not recommended for use during pregnancy, and higher dosages may interfere with vitamin B metabolism.[37]

Allium sativum. Garlic has demonstrated significant antifungal activity. Its inhibition of *C. albicans* in both animal and test tube (in vitro) studies has shown it to be more potent than nystatin, gentian violet, and six other reputed antifungal agents.[38–40] The active component is allicin—the pungent and odorous principle of garlic.

The clinical use of garlic features commercial preparations designed to offer the benefits of garlic without the odor. These preparations are designed to delay the formation of allicin until the enteric-coated tablet is delivered to the small and large intestines.

The treatment of chronic candidiasis requires a daily dose of at least 10 mg allicin or a total allicin potential of 4000 mcg. This amount is equal to approximately one clove (4 g) of fresh garlic. Higher dosages of these preparations usually result in the odor of garlic being detectable.

Enteric-Coated Volatile Oils

Volatile oils from oregano, thyme, peppermint, and rosemary are all effective antifungal agents. In one study, the sensitivity of 30 different strains of *C. albicans* to 12 essential oils was compared with the three mainly used drugs (clotrimazole, fluconazole, and itraconazole).[41] Mint, basil, lavender, tea tree oil, winter savory, and oregano essential oils inhibited both the growth and the activity of *C. albicans* more efficiently compared with the mainly used drugs (especially clotrimazole). The results showed that the essential oils primarily affected the cell wall and the membranes of the yeast. An additional study compared the anti–*C. albicans* effect of oregano oil with that of caprylic acid.[42] Although the minimum inhibitory concentration of oregano oil was

less than 0.1 mg/mL, and the 0.1% survival of *C. albicans* occurred at a concentration of 45 mg/mL, the minimum inhibitory concentration of caprylic acid was less than 500 mg/mL, and 0.1% survival occurred at a concentration of 5000 mg/mL. These results indicate that the anti–*C. albicans* activity of oregano oil is more than 100 times more potent than caprylic acid. Because volatile oils are quickly absorbed and associated with inducing heartburn, an enteric coating is recommended to ensure delivery to the small and large intestines. An effective dosage for an enteric-coated volatile oil preparation is 0.2 to 0.4 mL twice daily between meals.

Melaleuca alternifolia. In one open study, 27 patients with AIDS and oral candidiasis clinically refractory to fluconazole were randomized to receive either an alcohol-based or alcohol-free *Melaleuca alternifolia* oral solution 4 times daily for 2 to 4 weeks. Overall, 60% of patients demonstrated a clinical response to this oral solution (seven patients were cured, and eight patients clinically improved) at the 4-week evaluation.[43]

Propolis

Propolis has shown considerable in vitro antimicrobial activity against *C. albicans,* as well as an ability to enhance the effectiveness of conventional antifungal drugs.[44–47] Its cytotoxic activity against *C. albicans,* along with its immune-enhancing effects, make propolis a strong candidate for the treatment of chronic candidiasis.

THERAPEUTIC APPROACH

The following is a comprehensive, step-by-step approach to the successful elimination of chronic candidiasis.

Step 1. Identify and address predisposing factors:
- Eliminate the use of antibiotics, steroids, immune-suppressing drugs, and birth control pills (unless medically necessary).
- Perform a CDSA.
- Follow the specific recommendations if the identifiable predisposing factor is dietary factors, impaired immunity, impaired liver function, or an underlying disease state.

Step 2. Recommend the *C. albicans* control diet:
- Eliminate refined and simple sugars.
- Eliminate milk and other dairy products.
- Eliminate foods with a high content of yeast or mold, including alcoholic beverages, cheeses, dried fruits, melons, and peanuts.
- Eliminate all known or suspected food allergies.

Step 3. Provide nutritional support:
- A high-potency multiple vitamin and mineral formula
- Additional antioxidants
- 1 Tbs of flaxseed oil daily

Step 4. Support immune function:
- Promote a positive mental attitude.
- Help patients deal with stress by teaching positive stress-coping techniques.
- Recommend avoiding alcohol, sugar, smoking, and elevated cholesterol levels, which can impair immune function.
- Recommend plenty of rest and good sleep.
- Follow the supplement recommendations given in Chapter 136 on immune support.

Step 5. Promote detoxification and elimination:
- Recommend 3 to 5 g of a water-soluble fiber source, such as guar gum, psyllium seed, or pectin at night.
- If necessary, recommend lipotropic factors and silymarin to enhance liver function.

Step 6. Recommend probiotics:
- Dose: 5 to 10 billion viable *L. acidophilus* and *B. bifidum* cells daily

Step 7. Use appropriate antiyeast therapy:
- Ideally, use the recommended nutritional or herbal supplements, or both, to help control against yeast overgrowth and promote a healthy bacterial flora.
- If necessary, use prescription antiyeast drugs appropriately.

These steps should resolve chronic candidiasis in most cases. If a patient follows these guidelines and fails to achieve significant improvement or complete resolution, further evaluation is necessary to determine whether chronic candidiasis is the underlying factor. Repeat stool cultures and antigen levels are often helpful. If the organism has not been eradicated, stronger prescription antibiotics can be used, along with the other general recommendations.

Chronic Fatigue Syndrome

John Nowicki, ND, Michael T. Murray, ND,* and *Mark Dreher*, PhD*

OUTLINE

DIAGNOSTIC SUMMARY

- Mild fever
- Recurrent sore throat
- Painful lymph nodes
- Muscle weakness
- Muscle pain
- Prolonged fatigue after exercise
- Recurrent headache
- Migratory joint pain
- Depression
- Sleep disturbance (hypersomnia or insomnia)

INTRODUCTION

Chronic fatigue syndrome (CFS), now also called myalgic encephalomyelitis, describes varying combinations of symptoms, including recurrent fatigue, sore throat, low-grade fever, swollen lymph nodes, headache, muscle and joint pain, intestinal discomfort, emotional distress, depression, and loss of concentration. Although newly defined and currently popular, CFS is not a new disease. References to a similar condition in the medical literature go back as far as the 1860s. In the past, CFS has been known by various names, including the following:

- Chronic mononucleosis-like syndrome or chronic Epstein–Barr virus (EBV) syndrome
- Yuppie flu
- Postviral fatigue syndrome
- Postinfectious neuromyasthenia
- Chronic fatigue and immune dysfunction syndrome (CFIDS)
- Iceland disease
- Royal Free Hospital disease

In addition, the symptoms of CFS mirror the symptoms of neurasthenia, a condition first described in 1869.

Definition

In response to the growing interest, CFS was formally defined in 1988 by a consensus panel convened by the Centers for Disease Control and Prevention (CDC) in an attempt to establish a guide for evaluating patients with chronic fatigue of unknown cause by clinical physicians and researchers.[1]

The CDC established a formal (and controversial) set of diagnostic criteria (Box 160.1). These are controversial for many reasons, including that psychological symptoms are both a minor criterion and potential grounds for exclusion. One of the major complaints from physicians about the CDC definition is that it appears better suited for research than for clinical purposes. A significant problem with the CDC criteria is that they ignore many of the common symptoms reported by patients with CFS (Table 160.1).

The British and Australian criteria for the diagnosis of CFS are less strict than those of the CDC.[2] In particular, the minor diagnostic criteria are not required, and the major diagnostic criteria are not as strict. For example, in the Australian definition, the major criterion is simply fatigue at a level that causes disruption of daily activities in the absence of other medical conditions associated with fatigue.

Using the CDC criteria, the prevalence of CFS in individuals suffering from chronic fatigue in the United States is thought to be about 11.5%. Using the British criteria, it is about 15%, and using the Australian criteria, it is about 38%.[2]

* Previous edition contributor

BOX 160.1 Centers for Disease Control and Prevention Diagnostic Criteria for Chronic Fatigue Syndrome

Major Criteria

- New onset of fatigue causing 50% reduction in activity for at least 6 months
- Exclusion of other illnesses that can cause fatigue

Minor Criteria

- Presence of 8 of the 11 symptoms listed, or 6 of the 11 symptoms and 2 of the 3 signs

Symptoms

1. Mild fever
2. Recurrent sore throat
3. Painful lymph nodes
4. Muscle weakness
5. Muscle pain
6. Prolonged fatigue after exercise
7. Recurrent headache
8. Migratory joint pain
9. Neurological or psychological complaints
   - Sensitivity to bright light
   - Forgetfulness
   - Confusion
   - Inability to concentrate
   - Excessive irritability
   - Depression
10. Sleep disturbance (hypersomnia or insomnia)
11. Sudden onset of symptom complex

Signs

1. Low-grade fever
2. Nonexudative pharyngitis
3. Palpable or tender lymph nodes

TABLE 160.1 Frequency of Symptoms in Chronic Fatigue Syndrome

Symptom/Sign	Frequency (%)
Fatigue	100
Low-grade fever	60–95
Muscle pain	20–95
Sleep disorder	15–90
Impaired mental function	50–85
Depression	70–85
Headache	35–85
Allergies	55–80
Sore throat	50–75
Anxiety	50–70
Muscle weakness	40–70
Postexercise fatigue	50–60
Premenstrual syndrome (women)	50–60
Stiffness	50–60
Visual blurring	50–60
Nausea	50–60
Dizziness	30–50
Joint pain	40–50
Dry eyes and mouth	30–40
Diarrhea	30–40
Cough	30–40
Decreased appetite	30–40
Night sweats	30–40
Painful lymph nodes	30–40

Etiology

Infectious Agents

Owing in part to the similarity of CFS to acute or chronic infection, it was initially thought to be caused by a virus (e.g., EBV mononucleosis).[3] It now seems clear that CFS is not caused by any single recognized infectious disease agent. The CDC's four-city surveillance study found no association between CFS and infection by a wide variety of human pathogens, including EBV, human retroviruses, herpesvirus, rubella, *Candida albicans,* and others. No one pathogen appears to be causing CFS. However, the possibility remains that CFS may have multiple causes leading to a common endpoint, in which case, some viruses or other infectious agents may play a contributing role (Fig. 160.1).

Immune System Abnormalities

There is little argument that a disturbed immune system plays a central role in CFS. A variety of such abnormalities have been reported in CFS patients (Box 160.2). Although no specific immunological dysfunction pattern has been recognized, the most consistent abnormality is a decreased number or activity of natural killer (NK) cells.[4–7] NK cells received their name because of their ability to destroy cells that have become cancerous or infected by viruses. In fact, for a time, CFS was also referred to as *low natural killer cell syndrome* (LNKS).

Other consistent findings include a reduced ability of lymphocytes, key in the battle against viruses, to respond to stimuli.[7] One reason for this lack of response may be reduced activity or decreased production of interferon. Although both low and high levels of interferon have been reported in CFS, levels are depressed in most cases. When interferon levels are low, reactivation of latent viral infection is likely. Conversely, when interferon (as well as other chemical mediators like interleukin-1) levels are high, many of the symptoms may be related to the physiological effects of interferon. When interferon is used as a therapy in cancer and viral hepatitis, the side effects produced are similar to the symptoms of CFS.

Other Causes of Chronic Fatigue

Chronic fatigue can be caused by various physical and psychological factors. Box 160.3 lists the major causes of chronic fatigue in an order of importance that represents how common the cause is among sufferers of chronic fatigue in the general population. The list is based on the findings of several large studies as well as the author's clinical experience (CFS is listed under a broader category of impaired immune function).

Chronic Fatigue Syndrome, Fibromyalgia, and Multiple Chemical Sensitivities

Fibromyalgia (FM) and multiple chemical sensitivities (MCS), like CFS, are recognized disorders with a substantial overlap of symptomatology.[4,5,8,9] The only difference in the diagnostic criteria for FM and CFS is the requirement of musculoskeletal pain in fibromyalgia and fatigue in CFS. The likelihood of being diagnosed as having fibromyalgia or CFS depends on the type of physician consulted. Specifically, if a rheumatologist or orthopedic specialist is consulted, the patient is much more likely to be diagnosed with fibromyalgia. (Box 160.4 presents the diagnostic criteria for fibromyalgia.)

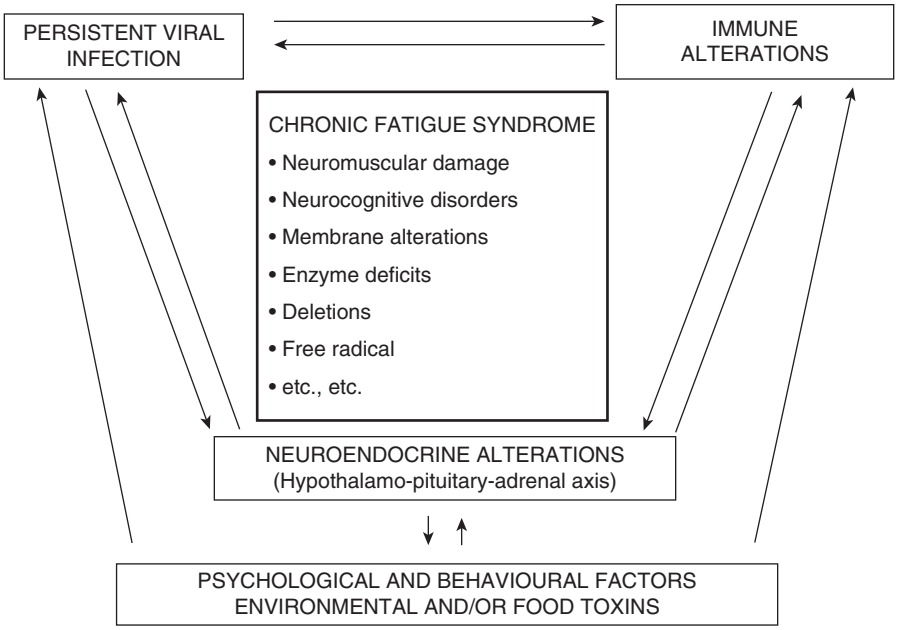

Fig. 160.1 Pathogenic Hypotheses of Chronic Fatigue Syndrome. (From Eligio P. Delia R, Valeria G. EBV chronic infections. *Mediterr J Hematol Infect Dis.* 2010;2[1]:e2010022. PubMed PMID: 21415952.)

BOX 160.2 Immunological Abnormalities Reported for Chronic Fatigue Syndrome

- Elevated levels of antibodies to viral proteins
- Decreased activity of natural killer cells
- Low or elevated antibody levels
- Increased or decreased levels of circulating immune complexes
- Increased cytokine (e.g., interleukin-2) levels
- Increased or decreased interferon levels
- Altered ratio of T-helper cells to T-suppressor cells

One group of researchers carefully compared the symptomatology of 90 patients who had been diagnosed as having CFS, MCS, or FM (30 in each category).[9] Using the same questionnaire for all 90 patients, 70% of the patients diagnosed with FM and 30% of those with MCS met the CDC criteria for CFS. Particularly significant was the observation that 80% of both the FM and MCS patients met the CFS criteria of fatigue lasting more than 6 months, with a 50% reduction in activity. More than 50% of the CFS and FM patients reported adverse reactions to various chemicals.

DIAGNOSIS

A great number of factors must be considered when evaluating a patient with chronic fatigue. Women tend to be at higher risk than men.[10] A detailed medical history and review of body systems goes a long way toward identifying important factors. The goal is to identify as many factors as possible that may be contributing to the patient's feeling of fatigue. For example, if a patient has heart disease, diabetes, or some other health condition and the condition or the drug he or she is taking is clearly responsible for the fatigue, the treatment of the fatigue becomes secondary to the treatment of his or her underlying health condition.

In many cases of chronic fatigue, further evaluation is necessary. The next steps can include a complete physical examination and laboratory studies. In the physical examination, it is important to look for clues that may point to the cause of chronic fatigue. For example, swollen lymph nodes may indicate a chronic infection, and the presence of a diagonal crease on both earlobes usually indicates impaired blood flow to the brain, a significant cause of fatigue in the elderly.

BOX 160.3 Causes of Chronic Fatigue

- Preexisting physical condition
  - Diabetes
  - Heart disease
  - Lung disease
  - Rheumatoid arthritis
  - Chronic inflammation
  - Chronic pain
  - Cancer
  - Liver disease
  - Multiple sclerosis
- Prescription drugs
  - Antihypertensives
  - Anti-inflammatory agents
  - Birth control pills
  - Antihistamines
  - Corticosteroids
  - Tranquilizers and sedatives
- Depression
- Stress and/or low adrenal function
- Impaired liver function, environmental illness, or both
- Impaired immune function
  - Chronic *Candida* infection
  - Other chronic infections
- Food allergies
- Hypothyroidism
- Hypoglycemia
- Anemia and nutritional deficiencies
- Sleep disturbances
- Cause unknown

BOX 160.4 Diagnostic Criteria for Fibromyalgia[a]

Major Criteria

- Generalized aches or stiffness of at least three anatomical sites for at least 3 months
- Six or more typical reproducible tender points
- Exclusion of other disorders that can cause similar symptoms

Minor Criteria

- Generalized fatigue
- Chronic headache
- Sleep disturbance
- Neurological and psychological complaints
- Joint swelling
- Numbness or tingling sensations
- Irritable bowel syndrome
- Variation of symptoms in relation to activity, stress, and weather changes

[a]Fulfillment of all three major criteria and four or more minor criteria required.
Data from Murphree R. Treating and beating fibromyalgia. http://drrodgermurphree.com/fibromyalgia/.

Plasma neuropeptide Y (PNY) has been reported as a potential biomarker for symptom severity in CFS.[11] Clinical research has demonstrated a significant correlation of PNY with stress, negative mood, general health, depression, and impaired cognitive function. However, expensive laboratory tests are best not ordered unless they are absolutely necessary. For example, if it is quite obvious that the patient has impaired immunity, it does not make much sense to perform elaborate and expensive blood tests on immune function because the results of these tests are not likely to influence the method of treatment.

Of particular value are assessments of liver detoxification function, bowel dysbiosis, and gastrointestinal permeability (see Chapters 9, 19, and 28).

THERAPEUTIC CONSIDERATIONS

Because chronic fatigue and CFS are generally multifactorial conditions, the therapeutic approach typically involves multiple therapies that address different facets of the clinical picture.

A person's energy level, as well as his or her emotional state, is determined by an interplay between two primary factors—internal focus and physiology. Many people with chronic fatigue focus on how tired they are. They repeatedly reaffirm their fatigue to themselves and to anyone who will listen. Their physiology includes not only the chemicals and hormones circulating in the body but also the way they hold their bodies (usually slouched) and the way they breathe (shallow). In most patients with chronic fatigue, both the mind and the body must be addressed. The most effective treatment is a comprehensive program designed to help people use their minds, attitudes, and physiologies to fuel higher energy levels.

Underlying Physiological Dysfunctions

Depression

The first factor to address is any underlying depression. Depression is one of the major causes of chronic fatigue, and it is a common feature of CFS. In the absence of a preexisting physical condition, depression is generally regarded as the most common cause of chronic fatigue. However, it is often difficult to determine whether the depression preceded the fatigue or vice versa. Depression is fully discussed in Chapter 142.

Stress

Stress is another factor to consider in the patient with chronic fatigue or CFS (Fig. 160.2). Stress can be the underlying factor in the patient with depression, low immune function, or another cause of chronic fatigue (see Chapter 140 for guidelines on assessing the role of stress).

One of the tools recommended to rate stress levels is the Social Readjustment Rating Scale developed by Holmes and Rahe.[12] The scale was originally designed to predict the likelihood of a person getting a serious disease due to stress. Various life-changing events are numerically rated according to their potential for causing disease. Even events commonly viewed as positive, such as an outstanding personal achievement, carry stress with them.

Impaired Liver Function, Environmental Illness, or Both

Exposure to food additives, solvents (e.g., cleaning materials, formaldehyde, toluene, benzene), pesticides, herbicides, toxic metals (e.g., lead, mercury, cadmium, arsenic, nickel, aluminum), and other toxins can greatly stress the liver and detoxification processes.[13,14] This exposure can lead to a condition labeled by many naturopathic and nutrition-oriented physicians as the "congested liver," "sluggish liver," or the more recently coined "impaired hepatic detoxification." These terms signify a reduced ability of the liver to detoxify. The congested or sluggish liver is characterized by a diminished bile flow, a condition known in medical terms as cholestasis or steatohepatitis, whereas the term *impaired hepatic detoxification* refers to decreased Phase I or II enzyme activity, or both. Phase I detoxification rates in excess of Phase II activity also cause toxicity problems owing to excessive accumulation of activated intermediates. In addition to exposure to toxic chemicals, various other agents and conditions, as listed in Box 160.5, can cause impairment of bile flow within the liver.

Although many of the conditions listed in Box 160.5 are typically associated with alterations in laboratory tests of liver function (e.g., serum bilirubin, aspartate aminotransferase, alanine transaminase, lactate dehydrogenase, γ-glutamyl transpeptidase), these tests alone may not be adequate to evaluate liver function because they are elevated only when the liver has been significantly damaged, and many of these conditions in the initial or "subclinical" stages of chronic fatigue may yield normal laboratory values.

Although there are more sensitive tests to determine the functional activity of the liver, such as the serum bile acid assay and various clearance tests, clinical judgment based on medical history remains the major diagnostic tool for the "sluggish liver" or impaired hepatic detoxification enzymes, the presence of chronic fatigue being the hallmark symptom.

People with a sluggish liver may also complain of the following:

- Depression
- General malaise
- Headaches
- Digestive disturbances
- Allergies and chemical sensitivities
- Premenstrual syndrome
- Constipation

Not surprisingly, people exposed to toxic chemicals often complain of the same symptoms. Many toxic chemicals (especially solvents) and toxic metals have an affinity for nervous tissue, giving rise to various psychological and neurological symptoms[14,15]:

- Depression
- Headaches

BOX 160.5 Causes of Cholestasis

- Dietary factors
  - Saturated fat
  - Refined sugar
  - Low fiber intake
  - Obesity
- Diabetes
- Presence of gallstones
- Alcohol
- Endotoxins and other gut-derived bacterial toxins
- Hereditary disorders such as Gilbert's syndrome
- Pregnancy
- Natural and synthetic steroid hormones
- Anabolic steroids
- Estrogens
- Oral contraceptives
- Certain chemicals or drugs
- Cleaning solvents
- Pesticides
- Antibiotics
- Diuretics
- Nonsteroidal anti-inflammatory drugs
- Thyroid hormone
- Viral hepatitis

- Mental confusion
- Mental illness
- Tingling in the extremities
- Abnormal nerve reflexes
- Other signs of impaired nervous system function

A hair mineral analysis is a possible screening test for metal toxicity. Refer to Chapter 22 (Metal Toxicity: Assessment of Exposure and Retention) for further discussion.

A multiclinic research study of chronically ill patients, many of whom were diagnosed as suffering from CFIDS, evaluated the efficacy of a comprehensive detoxification program. Patients were placed on a hypoallergenic diet and given a dietary food supplement rich in nutrients that assist in liver detoxification. These patients reported a 52% reduction in symptoms after 10 weeks, and symptom improvement was mirrored by normalization of hepatic Phase I and Phase II detoxification.[15]

Gastrointestinal Permeability

Excessive gastrointestinal permeability, as measured by the lactulose-mannitol absorption test (see Chapter 19), is a common finding in CFS.[16]

Hepatic Detoxification Functions

A treatment program using hypoallergenic rice protein food replacement formula to support hepatic Phases I and II detoxification was provided to patients who fulfilled the classic criteria of the CDC

BOX 160.6 Questionnaire for the Recognition of Impaired Immune Function

- Do you get more than two colds per year?
- When you catch a cold, does it take more than 5 to 7 days to get rid of the symptoms?
- Have you ever had infectious mononucleosis?
- Do you have herpes?
- Do you suffer from chronic infections of any kind?

and National Institutes of Health for CFS. The treatment resulted in symptom reduction, with clinical improvement being paralleled by improved hepatic detoxification function.[17]

Impaired Immune Function, Chronic Infection, or Both

When the immune system is impaired, infections can linger, and fatigue can persist. There is a good reason for this: fatigue is the body's response mechanism to infection because the immune system works best when the body is at rest.

To determine the role that the immune system is playing in patients with chronic fatigue, the series of questions listed in Box 160.6 can be used during the patient interview to indicate an impaired immune system. Chapter 18 describes in substantial detail the laboratory methodologies for assessing immune function.

Chronic Candidal Infection

One of the most common findings in individuals with impaired immune function is gastrointestinal overgrowth of *Candida albicans*. Candidal overgrowth is now becoming recognized as a complex medical syndrome also known as the "yeast syndrome" and "chronic candidiasis." This overgrowth is believed to cause a wide variety of symptoms in virtually every system of the body, with the gastrointestinal, genitourinary, endocrine, nervous, and immune systems being the most susceptible. Box 160.7 lists the profile of a typical patient with chronic candidiasis (see Chapter 159 for a comprehensive discussion).

The diagnosis of chronic candidiasis is often difficult because there is no specific diagnostic test. Stool cultures and elevated antibody levels to *Candida* are useful diagnostic aids, but they should not be relied on for diagnosis. The best method for diagnosing chronic candidiasis in most cases is a detailed medical history and patient questionnaire (see Appendix 1). Box 160.8 lists the factors that typically predispose a patient to candidal overgrowth.

Food Allergies

As far back as 1930, chronic fatigue was recognized as a key feature of food allergies.[18] Originally, Rowe and Rowe[19] used the term *allergic toxemia* to describe a syndrome that included the symptoms of fatigue, muscle and joint aches, drowsiness, difficulty in concentration, nervousness, and depression. Around the 1950s, this syndrome began to be referred to as the "allergic tension-fatigue syndrome."[19] With the popularity of CFS, many physicians and others are forgetting that food allergies can lead to chronic fatigue. Furthermore, between 55% and 85% of individuals with CFS have allergies. For more information on food allergies, see Chapter 14.

Hypothyroidism

Hypothyroidism is a common cause of chronic fatigue. However, the condition is often overlooked. The reason for this may be the reliance on standard blood measurements of thyroid hormone levels as the method of diagnosis.[20–22] Undiagnosed hypothyroidism is a serious concern because failure to treat such a critical and underlying problem

BOX 160.7 Typical Profile of Patient With Chronic Candidiasis

- Gender: female
- Age: 15 to 50 years

General Symptoms
- Chronic fatigue
- Loss of energy
- General malaise
- Decreased libido

Gastrointestinal Symptoms
- Thrush
- Bloating, gas
- Intestinal cramps
- Rectal itching
- Altered bowel function

Genitourinary System Complaints
- Vaginal yeast infection
- Frequent bladder infections
- Primarily menstrual complaints

Nervous System Complaints
- Depression
- Irritability
- Inability to concentrate

Immune System Complaints
- Allergies
- Chemical sensitivities
- Low immune function

Past History
- Chronic vaginal yeast infections
- Chronic antibiotic use for infections or acne
- Oral birth control use
- Oral steroid hormone use

Associated Conditions
- Premenstrual syndrome
- Sensitivity to foods, chemicals, and other allergens
- Endocrine disturbances
- Psoriasis
- Irritable bowel syndrome

BOX 160.8 Factors Predisposing to Candidal Overgrowth

- Impaired immune function
- Antiulcer drugs
- Broad-spectrum antibiotics
- Cellular immunodeficiency
- Corticosteroids
- Diabetes mellitus
- Excessive sugar in the diet
- Intravascular catheters
- Intravenous drug use
- Lack of digestive secretions
- Oral contraceptive agents

reduces the effectiveness of every other measure designed to increase energy levels. For more information, see Chapter 182.

Hypoglycemia

The association between hypoglycemia and fatigue is well known. Numerous studies have shown that depressed individuals suffer from hypoglycemia.[23–26] Because depression is the most common cause of chronic fatigue, hypoglycemia must always be ruled out (see Chapter 181).

Hypoadrenalism

Adrenal exhaustion was first proposed as a cause of chronic fatigue more than 50 years ago by Tintera.[27] A small but growing body of evidence now supports the role of a disruption of the hypothalamic–pituitary–adrenal (HPA) axis in CFS.[28] Salivary tests of patients with chronic fatigue show lower cortisol levels on wakening.[29] Other research suggests that there is no specific change to the HPA axis in CFS and that the observed changes are of multifactorial etiology, with some factors occurring as a consequence of the illness. This second school of thought suggests that the HPA axis might play a role in exacerbating or perpetuating symptoms late in the course of the illness but not as a primary etiology.[30]

Either way, one of the major symptoms of glucocorticoid deficiency is debilitating fatigue. Glucocorticoid insufficiency is also characterized by a stressing event followed by feverishness, arthralgias, myalgias, adenopathy, postexertional fatigue, exacerbation of allergic responses, and disturbances of mood and sleep (i.e., the typical presentation of CFS). These symptoms are seen in partial or subclinical adrenal insufficiency, which may be detected only by the adrenocorticotropic hormone (ACTH) stimulation test or other endocrine testing. Glucocorticoids have a profound endogenous immunosuppressive effect. In subclinical adrenal insufficiency, this may allow for the symptoms of chronic fatigue, including exacerbation of allergic responses, enhanced antibody titers to various viral antigens, and elevations in cytokine levels. A group of CFS researchers believes that these patients form a heterogeneous group with various infectious and noninfectious antecedents.[28] They feel that CFS does not represent a discrete disease with a singular cause but rather a clinical condition. CFS is analogous to a number of complex medical conditions, such as hypertension, in which various direct and indirect factors lead to the development of the clinical syndrome.

The researchers hypothesize that in CFS, specific pathophysiological antecedents such as acute infection, stress, and preexisting or concurrent psychiatric illness may ultimately converge in a final common biological pathway, resulting in the clinical syndrome of CFS. They believe that their data and those of others suggest that a reduction in adrenocortical secretion is an important pathophysiological component in the development of many biological and behavioral features of the syndrome.

For example, in one of their studies, 30 patients with classically defined CFS were compared with 72 normal volunteers and patients.[31] The CFS patients were found to have significantly reduced evening cortisol levels and low 24-hour urinary-free cortisol excretion. The CFS patients also had elevated basal ACTH concentrations and increased adrenocortical sensitivity to ACTH but a reduced maximal response, and they showed an attenuated net integrated ACTH response to corticotrophin-releasing hormone. These results are most compatible with a mild central adrenal insufficiency secondary to either a deficiency of corticotrophin-releasing hormone (CRH) or some other central stimulus to the pituitary–adrenal axis. The authors feel that the hyperresponsiveness of the adrenal cortex to ACTH in patients with CFS may reflect a secondary adrenal insufficiency in which adrenal ACTH receptors have become hypersensitive owing to inadequate exposure to ACTH. The reduction in response to large doses of ACTH might suggest overall adrenal atrophy. The evidence suggests that the mild hypocortisolism in these patients reflects a defect at or above the level of the hypothalamus, resulting in a deficiency in the release of CRH or other secretagogues, or both, that serve to activate the pituitary–adrenal axis.

Endotoxins

Endotoxins are lipopolysaccharides (LPSs) from the cell walls of gram-negative bacteria. One bacterial cell contains approximately 3.5 million LPS molecules. Upon bacterial cell death, cell-wall lysis occurs, releasing LPS to interact with intestinal cell membranes and surface proteins, triggering local and systemic inflammatory reactions. Patients with diagnosed CFS have been shown to have significantly higher circulating LPS levels than healthy controls (119.43 pg/mL versus 74.74 pg/mL).[32] They also have higher levels of CD 14 (49 µg/mL versus 39 µg/mL in controls) and high sensitivity C-reactive protein (46 mg/L versus 34 mg/L in controls). In addition, CFS patients had lower intestinal microbiome diversity with significantly diminished *Firmicutes* population.

Mind and Attitude

The mind and attitude play a critical role in determining the status of the immune system and energy levels. Many patients with chronic fatigue (including CFS) are either depressed or just seem to have lost a real enthusiasm for life. It is not easy to have much enthusiasm when you do not have much energy, but the two usually go hand in hand. Related to these psychological difficulties, it has been shown that there is a lack of social support for CFS patients.[33] It is a question of whether the lack of energy affects the CFS patient's ability to maintain a relationship, or vice versa, or possibly both.

Cognitive-behavioral therapy has shown some effective results in clinical use.[34,35] The first step is to convey to CFS patients that they can get better. Many patients with CFS are told that this is "something they will have to live with" and that "there is no cure." Achieving or maintaining a positive mental attitude is critical to good health and high energy levels, especially in patients with CFS. To achieve a positive mind-set, a person must exercise or condition the attitude, much as one would condition the body. To help patients, physicians can prescribe mental exercises such as visualizations, goal setting, affirmations, and empowering questions, as detailed in Chapter 142.

Diet

Energy level appears to be directly related to the quality of foods routinely ingested. Patients should be encouraged to adhere to the dietary guidelines given in Chapter 44. It is especially important to eliminate or restrict caffeine and refined sugar.

Although acute caffeine consumption provides stimulation, regular caffeine intake may actually lead to chronic fatigue. Although mice fed one dose of caffeine demonstrated significant increases in their swimming capacity, when the dose of caffeine was given repeatedly for 6 weeks, a significant decrease in the mice's swimming capacity was observed.[36]

Several studies have found caffeine intake to be extremely high in individuals with psychiatric disorders. Another interesting finding is that the degree of fatigue experienced is often related to the quantity of caffeine ingested. In one survey of hospitalized psychiatric patients, 61% of those ingesting at least 750 mg/day (at least five cups of coffee) complained of fatigue, compared with 54% of those ingesting 250 to 749 mg/day and only 24% of those ingesting less than 250 mg/day.[37]

In patients who routinely drink coffee, abrupt cessation of coffee drinking will probably result in symptoms of caffeine withdrawal, including fatigue, headache, and an intense desire for coffee.[38,39] Fortunately, this withdrawal period does not last more than a few days.

Nutritional Supplements

Nutritional supplementation is essential in the treatment of chronic fatigue. A deficiency of virtually any nutrient can produce the symptoms of fatigue as well as render the body more susceptible to infection. Individuals with chronic fatigue require, at the bare minimum, a high-potency multivitamin-multimineral formula along with extra vitamin C (3000 mg/day in divided doses) and magnesium (500–1200 mg/day in divided doses).

Magnesium

An underlying magnesium deficiency, even if subclinical, can result in chronic fatigue and symptoms similar to those of CFS. In addition, low red blood cell magnesium levels, a more accurate measure of magnesium status than routine blood analysis, have been found in many patients with chronic fatigue and CFS. The literature demonstrates that magnesium deficiency is not necessarily due to low dietary intake,[40] and several studies have shown good results with supplementation with improvements in magnesium stores.

For example, in one double-blind, placebo-controlled trial, 32 patients with CFS received an intramuscular injection of either magnesium sulfate (1 g in 2 mL of injectable water) or a placebo (2 mL of injectable water) for 6 weeks. At the end of the study, 12 of the 15 patients receiving magnesium reported, on the basis of strict criteria, significantly improved energy levels, improved emotional state, and less pain. In contrast, only 3 of the 17 placebo patients reported that they felt better, and only 1 reported improved energy levels.[41]

This study seems to confirm some impressive results obtained in clinical trials during the 1960s on patients suffering from chronic fatigue.[42–45] These studies used oral magnesium and potassium aspartate (1 g each) rather than injectable magnesium. Between 75% and 91% of the nearly 3000 patients studied experienced relief of fatigue during treatment with the magnesium and potassium aspartate. In contrast, the number of patients responding to a placebo was between 9% and 26%. The beneficial effect was usually noted after only 4 to 5 days, but sometimes it took as long as 10 days to achieve results. Patients usually continued treatment for 4 to 6 weeks; afterward, fatigue frequently did not return.

Injectable magnesium is not necessary to restore magnesium status.[46] Absorption studies indicate that magnesium is easily absorbed orally when it is bound to aspartate or citrate. In addition, both of these compounds may also help fight fatigue. Aspartate feeds into the Krebs cycle, the final common pathway for the conversion of glucose, fatty acids, and amino acids to chemical energy (adenosine triphosphate [ATP]), whereas citrate is itself a component of the Krebs cycle. Krebs cycle components, including aspartate, citrate, fumarate, malate, and succinate, usually provide a better mineral chelate; evidence suggests that minerals chelated to the Krebs cycle intermediates are better absorbed, used, and tolerated compared with inorganic or relatively insoluble mineral salts, including magnesium chloride, oxide, or carbonate.[46,47]

Essential Fatty Acids

In one study, essential fatty acid supplementation was shown to improve the clinical picture and red blood cell phospholipid membrane profile of patients with postviral fatigue. The preparation given contained linoleic, gamma-linolenic, eicosapentaenoic, and docosahexaenoic acids and was given as eight 500-mg capsules per day over a 3-month period.[48] In another study, an essential fatty acid supplement rich in eicosapentaenoic acid (EPA) was given daily to a female patient with a 6-year history of unremitting symptoms of CFS.

Within 6 to 8 weeks, the EPA-rich essential fatty acid supplementation led to a marked clinical improvement in the symptoms of CFS.[49] Previous research suggests that CFS is associated with pathophysiological brain changes, such as an enlargement in cerebral ventricular volume.[50] More clinical research is needed.

Nicotinamide Adenine Dinucleotide

Nicotinamide adenine dinucleotide (NADH), the active coenzyme form of vitamin B_3, has been shown to be effective in countering the negative effects of jet lag on cognition and wakefulness.[51] It is also known to encourage energy production through increased ATP generation. One small trial of NADH found a beneficial effect and improvement in quality of life in patients with CFS. This study supplemented the stabilized oral absorbable form in a 26-subject randomized, double-blind, placebo-controlled crossover study. Subjects were randomly assigned to receive either 10 mg of NADH or placebo for 1 month. After a 1-month washout period without supplement, subjects were then crossed to the alternate regimen for a final 1-month period. Within this cohort of 26 patients, 8 of 26 (31%) responded favorably to NADH, in contrast to 2 of 26 (8%) to placebo. No severe adverse effects were observed related to NADH,[52] nor have studies in animals shown any toxicity, even at megadoses.[53] More clinical research is necessary to fully elucidate the possible beneficial effects of NADH in patients with CFS.

L-Carnitine

Carnitine is an essential nutrient for the transport of long-chain fatty acids into the mitochondrial matrix. One randomized controlled crossover study compared the efficacy of L-carnitine with amantadine, a drug known to relieve fatigue in patients with multiple sclerosis. Each intervention was given for 2 months, with a 2-week washout period between medicines. In 30 patients with CFS, L-carnitine or amantadine was given as the first medicine. Amantadine was poorly tolerated by the CFS patients, of whom only 15 were able to complete the 8 weeks of treatment. In those individuals who completed 8 weeks of treatment, there was no statistically significant difference in any of the clinical parameters. With L-carnitine, there was a statistically significant clinical improvement in 12 of the 18 studied parameters after 8 weeks of treatment, with none of the clinical parameters showing any deterioration. The greatest improvement took place between weeks 4 and 8 of L-carnitine treatment. Only one patient, owing to diarrhea, was unable to complete the eight-treatment course.[54] L-Carnitine is extremely safe, with no significant side effects having been reported in any of the human clinical studies.

Coenzyme Q10 (CoQ10)

CoQ10 plays a role as a mitochondrial nutrient that acts as an essential cofactor to produce ATP in the mitochondria.[55] Plasma CoQ10 has been found to be significantly lower ($P = 0.00001$) in CFS patients than in controls. Symptoms such as fatigue and neurocognitive impairment may be related to CoQ10 depletion. In one randomized controlled trial, 43 patients with CFS were randomly assigned to receive either ubiquinol-10 (150 mg/day) or placebo every day for 12 weeks.[56] Although no direct improvement in fatigue was observed, measured with Chandler's Fatigue Scale, ubiquinol-10 supplementation improved several CFS symptoms (e.g., nighttime awakenings), which may have longer-term effects on reducing fatigue in CFS patients.

Melatonin

Dim-light melatonin onset (DLMO) is a naturally occurring event that may account for delayed-sleep-phase syndrome in 10% of patients with chronic insomnia. Research on DLMO concluded that a certain subset of CFS patients may respond to the therapeutic use of melatonin.

In one study, 29 patients with CFS were asked to take 5 mg of melatonin at bedtime for 3 months.[57] Several variables were measured using the Checklist Individual Strength (CIS) questionnaire. The authors determined that the total score ($P = 0.006$), as well as the subscores of fatigue ($P = 0.017$), concentration ($P = 0.031$), motivation ($P = 0.010$), and activity ($P = 0.008$), improved significantly after 90 days of melatonin use. Additionally, in those patients with late DLMO (>21.30 hours), overall CIS scores and its subscores were better than in those CFS patients with early DLMO.

Botanical Medicines

Several botanical medicines support adrenal function and may offer significant benefits in CFS. Most notable are adaptogens, such as Chinese ginseng *(Panax ginseng)*, Siberian ginseng *(Eleutherococcus senticosus)*, rhodiola (*Rhodiola rosacea*), and ashwaganda (*Withania somnifera*). The effects of these herbs as "adaptogens" are discussed in Chapter 140, Stress Management. Of these herbal adaptogens, both Siberian ginseng and rhodiola have shown effects specific to CFS.

Siberian Ginseng *(E. senticosus)*

In addition to supporting adrenal function and acting as a nonspecific adaptogen, Siberian ginseng has been shown to exert a number of beneficial effects on immune function that may be useful in the treatment of CFS. In one double-blind study, 36 healthy subjects received either 10 mL of a fluid extract of ginseng or placebo daily for 4 weeks.[58] The group receiving the ginseng demonstrated significant improvements in various immune system parameters. Most notable were a significant increase in T-helper cells and an increase in NK cell activity—both of which are of value in the treatment of CFS.

Rhodiola rosea

Rhodiola rosea (artic root) is a popular plant in traditional medical systems in Eastern Europe and Asia, where it has traditionally been recommended to help combat fatigue and restore energy. In one randomized, placebo-controlled trial of 60 patients with stress-related fatigue, Rhodiola was found to have an antifatigue effect that increased mental performance, particularly the ability to concentrate, and decreased the cortisol response to awakening stress.[59]

Licorice Root *(Glycyrrhiza glabra)*

Considering the possible roles of viral infection and hypoadrenalism in CFS, licorice root, with its antiviral and glucocorticoid-potentiating properties (see Chapter 85 for documentation of these properties), would seem to be an ideal botanical for this condition.[60] Unfortunately, this has not been rigorously evaluated, although an excellent response in a single patient has been reported.[61] The whole root must be used to ensure glucocorticoid-potentiating glycyrrhizic and glycyrrhetinic acid activity.

Other Therapies

Breathing, Posture, and Bodywork

Proper care of the body is critical to the achievement of high levels of energy. Breathing with the diaphragm, good posture, and bodywork (e.g., massage, spinal manipulation) are all important in helping relieve the stress that is a common contributor to fatigue.

Exercise

Exercise alone has been demonstrated to have a tremendous effect on mood and the ability to handle stressful life situations.[62] Regular exercise has also been shown to lead to improved immune status. For CFS patients, regular exercise has been shown to lead to a significant increase (up to 100%) in NK cell activity.[63,64] Although more strenuous exercise is required to benefit the cardiovascular system, light to moderate exercise may be best for the immune system. One study found that immune function was significantly increased by the practice of tai chi exercises.[65] Tai chi is a martial art technique that features movement from one posture to the next in a flowing motion that resembles dance.

Research suggests that light to moderate exercise stimulates the immune system, whereas intense exercise (e.g., training for the Olympics) can have the opposite effect.[36,66] Graded exercise therapies, in which the patient begins with gradual walking and weight exercises and increases duration and intensity as is comfortable over time, may be the best approach.[67] Although there is a concern for overtraining, one study has shown this method to be superior to relaxation and flexibility exercises.[68]

THERAPEUTIC APPROACH

Successful treatment of CFS requires a comprehensive diagnostic and therapeutic approach. Especially important is identifying underlying factors that may be affecting the patient's energy levels or immune system. The strong correlation between CFS, FM, and MCS suggests that all may respond to hepatic detoxification, food allergy control, and a gut-restoration diet. Special attention should be paid to the advice on immune support in Chapter 136.

Diet

Food allergies should be identified and controlled. Water consumption should increase, whereas the consumption of caffeine-containing drinks and alcohol should stop. A diet of whole organically grown foods should be encouraged. Hypoglycemia should be controlled through the elimination of sugar and other refined foods and the regular consumption of small meals and snacks.

Lifestyle

The patient should be taught diaphragmatic breathing and proper posture. A regular exercise program should be prescribed; low-intensity activities may produce the greatest benefits.

Supplementation

- High-potency multivitamin and mineral formula according to guidelines given in Chapter 44
- Vitamin C: 500 to 1000 mg three times a day
- Vitamin E (mixed tocopherols): 200 to 400 IU/day
- Magnesium bound to citrate or Krebs cycle intermediates: 200 to 300 mg three times a day
- Pantothenic acid: 250 mg/day
- NADH: 10 mg/day on an empty stomach
- L-Carnitine: 1500 to 2000 mg/day in divided doses (if unresponsive, try acetyl-L-carnitine)
- Fish oil: 5 g/day for at least 3 to 4 months
- Coenzyme Q10: 200 to 300 mg/day

Botanical Medicines

- Siberian ginseng *(E. senticosus)*
  - Dried root: 2 to 4 g
  - Tincture (1:5): 10 to 20 mL
  - Fluid extract (1:1): 2 to 4 mL
  - Solid (dry powdered) extract (20:1 or standardized to contain >1% eleutheroside E): 100 to 200 mg
- *R. rosea*
  - The therapeutic dose varies according to the rosavin content. The typical dosage is 200 to 300 mg/day of the extract standardized to contain 3% rosavins and 0.8% to 1% of salidroside.

- Licorice root *(G. glabra)*
  - Powdered root: 1 to 2 g
  - Fluid extract (1:1): 2 to 4 mL
  - Solid (dry-powdered) extract (4:1): 250 to 500 mg

Counseling

The patient should either be counseled directly or referred to a professional counselor for cognitive-behavioral therapy[69] and to establish a regular pattern of mental, emotional, and spiritual affirmations.

Congestive Heart Failure

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Left ventricular failure—exertional dyspnea, cough, fatigue, orthopnea, cardiac enlargement, rales, gallop rhythm, and pulmonary venous congestion
- Right ventricular failure—elevated venous pressure, hepatomegaly, dependent edema
- Both left and right ventricular failure
- Diagnosis confirmed by echocardiography

GENERAL CONSIDERATIONS

Congestive heart failure (CHF) refers to the inability of the heart to pump enough blood. The contractile function of the heart is governed by five primary factors:

- The contractile state of the myocardium
- The preload of the ventricle
- End-diastolic volume
- Impedance to left ventricular ejection
- Heart rate

Chronic CHF is most often due to the long-term effects of high blood pressure, previous myocardial infarction, disorder of a heart valve, cardiomyopathy, or chronic lung disease. These conditions produce CHF by affecting one or more of the primary determinants of myocardial contractile function. (Precipitating or exacerbating factors in CHF are presented in Box 161.1.)

One of the most serious consequences of reduced cardiac output is a reduction in renal blood flow and the glomerular filtration rate, which in turn leads to fluid retention and dilutional hyponatremia (Fig. 161.1). In addition, activation of the renin–angiotensin–aldosterone system leads to an increase in peripheral vascular resistance, increased ventricular afterload, and increased levels of circulating vasopressin, which also serves as a vasoconstrictor and antidiuretic.

To compensate for the reduced cardiac output, several mechanisms occur: tachycardia, increased activation of the sympathetic nervous system, ventricular dilation, and hypertrophy. Although the increase in sympathetic activity increases cardiac output by increasing heart rate and force of contraction, it also leads to increased vascular resistance.

The signs and symptoms of CHF depend on which ventricle has failed. The clinical symptoms of left ventricular failure are dominated by symptoms of pulmonary congestion and edema, whereas right ventricular failure is characterized by signs of systemic venous congestion and peripheral edema. Weakness, fatigue, and shortness of breath are common to both right and left ventricular failure as well as biventricular failure.

DIAGNOSTIC CONSIDERATIONS

CHF is most effectively treated via natural measures in the early stages. Hence, early diagnosis and prevention by addressing causative factors are imperative. The first symptom of CHF is usually shortness of breath. A chronic nonproductive cough may also be the first manifesting symptom. Patients suspected of having CHF should have an extensive cardiovascular evaluation, including a complete physical examination to look for the characteristic signs of CHF (e.g., peripheral signs of heart failure, enlarged and sustained left ventricular impulse, diminished first heart sound, gallop rhythm), electrocardiography, and echocardiography.

THERAPEUTIC CONSIDERATIONS

In the initial stages of CHF, natural measures designed to address the underlying cause (e.g., hypertension) or improve the metabolic functions of the myocardium (described later, as well as measures described in Chapter 145) are often effective. In later stages, however, medical treatment involving the use of diuretics and angiotensin-converting enzyme (ACE) inhibitors, digitalis glycosides, or both is indicated in most cases. The measures described here can be used as adjunctive therapy in these more severe cases. The New York Heart Association (NYHA) staging system for CHF can be used in an effort to better identify likely respondents to natural therapy alone (Table 161.1). In general, excellent clinical results can be expected in stages I and II with the use of the natural measures described in this chapter.

Nutritional Supplements

The natural approach focuses on improving myocardial energy production because CHF is always characterized by a state of energy

BOX 161.1 Precipitating or Exacerbating Factors in Congestive Heart Failure

- Low levels of essential fatty acids
- Increased platelet aggregation
- Increased demand
  - Anemia
  - Fever
  - Infection
  - Fluid overload
  - Increased sodium intake
  - High environmental temperature
  - Renal failure
  - Hepatic failure
  - Thyrotoxicosis
  - Arteriovenous shunt
  - Respiratory insufficiency
  - Emotional stress
  - Pregnancy
  - Obesity
- Arrhythmias
- Pulmonary embolism
- Ethanol ingestion
- Nutrient deficiency
- Uncontrolled hypertension
  - Drugs
  - Beta-adrenergic blockers
  - Antiarrhythmic drugs
  - Sodium-retaining drugs
    - Corticosteroids
    - Nonsteroidal anti-inflammatory drugs

depletion. This impaired energy production is often the result of a nutrient or coenzyme deficiency (e.g., magnesium, thiamine, coenzyme Q_{10} [CoQ_{10}], carnitine). The dietary recommendations given in Chapter 174 are appropriate for most patients with CHF, especially if the CHF is due to long-term hypertension. Of particular importance is a diet low in sodium and high in potassium. A high intake of sodium greatly exacerbates the hemodynamic aspects of CHF. Sodium intake should be restricted to below 1.8 g daily. Furthermore, the dietary intake of several nutrients is usually well below recommended levels in patients with CHF.[1] Most notably low are magnesium, calcium, zinc, copper, manganese, thiamine, riboflavin, and folic acid. A high-potency multivitamin/multimineral formula is critical in these patients, especially if they are taking a diuretic.

Magnesium

Low magnesium levels (particularly white blood cell [WBC] magnesium) are commonly found in patients with CHF. This association is extremely significant because magnesium levels have been shown to correlate directly with survival rates. In one study, CHF patients with normal levels of magnesium had 1- and 2-year survival rates of 71% and 61%, respectively, compared with rates of 45% and 42%, respectively, in patients with lower magnesium levels.[2] These results are not surprising considering that magnesium deficiency is associated with cardiac arrhythmias, reduced cardiovascular prognosis, worsened ischemia, and increased mortality in acute myocardial infarction.

The magnesium deficiency probably stems from a combination of inadequate intake and increased wasting due to overactivation of the renin–angiotensin–aldosterone system, as is commonly seen in patients with heart failure. It can also be the effect of diuretics like furosemide.

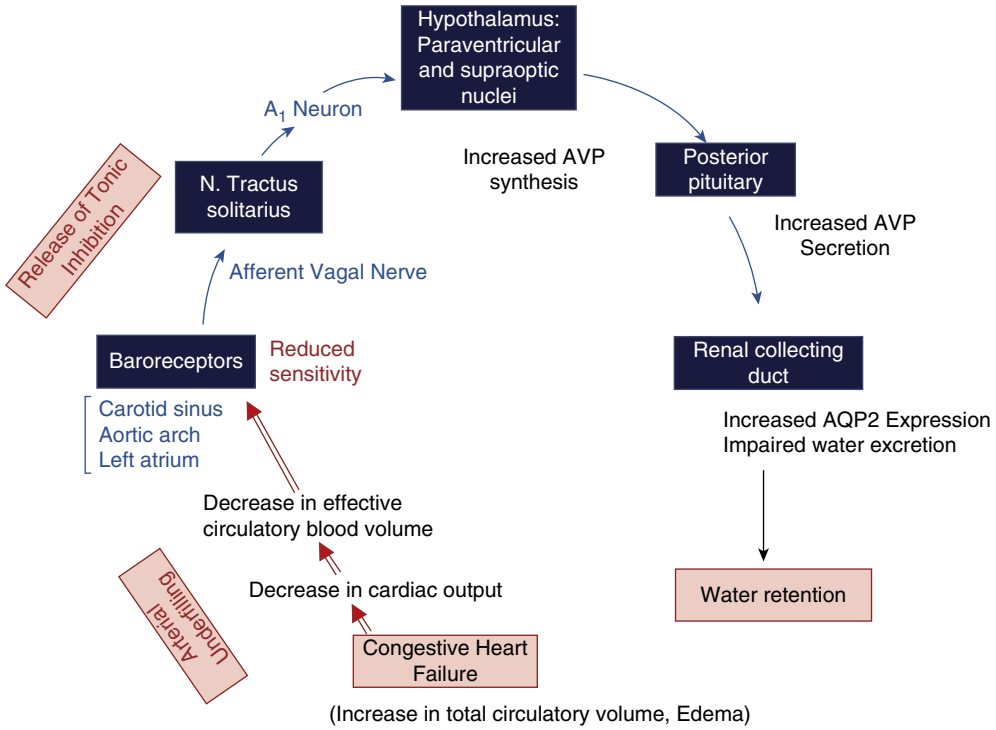

Fig. 161.1 Pathological role of AVP in impaired water excretion in congestive heart failure. *AQP2,* aquaporin-2; *AVP,* arginine vasopressin. (Ishikawa, SE. Hyponatremia associated with heart failure: pathological role of vasopressin-dependent impaired water excretion. *J Clin Med.* 2015;4[5]:933–947. PubMed PMID: 26239456.)

TABLE 161.1 Stages of Congestive Heart Failure as Defined by the New York Heart Association

Stage	Symptoms
Stage I	Patient is symptom-free at rest and with treatment.
Stage II	Patient experiences impaired heart function with moderate physical effort. Shortness of breath with exertion is common. There are no symptoms at rest.
Stage III	Even minor physical exertion results in shortness of breath and fatigue. There are no symptoms at rest.
Stage IV	Symptoms such as shortness of breath and signs such as lower extremity edema are present when the patient is at rest.

In addition to providing benefits of its own in CHF, magnesium supplementation prevents the magnesium depletion caused by the conventional drug therapy for CHF (e.g., digitalis, diuretics, and vasodilators such as beta blockers and calcium channel blockers). Magnesium supplementation has even been shown to produce positive effects in patients with CHF receiving conventional drug therapy even if serum magnesium levels are normal.[3] However, magnesium supplementation is not indicated in patients with renal failure, because this condition predisposes them to hypermagnesemia—a significant risk factor for mortality.[4] ACE inhibitors appear to produce a magnesium-sparing effect in patients on furosemide.[5] Typical dosages are 200 to 300 mg one to three times per day of magnesium in the citrate form. Oral magnesium can be effective in raising WBC magnesium and potassium levels.[6] It is highly important to monitor serum magnesium levels so as to prevent hypermagnesemia in patients with renal impairment as well as those on digoxin. Magnesium significantly reduces the frequency and complexity of ventricular arrhythmias in digoxin-treated patients with CHF even without the presence of digoxin toxicity, but too much magnesium may interfere with digoxin.[7]

Thiamine

Interest has increased regarding the potential role of thiamine deficiency in CHF. Thiamine was the first B vitamin discovered, hence its designation as vitamin B_1. It is well established that thiamine deficiency can result in the cardiovascular manifestations of "wet beriberi," sodium retention, peripheral vasodilation, and heart failure. It is also well established that furosemide (Lasix), the most widely prescribed diuretic, has been shown to cause thiamine deficiency in animals and patients with CHF. Diuretic use, changes in dietary habits, and altered thiamine absorption and metabolism have all been identified as possible mechanisms of thiamine deficiency in heart failure.[8]

Although severe thiamine deficiency is relatively uncommon except in alcoholics, many Americans do not consume the recommended daily allowance of 1.5 mg, especially elderly patients in hospitals or nursing homes. To gauge the prevalence of thiamine deficiency in the geriatric population, 30 consecutive patients visiting a university outpatient clinic in Tampa, Florida, were tested for thiamine levels. Depending on the thiamine measurement, plasma versus red blood cell thiamine, low levels (defined as a level below the lowest reference range for younger age groups) were found in 57% and 33%, respectively.[9]

These results highlight the growing body of evidence that a significant percentage of the geriatric population is deficient in one or more of the B vitamins. Given the essential role of thiamine and other B vitamins in normal human physiology, especially cardiovascular and brain function, routine supplementation of B vitamins in this age group appears to be worthwhile.

The association between thiamine deficiency and long-term furosemide use was discovered in 1980, when it was shown that after only 4 weeks of furosemide use, thiamine concentrations and the activity of the thiamine-dependent enzyme transketolase were significantly reduced. The first study looking at thiamine as a potential adjunct in the treatment of CHF showed only modest benefits. However, several subsequent studies have shown that daily doses of 80 to 240 mg of thiamine daily improved the clinical picture, as indicated by a 13% to 22% increase of left ventricular ejection fraction.[10,11] This is quite significant, because an increase in ejection fraction is associated with a greater survival rate in patients with CHF. Thiamine has also been shown to improve cardiac function, urine output, and weight loss in patients with CHF.[12] In one study, biochemical evidence of severe thiamine deficiency was found in 98% of patients receiving at least 80 mg/day of furosemide and in 57% of patients taking 40 mg furosemide daily.[13]

Given the possible benefit, lack of risk, and low cost of thiamine supplementation, administration of 200 to 250 mg of thiamine daily appears to be warranted in patients with CHF, especially if they are on furosemide.

Carnitine

Normal heart function is critically dependent on adequate concentrations of carnitine and CoQ_{10}. These compounds are essential in the transport of fatty acids into the myocardium and mitochondria for energy production. Although the normal heart stores more carnitine and CoQ_{10} than it needs, if the heart does not have a good supply of oxygen, carnitine and CoQ_{10} levels quickly decrease. Both of these agents have shown benefit in the treatment of CHF.

Several double-blind clinical studies have shown that carnitine supplementation improves cardiac function in patients with CHF.[14–16] In one double-blind study, only 1 month of treatment (500 mg three times daily) was necessary to cause a significant improvement in heart function.[15] The longer carnitine was used, the more dramatic was the improvement. After 6 months of use, the carnitine group demonstrated an increase in maximum exercise time of 25.9% and a 13.6% increase in ventricular ejection fraction. Another double-blind study showed that after 6 months of treatment, maximum exercise time on the treadmill increased by 16.4%, and the ejection fraction increased by 12.1%.[16]

Even more obvious benefits were seen in a 3-year study of 80 patients with moderate to severe heart failure (NYHA classifications III to IV) caused by dilated cardiomyopathy. After a period of stable cardiac function up to 3 months, patients were randomly assigned to receive either carnitine (2 g/day orally) or placebo. After a mean of 33.7 months of follow-up (range, 10–54 months), 70 patients were in the study: 33 in the placebo group and 37 in the carnitine group. At the time of analysis, 63 patients were alive. Six deaths occurred in the placebo group and one death in the carnitine group. Survival analysis showed that patients' survival was statistically significant in favor of the carnitine group.[17]

A meta-analysis of 17 randomized controlled trials with 1625 CHF patients demonstrated that L-carnitine treatment was associated with considerable improvement in overall efficacy, left ventricular ejection fraction, stroke volume, and cardiac output.[18] In addition, treatment with L-carnitine resulted in significant decreases in serum levels of brain natriuretic peptide, N-terminal probrain natriuretic peptide, left ventricular end-systolic dimension, left ventricular end-diastolic dimension, and left ventricular end-systolic volume.

Coenzyme Q_{10}

Numerous studies have also shown CoQ_{10} supplementation to be extremely effective in the treatment of CHF. Most of these studies used

CoQ_{10} as an adjunct to conventional drug therapy. In one of the early studies, 17 patients with mild CHF received 30 mg/day of CoQ_{10}.[19] All patients improved, and 9 (53%) became asymptomatic after 4 weeks. In another early study,[20] patients with congestive heart failure due to either atherosclerosis or high blood pressure were treated with CoQ_{10} at a dosage of 30 mg/day for 1 to 2 months.[20] Of these patients, 55% reported subjective improvement, 50% showed a decrease in NYHA classification, and 30% showed a "remarkable" decrease in chest congestion as seen on chest radiography. Patients with mild disease tended to improve more often than those with more severe disease. Subjective improvements in these patients—including increased cardiac output, stroke volume, cardiac index, and ejection fraction—were confirmed by various objective tests. These results were consistent with CoQ_{10} producing an increased force of heart muscle contraction (a positive inotropic effect) similar to but less potent than the effect of digitalis.[21,22]

Three more studies have also shown CoQ_{10} to be effective in significantly improving heart function in patients with CHF. In a double-blind Scandinavian study of 80 patients, participants were given either CoQ_{10} (100 mg/day) or placebo for 3 months and then crossed. The improvements noted with CoQ_{10} were actually found to be more positive than those obtained from conventional drug therapy alone.[23] In another double-blind study, 641 patients with CHF received either CoQ_{10} (2 mg/kg) or a placebo for 1 year.[24] The number of patients requiring hospitalization or experiencing serious consequences due to CHF was significantly reduced in the CoQ_{10} group compared with the placebo group.

In the largest study to date, a total of 2664 patients in NYHA classes II and III were enrolled in an open study in Italy.[25] The daily dosage of CoQ_{10} was 50 to 150 mg orally for 90 days, with the majority of patients (78%) receiving 100 mg/day. After 3 months of CoQ_{10} treatment, the proportions of patients with improvement in clinical signs and symptoms were as follows:

- Cyanosis: 78.1%
- Edema (fluid retention): 78.6%
- Pulmonary edema: 77.8%
- Enlargement of liver area: 49.3%
- Venous congestion: 71.8%
- Shortness of breath: 52.7%
- Heart palpitations: 75.4%
- Sweating: 79.8%
- Subjective arrhythmia: 63.4%
- Insomnia: 66.2%
- Vertigo: 73.1%
- Nocturnal urination: 53.6%

Improvement of at least three symptoms occurred in 54% of patients, indicating a significantly improved quality of life (QoL) with CoQ_{10} supplementation. The results also showed a low incidence of side effects; only 36 patients (1.5%) reported mild side effects attributed to CoQ_{10}.

These positive results with CoQ_{10}, however, were not seen in one clinical trial. In this double-blind study, 55 patients with CHF NYHA classes III and IV, ejection fraction of less than 40%, and peak oxygen consumption less than 50% during standard therapy were randomly assigned to receive CoQ_{10} (200 mg) or placebo. Analysis indicated that there were no changes in ejection fraction, peak oxygen consumption, or exercise duration in either group. Possible explanations for failure to achieve a therapeutic benefit in this study may include the insufficient strength of CoQ_{10} to produce significant effects in more severe stages of CHF or the fact that blood levels of CoQ_{10} did not reach sufficient levels. Although the mean serum concentration of CoQ_{10} increased from 0.95 mcg/mL to 2.2 μg/mL in 19 of 22 patients on CoQ_{10}, blood levels were below the suggested threshold of 2.5 mcg/mL.[26]

Arginine

Another amino acid of value in CHF is arginine, although via totally different mechanisms from those of other nutrients. Patients with CHF are less able to achieve peripheral vasodilation during exercise due to endothelial dysfunction. Because the endothelial cells make the natural vasodilator nitric acid from arginine, several researchers have evaluated the efficacy of arginine in improving CHF. The first study of orally administered arginine showed promising results. In a randomized double-blind placebo-controlled study of 5.6 to 12.6 g/day of oral L-arginine, peripheral blood flow was found to increase by 29%; in addition, 6-minute walking distance increased by 8% and arterial compliance by 19%.[27] Subsequent studies have shown arginine supplementation to improve endothelial cell and renal function (as shown by improvements in glomerular filtration rate, natriuresis, and plasma endothelin level) in patients with CHF.[28,29] The use of arginine is cautioned by a report in one study in survivors of myocardial infarction, where supplementation with arginine (9 g/day for 6 months) was associated with an increase in mortality compared with the placebo group (8.6% vs. 0%).[30]

Botanical Medicines

Crataegus oxyacantha (Hawthorn)

Preparations of *Crataegus* sp. appear to be quite useful in CHF, especially in the early stages as a sole agent and in the later stages in combination with digitalis cardioglycosides. The effectiveness of *Crataegus* in CHF has been repeatedly demonstrated in double-blind studies.[31–33] For example, 30 patients with CHF (NYHA stage II) were assessed in a randomized double-blind study.[32] Treatment consisted of a *Crataegus* extract standardized to contain 15-mg procyanidin oligomers per 80-mg capsule. Treatment duration was 8 weeks, and the substance was administered at a dosage of one capsule taken twice daily. The group receiving the *Crataegus* extract showed a statistically significant advantage over placebo in terms of changes in heart function as determined by standard testing procedures. Systolic and diastolic blood pressures were also mildly reduced. As in all other studies with *Crataegus* extracts, no adverse reactions occurred.

In another study, 78 patients with CHF (NYHA stage II) were given either 600 mg of standardized *Crataegus* extract or placebo daily.[33] The parameter used to measure effectiveness was the patient's working capacity on a bicycle ergometer. After 56 days of treatment, the *Crataegus* group had a mean increase of 25 W compared with the placebo group's increase of only 5 W. In addition, the *Crataegus* group experienced a mild but significant reduction in systolic blood pressure (171–164 mm Hg) and heart rate (115–110 beats per minute). There was no change in blood pressure or heart rate in the placebo group.

In patients with NYHA stage III CHF, *Crataegus* may not be sufficient to produce clinical effects. In a double-blind, placebo-controlled trial of 120 ambulatory patients with NYHA class II to III CHF, patients received conventional medical therapy as tolerated and were randomized to either hawthorn 450 mg twice daily or placebo for 6 months. The primary outcome at 6 months was a change in the 6-minute walk distance. Secondary outcomes included QoL measures, peak oxygen consumption, and anaerobic threshold during maximal treadmill exercise testing, NYHA classification, left ventricular ejection fraction (LVEF), neurohormones, and measures of oxidative stress and inflammation. There were no significant differences between groups in the 6-minute walk distance or on measures of QoL, functional capacity, neurohormones, oxidative stress, or inflammation. However, a modest difference in LVEF favored hawthorn.[34]

Terminalia arjuna

A traditional Ayurvedic botanical for cardiac failure has been shown to be effective in controlled clinical studies. Twelve patients with severe refractory congestive heart failure (class IV NYHA) received an extract (500 mg every 8 hours) from the bark of *Terminalia arjuna* or placebo for 2 weeks. Those receiving the medicinal plant experienced, according to echocardiographic evaluation, statistically significant improvements in several parameters of cardiac function, such as end-systolic volume and left ventricular ejection fraction (LVEF). A second, uncontrolled phase of the study using a combination of *T. arjuna* with conventional medication found that after 2 years, nine patients showed a remarkable improvement to NYHA class II, with the other three improving to class III.[35] In addition, a 12-week, double-blind, parallel, randomized, placebo-controlled, add-on clinical trial of arjuna extract in patients with CHF demonstrated improvement in functional capacity, antioxidant reserves, and symptom-related QoL domains.[36]

THERAPEUTIC APPROACH

Treatment with diet and the natural agents as described earlier is effective in the initial stages of CHF (i.e., NYHA stages I and II; Fig. 161.2). In later stages, adjunctive drug therapy is usually necessary. Treatment is designed to address the underlying pathophysiology and to improve myocardial function through improved energy production.

Diet

Patients should be encouraged to achieve their ideal body weight, restrict sodium intake (below 1.8 g daily), increase the consumption of plant foods in the diet, reduce the intake of saturated fat, and follow the other dietary guidelines given for lowering blood pressure.

Exercise

Exercise training can produce significant benefits in patients with heart failure. A review of meta-analyses and randomized, controlled trials of exercise training in patients with heart failure demonstrated that exercise training improves functional capacity, QoL, hospitalization, and systolic and diastolic function in patients with heart failure (Fig. 161.3).[37] Exercise is beneficial for patients with heart failure with or without systolic dysfunction, although subtle differences in prescriptions may be required.

Sauna

Far-infrared sauna (FIR) has shown benefit for individuals with diagnosed CHF (NYHA functional class II or III). Compared with a control group that was only treated with bed rest, the FIR sauna group experienced improvement in endothelial-dependent dilation of the brachial artery after only 10 sauna sessions.[38] Whereas the control group had no change in improved blood flow or CHF symptoms, 17/20 in the sauna group reported an improvement in clinical symptoms. FIR daily for 4 weeks produced statistically significant reductions in systolic blood pressure and significant improvements in left ventricular ejection fraction, exercise tolerance, increased peak respiratory flow, and anaerobic threshold in patients with CHF.[39]

Nutritional Supplements

Magnesium: 200 to 400 mg three times a day
Thiamine: 200 to 250 mg a day
L-Carnitine: 500 to 1000 mg three times a day
CoQ_{10}: 100 to 300 mg a day
Arginine: 1000 to 2000 mg three times a day

Botanical Medicines

- *C. oxyacantha* (Hawthorn) extract (1.8% vitexin–4% rhamnoside or 10% procyanidin content): 200 to 300 mg three times a day
- *T. arjuna* extract: 500 mg three times a day

Constipation

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Infrequent bowel movements (typically three times or fewer per week)
- Difficulty during defecation (straining during more than 25% of bowel movements or a subjective sensation of hard stools)
- Sensation of anorectal obstruction/blockage for at least 25% of defecations
- Large, hard stools or small, pellet-like stools
- Loose or insufficient stools rarely present without the use of laxatives
- In children, withholding behaviors (infants and toddlers may withhold bowel motion to avoid pain of passing stool)

GENERAL CONSIDERATIONS

An old-time naturopathic belief is that "disease begins in the colon." There appears to be great wisdom in that statement: improper elimination of waste products has significant health repercussions. Constipation is the most common digestive complaint in the United States. More than 4 million Americans have frequent constipation, accounting for 2.5 million physician visits per year. A review conducted in the United States reported a prevalence range from 2% to 27%, with most estimates falling between 12% and 19%.[1] However, differences in the definition of constipation have led to a wide range of reported prevalence (i.e., between 1% and 80%). More than $725 million is spent on laxative products each year in America.

Constipation is characterized by infrequent bowel movements, decreased urgency, and/or difficult stool passage. Despite a wide variation between individuals, normal whole-gut transit time is between 30 and 40 hours.[2] Patients with constipation have an increased gut transit time compared with healthy controls, with the upper limit of normal considered to be 70 h. Although frequency varies among individuals, one bowel movement per day should be considered normal. Some people consuming a high-fiber diet may have up to three bowel movements per day. Three or more days without a bowel movement may certainly be concerning because the stool becomes harder and more difficult to pass. Constipation can most simply be defined by one or a combination of frequency, size, consistency, and ease of elimination.[3]

A variety of risk factors are associated with constipation. Increased age, lower socioeconomic status, and lower level of education have been strongly linked with an increased likelihood of constipation. In addition, lower parental education, physical inactivity, medications, depression, physical and sexual abuse, and everyday life events also contribute to constipation.

Constipation among older people is far more common than among younger people. Common causes of constipation in the elderly are linked to several factors, including a lack of proper diet, a lack of adequate fluid intake, a lack of adequate physical activity, illness, and the use of drugs. In addition, female gender has been identified as a risk factor. Hormonal factors, damage to the innervation of the pelvic floor musculature related to childbirth or gynecological surgery, and genital prolapse may explain the high prevalence of constipation in women.[4] Severe constipation is markedly seen in elderly women compared with male individuals.[5]

Chronic constipation can have a significant negative effect on health-related quality of life and has been associated with psychological distress in severely affected patients. Constipation has the potential to cause patients to curtail work, school, and social activities. It is important for clinicians to have a clear understanding of the different pathophysiological mechanisms associated with constipation, understand the different testing modalities and treatments that are available, including their appropriateness and limitations, and tailor that knowledge to the management of individual patients.

Etiology

Constipation can be divided into two categories: primary (functional) and secondary (organic). Primary causes are intrinsic problems of

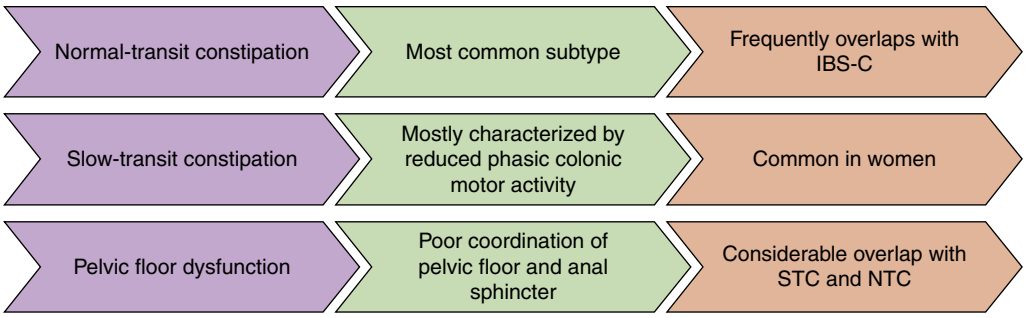

Fig. 162.1 Types of constipation. Primary (idiopathic) constipation can be conceptually categorized into three main types: normal transit, slow transit, and pelvic floor dysfunction. *IBS-C,* Constipation predominant irritable bowel syndrome; *STC,* slow-transit constipation. (From Tack J, Muller-Lissner S, Stanghellini V, Boeckxstaens G, Kamm MA, Simren M, Galmiche JP, Fried M. Diagnosis and treatment of chronic constipation—a European perspective. *Neurogastroenterol Motil.* 2011;23[8]:697–710. PubMed PMID: 21605282.)

colonic or anorectal function, whereas secondary causes are related to organic disease, systemic disease, or medications. Primary causes can be further subdivided into normal-transit constipation, slow-transit constipation, and anorectal dysfunction according to their pathophysiology (Fig. 162.1). Organic causes of constipation are the least common and include Hirschsprung's disease, anorectal malformation, spina bifida, and hypothyroidism. Functional constipation is usually caused by one or a combination of the following: dehydration, dysbiotic bowel flora, food sensitivity, and inadequate fiber intake.

Pathogenesis is multifactorial, with focuses on the type of diet, genetic predisposition, colonic motility, and absorption, as well as behavioral, biological, and pharmaceutical factors. Furthermore, low-fiber dietary intake, inadequate water intake, sedentary lifestyle, irritable bowel syndrome (IBS), failure to respond to urge to defecate, and slow transit have been revealed to be associated with a predisposition. Table 162.1 provides a more complete list of causes of constipation.

Several factors are vital to normal gut motility, including immune and nervous system function, bile acid metabolism and mucus secretion, and the gastrointestinal microbiota. An imbalance or dysfunction in any of these components may contribute to aberrant gut motility and, consequently, symptoms of constipation (Fig. 162.2). Normal-transit constipation is the most common form of constipation seen by clinicians. Although patients report symptoms they believe are consistent with constipation, such as the presence of hard stools or a perceived difficulty with evacuation, stool transit is not delayed, and stool frequency is typically within the normal range.[6] Slow-transit constipation causes infrequent bowel movements (typically less than once per week) and is most common in young women. Colonic transit time is prolonged in these patients, and patients may complain of associated bloating and abdominal discomfort because they do not feel the urge to defecate.[7] Defecation disorders (DDs) are a group of functional and anatomical abnormalities of the anorectum that lead to symptoms of constipation. Patients with DDs present with significant straining, often spending large amounts of time on the toilet daily, with frequent position changes and enema use. Dyssynergia, probably the most common functional DD, is an acquired behavioral DD resulting from poor toilet habits, painful defecation, obstetrical or back injury, or brain–gut dysfunction.[8]

Constipation in Children

Normal bowel movement frequency ranges from four stools per day in the first week of life to 1.2 per day at 4 years of age.[9] Constipation in children usually occurs at three distinct points in time: after starting formula or processed foods (while an infant), during toilet training in toddlerhood, and soon after starting school (nursery school or kindergarten). Factors that may contribute to functional constipation include pain, fever, dehydration, dietary and fluid intake, psychological issues, toilet training, medicines, and family history of constipation. As with adults, increasing fiber content usually produces the desired result. For children with a history of constipation, the initial step may be the elimination of milk and other dairy products from the diet. It is well accepted that cow's milk intolerance (either allergy or lactose intolerance) can produce diarrhea. Dairy intolerance is also a major cause of childhood constipation.[10] About 70% of cases of childhood constipation are improved with the elimination of cow's milk from the diet and substituting with nondairy milk alternatives (e.g., rice, almond, hemp, oat). Kids with constipation who respond to milk elimination also experience a decreased frequency of allergy symptoms (e.g., runny nose, eczema, asthma).

Slippery elm is effective in treating constipation in children from 4 months of age and above. The increased bulk stimulates peristalsis, and its mucilaginous properties create soft, slippery stools. From 12 months of age, freshly ground flax seeds can be added to pureed fruit/vegetables or mixed into water to increase fiber intake. Psyllium husks are slightly more abrasive than slippery elm and flax and thus may not be suitable to all children. Mineral oil and stimulant laxatives should be avoided unless necessary.

Microbiota

Research between intestinal diseases and gut microbiota has gradually revealed a connection between constipation and intestinal flora disturbance, providing a theoretical basis for microbial treatment in chronic constipation. Dysbiosis may be an effect as well as a cause of constipation.[11] Significant differences in bowel flora populations have been found in constipated individuals compared with nonconstipated individuals. Fecal microbiota composition is correlated with colonic transit time, and the colonic mucosal microbiota composition is associated with constipation status. More specifically, the abundance of *Bacteroides, Lactococcus,* and *Roseburia* was found to correlate with faster gut transit time, whereas *Faecalibacterium* was directly correlated to slower transit time.[12]

Gut microbiota modulation can be affected by probiotics, prebiotics, symbiotics, postbiotics, antibiotics, and fecal microbiota transplantation (FMT). Probiotics that have demonstrated a beneficial effect on bowel motion frequency and orofecal transit time include the following:

- *Bifidobacterium longum* 46 and 2C[13]
- *Bifidobacterium lactis* Bb-12, LKM512, and DN-173 010[14,15]
- *Lactobacillus casei* Shirota[16]

TABLE 162.1 Causes of Constipation

- Dietary
  - Highly refined, low-fiber foods
  - Inadequate fluid intake
  - Black tea
- Physical inactivity
  - Inadequate exercise
  - Prolonged bed rest
- Pregnancy
- Advanced age
- Psychogenic disorders
  - Anxiety
  - Depression
- Food sensitivities
- Dysbiosis
- Enemas (chronic use)
- Medications
  - Anesthetics
  - Antacids (aluminum and calcium salts)
  - Anticholinergics (bethanechol, carbachol, pilocarpine, physostigmine, ambenonium)
  - Anticonvulsants
  - Antidepressants (tricyclics, monoamine oxidase inhibitors)
  - Antihistamines
  - Antihypertensives (beta-adrenergic blocking agents, calcium channel blockers)
  - Anti-parkinsonism drugs
  - Antipsychotics (phenothiazines)
  - Bismuth salts
  - Diuretics
  - Iron salts
  - Laxatives and cathartics (chronic use)
  - Muscle relaxants
  - Nonsteroidal anti-inflammatory drugs
  - Opioids
  - Oral contraceptives
  - Progesterone
- Toxic metals
  - Arsenic
  - Lead
  - Mercury
- Metabolic abnormalities
  - Low potassium stores
  - Hyper- and hypocalcemia
  - Kidney disease

- *Lactobacillus reuteri* DSM 17938[19]

Toxins

Although uncommon, lead poisoning should be considered as a differential diagnosis in cases of unexplained acute abdominal pain in both adults and children. Although most cases of lead intoxication come from occupational exposures, traditional remedies, specifically Ayurvedic medicines, have been reported to contain toxic amounts of lead. A retrospective, observational case series from a tertiary care center in India evaluated the charts of patients who underwent blood lead level (BLL) testing as a part of a workup for unexplained abdominal pain between 2005 and 2013, and patients with lead intoxication (BLLs >25 µg/dL) were identified.[20] BLLs were tested in 786 patients, and high levels were identified in 75 (9.5%) of patients, of which a majority (73 patients, 9.3%) had a history of Ayurvedic medication intake, and only 2 had occupational exposure. Five randomly chosen Ayurvedic medications were analyzed, and lead levels were exceptionally elevated (14–34,950 ppm) in all of them. Besides abdominal pain, other presenting complaints were constipation, hypertension, neurological symptoms, and acute kidney injury. Discontinuing the Ayurvedic medicines and chelation with d-penicillamine led to an improvement in symptoms and reduction in BLLs in all patients within 3 to 4 months.

DIAGNOSTIC CONSIDERATIONS

Diagnosing constipation is primarily based on clinical history, physical examination, and initial workup to rule out secondary causes. A standardized definition of constipation is given in the Rome IV criteria for functional gastrointestinal disorders (FGIDs). According to the Rome IV criteria, functional constipation is defined when two or more of the following symptoms are present for the past 3 months with an onset at least 6 months before diagnosis: (1) straining during at least 25% of defecations, (2) lumpy or hard stools in at least 25% of defecations, (3) sensation of incomplete evacuation for at least 25% of defecations, (4) sensation of anorectal obstruction/blockage for at least 25% of defecations, (5) manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor), and (6) fewer than 3 defecations per week.[21] In addition, loose stools are rarely present without the use of laxatives, and the patient does not meet Rome IV criteria for irritable bowel syndrome.

A history and physical examination are often all that is needed to confirm the diagnosis of constipation. The physical examination should include an assessment of "alarm" signs and symptoms (i.e., fever, abdominal distention, anorexia, nausea, vomiting, weight loss, or poor weight gain). On abdominal examination, distention or a palpable "mass" may be appreciated in the lower abdomen. If treatment with fiber supplements and/or laxatives is unsuccessful, further workup is required. Blood tests such as complete blood count (CBC); thyroid function tests; blood glucose; and serum levels of electrolytes, calcium, and magnesium help rule out organic causes of constipation. Imaging studies, including abdominal x-ray, ultrasound, colonic transit tests, defecography, magnetic resonance (MR) defecography, and colonoscopy, may also provide information on the etiology of stool retention (Fig. 162.3). Currently, there is no uniform standardization of tests, and robust normative data for all measures of function remain inadequate, particularly regarding age and gender stratification.

THERAPEUTIC CONSIDERATIONS

Constipation will often respond to self-management strategies that include a high-fiber diet, plentiful fluid consumption, and exercise. These recommendations are well accepted. In fact, there is agreement across the medical community that these recommendations should constitute the first step in the treatment of chronic constipation. The treatment time for constipation can range from a few days in simple cases to more than 12 months in severe cases.

Dietary Factors

Fiber. It is well accepted that increasing dietary fiber is an effective treatment of chronic constipation. High levels of dietary fiber increase both the frequency and quantity of bowel movements, decrease the transit time of stools, decrease the absorption of toxins from the stool, and appear to be a preventive factor in several diseases. The recommended daily intake is 25 to 35 grams of fiber from dietary sources. However, higher amounts may be more optimal for health, as the human evolutionary diet contained approximately 100 grams of daily fiber. Most Western diets provide only 10 to 15 grams of fiber per day. The health-promoting effects of insoluble fiber from the bran of grains is well documented and extends beyond just its laxative effects.[22] The benefits of reduced stool transit time and increased fecal frequency may have more profound long-term benefits beyond the comfort that accompanies bowel regularity.[23] In addition, a systematic review showed that soluble fiber improved constipation symptoms in IBS, with varying effects on abdominal pain.[24]

A whole foods–based diet focusing on a large intake of vegetables and fruits as well as unrefined whole grains and legumes should be foundational. Foods particularly effective in relieving constipation are bran and prunes. The typical recommendation for bran is ½ cup of bran cereal, increasing to 1.5 cups over several weeks. A minimum of six to eight glasses of water should be consumed when using bran. Whole prunes, as well as prune juice, also possess good laxative effects. In one study, subjects suffering from chronic constipation received either dried prunes (50 g per day providing 6 g of fiber [about 10 prunes]) or psyllium (11 g per day providing 6 g of fiber) for 3 weeks each, in a crossover trial with a 1-week washout period.[25] Subjects maintained a daily symptom and stool diary. The number of complete spontaneous bowel movements per week (primary outcome measure) and stool consistency scores improved significantly with dried prunes compared with psyllium. However, straining and global constipation symptoms did not differ significantly between treatments. Four to eight ounces of prune juice or 5 to 10 prunes is usually an effective dose.

Exercise

Moderate to vigorous exercise, such as jogging, brisk walking, and water aerobics, is associated with a decreased prevalence of constipation. In multivariate analysis, women who reported daily physical activity had a 44% reduction in risk of constipation (prevalence ratio [PR] = 0.56, 95% confidence interval [CI]; 0.44–0.70).[26] One study reported that in the preparation for colonoscopy, patients who did walking exercise had better colon cleansing than those who rested.[27] Most walking patients (97.3%) considered walking exercise more comfortable than taking the polyethylene glycol solution. In addition, two studies on children have reported a negative association between physical activity and constipation. In the first study, children with moderate (615–1230 counts/15 seconds) and total activity (≥1231 counts/15 seconds) at the age of 2 years had significantly less functional constipation in the fourth year of life.[28] Additionally, children with physical activity of more than the World Health Organization (WHO) recommendation of 60 min/day

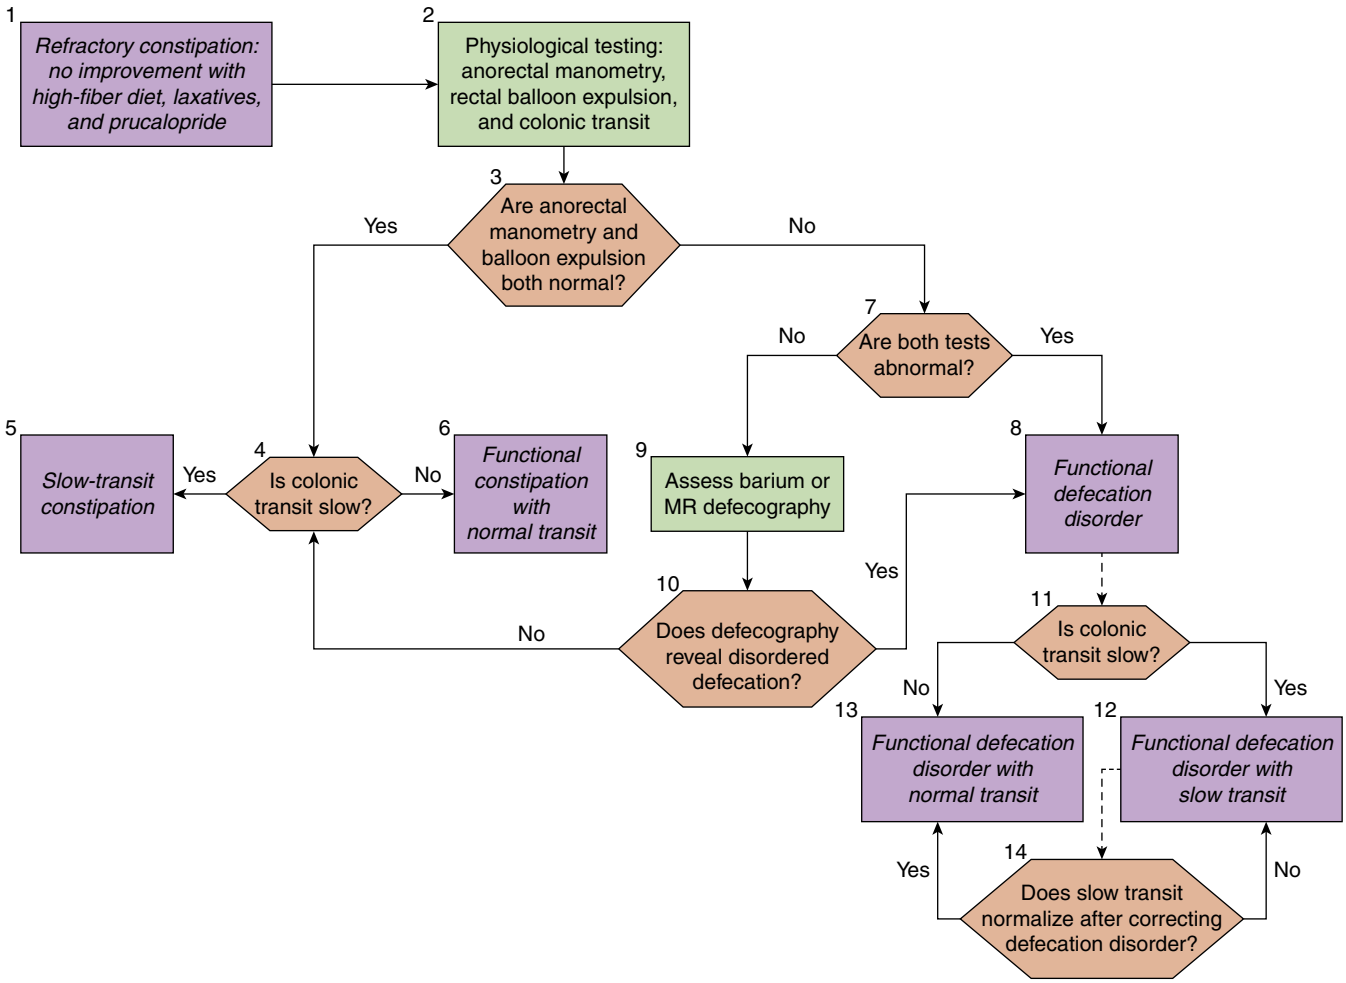

Fig. 162.3 Refractory constipation and difficult defecation. (1) Patients who fulfill the criteria for functional constipation and those who have not improved with an increase in dietary fiber and the use of simple laxatives, and with no alarm features, often warrant further physiological assessment. (2) The three key physiological investigations are anorectal manometry, the balloon expulsion test, and a colonic transit study. (3, 4) If both anorectal manometry and balloon expulsion are normal, the results of colonic transit testing enable characterization of the disorder as functional constipation with slow (5) or normal transit (6). (7, 8) If both manometry and the rectal balloon expulsion test are abnormal, this is sufficient to diagnose a functional defecation disorder. (9) If only one of the anorectal manometry and balloon expulsion is abnormal, further testing using barium or magnetic resonance defecography may be used to confirm or exclude the diagnosis. (10) If defecography reveals features of disordered defecation, a diagnosis of a functional defecation disorder can be made. (8) If defecography is not abnormal, then the patient does not fulfill criteria for the diagnosis of a functional defecation disorder; further diagnosis then depends on the presence or absence of colonic transit delay (see previous 4–6). (11–13) Treatment of choice for disordered defecation is biofeedback. If there is no adequate response to therapy, further investigation may be considered at this point. The presence of a functional defecation disorder does not exclude the diagnosis of slow colonic transit. Thus depending on the results of the colonic transit study, the patient can be characterized as suffering from a functional defecation disorder with slow (12) or normal colonic transit. (13, 14) Slow colonic transit may result from a defecation disorder. If it is felt appropriate to distinguish between the two possibilities, the colonic transit evaluation may be repeated after correction of the defecation disorder. If transit normalizes, the presumption is that the delay was secondary to the defecation disorder; if not, the delayed colonic transit is presumed to be a comorbid condition, which may require therapy if there is no clinical improvement with the treatment of functional defecation disorder. (From Tack J, Muller-Lissner S, Stanghellini V, Boeckxstaens G, Kamm MA, Simren M, Galmiche JP, Fried M. Diagnosis and treatment of chronic constipation—a European perspective. *Neurogastroenterol Motil.* 2011;23[8]:697–710. PubMed PMID: 21605282.)

had significantly less functional constipation in the fourth year of life. The second study was a cross-sectional evaluation that looked at factors associated with constipation in 1900 schoolchildren from ages 7 to 12 in Turkey.[29] Siblings with health problems, history of constipation in family members, abnormal oral habits, and little regular sporting activity were more common in constipated children than in those who were nonconstipated. Considering that insufficient physical activity and excessive sedentary behaviors are associated with constipation, incorporating exercise is advised as a preventative and, in some cases, therapeutic option.

Nutritional Factors

Magnesium

Magnesium-containing cathartics are used worldwide to treat chronic constipation.[30] Absorbable magnesium powders, such as magnesium citrate, alginate, oxalate, or amino acid chelate, can be used to help relax and promote healthy peristalsis of the smooth muscle of the intestinal tract. In addition, magnesium salts are known for their osmotic effects, accelerating intestinal transit time and leading to better stool consistency. A study in healthy human subjects demonstrated that high doses of orally administered magnesium sulfate accelerate small intestinal transit time and modulate antroduodenal motility in the fasting but not in the postprandial state.[31] A placebo-controlled, double-blind, randomized trial investigated whether a natural mineral water rich in magnesium sulfate and sodium sulfate (Donat Mg, 13g/L of dissolved mineral substances) may help improve bowel function.[32] A total of 106 otherwise-healthy subjects with functional constipation were randomly assigned to consume 300 or 500 mL of a natural mineral water, compared with placebo water, over a course of 6 weeks. Subjects documented complete spontaneous bowel movements, spontaneous and overall bowel movements/week, stool consistency, GI symptoms, and general well-being in a diary. For the 75 subjects in the 500-mL arms, stool consistency of spontaneous bowel movements ($p < 0.001$) and the subjectively perceived symptoms concerning constipation ($p = 0.005$) improved significantly with the natural mineral water compared with placebo.

Vitamin C

Vitamin C to bowel tolerance can be used as a bowel flush and may have added benefits in immune-challenged individuals.

Microbial Therapy

Microbial treatment mainly includes bacterial preparations such as probiotics, prebiotics, symbiotics, and FMT. Due to their safety, convenience, and curative effect, probiotic preparations have been widely accepted. Microbial treatment improves clinical symptoms, promotes the recovery of intestinal flora, and has no complications during the treatment process.

Prebiotics

Prebiotics are defined as "a non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, and thus improves host health."[33] *Lactobacilli* and *Bifidobacteria* feed on dietary plant fibers, allowing them to have strong populations and produce a tremendous amount of organic acids with far-reaching health benefits. Short-chain fatty acids help feed and fuel the cells of the colon and prevent dysbiosis and inflammation in the gut. Lactulose is a disaccharide manufactured from lactose that is poorly digested in the intestines. Lactulose is highly bifidogenic and is used in conventional medicine mainly for its laxative effects. Ingestion of lactulose was found to cause statistically significant increases in the frequency, weight, volume, and water content of stools and to produce stools of softer consistency compared with both baseline and placebo.[34] An intake of 15 g/day of either inulin or short-chain fructose oligosaccharides (FOSs) results in significant increases in bifidobacterial levels and increases the absorption of calcium and magnesium in the large intestine.[35,36] Several studies were conducted to evaluate the effects of galactooligosaccharide (GOS) administration on bowel function. Consuming 9 g/day of GOS was found to increase defecation frequency (from 5.9–7.1 movements per week) in elderly subjects over a 2-week treatment period.[37] There was also a trend for easier defecation during the GOS phase of the trial. Randomized controlled trials evaluating the laxative effects of GOS in healthy adult subjects with a tendency to constipation found that a daily dose of 5 or 10 g of GOS produced significant improvements in defecation frequency.[38] Foods high in prebiotics include artichokes, garlic, onion, leeks, asparagus, chives, legumes, peas, fruit, and okra.

Probiotics

Probiotics have long been used for the treatment of constipation. Studies have shown that specific probiotics may help decrease gut transit time in people with or without constipation. Meta-analyses of randomized controlled trials have demonstrated efficacy for several probiotic strains. A systematic review of randomized controlled trials combining data from a variety of probiotic strains found a significant reduction in whole-gut transit time (12.4-hr reduction; 95% CI: −22.3 to −2.5 hr) and increased stool frequency by an extra 1.3 bowel movements/week (95% CI: 0.7–1.9 bowel movements/week).[39] Stool consistency was also significantly improved. Another systematic review evaluating the capacity of probiotics to speed intestinal transit time found that probiotics could significantly reduce intestinal transit time, with large effect sizes seen in two probiotic strains: *Bifidobacterium lactis* HN019 and *Bifidobacterium lactis* DN-173 010.[40]

The mechanism of action of probiotics may involve the enteric nervous system. In a mouse study, administration of *Lactobacillus reuteri* has been shown to modulate reflexes that communicate with the brain.[41] In addition, *L. reuteri* has been shown to selectively increase the excitability of myenteric neurons in rats and interact with the gut–brain axis through the modulation of enteric sensory nerves that affect gut motility and pain perception.[42]

Botanicals

Although there is a paucity of research surrounding the use of herbal medicine in constipation, several herbs have properties that may provide benefit. Carminative herbs work by relaxing sphincters in the gastrointestinal tract and may aid in the treatment of constipation. Examples of carminative herbs include *Mentha piperita, Foeniculum vulgare, Zingiber officinalis, Melissa officinalis, Chamomilla recutita, Rosmarinus officinale, Curcuma longa,* and *Cinnamomum zeylanicum.* Demulcents, such as *Ulmus fulva, Althea officinalis,* and *Glycyrrhiza glabra,* are also sometimes used to ease constipation. From the whole plant, *Aloe vera* latex is a laxative that is regulated by the U.S. Food and Drug Administration.[43]

Laxatives

Bulk-forming fiber supplements are preferred to other forms of laxatives. Fiber formulas act as bulking agents and can be composed of natural soluble fibers derived from psyllium seed, kelp, agar, pectin, and plant gums like karaya and guar. Fiber formulas may also be composed of purified semisynthetic polysaccharides like methyl-cellulose and carboxymethyl cellulose sodium. Psyllium-containing laxatives are the most popular and usually the most effective. Psyllium is derived from the seed of the plant *Plantago ovago* native to Iran and India. The laxative properties of psyllium are due to the swelling of the husk when it contacts water. This forms a gelatinous mass and keeps the feces hydrated and soft. The resulting bulk stimulates a reflex contraction of the walls of the bowel, followed by emptying. Bulk-forming fiber formulas most closely approximate the natural mechanism that promotes a bowel movement and are both safe and effective in the treatment of chronic constipation.[44]

In difficult cases, the use of other laxatives is required to improve symptoms (Table 162.2). Conventional guidelines recommend daily polyethylene glycol (PEG) at a dose of 1 to 1.5 gm/kg per day for 3 to 6 days for initial fecal disimpaction, followed by a daily maintenance dose of 0.4 gr/kg per day for at least 2 months to prevent reaccumulation. A stimulant laxative should be added if PEG alone does not cause disimpaction after 2 weeks of treatment. Neuromuscular agents, such

TABLE 162.2 Types of Laxatives

Type of Laxative	How It Works	Side Effects
Bulk-forming fibers (psyllium, guar, methylcellulose)	Absorb water to form soft, bulky stool, prompting normal contraction of intestinal muscles	Bloating, gas, cramping, choking, or increased constipation if not taken with enough water
Oral osmotics (magnesium hydroxide)	Draw water into colon from surrounding body tissues to allow easier passage of stool	Bloating, cramping, diarrhea, nausea, gas, increased thirst
Oral stool softeners (docusate)	Add moisture to stool to allow strain-free bowel movements	Throat irritation, cramping
Oral stimulants (senna and cascara)	Trigger rhythmic contractions of intestinal muscles to eliminate stool	Belching, cramping, diarrhea, nausea, urine discoloration
Rectal stimulants (glycerine suppositories)	Trigger rhythmic contractions of intestinal muscles to eliminate stool	Rectal irritation, stomach discomfort, cramping

Cautions and Warnings

Do not use senna for more than 7 days unless directed by your doctor.

Stimulant laxatives should not be used in patients with abdominal pain, nausea or vomiting, intestinal obstruction, inflammatory bowel disease, or appendicitis or during pregnancy or lactation.

Do not take more than the recommended amount. Excessive laxative use or inadequate fluid intake may lead to significant fluid and electrolyte imbalance.

as tegaserod, a serotonin type 4 receptor antagonist, may also be used to stimulate peristalsis and fluid secretion.

Senna is a natural stimulant laxative that works by increasing the strength of contraction of the intestinal muscles. The laxative components are compounds known as sennosides. Senna should be used occasionally because tolerance can develop, and long-term use can lead to dependence. Senna is recommended to be taken on an empty stomach. Six to eight glasses of liquid should be consumed daily while taking senna or any other laxative.

Stimulant laxatives may cause abdominal cramping, nausea, and increased mucus secretion. Less common side effects are associated with chronic use and are usually related to loss of potassium and other electrolytes (e.g., muscle spasms, weakness, fatigue). A benign blackish-brown pigmentation of the lining of the colon (pseudomelanosis coli) may occur with prolonged use (at least 4 months) of senna due to the anthraquinones. This condition is generally reversible within 4 to 15 months after discontinuation. More significant side effects, including a sudden change in bowel habits that persists over a period of 2 weeks, rectal bleeding, or failure to have a bowel movement after use, require immediate attention.

Stimulant laxatives may decrease the absorption of drugs that pass through the GI tract. Individuals taking oral medications should talk to their pharmacist or physician before self-medicating with senna.

Senna may potentiate the action of digoxin and other heart medications due to potassium depletion. The use of senna with thiazide diuretics and corticosteroids may further decrease potassium levels.

If stimulant laxatives are used for long periods of time, the bowels will need to be "retrained." Table 162.3 provides recommended rules for reestablishing bowel regularity. The results of this procedure may take 4 to 6 weeks.

TABLE 162.3 Rules for Bowel Retraining

- Find and eliminate known causes of constipation.
- Never repress an urge to defecate.
- Eat a high-fiber diet, focusing on fruits and vegetables.
- Drink six to eight glasses of fluid per day.
- Sit on the toilet at the same time every day (even when the urge to defecate is not present), preferable immediately after breakfast or exercise.
- Exercise for at least 20 minutes, three times per week.
- Discontinue laxatives (except to reestablish bowel activity as described herein) and enemas.
- Week 1
  - Every night before bed, take a stimulant laxative containing either cascara or senna. Take the lowest amount necessary to reliably ensure a bowel movement every morning.
- Weekly
  - Each week, decrease dosage by ½. If constipation recurs, go back to the previous week's dosage. Decrease dosage if diarrhea occurs.

THERAPEUTIC APPROACH

General Recommendations

Constipation is a symptom, not a disease. The most common causes are inadequate consumption of dietary fiber, inadequate fluid intake, and/or a sedentary lifestyle. Determining the cause is the first step in treatment. In most cases, constipation is not serious and responds quickly to dietary and supplement strategies.

Diet

Follow the guidelines given in Chapter 5, Philosophy of Naturopathic Medicine.

- Obtain 25 to 35 g of fiber daily from dietary sources.
- Drink at least six to eight glasses of water per day.
- Four to eight ounces of prune juice or 5 to 10 prunes is effective.
- Incorporate a variety of prebiotic foods.

Nutritional Supplements

- Psyllium: 5 g one to two times per day. Mix each 5 g dose in at least 8 ounces of water immediately before consumption. After taking a dose of soluble fiber, drink a second glass of water.
- Probiotics
- Vitamin C: 1000 mg/hour to bowel tolerance
- Magnesium: 300 mg to 2000 mg depending on individual sensitivity and response. Dosage can be increased and repeated until the desired outcome is achieved.

Botanical Medicines

- Consider demulcent and/or carminative herbs.
- Senna: Follow manufacturer's instructions on package label. The usual dosage recommendation is based on sennoside content: 15 to 30 mg sennosides at bedtime.

Cystitis and Interstitial Cystitis/ Painful Bladder Syndrome

Geovanni Espinosa, ND, LAc, IFMCP, CNS, and *Ralph Esposito, ND, LAc*

OUTLINE

DIAGNOSTIC SUMMARY

- Burning pain on urination
- Increased urinary frequency, urgency, nocturia
- Turbid, foul-smelling, or dark urine
- Lower abdominal pain
- Urinalysis showing significant pyuria and bacteriuria with bacterial cystitis
- Pain in the pelvis (suprapubic) or between the vagina and anus in women or between the scrotum and anus in men (perineal)
- Chronic pelvic pain
- A persistent urgent need to urinate
- Pain during sexual intercourse

GENERAL CONSIDERATIONS

Bladder infections in women are surprisingly common: 10% to 20% of all women have urinary tract discomfort at least once a year, 37.5% of women with no history of urinary tract infection (UTI) will have such an infection within 10 years, and 2% to 4% of apparently healthy women have elevated levels of bacteria in their urine, indicative of an unrecognized UTI.[1] Women with a history of recurrent UTI will typically have an episode at least once every year.[2] Recurrent bladder infections can be a significant problem because 55% will eventually involve the upper urinary tract (i.e., the kidneys). Recurrent kidney infections can cause abscess formation, disseminated intravascular coagulation, acute respiratory distress syndrome, sepsis, and chronic progressive renal damage, resulting in scarring and, for some, kidney failure.

Except in infants, UTIs are much less common in males than females and in general indicate an anatomical abnormality, a prostate infection, or rectal intercourse. Table 163.1 lists incidence by age and gender.

Interstitial cystitis (IC)/painful bladder syndrome (PBS) is a chronic bladder disorder characterized by chronic pelvic pain (CPP) and irritative voiding symptoms. IC/PBS is not due to infection; it is characterized by symptoms similar to cystitis, and patients may also report otherwise undiagnosed CPP. The symptoms of IC/PBS can overlap with such conditions as endometriosis, recurrent UTI, CPP, overactive bladder, and vulvodynia. Studies have indicated that IC affects 52 to 67 per 100,000 people in the United States.[3] Some investigators believe these numbers are vastly underestimated owing to lack of proper diagnosis.

Cystitis and Irritants

Endogenous and exogenous irritants, including bacterial lipopolysaccharide (LPS), acid, turpentine, mustard oil, croton oil, and acrolein, have been used to induce cystitis in experimental studies. Cyclophosphamide is an antineoplastic agent, and hemorrhagic cystitis is a common complication observed in patients treated with this drug. Cyclophosphamide is metabolized by the liver to acrolein, and the presence of acrolein is thought to be the cause of cystitis in patients who receive cyclophosphamide.[4] Chemical irritants directly damage the urothelium and other cells of the bladder, resulting in various degrees of erosion of the mucosa, edema, hemorrhage, and leukocyte infiltration of the bladder wall.[5] Although the cause of chronic bladder pain is yet unknown, it is plausible that irritants may contribute to the etiology.

TABLE 163.1 Incidence of Urinary Tract Infection According to Age and Gender

Age Group	Incidence	Male:Female Ratio
Neonatal	1	1.5:1
Preschool age	1.5–3	1:10
School age	1.2	1:30
Reproductive age	3–5	1:50
Geriatric	10–30	1:1.5

Modified from Rubin RH. Infections of the urinary tract. In Dale DC, Federman DD, eds. *Scientific American Medicine*. New York: Scientific American; 1997.

TABLE 163.2 Results of Women Presenting With Typical Urinary Tract Infection Symptoms and No Fever, Vaginal Symptoms, or Toxicity

Diagnosis	Percentage of Subjects
Upper urinary tract infection	20
Bladder infection	40
Low levels of bacteria in urethra	16
Urethral *Chlamydia*	8
Unsuspected vaginitis	4
Other (e.g., herpes, gonorrhea, pelvic inflammatory disease)	12

Modified from Reilly BM. *Practical Strategies in Outpatient Medicine*. Philadelphia: Saunders; 1984: 277.

TABLE 163.3 Bacteriological Findings (Percentage Positive) in Outpatients and Inpatients With Urinary Tract Infections

Bacterial Species	Outpatients	Inpatients
Escherichia coli	89.2	52.7
Proteus mirabilis	3.2	12.7
Klebsiella pneumoniae	2.4	9.3
Enterococcus	2	7.3
Enterobacter aerogenes	0.8	4
Pseudomonas aeruginosa	0.4	6
Proteus spp.	0.4	3.3
Serratia marcescens	0	3.3
Staphylococcus epidermidis	1.6[a]	0.7
Staphylococcus aureus	0	0.7

[a]Recent evidence suggests that this may be more prevalent than is currently thought—in sexually active college-age women, it may account for as much as 20% of asymptomatic urinary tract infections.
Modified from Rubin RH. Infections of the urinary tract. In Dale DC, Federman DD, eds. *Scientific American Medicine*. New York: Scientific American; 1997.

DIAGNOSIS

The diagnosis of bladder infection is imprecise because clinical symptoms and the presence of significant amounts of bacteria in the urine do not correlate well. As indicated in Table 163.2, only 60% of women with the typical symptoms of UTI actually have significant levels of bacteria in their urine. Equally important, however, is the fact that 20% have the more potentially serious involvement of the upper tract.

In general, the diagnosis is made according to signs and symptoms and urinary findings. A pelvic examination is indicated if there is a history consistent with vaginitis or cervicitis or if there is confusion regarding diagnosis. Microscopical examination of the infected urine shows high levels of white blood cells (WBCs) and bacteria. Culturing the urine determines the quantity and type of bacteria involved. As shown in Table 163.3, *Escherichia coli* (from the colon) is by far the most common. The presence of fever, chills, and low back pain can indicate involvement of the kidneys. Those with recurrent infections should be examined by intravenous urogram to determine whether a structural abnormality is present.[6]

IC/PBS can also be difficult to diagnose because the symptoms overlap with a variety of other disorders, including endometriosis, UTI, CPP, overactive bladder (OAB), and vulvodynia.[7,8] Because there is no definitive diagnostic test, IC/PBS remains a diagnosis of exclusion. The presence of additional symptoms caused by other pain generators can confuse the diagnosis even further. Patients may not receive an accurate diagnosis for years. The median time between the development of IC/PBS symptoms and the diagnosis is approximately 5 years.[9]

CPP is pain lasting 6 months or longer that is severe enough to affect daily functioning or requires medical care.[7] The specific etiology of CPP is often unknown and may be multifactorial.[10] Gynecological conditions that can cause CPP include endometriosis, adhesions, pelvic inflammatory disease (PID), cysts, and polyps.[10] However, a retrospective cohort analysis of a large primary care database in the United Kingdom found that only 20.2% of all cases of CPP had a gynecological etiology,[11] and up to 55% of women had no known pathological cause for their pelvic pain.[12] Gastrointestinal diagnoses represented 37.7% of cases, with irritable bowel syndrome (IBS) accounting for 29.1%. Cystitis accounted for 30.8% of diagnoses in this population of women with noncyclic pain lasting for 6 months or longer. Up to one half of the women in primary care practices who have CPP may have more than one diagnosis for their pain. As described previously, it is common for a patient with CPP to have both endometriosis and IC/PBS.[10]

Physical examination is a critical component of diagnosing IC/PBS. In patients with IC/PBS, this can be emotionally distressing because of pain, so it is important that the physician proceed slowly and carefully.[13] Because the bladder is a pain generator in IC/PBS, tenderness with single-digit examination of the trigonal area (bladder base or urethra) can help establish a diagnosis of IC/PBS, as can pain in the pelvic floor or levator ani.[7] Patients with IC/PBS tend to have urethral or bladder tenderness, whereas those with vestibulodynia have vestibular tenderness.[14] Tenderness on single-digit examination of the vaginal fornices can help distinguish endometriosis from IC/PBS.[13]

Urinalysis can rule out hematuria, and urine culture is required to identify bladder infection.[13] Cytology and computed tomography (CT) with double contrast when indicated (hematuria, history of smoking, 40 years of age and older) can help rule out urinary tract malignancies.[15] Patients with results suggesting a malignancy should be referred to a urologist. Several optional diagnostic tests can help diagnose IC/PBS. The presence of glomerulations seen on cystoscopy with hydrodistension may aid in the diagnosis of IC/PBS. A negative cystoscopic evaluation should never be used to rule out IC/PBS, because many patients with early IC/PBS will not have glomerulations.[16] The potassium sensitivity test (PST) may indicate a defective bladder lining. The PST involves intravesical instillation of a potassium solution, which triggers symptoms of pain and urgency in patients with abnormal permeability of the bladder surface.[17] Intravesical instillation of an anesthetic cocktail can be used as a diagnostic tool as well as a treatment. Known as the "anesthetic bladder challenge," this test can help localize pain to the bladder.[18,19]

Collection of Urine Specimen for Culture

The optimal clinical method for obtaining a urine sample is the voided midstream specimen. It involves cleaning of the urethral meatus or vaginal vestibule before the sample is collected. If vaginal epithelial cells are present, a new specimen should be collected. To avoid repeating the collection, a satisfactory technique for the female, called the "clean catch," consists of spreading the labia and cleaning the area with two gauze sponges moistened with an antimicrobial solution and a dry gauze sponge. The washing is accomplished by making a single front-to-back motion with each of the two moist sponges and then the dry sponge. While the labia are still held apart, a small amount of urine is allowed to pass into the toilet (or bedpan); then a midstream specimen is collected in a sterile container and immediately closed.

Occasionally, the urine must be collected via catheterization. This is a more invasive procedure and carries with it a 1% to 2% chance of initiating a UTI via the introduction of microorganisms into the bladder. Suprapubic aspiration is the most accurate method of urine collection, but obviously, it is also the most invasive one.

Examination of the Collected Urine

Several methods are routinely employed in the detection of bacteria in the urine. They range from the use of dipsticks to microscopical examination and culture. For most accurate determinations, the urine should be examined within 1 hour. If examination must be delayed, refrigeration at 58°C preserves the urine for most routine examinations. However, culturing requires that the urine not be refrigerated for more than 8 hours.

Dipstick Methods

The modern examination of urine specimens typically involves the use of reagent strips, which are dipped into the urine and removed. Parts of each dipstick are impregnated with chemicals that react with specific substances in the urine to produce various colors. Color standards, with which the color can be compared, are provided. Careful attention must be paid to match the dipstick to the color standard at the appropriate time. Instructions accompany commercially prepared dipsticks.

Dipsticks are invaluable for qualitative and rough quantitative analysis. Typically, they provide information on pH, protein, glucose, ketones, bilirubin, hemoglobin, leukocyte esterase, nitrite, and urobilinogen. Some dipsticks also allow for the detection of WBCs and bacteria (including semiquantitative cultures).

Urinary infections typically increase the number of WBCs present. The leukocyte esterase test is used to detect WBCs in the urine. Because many common organisms contain enzymes that reduce nitrate in the urine to nitrite (Box 163.1), the measurement of urinary nitrite provides an inexpensive and rapid way to detect significant bacteriuria, but the findings should be confirmed by culture. Although both tests have a high specificity (approximately 95%), the leukocyte esterase test is approximately 80% to 90% sensitive, whereas the nitrite test is only approximately 50% sensitive compared with a quantitative culture as the gold standard. However, the combination of both tests improves the sensitivity up to 96%.[20,21]

Microscopic Examination

Microscopic examination should be performed within the first hour after collection. A drop of fresh urine or a drop of resuspended sediment from centrifuged fresh urine is placed on a microscope slide, covered with a coverslip, and examined with the high-dry objective under reduced illumination. The presence of more than 10 bacteria per field in an unstained specimen suggests a bacterial count of more than 100,000/mL of urine. Smears may also be made using a Gram stain and examined under the oil immersion objective. The presence of WBCs further indicates an infectious process. The presence of large quantities of protein, WBC casts, or both in the micrographic examination may be indicative of renal involvement, most commonly pyelonephritis.

BOX 163.1 Nitrates and Biological Organisms

Organisms That Reduce Nitrates to Nitrites

Citrobacter spp.
Escherichia coli
Klebsiella pneumoniae
Proteus spp.
Pseudomonas spp.
Serratia marcescens
Shigella
Staphylococcus spp. (most)

Organisms That Do Not Reduce Nitrates to Nitrites

Neisseria gonorrhoeae
Streptococcus faecalis
Mycobacterium tuberculosis

Urine Culture

Typically, only quantitative cultures are used. After the introduction of diluted urine to the suitable medium and incubation, the colonies are counted and multiplied by the dilution factor to yield the bacterial count per milliliter. Bacteriuria is considered significant if it is more than 100,000/mL, but even 1000/mL is considered clinically significant in the presence of symptoms characteristic of UTI. Most physicians are now employing semiquantitative tests[22] using dipsticks or glass slides coated with culture media. Colonies are counted, and the appearance is compared within 12 to 24 hours of incubation. For recurrent or chronic infection, sensitivity studies are often performed.

In more than 95% of UTIs, a single bacterial species is the problem. When mixed bacterial species are grown, the probability of contamination is high. Recurrence of UTI after the initial bacterial infection is resolved is common.[23]

Staphylococcus epidermidis, diphtheroids, and lactobacilli are commonly found in the distal urethra but rarely cause UTI. Symptoms of recurrent UTI include urgency, frequency, nocturia, and pelvic pain. Diagnosis is established by a positive urine culture.[24]

COEXISTING CONDITIONS AND DIFFERENTIAL DIAGNOSIS

Although bacterial cystitis usually appears acutely and by itself, IC/PBS typically manifests with comorbidities that include endometriosis, IBS, vulvodynia, and OAB.

A detailed medical history and physical examination are the basis for diagnosing the cause of CPP. The use of questionnaires, such as the Pelvic Pain, Urgency Frequency Questionnaire (PUF), or O'Leary Sant Questionnaire (OLS) indices, may elicit information about urinary symptoms. Tenderness of the bladder base on pelvic examination is a characteristic feature of IC/PBS that may help distinguish it from other causes of CPP.[13] Optional tests, including laparoscopy and diagnostic imaging, may also be helpful.[9] Additional useful information may be gained from the PST or intravesical anesthetic challenge.[17]

Endometriosis is characterized by the presence of endometrial-like glands and stroma outside the uterine cavity. Symptoms include pain in the lower abdomen, dysmenorrhea, and dyspareunia

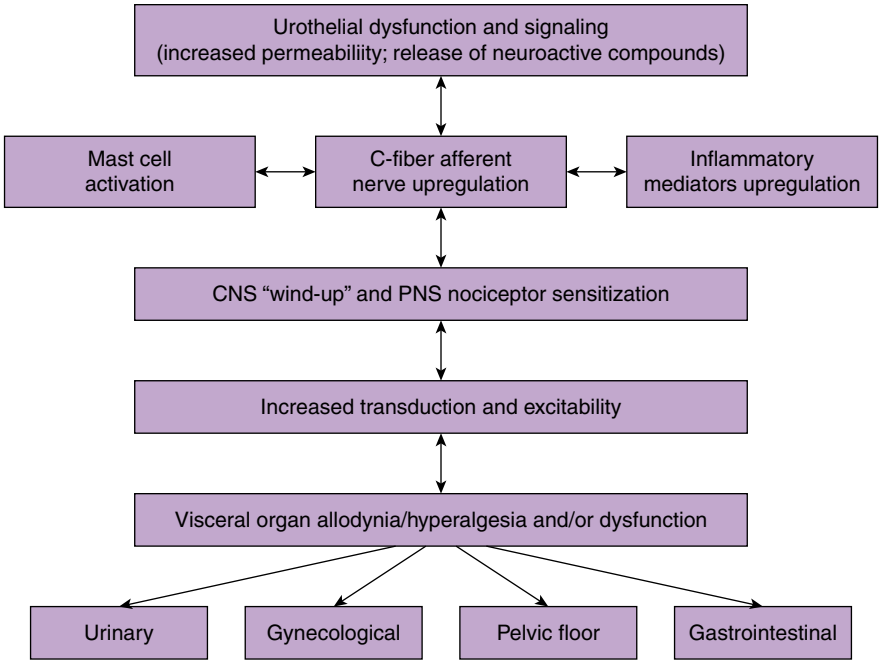

Fig. 163.1 Potential etiological cascade and pathogenesis underlying painful bladder syndrome (PBS)/interstitial cystitis (IC). It is likely that PBS/IC has a multifactorial etiology that may act predominantly through one or more pathways resulting in the typical symptom complex. There is a lack of consensus regarding the etiology or pathogenesis of PBS/IC, but a number of proposals include a "leaky epithelium," release of neuroactive compounds at the level of the urinary bladder with mast cell activation, "awakening" of C-fiber bladder afferents, and upregulation of inflammatory mediators including cytokines and chemotactic cytokines (chemokines). Inflammatory mediators can affect central nervous system (CNS) and peripheral nervous system (PNS) neural circuitry, including central "wind-up" and nociceptor sensitization, resulting in chronic bladder pain and voiding dysfunction. BPS/IC is associated with diseases affecting other viscera and pelvic floors. (From Gonzalez EJ, Arms L, Vizzard MA. The role(s) of cytokines/chemokines in urinary bladder inflammation and dysfunction. BioMed Res Int. 2014;120525. PubMed PMID: 24738044.)

and can also include such voiding symptoms as dysuria and frequency.[25] Endometriosis and IC/PBS frequently coexist in the same patient. In one study of women with CPP and bladder tenderness on examination, more than 70% had both endometriosis and IC/PBS.[26]

OAB is characterized by urgency with or without urge incontinence and usually includes frequency and nocturia. The key symptom is urgency.[27] OAB and IC/PBS can coexist in the same patient. Urgency can be caused by detrusor overactivity, which usually can be demonstrated through urodynamic testing. Urgency is a common symptom of both OAB and IC/PBS, although the cause differs. In patients with OAB, urgency results in a strong desire to avoid leakage, whereas in patients with IC/PBS, urgency results in a strong need to void to relieve pain caused by bladder fullness.[28]

Vulvodynia is characterized by vulvar discomfort, often reported as burning pain. Pain can occur during intercourse, during vigorous activity, after intercourse, or even at rest. The etiology of vulvodynia is unknown, and the diagnosis is one of exclusion. Symptoms of vulvodynia that overlap those of IC/PBS include pain and dyspareunia but not frequency or nocturia; this can help distinguish vulvodynia from IC/PBS. It is also possible for a patient to have both IC/PBS and vulvodynia. The history and physical examination are important in diagnosing vulvodynia. A history of chronic pain at the vestibule lasting more than 3 months can suggest vulvodynia. Infectious causes may include viral, bacterial, or fungal organisms; therefore these must be ruled out as causes of vulvar pain. Vulvar dermatoses may also account for vulvar symptoms.[29] Tenderness to pressure with a cotton swab at the vestibule is a hallmark of vulvodynia,[29] whereas tenderness at the bladder base is typical of IC/PBS.

THERAPEUTIC CONSIDERATIONS

The primary goal in the natural approach to treating infectious cystitis is enhancing normal host protective measures against UTI. Specifically, this means enhancing the flow of urine by achieving and maintaining proper hydration, promoting a pH that inhibits the growth of the organisms, preventing bacterial adherence to the endothelial cells of the bladder, and enhancing the immune system. In addition, several botanical medicines with antimicrobial activity can be employed.

Increasing Urine Flow

Increased urine flow can easily be achieved by increasing the quantity of liquids consumed. Ideally, these liquids should be in the forms of pure water and herbal teas. Fresh fruit and vegetable juices should be diluted with at least twice the amount of water. The patient should be encouraged to drink at least 2 L of liquid, with at least half being simply pure water. The patient should also be advised to avoid such liquids as soft drinks, concentrated fruit drinks, coffee, and alcoholic beverages.

Chronic Interstitial Cystitis

In addition to the general measures given later for cystitis, the focus for interstitial cystitis is on enhancing the integrity of the interstitium along with the lining of the bladder wall. The "leaky bladder urothelium" theory postulates that there is a problem with the glycosaminoglycan layer of the bladder epithelium, which results in making the bladder wall more permeable to potassium, causing inflammation and pain (Fig. 163.1).

The elimination of food allergies to reduce inflammation appears to be a valid goal, even though the association between food allergies and cystitis is not well established. Food allergies have been shown to produce cystitis in some patients. Repeated ingestion of a food allergen could easily explain the chronic nature of interstitial cystitis. For a complete discussion of food allergies, see Chapter 14.

Education of patients with IC/PBS helps empower them to control their symptoms and to be active participants in their own therapy. Patients should be counseled to avoid triggers that lead to increased IC/PBS symptoms. They should also be encouraged to reduce stress and use support groups to deal with the effect IC/PBS has on their daily lives. Dietary changes can provide relief of symptoms.[30]

Herati et al.[31] established the prevalence and characteristics of food sensitivities in patients with IC/PBS and chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS). Validated questionnaires containing a list of 175 comestibles as well as pain questions were mailed to 325 patients with IC/PBS and 286 with CP/CPPS. The researchers found that although patients with IC/PBS were more likely to be food sensitive than patients with CP/CPPS, these questionnaires showed that the symptoms of patients with both IC/PBS and CP/CPPS were aggravated by similar comestibles, such as grapefruit juice, spicy foods, alcohol, and caffeinated coffee. The findings also revealed that the symptoms of both groups of patients were improved by certain comestibles, namely, water and an antacid containing calcium glycerophosphate (Prelief).[31] In 2007, a study done at Long Island University reported that over 90% of patients with interstitial cystitis experience an increase in symptoms when they consume certain foods and beverages, especially coffee, tea, soda, alcoholic beverages, citrus fruits and juices, artificial sweeteners, and hot pepper.[30,32]

Food restrictions have not been conclusively proved to help slow the progression of the disease or to improve its course. Usually food restriction should be weighed against the decrease in the patient's quality of life. After 2 weeks, patients are usually asked to start adding one food item back into their diets every 3 days to identify any specific alimentary sensitivity.

Medical treatments include tricyclic antidepressants (amitriptyline being the most popular),[33] anticholinergics to reduce symptoms of urinary urgency, and antihistamines for their efficacy in decreasing mast cell activation and reducing inflammation.[34,35]

Mast cells, once thought to be responsible for allergic reactions, have in some studies been shown to be critically important in interstitial cystitis. Current evidence from clinical and laboratory studies confirms that they play a central role in IC/PBS.[36] Histamine causes pain, swelling, and scarring and prevents the lining of the bladder from healing.[37,38]

Pentosan polysulfate sodium (Elmiron) is a U.S. Food and Drug Administration (FDA)-approved oral treatment heparinoid compound that is thought to replenish the defective bladder lining. According to one placebo-controlled, randomized clinical trial, when it is taken orally, only 1% to 3% of the active drug reaches the bladder. Based on levels of improvement and side effects, treatment can be continued for 3 months and then extended as needed,[39] which may be necessary for proper epithelial healing.

Cimetidine, a histamine-2 antagonist traditionally used for acid reflux, has been used for IC/PBS with potential benefits. It has been shown to improve pain, nocturia, and overall symptom scores by about 50% in patients with IC/PBS, yet it showed no improvements in dysuria, frequency, relief after voiding, or incomplete emptying.[40] Given the complex nature of IC/PBS, this is not surprising—it is suspected that it is not simply a histamine-driven condition, which is further confirmed with histological studies showing that cimetidine did not change mast-cell or B-cell concentrations but still improved patient symptoms.[41]

Second-line therapies include immunosuppressive agents like prednisone, which was used to treat severe IC/PBS in one small clinical trial.[42] Thirty patients with the Hunner's ulcer subtype of IC/PBS showed considerable improvement after endoscopic submucosal injection of triamcinolone.[43] Cyclosporine has been shown in clinical trials to relieve the symptoms of severe IC/PBS.[44] Symptoms generally recur after treatment is discontinued.

Intravesical therapy can be used for flare management. Dimethylsulfoxide (DMSO) is the only FDA-approved intravesical IC/PBS treatment.[45] Intravesical instillation of anesthetic can bring immediate relief. A study of patients with IC/PBS receiving intravesical instillation of heparin and alkalinized lidocaine showed that this treatment provided immediate and sustained relief of pain and urgency.[19]

Various intravesical cocktails use combinations of heparin, lidocaine, sodium bicarbonate, gentamicin, and glucocorticoids for the treatment of patients with IC/PBS.[46]

Muscle relaxants, used to treat increased muscle spasticity of the pelvic floor associated with CPP, appear to have a beneficial effect. Cyclobenzaprine is an agent closely related to the tricyclic antidepressants. It is used at starting doses of 10 mg daily, which can be prescribed up to three times daily. Tizanidine is a centrally acting alpha$_2$ agonist shown to be superior to placebo in treating spasticity in several conditions. In addition, clonazepam has been useful in treating neuropathic pain.[47]

The American Urological Association recognizes the multiple facets of IC/PBS, suggesting the first line of therapy must be personalized, focusing on patient education, self-care practices, behavioral modification, and stress management.[48]

Alternative Treatments

Biofeedback is another aspect of physical therapy that can provide beneficial results for pelvic pain. Through biofeedback, the patient can learn to control the musculature of the pelvic floor by visualizing the activity of the muscle on a computer and using the visual feedback to achieve conscious control over muscular contractions, thus breaking the cycle of spasm. Ger et al. studied 60 patients with intractable rectal pain, 70% of whom were diagnosed with levator spasm. Biofeedback was performed on 14 of the 60 patients for 30- to 60-minute sessions a week for 6 weeks. In 6 of the 14 patients (43%), pain relief was rated as good or excellent at the 15-month follow-up.[49] A prospective trial using biofeedback and a rectal manometric balloon included 16 patients with levator ani syndrome. The median pain score before biofeedback therapy was 8 (on a 0–10 linear analog scale) and significantly improved to a median score of 2 after therapy. All patients reported nontender musculature after treatment.[50]

Herbal Medicine

Katherine Whitmore, a urologist from Drexel University, found that the Chinese herbs *Cornus,* garden rhubarb, *Psoralea,* and *Rehmannia* decreased pain after 4 weeks in 61% of the subjects studied ($n = 25$). In 3 months, an additional 22% of the subjects had a significant response.[51] The most consistent research evidence was found for *Centella asiatica* (gotu kola) and horsetail *(Equisetum arvense).*[51] *Centella* appears to address some other pathological features of chronic interstitial cystitis. Specifically, *Centella* extracts have been shown to improve the integrity of the connective tissue composing the interstitium as well as to heal ulcerations of the bladder.[52] Horsetail *(E. arvense)* has astringent properties.[53]

Aloe vera, also known as the "burn plant," has been used extensively to heal and relieve the pain of burns. In a small open-label, double-blind crossover study using a freeze-dried whole-leaf *A, vera* concentrate, three 600-mg capsules were given twice daily for 3 months, followed

or preceded by placebo. Of 12 patients with interstitial cystitis, 8 completed the study, and 7 had significant symptom relief.[54]

L-Arginine

L-arginine is an essential amino acid that increases the production of nitric oxide (NO), which is dependent on the enzyme nitric oxide synthetase (NOS). NO and NOS have antibacterial, smooth muscle–relaxing, hormone-releasing, and immune-modulating (by increasing T-cell counts) properties. In a randomized, double-blind trial of oral L-arginine in the treatment of interstitial cystitis, NOS production was found to be decreased in patients with interstitial cystitis and increased in patients with UTI compared with controls. L-arginine (1.5 g/day) was given to 10 patients with interstitial cystitis for 6 months. The urinary NOS was then measured and found to have increased, and clinical symptoms of frequency and nocturia improved in 8 of the 10 patients.[55] The same authors performed a randomized, double-blind trial using 1.5 g of L-arginine per day for 3 months. At the end of this period, 6 (29%) of the 21 patients in the L-arginine group and 2 (8%) of the 25 patients in the placebo group were clinically improved. When an intent-to-treat analysis was done, no significant difference was found between the L-arginine and placebo groups, although Likert scales showed a significant difference in pain intensity and global scores, favoring those taking L-arginine.[56] Another randomized controlled trial with L-arginine found no improvement in symptoms scores of interstitial cystitis compared with controls.[57] The efficacy of L-arginine, NO, and NOS in the treatment of interstitial cystitis remains controversial.

Quercetin

Quercetin is a naturally occurring flavonoid that inhibits histamine release from mast cells and has anti-inflammatory and antioxidant properties. It is rich in onions, seeds, citrus fruits, olive oil, tea, and red wine. A quercetin-containing compound was studied in 22 patients with interstitial cystitis given 500 mg twice a day for 4 weeks. Two patients dropped out of the study. Of the remaining 20 patients, 57% had a significant decrease in the O'Leary Sant Symptom and Problem indices and a decreased global assessment of pain (Likert scale; range 0–10).[56] A randomized, placebo-controlled trial is needed to determine the efficacy of quercetin.

Cranberry Juice *(Vaccinium macrocarpon)*

Cranberries and cranberry juice have been used for the treatment and prevention of UTI for several hundred years. Several clinical studies of benefit in patients with UTI have shown mixed results. In one study, 0.5 L/day of cranberry juice produced beneficial effects in 73% of the subjects (44 females and 16 males) with active UTI.[58] Furthermore, withdrawal of cranberry juice in the people who benefited resulted in recurrent bladder infection in 61%.

In vitro experiments have demonstrated that cranberry reduces adherence of *Escherichia coli* to uroepithelial cells. *E. coli* accounts for up to 80% of UTI acquired in the community. The effect of cranberry on *E. coli* adherence is dose dependent; exposure to cranberry also can displace preattached *E. coli.*[59] For bacteria to infect, they must first adhere to the mucosa. By interfering with adherence, cranberry juice greatly reduces the likelihood of infection and helps the body fight it off. This is the most likely explanation of cranberry juice's positive effects in bladder infections.

A large double-blind, placebo-controlled study evaluated the efficacy of 300 mL of cranberry juice in 153 women (average age 78.5) with confirmed bacteriuria.[60] Even this small an amount dramatically decreased the level of bacteria in the women's urine and the frequency of recurrence of infection. Interestingly, the researchers used saccharin-sweetened juice. Because saccharin is a suspected carcinogen, we strongly recommend avoiding this artificial sweetener.

In one study of seven juices (cranberry, blueberry, grapefruit, guava, mango, orange, and pineapple), only cranberry and blueberry demonstrated inhibitory effects.[61] Blueberry juice *(Vaccinium augustifolium)* is a strong cousin of cranberry juice and a suitable alternative to cranberry juice in bladder infections.

It must be pointed out that most cranberry juices on the market contain one-third cranberry juice mixed with water and sugar. Because sugar has such a detrimental effect on the immune system,[62–64] the use of sweetened cranberry juice cannot be recommended. Fresh cranberry (unsweetened) or blueberry juice is preferred to avoid the deleterious effects of sugar consumption.

Cranberry extracts are also available commercially in pill form. To compare the efficacy and cost of tablets with fresh juice for the prevention of UTI, 150 sexually active women between 21 and 72 years of age were studied in a randomized controlled trial for 1 year.[65] Tablets were taken twice daily, as well as juice at 250 mL three times daily. Both cranberry juice and cranberry tablets significantly decreased the number of patients experiencing at least one symptomatic infection per year (20% and 18%, respectively) compared with placebo (32%). The mean annual cost of cranberry tablets was $624, whereas the juice cost $1400. Furthermore, total consumption of antibiotics was less in both treatment groups compared with placebo. Although the cranberry tablets may be more cost-effective, it is important to remember that sufficient fluid intake is still important, so ample water should be ingested if tablets are used.

Of interest, in a large trial of cranberry juice compared with placebo juice conducted among 376 British inpatients 60 years of age and older, the incidence of symptomatic UTI was also lower than anticipated in the placebo group, but there was no significant difference between groups.[66] Both the active and placebo juices contained ascorbic acid.

Another randomized controlled trial of 305 individuals with neuropathic bladder after spinal cord injury found that the ingestion of cranberry tablets did not reduce rates of UTI relative to the standard regimen.[67]

A large study looked at 319 college women presenting with acute UTI. In this double-blind, randomized trial, participants were followed up until a second UTI or for 6 months, whichever came first. The study concluded that an 8-oz dose of low-calorie cranberry juice twice daily gave no protection against the risk of recurrent UTI among college-aged women.[68] The research juice was formulated to be similar to the commercially available Ocean Spray and was sweetened with Splenda (sucralose), exactly as is the retail juice. Batches of the tested juice were standardized to 112 mg per day of proanthocyanidin content. The placebo juice was formulated by Ocean Spray to imitate the flavor (sugar and acidity) and color of the cranberry beverage but without any cranberry content. In addition to other food and pharmaceutical-grade substances, both juices contained ascorbic acid in their formulations.

The most recent meta-analysis identified cranberry as a useful preventive therapeutic in UTIs, with analysis of more than 1400 women in seven clinical trials. Cranberry was shown to reduce recurrence in women by 26%. The authors, however, still question cranberry as a treatment option, and the most effective form and dose are unclear.[69]

Last, there is a theoretical concern regarding the use of cranberry juice and the formation of kidney stones. Because cranberries are considered an oxalate-containing food, it is thought that this may encourage the formation of oxalate-rich kidney stones. However, urinary oxalate excretion does not increase after drinking cranberry juice, and none of the studies using cranberries has reported an increased incidence of kidney stones.[70]

Acidify or Alkalinize?

Although many practitioners believe that acidification of the urine is the best approach in addressing cystitis, several arguments can be made for alkalinizing the urine. First, it is often difficult to acidify the urine. Many popular methods of attempting to acidify the urine, such as ascorbic acid supplementation and the drinking of cranberry juice, have little effect on pH at commonly prescribed doses.

The best argument for alkalinizing the urine is that it appears to be more effective, especially in women without pathogenic bacteria in their urine. The best method for alkalinizing the urine appears to be the use of citrate salts (e.g., potassium citrate, sodium citrate). These salts are rapidly absorbed and metabolized without affecting gastric pH or producing a laxative effect. They are excreted partly as carbonate, thus raising the pH of the urine.

Potassium citrate, sodium citrate, or both have long been employed in the treatment of lower UTI. They are often used as a "holding exercise" until the results of a urine culture become available. Some clinical studies support this practice. For example, in one study, women presenting with symptoms of UTI were given 4 g of sodium citrate every 8 hours for 48 hours.[71] Of the 64 women evaluated, 80% had relief of symptoms, 12% had deterioration of symptoms, and 91.8% rated the treatment as acceptable. Of the 64 women, 19 were shown to have positive bacterial cultures. There was more variation in response to treatment in the group with proved bacterial infection, with those having symptoms of urethral pain (7 of 10) and dysuria (13 of 18) improving more than those with symptoms of frequency (9 of 17) and urgency (6 of 13). These results were similar to those of a previous study demonstrating significant symptomatic relief and abacteriuria in 80% of the 159 women studied.[72]

Because of these positive results, it has been suggested that urine culture could be restricted to those women who fail to respond to alkalinization therapy. Restricting urine cultures to nonresponders would also lower health care costs.

Acupuncture

Acupuncture is attracting the interest of patients with all kinds of urological conditions. The use of acupuncture also gives urologists an opportunity to collaborate with other health care professionals, such as acupuncturists.[73]

Patients with IC/PBS can potentially gain benefit from 10 to 20 sessions of acupuncture.[51] Alraek has been able to show in a study with 61 women that a traditional Chinese medicine diagnosis can be useful in cystitis.[74]

In a study of 14 patients, Rapkin and Kames found that 6 to 8 weeks of acupuncture reduced the pain of interstitial cystitis.[75]

One reported a case study involves a 31-year-old woman whose symptoms of interstitial cystitis were reduced with acupuncture to the kidney and bladder meridians.[76]

In a Norwegian study, 67 adult women with a history of recurrent lower UTI were randomized into three groups: one receiving acupuncture treatment, one receiving sham acupuncture, and one given no treatment. A statistically significant 85% of patients in the acupuncture group were free of cystitis during the 6-month observational period, compared with 58% in the sham group and only 36% in the control group.[77] Although more clinical studies are necessary to thoroughly elucidate the efficacy of acupuncture, this safe treatment method seems to be a reliable choice as a primary or adjunctive treatment option. Some practitioners also combine acupuncture with the Chinese herbal tradition, which can also be useful in the treatment of long-term chronic conditions.

Nutrient Supplementation

D-Mannose

D-mannose is a simple sugar that acts similarly to cranberry juice in that it helps prevent the pili of *E. coli* and other bacteria from adhering to the bladder wall. In fact, D-mannose is contained in cranberry juice but in lower doses than are available through specific supplementation. Although there are no clinical trials available to support the use of D-mannose powder, a handful of research articles explaining its function strongly support its use.

One in vitro study evaluated the effect of D-mannose on 73 *E. coli* strains of epithelial vaginal and buccal cells from women who suffered recurrent UTI. Of the strains from urinary, vaginal, or anal isolates, 66 (90%) demonstrated adherence to vaginal epithelial cells. When applied, D-mannose completely inhibited the adherence of 25 strains (42%) to epithelial cells and inhibited an additional 11 strains (18%) by at least 50%. Similar results were obtained with buccal cells. The inhibitory effect of D-mannose was similar regardless of the origin of the strains.[78] Another study of Sprague Dawley rats given intravesicular injections of D-mannose found significant improvement in bacteruria in a dose-dependent manner in the animals given D-mannose.[79]

More recent studies further support the use of D-mannose and a prophylactic and possible therapeutic for chronic UTIs. Domenici et al. showed that 1.5 g twice daily of D-mannose for 3 days and then 1.5 g daily for 7 subsequent days resulted in negative urine culture, improvements in symptoms, and improved Urinary Tract Infection Symptoms Assessment (UTISA) scores. Further, it proved to be effective as a prophylaxis for 6 months.[80] Further studies confirm the benefit of D-mannose in acute cystitis in combination with other therapeutics such as cranberry.[81]

As a combination therapy, D-mannose has shown benefit when used with berberine, arbutin, birch, and forskolin in uncomplicated recurrent UTIs.[82] This combination not only targeted uropathogens but also improved vaginal microflora overall, thus providing direct UTI effects but also lateral benefit.

Jonathan Wright recommends an adult dose of 0.5 to 1 tsp three times daily mixed in a little water. It is sweet-tasting and has been used successfully in appropriately reduced doses for pediatric UTI as well. Admittedly, more research is necessary to fully evaluate the usefulness and efficacy of this therapy.

Botanical Medicines

Many herbs have been used through the centuries in the treatment of UTIs (Table 163.4). The following sections discuss several whose use is supported by both folk medicine and scientific evidence.

Arctostaphylos uva ursi

Most research has focused on the urinary antiseptic component, arbutin, of *Arctostaphylos uva ursis* (bearberry or upland cranberry), which typically comprises 6.3% to 9.6% of the leaves.[83] Arbutin is hydrolyzed to hydroquinone and glucose in the body. Hydroquinone is most effective in an alkaline urine. However, crude plant extracts are more effective medicinally than isolated arbutin.[83] *A. uva ursi,* reported to be especially active against *E. coli,* also has diuretic properties.[84] However, recent research has challenged this theory. It is believed that the main antimicrobial constituent, arbutin, requires an alkaline environment to be activated to hydroquinone. In fact, uropathogens may deconjugate arbutin independent of urinary pH and still prove efficacious. This also explains the clinical benefits seen when combining cranberry and *A. uva ursi.*[85]

The prophylactic effect of a standardized *A. uva ursi* extract on recurrent cystitis was evaluated in a double-blind study in 57 women.[86] At the end of 1 year, 5 of 27 women in the placebo group

TABLE 163.4 Bacteriological Susceptibility to Nutrients and Botanical Medicines

Bacterial Species	Agent
Escherichia coli	*Allium sativum, Hydrastis canadensis, Arctostaphylos uva ursi*
Klebsiella pneumoniae	*A. sativum, H. canadensis*
Proteus mirabilis	*A. sativum, H. canadensis*
Pseudomonas aeruginosa	*H. canadensis*
Staphylococcus saprophyticus	*A. sativum, H. canadensis*

had a recurrence, whereas none of the 30 women receiving *A. uva ursi* extract had a recurrence. No side effects were reported in either group. These impressive results indicate that the regular use of *A. uva ursi,* like cranberry, may prevent bladder infections.

A. uva ursi has also been shown to be helpful in increasing the susceptibility of antibiotic-resistant bacteria to antibiotics like beta-lactams. A Japanese group studied the effect of corilagin, a polyphenolic compound from *A. uva ursi,* used against methicillin-resistant *Staphylococcus aureus.* Corilagin reduced the minimal inhibitory concentration of oxacillin and other beta-lactam antibiotics by 100- to 2000-fold. The effect of corilagin and oxacillin was synergistic and bactericidal. Some other antibiotics studied were not enhanced by corilagin. The authors also mentioned that catechins, compound P, and epicatechin gallate from green tea, as well as baicalin from *Scutellaria amoena,* may also produce similar effects.[87]

Although there has been worry about the use of *A. uva ursi,* due to the content of arbutin and hydroquinone, there has been no direct human data indicating arbutin or hydroquinone conjugates to be toxic. It appears that humans are able to eliminate the hydroquinone as conjugates at a rate that is negligible to humans. However, it would be prudent to be aware of toxic signs, including the following[88]:

- Ringing in the ears
- Nausea
- Vomiting
- Sense of suffocation
- Shortness of breath
- Convulsions
- Delirium
- Collapse

Allium sativum

Garlic has been shown to have antimicrobial activity against many disease-causing organisms, including those associated with urinary tract infections, such as the following[89,90]:

- *E. coli*
- *Proteus* spp.
- *Klebsiella pneumoniae*
- *Staphylococcus* spp.
- *Streptococcus* spp.

Hydrastis canadensis

Goldenseal is among the most effective of the herbal antimicrobial agents. Its long history of use by herbalists and naturopathic physicians for the treatment of infection is well documented in the scientific literature. Of particular importance here is its efficacy against *E. coli, Proteus* species, *Klebsiella* species, *Staphylococcus* species, *Enterobacter aerogenes* (large dose required), and *Pseudomonas* species.[91,92]

THERAPEUTIC APPROACH

Although most cases of cystitis are relatively benign, it is extremely important that the patient be properly diagnosed, treated, and monitored. Proper monitoring includes having the patient notify the physician of any change in his or her condition. If the original culture was positive, it is appropriate to follow up with another culture 7 to 14 days after treatment was started. Citrates can be used to ameliorate symptoms. Because of the possibility of a kidney infection, patients should notify their physician if there is fever, low back pain, nausea, or vomiting. Pyelonephritis requires immediate antibiotic therapy and sometimes hospitalization.

Although the occasional acute bladder infection is easily treated, treating women with chronic cystitis can be a significant challenge. Long-term success requires determining the underlying cause: structural abnormalities, excessive sugar consumption, food allergies, nutritional deficiencies, chronic vaginitis, local foci of infection (e.g., prostate, kidneys), and current or childhood sexual abuse. All potential causes must be evaluated and resolved.

Although the causative agents of cystitis have not changed over time, bacterial resistance to antibiotics is fast becoming an issue; even one-time cases of simple acute cystitis have become recalcitrant.[87,93] Resistance to common antibiotics—including trimethoprim-sulfamethoxazole, beta-lactam drugs, and fluoroquinolone—is emerging at an alarming rate. In this milieu, it makes sense to use natural therapeutics that involve fluid intake to protect the urinary tract, immune support, plus nutrient and botanical medicines as first-line therapy in nonpyelonephritic cases and as adjunctive therapy to increase the efficacy of antibiotic treatment if necessary.

General Measures

Patients should be advised to drink large amounts of fluids (at least 2 L/day), including at least 0.5 L of unsweetened cranberry or 0.25 L of blueberry juice.

Patients should be taught to urinate after intercourse. Women who develop bladder infections after intercourse should wash the labia and urethra with a strong tea of *H. canadensis* (2 tsp/cup) both before and after. If this is inadequate, a dilute solution of povidone-iodine usually proves effective.

Diet

UTIs are mostly ascending infections caused by bacteria derived from stools. Because alterations in the bacterial composition of stools depend on the diet, it is reasonable that the risk for infection will change with dietary modifications. Patients should avoid all simple sugars, refined carbohydrates, full-strength fruit juice (diluted fruit juice is acceptable), and food allergens. Yogurt products with live probiotics are also recommended. Patients should restrict calories and eat liberal amounts of garlic and onions.

Patients with IC/PBS should exclude coffee, tea, soda, alcoholic beverages, citrus fruits and juices, artificial sweeteners, and hot pepper from their diets. Other foods, such as gluten and dairy products, may also be suspect. Although no scientific data exist to support or reject this hypothesis, the authors believe, on the basis of clinical experience, that patients benefit from the exclusion of these foods.[94] An elimination/challenge diet may be worthwhile for this group of patients.

Nutritional Supplements for Bacterial Cystitis

- D-mannose powder: 0.75 tsp three times a day
- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1000 mg/day
- Vitamin A: 25,000 IU/day

- Beta-carotene: 200,000 IU/day
- Zinc: 30 mg/day
- Choline: 1000 mg/day

Nutritional Supplements for Nonbacterial Interstitial Cystitis/Painful Bladder Syndrome

- L-arginine: 1500 mg in divided doses
- Quercetin: 500 mg twice a day

Botanical Medicines for Bacterial Cystitis

Dosages are three-times-a-day quantities:

A. uva ursi

- Dried leaves or as a tea: 1.5 to 4 g (1–2 tsp)
- Freeze-dried leaves: 500 to 1000 mg
- Tincture (1:5): 4 to 6 mL (1–1.5 tsp)
- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp)
- Powdered solid extract (10% arbutin): 250 to 500 mg

H. canadensis

- Dried root (or as tea): 1 to 2 g
- Freeze-dried root: 500 to 1000 mg
- Tincture (1:5): 4 to 6 mL (1–1.5 tsp)
- Fluid extract (1:1): 2 to 4 mL (0.5–1 tsp)
- Powdered solid extract (8% alkaloid): 250 to 500 mg
- Sandalwood oil: 1 to 2 drops

Botanical Medicines for Nonbacterial Interstitial Cystitis/Painful Bladder

Centella asiatica

- Dried herb: a tea can be made of the dried leaf, to be taken three times a day.
- Powdered herb (available in capsules): 1000 to 4000 mg, three times a day
- Tincture (1:2 w/v, 30% alcohol): 30 to 60 drops (equivalent to 1.5–3 mL; there are 5 mL in a teaspoon), three times a day
- Standardized extract: 50 to 250 mg two to three times a day. Standardized extracts should contain 40% asiaticoside, 29% to 30% asiatic acid, 29% to 30% madecassic acid, and 1% to 2% madecassoside.

Equisetum arvense

- Standardized dose: 300 mg three times a day, standardized to contain 10% to 15% silica
- Herbal infusion (tea): 2 to 3 tsp three times a day. Hot water is poured onto the herb, steeped for 5 to 10 minutes, and taken as directed.
- Tincture (1:5): 1 to 4 mL three times a day
- External (compresses): 10 g of herb per 1 L water a day

Dermatitis Herpetiformis

Michael Traub, ND, DHANP, FABNO

OUTLINE

DIAGNOSTIC SUMMARY

- Pruritic papulovesicular eruption, usually on the extensor surfaces
- Most common in middle-aged white males but may be seen in individuals of any age
- Pathognomic granular IgA deposits at the dermal–epidermal junction; confirmed by immunofluorescence biopsy of unaffected skin in close proximity to an active lesion
- Asymptomatic celiac disease (gluten-sensitive enteropathy) in 75% to 90% of patients

GENERAL CONSIDERATIONS

Dermatitis herpetiformis (DH) is the most common extraintestinal manifestation of gluten-sensitive enteropathy (celiac disease; Fig. 164.1). The incidence of DH is decreasing, whereas the opposite is true for celiac disease (CD). Presently, the prevalence ratio of the disorders is 1:8. Subclinical CD is a prerequisite for developing DH. It remains a mystery why only some patients with undiagnosed CD develop DH. The increased age at diagnosis and less severe small intestinal damage in both DH and CD suggest changes in environmental factors, such as a lowered lifetime gluten load.[1]

Patients with DH demonstrate serum IgA antibodies against epidermal transglutaminase and tissue transglutaminase.[2] The putative autoantigen of DH is epidermal transglutaminase. DH has been referred to as "celiac disease of the skin."[3] Just as in celiac disease (CD), a gluten-free diet (GFD) is most often all that is required to resolve the lesions. The response is slow, sometimes taking months, in comparison to the gastrointestinal symptoms (GI) of CD that typically respond in days or weeks.[1] Absorption studies (see Chapter 19) can be used to assess the degree of enteropathy.

Almost all individuals with CD have celiac-associated antibodies and specific pairs of allelic variants in two HLA genes, *HLA-DQ2* (>90%) and *HLA-DQ8* (5%–10%).[4] Only 3% of individuals with one or both of these alleles develop CD, yet up to 40% of the general population has one of them. Therefore their presence is not diagnostic of CD, but their absence excludes a diagnosis of CD. Genetic testing is available for the assessment of CD. Findings of inflammatory changes in jejunal biopsies, ranging from lymphocytic enteritis to various degrees of villous atrophy, are the gold standard for CD diagnosis, even in the absence of negative serology for CD.

In the past, CD was considered to be an uncommon disease, affecting mostly children and limited to people of European ancestry. Now it is known that CD may be discovered at any age and is one of the most common chronic diseases worldwide, with a prevalence of 1% to 2%.[5] The mean age of adult CD diagnosis is 45 years, although up to 20% of patients are diagnosed at age 60 or older. CD is underdiagnosed in adults partly because they may lack the classic symptoms of diarrhea or signs of malabsorption. Clinical suspicion may arise from manifestations such as anemia, skin disorders (in addition to DH), neurological disease, osteoporosis, and abnormal liver function tests.[6]

Patients with CD have an increased incidence of other immune-mediated disorders in comparison to the general population, including thyroid disorders, type 1 diabetes mellitus, and other skin diseases such as psoriasis, atopic dermatitis, vitiligo, rosacea, systemic lupus erythematosus, alopecia areata, chronic urticaria, recurrent aphthous stomatitis, and oral lichen planus.[7] (For more comprehensive discussion, see Chapter 157.)

DH has a predilection for the elbows, knees, and buttocks. Skin biopsy shows granular or fibrillar IgA deposits.[8] The characteristic skin

Fig. 164.1 Dermatitis Herpetiformis.

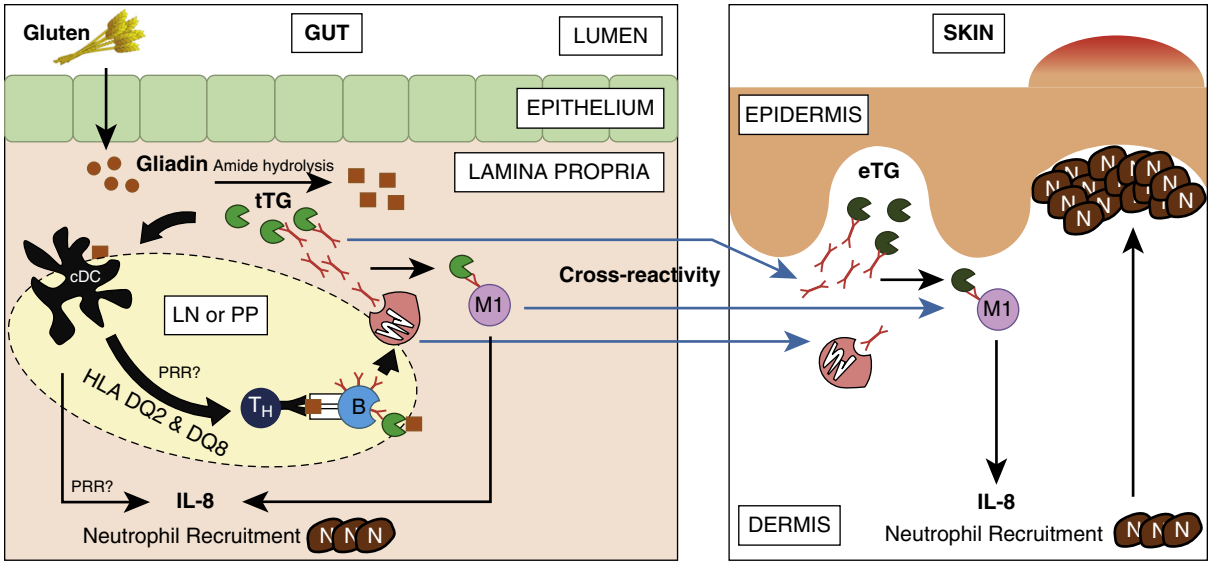

Fig. 164.2 Cross-reactivity Hypothesis of Dermatitis Herpetiformis in Celiac Disease.

lesions found in patients with DH are extremely itchy grouped vesicles most frequently located on extensor surfaces. Intense pruritus is the predominant symptom; however, DH is a clinical chameleon and can present with excoriations, eczematous lesions, or minimal patterns of discrete erythema or digital purpura.[9]

PATHOGENESIS OF DH: FROM GUT TO SKIN

At the present time, the immunopathogenesis of DH is believed to originate from occult CD in the gut with a tissue transglutaminase (TG2) autoantigen response, and possibly also an IgA epidermal transglutaminase (TG3) autoantibody response (Fig. 164.2). This results in an immune complex deposition of high-avidity IgA TG3 antibodies to the TG3 enzyme in the papillary dermis. This mechanism is supported by GFD results. TG3 and TG2 antibodies in serum disappear with the diet, the small intestine heals, and eventually the rash clears. However, the IgA–TG3 complexes in the dermis disappear quite slowly with the GFD, presumably because the active TG3 enzyme in the complexes results in cross-linkage of the complex to the dermal structures.[10]

THERAPEUTIC CONSIDERATIONS

Gluten

The most important factor in the treatment of patients with DH is the elimination of all sources of gluten. Frazer's criteria for the diagnosis of gluten-sensitive enteropathy (improvement on a GFD and relapse after reintroduction) have been used in many studies and have shown conclusively that the rash and villous atrophy of DH are largely gluten dependent.[11–16] Gluten elimination results in an improvement in virtually all patients, including the elimination of the reticulin and gluten antibodies found in patients with DH.[3,17]

Further study of the wheat connection has shown that the gliadin polypeptide of gluten is most likely the key antigen. Indirect immunofluorescence shows antibodies to gliadin in the sera of 45% of patients with DH. The titer and correlation increase with increasing severity of the disease; 81% of patients with severe jejunal abnormalities show antibodies to gliadin.[18]

Despite the published benefits of a GFD in the treatment of DH for more than 30 years, this treatment is still often omitted from conventional dermatology and medical textbooks. The advantage of a GFD over drugs like dapsone (the most widely prescribed drug for DH) is obvious because this drug is often associated with severe side effects. In contrast, with a GFD:

- Most patients (more than 65%) experience complete resolution, and the rest improve substantially.
- There is complete resolution of the enteropathy associated with DH.
- Harsh medications can be eliminated or substantially reduced.
- Most patients experience an improved sense of well-being.

Also of importance is that individuals who used a GFD rather than drugs are protected against developing non-Hodgkin's lymphoma (NHL)[19] because the risk of NHL is significantly increased in DH and CD.

Food Allergy

Although gluten control is critical in the treatment of patients with DH, some (about 35%) are not adequately helped. In particular, only 50% of patients totally eliminate the cutaneous IgA deposits and develop normal jejunal tissue. This is probably because of the presence of other food allergies that, although not initiating, developed as a result of the increased leakage of macromolecules across the damaged intestinal mucosa. Milk has been found to be significantly problematic in some patients.[20,21] Using a sensitive enzyme-linked immunoassay (ELISA), 75% of DH patients were shown to have serum antibodies reactive against gliadin, bovine milk, or ovalbumin.[22] These results suggest that other food sensitivities are implicated in DH. An elemental diet followed by careful food reintroduction usually produces better results than a simple gluten-free diet.[23]

Para-Aminobenzoic Acid

Para-aminobenzoic acid (PABA) has been used successfully in the control of DH, even in those patients who are not controlling the gluten content of their diet.[24] However, because its use is recommended only for symptom control and it probably does not result in repair of the villous atrophy, it is not recommended as the treatment of choice but rather as an adjunct in unresponsive cases or to assist in particularly severe cases.

Treatment of Nutritional Deficiencies

Evaluations for deficiencies of iron, zinc, calcium, fat-soluble vitamins, and folic acid should be conducted; also, the possibility of homocysteinemia, osteopenia, and osteoporosis should be assessed and treated if found.

THERAPEUTIC APPROACH

After all sources of gluten and gliadin have been eliminated (see Appendix 6 for the gluten content of foods), a careful search should be made for other food allergies (for more detail, see Chapter 14). Once allergens have been identified and avoided, a therapeutic regimen similar to that for atopic dermatitis (see Chapter 150) should be used. Patience is necessary because a response may take several weeks to 6 months to be seen.

Diet

Use a healthy, whole-foods diet free of processed foods, gluten-containing grains, and foods found to be allergenic.

Supplement

PABA: 5 g/day until remission (maximum of 3 months)

Diabetes Mellitus Types I and II

Michael T. Murray, ND

OUTLINE

DIAGNOSTIC SUMMARY

Elevated blood glucose is determined by the following:

- Fasting (overnight): venous plasma glucose concentration greater than or equal to 126 mg/dL on at least two separate occasions.
- Following ingestion of 75 g of glucose: venous plasma glucose concentration greater than or equal to 200 mg/dL at 2 hours postingestion and at least one other sample during the 2-hour test.
- A random blood glucose level of 200 mg/dL or more plus the presence of suggestive symptoms.
- Classic symptoms of polyuria, polydipsia, and polyphagia.
- Fatigue, blurred vision, poor wound healing, periodontal disease, and frequent infections are often manifesting symptoms as well in type 2 diabetes.

GENERAL CONSIDERATIONS

Diabetes is a chronic disorder of carbohydrate, fat, and protein metabolism characterized by fasting elevations of blood glucose levels and a greatly increased risk of cardiovascular disease, renal disease, and neuropathy. Diabetes is divided into two major categories: types 1 and 2. Type 1 diabetes (T1DM) occurs most often in children and adolescents. For this reason, it is often referred to as juvenile-onset diabetes. About 5% to 10% of all diabetic patients have T1DM. (Box 165.1 lists the major complications of diabetes.)

T1DM is an autoimmune disease caused by the destruction of the beta cells of the pancreas, which manufacture insulin. Positive antibodies against beta cells or insulin occur in 75% of patients with T1DM. Why the immune system is activated to attack the pancreas is not fully clear, but viral infection, food sensitivities, and chemical or free radical damage are likely possibilities, combined with genes that may predispose to T1DM. These individuals will require lifelong insulin for the control of blood glucose levels. The individual with T1DM must learn how to manage blood glucose levels on a day-by-day basis, modifying insulin types and dosages as necessary according to meals eaten, liver production of glucose, and the results of regular blood glucose testing.

Type 2 diabetes (T2DM) historically has had an onset after age 40 in overweight individuals, but today it is seen even in pediatric patients because of the obesity epidemic, which affects all age groups in America. It is generally thought that up to 90% of all those with diabetes have T2DM. Initially, insulin levels are typically elevated in T2DM, indicating a loss of sensitivity to insulin by the body's cells. Obesity is a major contributing factor to this loss of insulin sensitivity. Approximately 90% of individuals categorized as having T2DM are obese. The achievement of an ideal body weight in these patients is often associated with the restoration of normal blood glucose levels. Even if T2DM has progressed to the point where insulin deficiency is present, weight loss nearly always results in significant improvements in blood glucose control and dramatic reductions in other health risks, such as cardiovascular disease (Table 165.1).

BOX 165.1 Major Complications of Diabetes

- Cardiovascular disease: Adults with diabetes have death rates from cardiovascular disease about two to four times higher than that for adults without diabetes.
- Hypertension: About 75% of adults with diabetes have high blood pressure.
- Retinopathy: Diabetes is the leading cause of blindness among adults.
- Renal disease: Diabetes is the leading reason for dialysis treatment, accounting for 43% of new cases.
- Neuropathy: About 60% to 70% of people with diabetes have mild to severe forms of nervous system damage. Severe forms of diabetic nerve disease are a major contributing cause of lower-extremity amputations.
- Amputations: More than 60% of lower-limb amputations in the United States occur among people with diabetes.
- Periodontal disease: Almost one third of people with diabetes have severe periodontal (gum) disease.
- Pain: Many people with diabetes fall victim to chronic pain due to conditions such as arthritis, neuropathy, circulatory insufficiency, or muscle pain (fibromyalgia).
- Depression: This is a common accompaniment of diabetes. Clinical depression can often begin to occur even years before diabetes is fully evident. It is difficult to treat in those with poorly controlled diabetes.
- Autoimmune disorders: Thyroid disease, inflammatory arthritis, and other diseases of the immune system commonly add to the suffering of people with diabetes.

TABLE 165.1 Differences Between Type 1 and Type 2 Diabetes

Features	Type I	Type 2
Age at onset	Usually younger than 40 years	Usually older than 40 years
Proportion of all diabetics	<10%	>90%
Family history	Uncommon	Common
Appearance of symptoms	Rapid	Slow
Obesity at onset	Uncommon	Common
Insulin levels	Decreased	Normal to high initially, decreased after several years
Insulin resistance	Occasional	Often
Treatment with insulin	Always	Usually not required

T2DM is a disease characterized by progressive worsening of glycemic control, which starts with mild alterations in postprandial glucose homeostasis followed by an increase in fasting plasma glucose and often ultimately a lack of production of insulin and the need for insulin therapy.

There are other types of diabetes, such as latent autoimmune diabetes of the adult, sometimes termed *type 1.5*. This is a slower-onset autoimmune type of diabetes that occurs later in life, often after people reach 35 years of age. Diabetes may also occur as a result of chronic pancreatitis and other insults to the pancreas. Gestational diabetes, another type, affects about 4% of all pregnant women, adding up to about 135,000 cases in the United States each year. This occurs in women who were not diabetic before they became pregnant but developed diabetes during pregnancy. Gestational diabetes occurs more frequently among African Americans, Hispanic/Latino Americans, and American Indians. It is also more common among obese women and women with a family history of diabetes. After pregnancy, 5% to 10% of women with gestational diabetes are found to have T2DM. Women who have had gestational diabetes have a 20% to 50% chance of developing diabetes in the following 5 to 10 years. The least common types of diabetes are genetic disorders, such as neonatal diabetes and mature-onset diabetes of youth, which are generally due to faulty genes causing impaired insulin function.

Prediabetes and Metabolic Syndrome

Prediabetes (also called "impaired glucose tolerance") is characterized by a glycosylated hemoglobin (A_{1c}) from 5.7% to 6.4%, a fasting glucose between 100 and 125 mg/dL, and/or a postprandial glucose of 140 to 199 mg/dL. It is the first step in insulin resistance and estimated to affect more than 60 million Americans. Many people with prediabetes will go on to develop full-blown T2DM despite the fact that prediabetes is usually reversible and, in most cases, diabetes can be completely avoided through dietary and lifestyle changes. Factors implicated in contributing to prediabetes, insulin resistance, and the progression to T2DM include a diet high in refined carbohydrates, particularly high-fructose corn syrup; an elevated intake of saturated fats; overeating due to increased portion sizes of food; increases in inflammatory markers; lack of exercise; industrial pollution; abdominal weight gain; hormonal imbalances; inadequate sleep; and nutritional deficiencies.

Research increasingly indicates that prediabetes is accompanied by serious health risks, especially an increased risk for cardiovascular disease. Individuals with prediabetes often meet the criteria for the metabolic syndrome (MetS). This is a cluster of factors that together carry a significantly greater risk for cardiovascular disease and the development of T2DM. They include the following:

- Greater waist-to-hip ratio
- Two of the following:
  - Triglycerides greater than 150 mg/dL
  - High-density lipoprotein cholesterol (HDL-C) less than 40 mg/dL for men, less than 50 mg/dL for women
  - Blood pressure equal to or greater than 130/85 mm Hg
  - Fasting plasma glucose equal to or greater than 100 mg/dL

By this definition and using data from the National Health and Nutrition Examination Survey (2012), the prevalence of MetS in the United States is 34.2% among men and women aged 18 and above.[1] Among adolescents and using a similar definition, approximately 5.8% meet the established criteria.[2] In addition to an elevated risk for cardiovascular disease and diabetes, individuals with MetS report poorer health-related quality of life, both physically and mentally.[3]

DIAGNOSTIC CONSIDERATIONS

The classic symptoms of T1DM are frequent urination, weight loss, impaired wound healing, infections, and excessive thirst and appetite. Such individuals may suffer from diabetic ketoacidosis upon diagnosis, and they are usually lean in presentation. In T2DM, the symptoms are generally milder and may go unnoticed. For that reason and others, many people with T2DM do not even know that they have the disease. Abdominal obesity, fatigue, blurred vision, poor wound healing, periodontal disease, and frequent infections are often manifesting symptoms of T2DM.

The standard method for diagnosing diabetes involves the measurement of blood glucose levels. The initial measurement is generally a fasting blood glucose taken after the patient has avoided food for at least 10 hours but not more than 16. The normal reading is between 70 and 99 mg/dL. If a person has a fasting blood glucose measurement greater than 126 mg/dL (7 mmol/L) on two separate occasions, the diagnosis is diabetes. As mentioned previously, a fasting glucose greater than 100 but less than 126 mg/dL is classified as prediabetes.

A postprandial and a random glucose determination are also helpful in diagnosing diabetes. A postprandial measurement is usually made 1 to 2 hours after a meal, whereas a random measurement is

TABLE 165.2 Criteria for Response to the Glucose Tolerance Test

Type	Criteria
Normal	No elevation > 160 mg/dL (9 mmol/L); <150 mg/dL (8.3 mmol/L) at end of first hour, below 120 mg/dL (6.6 mmol/L) at end of second hour
Flat	No variation of more than ± 20 mg/dL (1.1 mmol/L) from fasting value
Prediabetic	Blood glucose levels of 140 mg/dL (7.8 mmol/L) to 180 mg/dL (10 mmol/L) at end of second hour
Diabetic	>180 mg/dL (10 mmol/L) during first hour, 200 mg/dL (11.1 mmol/L) or higher at end of first hour, 150 mg/dL (8.3 mmol/L) or higher at end of second hour

one that is made at any time during the day without regard to the time of the last meal. Any reading greater than 200 mg/dL (11 mmol/L) is considered indicative of diabetes (Table 165.2).

Glycosylated Hemoglobin

The measurement glycosylated $HgbA_{1c}$ is a valuable laboratory test for evaluating long-term blood glucose levels. Proteins that have glucose molecules attached to them (glycosylated peptides) are elevated several-fold in diabetic patients. Normally, about 4.6% to 5.7% of hemoglobin is combined with glucose. An $HgbA_{1c}$ from 5.7% to 6.4% indicates prediabetes. An $HgbA_{1c}$ of 6.5% or higher, particularly when done as a screening test, can diagnose diabetes and is particularly helpful in patients with nondiagnostic fasting blood sugar levels. Nonetheless, it is best coupled with a fasting blood glucose measurement and a 2-hour postprandial glucose level for a more accurate diagnosis. Because the average life of a red blood cell (RBC) is 120 days, the $HgbA_{1c}$ assay represents time-averaged values for blood glucose over the preceding 2 to 4 months. An $HgbA_{1c}$ at 5% indicates that the glucose median for the previous 3 months was around 100 mg/dL; for each digit of elevation in the percentage, a rough addition of 35 mg/dL is followed. Thus an $HgbA_{1c}$ of 7% means that on average over the preceding 3 months, the patient's blood glucose was 170 mg/dL. The $HgbA_{1c}$ index is extremely valuable in providing a simple, useful method for assessing the effectiveness of treatment as well as patient compliance; it should be checked every 3 to 6 months.[4]

Criteria for the Screening and Diagnosis of Diabetes[4]

	Prediabetes	Diabetes
A_{1c}	5.7–6.4%[a]	≥6.5%[b]
FPG	100–125 mg/dL (5.6–6.9 mmol/L)[a]	≥126 mg/dL (7.0 mmol/L)[b]
OGTT	140–199 mg/dL (7.8–11.0 mmol/L)[a]	≥200 mg/dL (11.1 mmol/L)[b]
RPG	—	≥200 mg/dL (11.1 mmol/L)[c]

[a]For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at the higher end of the range.
[b]In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.
[c]Only diagnostic in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis.
FPG, Fasting plasma glucose; *OGTT,* oral glucose tolerance test; *RPG,* random plasma glucose.

RISK FACTORS FOR TYPE 1 DIABETES

In T1DM the insulin-producing cells of the pancreas are ultimately destroyed, in most cases by the body's own immune system, but what triggers this destruction can vary from one case to another. Genetic factors may predispose a person to damage to the insulin-producing cells through either impaired defense mechanisms, immune system sensitivity, or a defect in tissue-regeneration capacity. The entire set of genetic factors linked to T1DM have been termed "susceptibility genes" because they modify the risk of diabetes but are neither necessary nor sufficient for disease to develop.[5] Rather than acting as the primary cause, the genetic predisposition simply sets the stage for the environmental or dietary factor to initiate the destructive process.[6] The very term *predisposition* clearly indicates that something else must occur: less than 10% of those with increased genetic susceptibility for T1DM actually develop the disease.[7]

In detailed studies, the concordance rate for developing T1DM in identical twins was only 23% in one study[8] and 38% in another.[9] If one twin develops T1DM after age 24, the concordance rates drops all the way down to 6%, meaning that the other twin is at very low risk for developing the disease. These results and others indicate that in most cases, even where there is a true genetic predisposition, environmental and dietary factors may be more important in determining whether diabetes will develop.[10]

Additional evidence supporting the need to focus on dietary and environmental triggers follows:

- There has been a threefold to tenfold increase in the number of people with T1DM throughout the world over the past 40 years. Such a rise simply cannot be explained by an increased number of people genetically predisposed to T1DM. Changes to the human genetic code across large populations take more than one generation.[11]
- The rate of T1DM can increase dramatically when children in areas where T1DM is relatively rare move to developed countries.[12] For example, the rate of T1DM increased by nearly fourfold in one 10-year period in children of Asian origin moving to Great Britain, and the rate increased more than sevenfold in Polynesians migrating to New Zealand.[13,14] Genetic factors cannot explain such a rapid change.

Environmental and Dietary Risk Factors

Accumulating data indicate that abnormalities of the gut immune system and microbiome may play a fundamental role in the development of the immune attack on beta cells and the subsequent development of T1DM.[15] The intestinal immune system serves a vital role in processing the many food and microbial antigens to protect the body from infection and allergy. What appears to happen in the development of some cases of T1DM is the development of antibodies by the gut immune system that ultimately attack the beta cells. Possibly an underlying factor that may contribute to T1DM is poor protein digestion.

Poorly digested dietary proteins can cross-react with antigens on or within the beta cells of the pancreas. In humans, two proteins that have had the highest degree of incrimination are those found in milk (which contains bovine serum albumin and bovine insulin) and wheat (which contains gluten). For example, dietary bovine insulin differs from human insulin by only three amino acids. If a person develops antibodies to bovine insulin, there is a good chance that these antibodies will also attack their own insulin. In addition to causing antibody-mediated destruction of the beta cells, bovine insulin is able to activate T cells in those predisposed to diabetes in a manner that can also lead to beta-cell destruction by direct attack from T-killer cells.

Strong evidence implicates dietary factors like cow's milk and gluten as important triggers of the autoimmune process that leads to T1DM. In contrast, breastfeeding has been identified as an important factor in

establishing proper intestinal immune function and reducing the risk of T1DM. It is well known that breastfeeding confers a reduction in the risk of food allergies as well as better protection against both bacterial and viral intestinal infections. In case-controlled studies, patients with T1DM were more likely to have been breastfed for less than 3 months and to have been exposed to cow's milk or solid foods before 4 months of age. A critical review and analysis of all relevant citations in the medical literature indicate that early cow's milk exposure may increase the risk by about 1.5 times.[14,16] In addition, although the risk of diabetes associated with exposure to cow's milk was first thought to relate only to intake during infancy, additional studies showed that ingestion at any age may increase the risk of T1DM.

There is also considerable evidence that sensitivity to gluten—the major protein component of wheat, rye, and barley—may also play a role. Gluten sensitivity produces celiac disease, another autoimmune disorder. Celiac disease, like T1DM, is associated with abnormalities in intestinal immune function. And as in the case of diabetes, breastfeeding appears to have a preventive effect, whereas the early introduction of cow's milk is believed to be a major causative factor. The risk of developing T1DM is higher in children with celiac disease. Not surprisingly, the highest level of antibodies to cow's milk proteins is found in people with celiac disease.[17]

Enteroviruses and Type 1 Diabetes

Population-based studies, as well as prospective studies, have strengthened the hypothesis that T1DM can be the result of viral infection both during pregnancy and after birth.[18,19] A working theory in this regard is that the immune system becomes slightly confused as to which proteins to attack—the food-based ones such as those from dairy or gluten or the similar proteins on the pancreatic beta cells or insulin. When the person then has a viral infection, the increased stimulation of the immune system is the key that prompts it to become more active, and those confused immune cells begin to damage the pancreas. Gastrointestinal infections due to enteroviruses (e.g., polioviruses, coxsackieviruses, echoviruses) and rotavirus are common, especially in children. All of these viruses replicate in the gut and stimulate the intestinal immune system, which may then activate the insulin-specific immune cells to seek out and destroy beta cells. These viruses and others are also capable of infecting pancreatic beta cells, causing the leukocytes to attack and destroy the beta cells in an attempt to kill the virus. Gastrointestinal viral infections may also increase intestinal permeability and enhance the antibody response to dietary bovine insulin as a result of increased absorption of the intact protein. The severe "leaky gut"—or increased permeability of the small intestine that occurs during and for some time after rotavirus infections (one of the most common causes of acute diarrheal illness in children)—exposes the gut-associated immune cells to large quantities of intact protein.

Vitamin D Deficiency

Cod liver oil may offer significant protection against the development of diabetes because of its high content of vitamin D. The use of cod liver oil became popular during the 1890s to treat rickets, a vitamin D–deficiency disease characterized by an inability to calcify the bone matrix, resulting in softening of the skull bones, bowing of the legs, spinal curvature, and enlarged joints. Beginning in the 1930s, vitamin D was added to milk at a level of 100 IU per 8 oz. As a result, rickets is now uncommon in most developed countries.

Emerging evidence indicates that vitamin D supplementation from cod liver oil and other sources during early childhood can prevent not only rickets but also T1DM.[20] In fact, vitamin D fortification may offset some of the "diabetogenic" effect of cow's milk, but the dosage level in milk may not be sufficient to do so; the level that was shown to be protective was about 2000 IU—much higher than the amount typically ingested from the consumption of vitamin D–fortified milk.

The most extensive study looking at vitamin D and T1DM enrolled all pregnant women in northern Finland who were due to give birth in 1966 (more than 12,000 women), and their children were then monitored until December 1997.[21] Final analysis of 10,366 enrollees demonstrated that children who regularly took vitamin D, primarily from cod liver oil, had an 80% reduced risk of developing T1DM, whereas those who had a vitamin D deficiency actually had a 300% increased risk of developing the disease. One study found that the use of vitamin D from cod liver oil during pregnancy significantly reduced the frequency of T1DM in the offspring.[22] Furthermore, studies looking at vitamin D status in the blood of newly diagnosed individuals with T1DM have found much lower levels of the vitamin in these patients than in healthy controls. Because vitamin D can be produced in the body by the action of sunlight on the skin, lack of sun exposure during childhood may also play a role and partially explain the higher T1DM rates in northern countries. Vitamin D in recent research has been shown to prevent autoimmune conditions, including those that attack beta cells, from developing in the body, and observational studies have shown a dose-dependent degree of protection.[23]

This research indicates that ensuring adequate vitamin D supplementation during pregnancy and early childhood may reduce the risk of T1DM. Vitamin D is important for the normal development of the immune system. In addition, it has been shown that vitamin D inhibits some of the autoimmune reactions that target the beta cells.

Omega-3 Fatty Acid Deficiency

In addition to the strong case that can be made for vitamin D as a protective factor, an equally strong case can be made for the benefits of the omega-3 fatty acids in cod liver oil and other fish oils. Human studies have shown that when essential fatty acids (EFAs) are given, the onset of T1DM was significantly reduced. Also, higher levels of n-3 polyunsaturated fatty acids in RBCs have also been associated with reduced risk.[24] For one thing, cod liver oil also provides both EPA and DHA, which are vital EFAs in humans. Other studies support the benefit of supplementing EFAs in pregnant women and children. The mechanisms responsible for this effect may be related to improved cell membrane function, leading to enhanced antioxidant status and the reduced formation of inflammatory compounds called cytokines.[25]

Nitrates

Clear links between increased levels of nitrates (from both dietary sources and water) and an increased rate of T1DM have been established. Nitrates are produced by agricultural runoff from fertilizers and are found in cured or smoked meats such as ham, hot dogs, bacon, and jerky to keep the food from spoiling. Nitrates react within the body to form compounds known as nitrosamines. (Note: The U.S. Department of Agriculture [USDA] requires all manufacturers of processed meats to add vitamin C to their products to prevent the formation of nitrosamines.) Nitrates and nitrosamines are known to cause diabetes in animals. Infants and young children are believed to be particularly vulnerable to the harmful effects of nitrate exposure.

One of the most alarming features of T1DM is that it is becoming much more prevalent, with a current growth rate of 3% per year worldwide. Some areas have been hit particularly hard, such as Finland, Great Britain, Canada, and the United States. Increased nitrate exposure may be a key factor; the nitrate levels in ground and surface waters of agricultural regions have increased over the past 40 years owing to the use of nitrogen fertilizers. Nitrate contamination occurs in geographical patterns related to the amount of nitrogen contributed by fertilizers, manure, and airborne sources such as automobile and

industrial emissions. Nitrate exposure may explain why some geographical pockets have substantially higher rates of T1DM.[26,27]

Circumstantial evidence from population-based studies also suggests that a higher dietary intake of nitrates from smoked/cured meats is associated with a significantly higher risk for T1DM. These foods severely stress body defense mechanisms and are to be avoided. The habit of feeding children hot dogs, cold cuts, and ham would be a good one for parents to break. Health food stores now carry nitrate-free alternatives to these toxic food choices. Also, investing in a high-quality water purifier is good insurance against ingesting nitrate-contaminated drinking water.

EARLY TREATMENT AND POSSIBLE REVERSAL OF TYPE 1 DIABETES

Early intervention in T1DM designed to affect the autoimmune or oxidative process theoretically may be capable of lengthening the "honeymoon" phase or even completely reversing the process. This goal appears to have two candidates: niacinamide and epicatechin. Removing gluten and dairy from the diet and supporting gut health as well as immune system balance are also important considerations.

Niacinamide

Niacinamide, also called nicotinamide, has been shown to prevent some of the immune-mediated destruction of the pancreatic beta cells and may actually help reverse the process in some patients.[28,29] Observations that niacinamide can prevent the development of T1DM in experimental animals led to several pilot clinical trials that initially confirmed these observations and suggested that if given soon enough at the onset of diabetes, niacinamide could help restore beta cells or at least slow down their destruction. In one of the first pilot studies of people newly diagnosed with T1DM, seven patients were given 3 g of niacinamide daily, and nine were given a placebo. After 6 months, five patients in the niacinamide group and two in the placebo group were still not taking insulin and had normal blood glucose and $HgbA_{1c}$. At 12 months, three patients in the niacinamide group but none in the placebo group were in clinical remission.[30]

The results of this pilot study and others suggest that niacinamide can prevent T1DM from progressing in some patients if given soon enough at the onset of diabetes by helping restore beta cells. As of 2004, there had been 12 studies of niacinamide treatment in recent-onset T1DM or T1DM of less than 5 years' duration and residual beta-cell mass. Ten of these were double-blind placebo-controlled studies, of which half showed a positive effect compared with placebo in terms of prolonged non–insulin-requiring remission, lower insulin requirements, improved metabolic control, and increased beta-cell function as determined by secretion of a substance known as C-peptide. The main differences between the positive and negative studies in recent-onset T1DM were older age and higher baseline fasting C-peptide in positive studies.[31–34]

Although some of the studies have shown positive results, it is important to point out that two large studies designed to evaluate the effectiveness of niacinamide in preventing the development of T1DM in high-risk individuals—such as siblings of children who developed T1DM or in individuals who already show elevations in antibodies directed against the beta cells—did not show niacinamide to be effective. The first of these, the German Nicotinamide Intervention Study, did not show much of an effect with 1.2 g of niacinamide daily, and results from the larger study, the European Nicotinamide Diabetes Intervention Trial, did not show benefit with dosages as high as 3 g a day.[35,36] A possible shortcoming of these studies was the choice of a timed-released niacinamide. It is possible that such a formulation did provide the peak levels of niacinamide required to block autoimmune mechanisms such as cytokine production.[37]

In the best-case scenario, niacinamide will likely work for only a few individuals with T1DM of recent onset. Nonetheless, the fact that some patients have had a complete reversal of their disease makes a trial of niacinamide worth the effort, especially because there is currently no reasonable alternative.

The dosage recommendation is based on body weight: 25 to 50 mg of niacinamide for every 2.2 lb of body weight or a maximum dosage of 3 g/day in divided doses. Niacinamide is generally well tolerated and without side effects. In fact, no side effects have been reported in clinical trials in T1DM. It does not cause the flushing of the skin characterizing high dosages of niacin. However, because it could possibly harm the liver, a blood test for liver enzymes should be performed every 3 months to rule out liver damage.

Epicatechin

The second natural compound that may offer benefit is epicatechin. The line of research on its potential role in T1DM of recent onset began with examining the bark of the Malabar kino tree *(Pterocarpus marsupium)*. This botanical medicine has a long history of use in India as a treatment for diabetes. Initially, epicatechin extracted from the bark was shown to prevent beta-cell damage in rats. Further research indicated that both epicatechin and a crude alcohol extract of *P. marsupium* were actually able to promote the regeneration of functional pancreatic beta cells in diabetic animals.[38]

Green tea *(Camellia sinensis)* extract appears to be a better choice than extracts of *P. marsupium* because the epicatechin content in a high-quality green tea extract is actually higher than that found in extracts of *P. marsupium.* Second, green tea extract exerts a broader range of beneficial effects. Green tea polyphenols also exhibit significant antiviral activity against rotavirus and enterovirus—two viruses suspected of causing T1DM.[39] Last, green tea extract is considerably easier to find commercially than *P. marsupium.* Recommended dosages for children below age 6 is 50 to 150 mg; for those 6 to 12 years old, 100 to 200 mg; and for children older than 12 years old and adults, 150 to 300 mg. The green tea extract should have a polyphenol content of 80% and be decaffeinated.

Although the focus in the research has been on the reversal of T1DM, epicatechin may have more meaningful effects in prevention; epicatechin effectively prevented T1DM in nonobese diabetic (NOD) mice. At 32 weeks of age, 66.7% of control mice had overt diabetes, whereas only 16.6% of epicatechin-treated mice became diabetic. Consistently, epicatechin-treated mice had significantly higher plasma insulin levels but lower glycosylated hemoglobin concentrations compared with control mice. Treatment with epicatechin elevates circulating anti-inflammatory cytokine interleukin-10 levels, ameliorates pancreatic insulitis, and improves pancreatic islet mass—all important factors that may help prevent T1DM by modulating immune function and thereby preserving islet mass.

RISK FACTORS IN TYPE 2 DIABETES

Several factors are involved in the development and progression of diabetes. The most well-accepted major risk factor for T2DM is obesity or, more precisely, excess body fat. Approximately 80% to 90% of individuals with T2DM are obese (a body mass index above 30). When adipocytes, particularly those around the abdomen, become full of fat, they secrete several biological products (e.g., resistin, leptin, tumor necrosis factor, free fatty acids, cortisol) that dampen the effect of insulin, impair glucose utilization in skeletal muscle, promote glucose production

by the liver, and impair insulin release by pancreatic beta cells. Also important is that as the number and size of adipocytes increase, there is a reduction in the secretion of compounds that promote insulin action, including a novel protein produced by fat cells known as adiponectin. Adiponectin is associated not only with improved insulin sensitivity but also with anti-inflammatory activity; moreover, it lowers triglycerides and blocks the development of atherosclerosis, or hardening of the arteries. The net effect of these negative actions of fat cells is that they severely stress blood glucose control mechanisms while also leading to the development of the major complication of diabetes: atherosclerosis. Because of all these newly discovered hormones secreted by adipocytes, many experts now consider the adipose tissue a member of the endocrine system (e.g., the pituitary, adrenals, and thyroid).[40]

Measurements of blood levels of adiponectin and other hormones secreted by fat cells may turn out to be the most meaningful predictors of the likelihood of developing T2DM as well as gestational diabetes.[41,42]

In the early stages of the increased metabolic stress produced by the various secretions of adipocytes and the lack of adiponectin, blood glucose levels remain normal despite insulin resistance because pancreatic beta cells compensate by increasing insulin output. As metabolic stress increases and insulin resistance becomes more significant, the conventional explanation is that eventually the pancreas cannot compensate and elevations in blood glucose levels develop. As the disease progresses from insulin resistance to full-blown diabetes, the pancreas starts to "burn out" and produces less insulin. Avoiding this occurrence is a key therapeutic goal and is achievable with good diabetes care and if a patient's $HgbA_{1c}$ remains at 5.7 or less. (See Box 165.2 for risk factors.)

Genetics of Type 2 Diabetes and Obesity

In studies of identical twins, the concordance rate was between 70% and 90% for T2DM. This high concordance points to a strong genetic relationship. Data from family studies also provide additional support: children with one parent with T2DM have an increased risk of developing diabetes at some point in their lives. If both parents have the disease, the risk in offspring is nearly 40%. However, even with the strongest predisposition, diabetes can be avoided in most cases.[43]

The Case of the Pima Indians

The Pima Indians of Arizona have the highest rate of T2DM and obesity anywhere in the world. Research has demonstrated a strong genetic predisposition, but even with this strong tendency, the high rate of T2DM in this group is clearly related to diet and lifestyle. The Pima Indians living traditionally in Mexico still cultivate corn, beans, and potatoes as their main staples, plus a limited amount of seasonal vegetables and fruits such as zucchini squash, tomatoes, garlic, green pepper, peaches, and apples. The Pimas of Mexico also make heavy use of wild and medicinal plants in their diet. They work hard, have no electricity or running water in their homes, and walk long distances to bring in drinking water or wash their clothes. They use no modern household devices; consequently, food preparation and household chores require extra effort from the women. In contrast, the Pima Indians of Arizona are largely sedentary and follow the dietary practices of typical Americans. The results are astounding. Although roughly 16% of U.S. Native Americans have T2DM, 50% of Arizona Pimas have T2DM, and 95% of them are overweight or obese. T2DM is a rarity among the Mexican Pimas, and only about 10% can be classified as obese. The average difference in body weight between the Arizona and Mexican Pima men and women was more than 60 lb.[44]

Further evidence that diet and lifestyle appear to be able to overcome even the strongest genetic predisposition is shown by some of the intervention studies among Pima Indians. When these people were placed on a more traditional diet along with physical exercise, their blood glucose levels improved dramatically, and they lost weight. The focus right now, by various medical organizations such as the National Institute of Health, in dealing with the epidemic of diabetes and obesity among the Pima Indians is to educate children on the importance of exercise and dietary choices to reduce diabetes risk.

Other Genetic and Racial Factors

Other racial and ethnic groups beside Pima Indians that have a higher tendency to develop T2DM include other Native Americans, African Americans, Hispanic Americans, Asian Americans, Australian Aborigines, and Pacific Islanders. It is important for all these higher-risk groups to learn that when they follow the traditional dietary and lifestyle practices of their original cultures, their rates of diabetes will be extremely low. It appears that these groups are simply highly sensitive to the "Western diet" and lifestyle.

Diet, Exercise, Lifestyle, and Diabetes Risk

Findings from the U.S. government's Third National Health and Nutrition Examination Surveys (NHANES) make it clear that diabetes is a disease of diet and lifestyle. Of individuals with T2DM, 69% did not exercise at all or did not engage in regular exercise, 62% ate fewer than five servings of fruits and vegetables per day, 65% consumed more than 30% of their daily calories from fat and more than 10% of total calories from saturated fat, and 82% were either overweight or obese.[45]

Insights into the independent role of the modern lifestyle versus diet and obesity in the development of T2DM can be gleaned from the Old Order Amish. These 30,000 or so individuals, whose ancestors arrived on U.S. shores in the 18th century, maintain religious and cultural beliefs that preclude regular use of modern conveniences such as electrical appliances, telephones, and cars, and they have a physically active lifestyle. By comparison, the 200 million typical Americans living alongside them have, over the past 250 years, willingly adopted the advances of modern technology, making life less physically demanding.

Although the typical Amish diet and rate of obesity do not differ from those of the typical American, the rate of diabetes among the Amish is considerably less—about 50% lower. Although the percentage of Amish with impaired glucose tolerance (prediabetes) is about the same as in other whites in America, apparently not as many Amish go on to develop diabetes. This suggests that physical activity has a

BOX 165.2 Risk Factors for Type 2 Diabetes Mellitus

- Family history of diabetes (i.e., parent or sibling with type 2 diabetes)
- Obesity
- Increased waist-to-hip ratio
- Age: increasing age is associated with increased risk, beginning at age 45
- Race/ethnicity (e.g., African American, Hispanic American, Native American/Canadian, Native Australian or New Zealander, Asian American, Pacific Islander)
- Previously identified impaired fasting glucose or impaired glucose tolerance
- History of gestational diabetes (diabetes during pregnancy) or delivery of a baby weighing more than 9 lb
- Hypertension (blood pressure >140/90 mm Hg)
- Triglyceride level >250 mg/dL
- Low levels of adiponectin, elevated levels of fasting insulin
- Polycystic ovary syndrome (to be considered in any adult woman who is overweight with both acne and infertility)

protective effect against T2DM independent of obesity or percentage of body fat.[46,47]

Results from other studies corroborate this hypothesis. Lifestyle changes alone are associated with a 58% reduced risk of developing diabetes among those at high risk because they show evidence of impaired glucose tolerance (as based on results from the Diabetes Prevention Program—a large intervention trial of more than 1000 subjects). The two major goals of the program were a minimum of 7% weight loss/weight maintenance and a minimum of 150 min/week of physical activity similar in intensity to brisk walking.[48]

A Diet High in Refined Carbohydrates

Dietary carbohydrates play a central role in the causes, prevention, and treatment of T2DM. In an effort to qualify carbohydrate sources as acceptable or not, two indices have been developed: the glycemic index (GI) and glycemic load (GL). The GI is a numerical value that expresses the rise in blood glucose after a particular food is eaten. The standard value of 100 is based on the rise seen with the ingestion of glucose. The GI ranges from about 20 for fructose and whole barley to about 98 for a baked potato. The insulin response to carbohydrate-containing foods is similar to the rise in blood sugar. The GI is often used as a guideline in dietary recommendations for people with either diabetes or hypoglycemia. In addition, eating foods with a lower GI is associated with a reduced risk for obesity and diabetes.[49–51]

One of the shortcomings of the GI is that it tells us only about the quality of the carbohydrates, not the quantity. Obviously, quantity matters too, but measurement of the GI of a food is not related to portion size. That is where the GL comes into play. The GL takes the GI into account but provides much more accurate information than the GI alone. The GL is calculated by multiplying the amount of carbohydrate in a serving of food by that food's GI (compared with glucose) and then dividing it by 100. The higher the GL, the greater the stress on insulin. In Appendix 7, we provide the GI and GL for many common foods.

Research studies are just starting to use the GL as a more sensitive marker for the role of diet in chronic conditions like diabetes and heart disease. The preliminary results are showing an even stronger link in predicting diabetes than the one shown for the GI.[49,51] Researchers are also showing that a high-GL diet is also associated with an increased risk for heart disease. For example, when researchers from the Nurse's Health Study used GL measures to assess the effect of carbohydrate consumption on women, they found that high-GL diets (and, by extension, high-GI foods and greater total carbohydrate intake) correlated with even more significantly greater risk for heart disease than the GI because of lower levels of protective HDL-C and higher triglyceride levels.[52] Increased risk for diabetes and heart disease started, on average, at a daily GL of 161. Therefore we recommend using the information in Appendix 7 to help determine how to prevent the total daily GL from exceeding 150. Keep in mind that the GL is based on the stated serving size; the larger the serving size, the greater the GL.

The Importance of Dietary Fiber in Reducing the Risk of Developing Diabetes

Population studies, as well as clinical and experimental data, show diabetes to be one of the diseases most clearly related to an inadequate intake of dietary fiber. Different types of fiber possess different actions. The type of fiber that exerts the most beneficial effects on blood sugar control is the water-soluble form. Included in this class are hemicelluloses, mucilages, gums, and pectins. These types of fiber are capable of slowing down the digestion and absorption of carbohydrates, thereby preventing rapid rises in blood sugar. They are also associated with increasing the sensitivity of tissues to insulin and improving the uptake of glucose by the muscles, liver, and other tissues, thereby preventing a sustained elevation of blood sugar.[53,54]

Particularly good sources of water-soluble fiber are legumes, oat bran, nuts, seeds, psyllium seed husks, pears, apples, and most vegetables. Large amounts of plant foods must be consumed to obtain adequate levels of dietary fiber, although beans, peas, and legumes are overall the best sources for high fiber intake in relatively easy amounts to ingest. Even the simple change from white flour products to whole-grain versions is associated with a reduced risk for T2DM[55,56]; our recommendation is to consume at least 35 g of fiber a day from various food sources, especially vegetables. Fiber supplements can also be taken to achieve greater effects in lowering the GI.

The Wrong Types of Fats

Dietary fat also plays a central role in the likelihood of developing T2DM. Large controlled trials have shown that a reduction of fat intake as part of a healthy lifestyle, combined with weight reduction and exercise, reduces the risk for T2DM. However, more important than the amount of fat in the diet is the *type* of fat consumed.[57] The types of dietary fats linked to T2DM include saturated fats and trans fatty acids (partially hydrogenated vegetable oils) taken in large amounts along with a relative insufficiency of monounsaturated and omega-3 fatty acids.

One of the key reasons why dietary fats appear to be related to the risk for T2DM is that they determine cell membrane composition. That is, a "bad fat" pattern leads to reduced membrane fluidity, which in turn causes reduced insulin binding to receptors on cellular membranes, reduced insulin action, or both. Particularly harmful to cell membrane function are margarine, vegetable oil shortening, and other foods containing trans fatty acids and partially hydrogenated oils. These fatty acids interfere with the body's ability to use important essential fatty acids (EFAs). One study estimated that by substituting polyunsaturated vegetable oils for margarine containing partially hydrogenated vegetable oil, the likelihood of developing T2DM could be reduced by 40%.[58]

In contrast to the dampening of insulin sensitivity caused by margarine and saturated fats, clinical studies have shown that monounsaturated fats and omega-3 oils improve insulin action.[59] Adding further support is the fact that population studies have also indicated that the frequent consumption of monounsaturated fats such as olive oil, raw or lightly roasted nuts and seeds, nut oils, and omega-3 fatty acids from fish protect against the development of T2DM. Healthy omega-3 fish include wild salmon, trout, sardines, halibut, and herring. All of this evidence indicates that altered cell membrane composition and fluidity play a critical role in the development of T2DM.

One of the most useful food groups to reduce the risk of T2DM is nuts. Studies have shown that consumption of nuts is inversely associated with the risk of T2DM, independent of known risk factors for T2DM, including age, obesity, family history of diabetes, physical activity, smoking, and other dietary factors.[60] In addition to providing beneficial monounsaturated and polyunsaturated fats that improve insulin sensitivity, nuts are also rich in fiber and magnesium and have a low GI. Higher intakes of fiber and magnesium and foods with a low GI has been associated with a reduced risk of T2DM in several population-based studies. Eating mostly raw or lightly roasted fresh nuts and seeds rather than commercially roasted and salted nuts and seeds should be advocated.

Low Intake of Antioxidant Nutrients

Cumulative free-radical damage leads to cellular aging and is a major factor contributing to T2DM as well as many other chronic degenerative diseases. Several large population-based studies have shown that

the higher the intake of fruit and vegetables, the better blood glucose levels are controlled and the lower the risk for T2DM.[61] Many factors could explain this inverse correlation. Fruits and vegetables are good sources of fiber and also provide many nutrients and antioxidants. Even something as simple as the regular consumption of salads is associated with a reduced risk for T2DM.[62]

Studies looking at levels of individualized antioxidants have also shown similar inverse correlations—the higher the level of vitamin C, vitamin E, or carotenes, for example, the lower the risk for T2DM.[63–65] Likewise, the lower the levels of antioxidants and higher the levels of fats damaged by free radicals (lipid peroxides), the greater the risk for T2DM.[66] In one study, 944 men 42 to 60 years of age were followed closely for 4 years. None of them had diabetes at the beginning of the study. At the end of this time, 45 men had developed diabetes. The researchers found that a low vitamin E concentration was associated with 3.9-fold (390%) increased risk for T2DM in the study subjects.[67]

Free Radicals and Diabetes

One of the hallmark features of T2DM is the presence of higher levels of free radicals and prooxidants,[68] particularly an increased production of reactive oxygen species (ROS) and reactive nitrogen species (RNS).[69] These compounds are also activated by high blood glucose and elevated levels of saturated fat and, as already mentioned, are produced in the abdominal fat cells of individuals who are overweight or obese.

These compounds greatly stress antioxidant mechanisms; they directly oxidize and damage cellular components such as DNA, proteins, and cell membrane fatty acids. In addition to their ability to directly inflict damage on these structures, ROS and RNS indirectly induce damage to tissues by activating several inflammatory compounds, such as nuclear factor-kappa B, which ultimately leads to both insulin resistance and impaired insulin secretion.

Environmental Toxins

Persistent Organic Pollutants

Persistent organic pollutants (POPs) include such chemical compounds as polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), hexachlorobenzene (HCB), organophosphates, dichlorodiphenyldichloroethylene (DDE), and bisphenol A. These compounds have been linked to the development of T2DM. In addition, research indicates that the body load of POPs is not only a significant predictor of T2DM but may also be a more significant risk factor than obesity.[70]

Individuals in the top quintile of exposure to six common POPs have a 37.7-fold increased risk of diabetes—much stronger than any other known risk factor. Because many POPs block insulin receptor sites, decrease glucose transporter type 4 (GLUT-4) activity in muscles, and decrease insulin production, a causal relationship appears highly probable. Beginning in the 1960s, the production of synthetic organic chemicals began to escalate along with the incidence of diabetes (Fig. 165.1). The total load of toxicants may be the strongest contributing factor in the development of diabetes, with data so compelling that some researchers now label these toxicants as "diabetogens."

More convincing is the correlation between body load of POPs and the risk of metabolic syndrome, as shown in Fig. 165.2. The association is synergistic. When the relationship between POP levels and diabetes risk is examined, the case becomes even more compelling. Those in the top 10% of transnonachlor level, a common termiticide used in North America for decades, have a remarkable twelvefold increased risk of developing diabetes. Those with levels of organochlorine pesticides in the top quartile have an odds ratio of 5.3 for metabolic syndrome.[71]

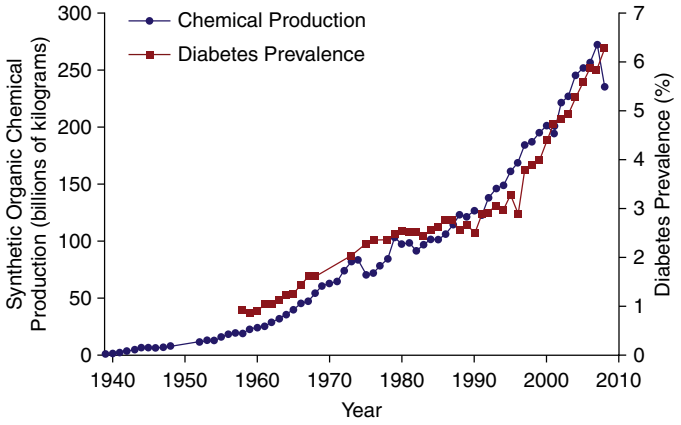

Fig. 165.1 The diabetes epidemic correlates with the release of persistent organic pollutants (POPs) into the environment. (From Ionnou GN, Bryson CL, Boyko EJ. Prevalence and trends of insulin resistance, impaired fasting glucose, and diabetes. *J Diabetes Complications.* 2007;21[6]:363–370.)

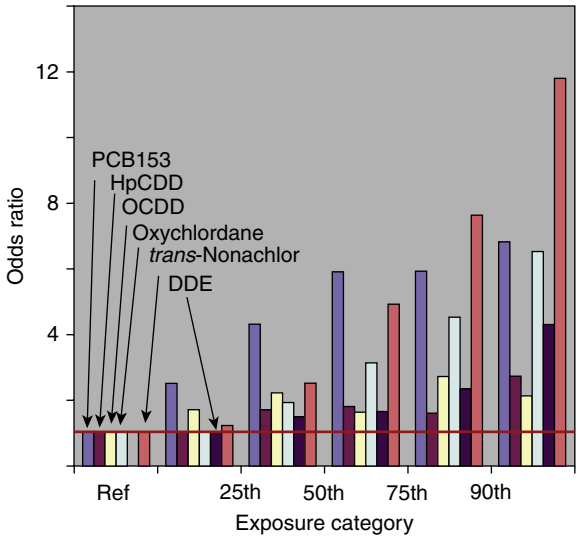

Fig. 165.2 Diabetes risk (odds ratio [OR]) for individual persistent organic pollutants (POPs) according to percentiles. *Blue rectangle,* PCB153; *red rectangle,* HpCDD; *yellow rectangle,* OCDD; *green rectangle,* oxychlordane; *pink rectangle,* trans-nonachlor; *purple rectangle,* DDE. Joseph Pizzorno, ND, Is the Diabetes Epidemic Primarily Due to Toxins?, *Integr Med (Encinitas).* 2016;15(4):8–17.

Unfortunately, direct measurement of POP levels is difficult and very expensive. However, a good indirect measure is gamma-glutamyltransferase (GGTP). An elevated level of GGTP is a strong predictor of diabetes risk. Those with levels above 40 IU/L have a twentyfold increased risk.[72]

Arsenic

Arsenic exposure occurs primarily through diet and water. A surprising 13 million people in the United States use public water that exceeds the Environmental Protection Agency (EPA) limit of 10 ug/L. There is a direct correlation between the amount of arsenic in a person's body and the risk of diabetes. In this case the primary mechanism appears to be the result of damaged pancreatic beta cells with resultant decrease insulin production.[73]

Arsenic has been shown to increase diabetes risk in a dose-dependent fashion. Comparing participants at the 80th versus the 20th percentiles, the odds ratios (ORs) for T2DM were 3.58 for the total level of arsenic, 1.57 for dimethylarsenate, and 0.69 for arsenobetaine.[74]

Bisphenol A and Phthalates

Higher urinary bisphenol A (BPA) concentrations are associated with type 2 diabetes, with an OR of 1.39 per 1-standard-deviation increase in BPA concentration.[75] BPA blocks insulin receptor sites resulting in insulin resistance. This increases the incidence of diabetes as well as obesity, especially the accumulation of visceral fat. The threshold for doubling the risk for diabetes is 5.0 ug/L urine.

Phthalates, such as di-2-ethyl-hexl phthalate, diethyl phthalate, dibutyl phthalate, dimethyl phthalate, dibenzyl phthalate, and diisononyl phthalate, are associated with the development of T2DM and obesity by interfering with various cell-signaling pathways involved in weight and glucose homeostasis.[76] Mitochondrial inhibition by phthalates likely contributes significantly to their role in obesity and diabetes.

Ambient Air Pollutants

A 3+ year study of overweight and obese Latino children from Los Angeles, California, showed significant effects of elevated NO_2 and particulate matter (PM) with an aerodynamic diameter of less than 2.5 ($PM_{2.5}$) on insulin homeostasis and beta-cell function that were independent of body fat percentage.[77] Epidemiological studies have also shown that greater exposure to NO_2 and $PM_{2.5}$ is associated with a greater risk for T2DM in adults.[78]

Lifestyle Management Versus Drugs to Prevent Type 2 Diabetes

Several well-designed large trials have shown that lifestyle and dietary modifications can be used to effectively prevent T2DM. That fact has not dissuaded drug companies from sponsoring studies attempting to prevent diabetes with drugs. However, the degree of prevention with drugs pales in comparison with that of diet and lifestyle. For example, in one of the most celebrated studies, 3234 subjects with impaired glucose tolerance (prediabetes) were randomly assigned to be in a group receiving a placebo, the blood glucose–lowering drug metformin (850 mg twice daily), or a lifestyle modification program with the goals of at least a 7% weight loss and at least 150 minutes of physical activity per week. The average follow-up was 2.8 years. The incidence of diabetes was 11, 7.8, and 4.8 cases per 100 person-years in the placebo, metformin, and lifestyle groups, respectively. The lifestyle intervention reduced the incidence of diabetes by 58% and metformin by 31% compared with placebo. Clearly, the lifestyle intervention was significantly more effective than metformin—a drug with sometimes serious side effects.[79]

Environmental Toxicity

Given the fact that environmental pollutants can increase the risk of developing T2DM, steps can be taken to reduce patients' exposure to them. This can be done, for example, by eating organic foods, using natural cleaning agents in the home, and avoiding chemical pesticides. These are all valid steps in preventing environmental toxins undermining the regulation of insulin.

CLINICAL MONITORING OF DIABETES

Knowledge and awareness are the greatest allies of people with diabetes. An individual with diabetes who makes a strong commitment to learning about his or her condition and accepts the lead role in a carefully supervised monitoring program that breaks away from the standard recommended by the American Diabetes Association (ADA) greatly improves the likelihood that he or she will lead a long and healthy life. On the other hand, individuals who remain blissfully ignorant about their disease and refuse to undergo regular testing or self-monitoring are far more likely to face years of unnecessary suffering and, more often than not, catastrophic health problems.

Unless it is properly managed and supervised, diabetes can be viewed as a state of biochemical and hormonal anarchy that will lead to organ injury and accelerated aging. Many of the complex control systems that faithfully govern and protect the body are damaged in the diabetic individual. For such a person to regain control, he or she must learn how to maintain an intimate awareness of blood sugar, risk factors for atherosclerosis (hardening of the arteries), blood pressure, body mass index, level of fitness, and other factors that determine the risk of developing diabetic complications and experiencing an erosion of his or her quality of life.

Fortunately, diabetic patients who do develop a keen awareness of these risk factors through regular testing and a properly supervised self-monitoring program are also those who are much more likely to benefit from changes in lifestyle: diet, supplements, and when necessary, medications.

Urinary Glucose Monitoring

The measurement of glucose in the urine is now entirely passé. Until the mid-1970s, the only option that diabetic patients had to monitor blood glucose was indirectly through urine glucose testing. Normally, the kidneys are able to conserve all of the glucose in the blood that they constantly filter. However, if blood glucose gets too high, the kidneys become unable to conserve all of the glucose, which then begins to appear in the urine. Because the average diabetic patient's kidneys can completely conserve glucose until the blood glucose reaches about 200 to 250 mg/dL (10 mmol/L), a negative urine glucose reading indicates that the blood glucose since the time of the previous voiding has been less than 200 to 250 mg/dL (10 mmol/L). Therefore the measurement of glucose in the urine is only a crude measurement of blood glucose control and is completely worthless in detecting severe hypo- or hyperglycemia.[80] Thus urinary glucose monitoring is of little value in determining the success of blood glucose control, and it does not provide adequate feedback when lifestyle, diet, or other treatments are adjusted. These days, all diabetic patients should own a glucometer and know how to test their own blood glucose levels.

Urinary Ketone Testing

In any circumstance when the body must derive its primary source of energy from fat, ketones are produced as a by-product. If the level of ketone production is high enough, ketones appear in the urine. In the patient with T1DM or T2DM who cannot produce any innate insulin, ketones appear in the urine when there is a severe deficiency in or activity of insulin. In general this is associated only with T1DM because the vast majority of patients with T2DM do not develop ketoacidosis. This can occur if a patient with insulin-dependent diabetes accidentally or purposefully forgets to take insulin. It can also occur when such a patient becomes ill or injured or is given high doses of cortisone-related drugs. All of these phenomena may result in a severe loss of insulin effectiveness, resulting in the cells' inability to take up and use glucose. In such circumstances, blood glucose rises to high levels, high amounts of fat are used by cells that cannot take in glucose, and the blood becomes polluted with toxic levels of acidic ketones. Severe dehydration occurs rapidly because the kidneys are unable to conserve water in the presence of such extraordinary levels of blood glucose. This dangerous state is referred to as diabetic ketoacidosis, and it must be treated as a medical emergency, usually necessitating intravenous

BOX 165.3 Optimal Range for Self-Monitored Blood Glucose

- Fasting or before meals: 80 to 110 mg/dL (4.4–6.7 mmol/L)
- 2 hours after eating (postprandial): <140 mg/dL (7.8 mmol/L)
- At bedtime: 100 to 140 mg/dL (5.6–7.8 mmol/L)
- Note that these are whole-blood values that typically run 10 mg/dL (0.6 mmol/L) higher than serum values. To avoid confusing numbers, some home glucose-monitoring kits, even those using whole-blood samples, are now calibrating to serum levels. Check the glucose monitor's documentation to find out if it is set up to determine whole-blood or serum glucose levels.
- Slightly higher values may be acceptable in the elderly or in young children because of their higher risk of developing dangerous hypoglycemia.

BOX 165.4 Optimal Schedule for Self-Monitored Blood Glucose

1. Test on awakening and just before each meal. Ideal blood sugar before meals is <120 mg/dL (6.7 mmol/L).
2. Test 2 hours after each meal. Ideal blood sugar 2 hours after meals is <140 mg/dL (7.7 mmol/L).
3. Test at bedtime. Ideal blood sugar at bedtime is <140 mg/dL (7.7 mmol/L).

insulin, large amounts of intravenous fluids, and careful monitoring, usually in an intensive care unit. Ignoring ketoacidosis can rapidly lead to death.

Because of the events just outlined, the testing of urine or, even better, blood for ketones remains an important part of monitoring only in patients with T1DM who have no remaining pancreatic function. The presence of urine or blood ketones accompanied by high blood sugar readings can be interpreted to determine how far along the ketoacidosis has developed and what type of medical attention is required. For this reason, all patients with T1DM should test their urine for ketones frequently during acute illness or severe stress, especially when blood glucose levels are consistently elevated (>300 mg/dL [16.7 mmol/L]); regularly during pregnancy; or when symptoms suggestive of ketoacidosis, such as nausea, vomiting, or abdominal pain, are present.

Self-Monitoring of Blood Glucose

Since its introduction, self-monitoring of blood glucose (SMBG) has revolutionized the management of diabetes.[81] The publication of the landmark Diabetes Control and Complications Trial,[82] which examined intensive glucose control in people with T1DM, and the United Kingdom Prospective Diabetes Study,[83] which examined intensive glucose control in those with T2DM, scientifically proved that the most important factor in determining the long-term risk of serious diabetic complications in both types of diabetes is blood glucose control. Patients who do not maintain vigilant awareness of their blood glucose and who do not make every effort to keep their blood sugar under tight control can expect a significant increase in their risk of serious health problems such as eye, kidney, and heart disease as well as a whole host of other problems, including depression, fatigue, impotence, and chronic infections. SMBG is important for a number of reasons[84]:

1. Modifications of treatment to achieve appropriate blood glucose control
2. Detection and diagnosis of hypoglycemia
3. Adjusting care in response to daily life circumstances (e.g., food intake, exercise, stress, illness)
4. Detection and treatment of severe hyperglycemia
5. Increasing compliance with therapy (helps combat apathy and denial)
6. Improvement in motivation because of immediate positive and negative feedback (Boxes 165.3 and 165.4)

Type 1 Diabetes and Self-Monitoring of Blood Glucose

Without question, all individuals with T1DM must monitor their blood glucose frequently if they want to achieve and maintain good health. In the absence of diabetes, the pancreas monitors blood glucose continuously and adjusts its insulin output depending on moment-by-moment changes. To achieve blood glucose levels that are consistently as close to normal as possible, those with T1DM must replicate this natural situation as closely as possible. This means that they must monitor their blood glucose frequently, and they must learn to use this information to make ongoing adjustments to their insulin injections, diet, and exercise.

Intensive insulin therapy allows a diabetic patient to achieve near-normal levels of blood glucose, along with enjoying improved lifestyle flexibility. With conventional, infrequent insulin injections, the diabetic patient must structure meals and other aspects of lifestyle around his or her injections or face serious abnormalities of blood glucose. On the other hand, with intensive insulin therapy that relies on rapid-acting, short-duration insulin or the use of an insulin pump (an electronic device that provides a continuous injection of short-acting insulins with extra boluses before meals), the timing and size of doses can be adjusted to suit the events of the day.[85] Even though it may involve multiple injections (usually before each meal and often at bedtime) and blood glucose measurements up to six times or more each day, intensive insulin therapy results in greater dietary and lifestyle freedom, a higher quality of life and well-being, and near nondiabetic blood glucose control, which is vital for long-term health.

Type 2 Diabetes and Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose has an important place in the management of T2DM as well. Each such patient lies somewhere on a spectrum that ranges from mild glucose intolerance (accompanied by insulin resistance and higher-than-normal levels of insulin) to more advanced forms (with more severe insulin resistance, the potential for high levels of blood glucose, ketoacidosis, and partial or nearly complete pancreatic failure with an accompanying lack of insulin). Depending on the severity of the individual's diabetes, SMBG plays a varying role. Each such patient should own a blood glucose monitor and have become intimately familiar with its use. Even those whose blood glucose is well controlled through diet, lifestyle, and supplements should measure their blood glucose regularly.

Numerous dietary factors, supplements, exercise, stress, and illness can all have a significant effect on blood glucose control. Becoming intimately aware of how all these factors influence diabetes will help motivate these patients to make positive changes and provide immediate feedback as to the success of any changes that have been made.

Those whose disease is more advanced and who have diminished pancreatic insulin production may also benefit from efforts to establish consistently near-normal blood glucose control using intensive insulin therapy similar to that of patients with T1DM.[86] A C-peptide blood test can provide an estimate of how much insulin a patient is producing and is one way to help determine the appropriateness of using insulin. If patients with T2DM are placed on an intensive insulin therapy program, they must perform SMBG as frequently as those with T1DM who are receiving intensive insulin therapy (usually before and 2 hours after each meal).

TABLE 165.3 Interpreting Levels of C-Peptide

C-Peptide Results	Interpretation
Normal	Insulin production at normal level
Below normal	Newly diagnosed type 1 diabetic or chronic, long-term type 2 diabetic
Above normal	Newly diagnosed type 2 diabetic or a benign pancreatic tumor (insulinoma; rare)
Undetectable	Chronic type 1 diabetic or postsurgical removal of pancreas (rare)

Many patients with advanced T2DM have diminished insulin production (evidenced by lower-than-normal C-peptide levels). A common way to achieve optimal blood glucose in these individuals is to give one injection of the new, long-acting insulin glargine (Lantus), which provides a smooth, continual release of insulin for 24 hours, along with diet and other medication. Patients on this type of program must measure their blood glucose frequently (usually before and 2 hours after each meal).

C-Peptide Determination

Often it is important to know whether a diabetic patient's pancreas is making insulin, and if so, how much. This assessment can greatly influence treatment, especially in a patient hoping to avoid or cease using injected insulin. The level of pancreatic insulin production can also partially determine the type of medication or natural health products that are more likely to be effective. Once it is known how well the pancreas is producing insulin, the focus may be shifted toward replacing deficiencies in insulin production, stimulating insulin production, preserving pancreatic function, reducing insulin resistance, or a combination of these therapeutic efforts.

One way to determine the level of insulin production is by measuring C-peptide. The pancreas manufactures a large protein called *proinsulin* first. A piece of this protein (C-peptide) is then snipped off by enzymes, and both C-peptide and the remaining insulin are released into the bloodstream. Injected insulin has no C-peptide, nor does the body ever produce antibodies against it, as it can against insulin. Patients with T1DM and those who have injected insulin even once are at high risk of having developed insulin antibodies, which can destroy the molecule. The benefits of measuring C-peptide are helpful for both patients with T1DM and those with T2DM, but generally more so for those with T2DM. C-peptide can uncover how much insulin the pancreas is making, which may help determine how much of a T1DM pancreas is still active. It may even sometimes make it possible, with alternative care, to stabilize the patient's condition. In T2DM, high C-peptide levels confirm that the patient is highly insulin resistant. If the C-peptide is low, it indicates that the pancreas is so damaged that some type of insulin therapy will be required (Table 165.3).

Physician Monitoring

Although patients with diabetes must take charge of their illness and be in control of their diet, lifestyle, and glucose monitoring, they are rarely successful without professional guidance. Numerous studies have determined that physician monitoring through laboratory measurements of blood glucose levels can have a major effect on a diabetic patient's long-term health.

One of the key determinants of blood glucose control is the $HgbA_{1c}$ test (see earlier discussion). Unlike direct measurements of blood glucose, which detect the level at the moment of testing, the $HgbA_{1c}$ test reflects the average level of blood glucose over the preceding 3 months. Studies have shown that the level of $HgbA_{1c}$ closely correlates with the level of risk for diabetic complications. However, an $HgbA_{1c}$ may not be entirely accurate. A patient may have steady, regulated blood sugars that return an $HgbA_{1c}$ of 6%, or he or she may have very high numbers in combination with hypoglycemic events, which can also—because the $HgbA_{1c}$ is an average, median index—show the same $HgbA_{1c}$ of 6%. Having an $HgbA_{1c}$ level of less than 5.5% or less is ideal and indicates that blood glucose levels have averaged in a range that is essentially nondiabetic (meaning that the patient is suffering no damage because of his or her glucose level). Owing to the great importance of adequate glucose control, all patients with diabetes should have their $HgbA_{1c}$ levels measured every 3 to 4 months, depending on the stability of their condition. If the $HgbA_{1c}$ number is not clearly known to be the result of good control or fluctuating highs and lows, then a second laboratory test, called GlycoMark, is a good one to consider.[87] The GlycoMark assay measures blood levels of 1,5-anhydroglucitol. 1,5-AG is found in nearly all foods and is ingested in a regular diet. Once ingested, 1,5-AG is nearly 100% nonmetabolized and remains in a relatively constant amount in the blood and tissues. When blood glucose exceeds 180 mg/dL for any period of time, the kidney attempts to reabsorb as much glucose back into the blood as it can. During times of glucosuria, the additional amount of glucose in the kidney blocks 1,5-AG from being reabsorbed into the blood, and 1,5-AG is excreted in the urine at a higher rate than normal. Due to the lack of 1,5-AG being reabsorbed, blood levels of 1,5-AG decrease immediately and continue to decrease until glucose values go below 180 mg/dL. It is this competitive inhibition of 1,5-AG from glucose that allows GlycoMark to accurately reflect any hyperglycemic episodes over 180 mg/dL. The GlycoMark test has been shown to be more accurate than an $HgbA_{1c}$ and offers the physician a clearer picture of how well a patient's glucose levels are being controlled and also shows postprandial spikes more clearly.

Although it is clear that optimal blood glucose control is critical to the health of patients with diabetes, several other risk factors must be carefully monitored in all diabetic patients. Early detection of problems through a program of regular screening and monitoring will enable preventive efforts and treatments to be put in place before serious complications or catastrophic problems occur. Table 165.4 provides a checklist for the proper evaluation and monitoring of patients with diabetes.

THE COMPLICATIONS OF DIABETES

In diabetes, problematic regulation of glucose levels can lead to acute complications, and long-term elevations of blood glucose cause inflammatory and oxidative damage that will lead to chronic disease progression and the development of complications (Box 165.5).

Acute Complications

As described previously, the acute complications of diabetes may represent a medical emergency and possibly a life-or-death situation. Any diabetic patient experiencing any symptom even remotely suggestive of an acute complication should consult medical care immediately. The major acute complications of diabetes are hypoglycemia, ketoacidosis, and nonketogenic hyperosmolar syndrome.

Hypoglycemia

Hypoglycemia is usually seen in T1DM. It is the result of excessive insulin injection, decreased or delayed food ingestion, use of alcohol or drugs that interfere with the liver's production of glucose, or an unaccustomed increase in exercise. Severe hypoglycemia can also occur unpredictably in

TABLE 165.4 Clinical Management of the Patient With Diabetes

	Quarterly	Annually
Review Management Plan		
Blood glucose self-monitoring results	X	X
Medication/insulin regimen	X	X
Nutritional plan	X	X
Exercise program	X	X
Psychosocial support	X	X

patients with "brittle" T1DM or in any patient on insulin or sulfonylurea drugs who neglects the need for the proper monitoring of blood glucose. Daytime hypoglycemic episodes are usually recognized by symptoms such as sweating, nervousness, tremor, and hunger. Nighttime hypoglycemia may be without symptoms or manifest as night sweats, unpleasant dreams, or early-morning headache.

The earliest autonomic symptom of hypoglycemia is hunger and occurs when the glucose is at or below 65 to 70 mg/dL. Patients may also experience irritability, anxiety, heart palpitations, pallor, and sweating. Neuroglycopenic symptoms, which occur when the brain becomes starved of glucose, start with blurry vision and can progress to headache, tiredness, abnormal behavior, slurred speech, unconsciousness, and seizures. Treatment of hypoglycemia follows the 15-15 rule, whereby patients are told to ingest 15 g of carbohydrate and then recheck their glucose in 15 minutes. If the glucose is still below 80 mg/dL, another 15 g of carbohydrate should be taken and the glucose rechecked in an hour. When glucose sinks below 55 mg/dL, the patient will probably need help from another person, and when it is below 20 mg/dL, a seizure is highly likely to follow, and glucagon should be injected. Any hypoglycemic event should be recorded and reported to a physician.

BOX 165.5 Acute and Chronic Complications of Diabetes

Acute Complications

- Hypoglycemia
- Diabetic ketoacidosis
- Nonketotic hyperosmolar hyperglycemia

Chronic Complications

- Atherosclerosis and other vascular lesions
- Retinopathy and cataracts
- Neuropathy
- Nephropathy
- Poor wound healing
- Foot ulcers

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is most commonly seen in patients with newly diagnosed T1DM when they have infections; when they have deliberately or accidentally omitted their insulin; and under other circumstances such as trauma, myocardial infarction or stroke, during surgery, and with dental abscess and other types of physiological stress. The lack of insulin leads to extremely high levels of blood glucose and a buildup of acidic ketone molecules as fat stores are burned to provide energy. If progressive, ketoacidosis can lead to numerous metabolic problems and even coma or death. Because ketoacidosis is a medical emergency, its prompt recognition is imperative. Patients should be taught to check for ketones in their urine or blood when their glucose is above 250 mg/dL for more than a few hours, if they are feverish or have an infection, if they do not "feel well," and regularly during pregnancy because DKA is usually fatal to the fetus. The symptoms of DKA include fruity breath, disorientation, abdominal tenderness, polyuria and polydipsia, hyperventilation, and signs of dehydration. Treatment of DKA depends on the severity of the situation and where the glucose level is—it can require injecting insulin, eating as well as insulin injection, or referral to an emergency department.

Hyperosmolar Hyperglycemic State

The hyperosmolar hyperglycemic state (HHS) occurs mostly in older patients with T2DM, usually in the seventh decade of life. It develops gradually, taking days to weeks to manifest itself. There is no ketoacidosis with this condition, but it has a higher mortality because it tends to occur in patients who have other serious problems, such as acute illness, recent surgery, congestive heart failure, renal dysfunction, or cardiovascular disease, or who are taking certain drugs, are victims of elder abuse or neglect, or are simply noncompliant with their diabetic therapy protocols. The diagnostic criteria include a glucose level above 600 mg/dL, profound dehydration, other changes in pH, and some alteration in consciousness. Patients may present with drowsiness, coma, visual changes, sensory deficits, and even paralysis or seizures.

HHS is a medical emergency, and the patient must be taken to an emergency room. Injecting insulin can cause severe complications, so hospital care is best.

Chronic Complications

Much more common than the acute complications of diabetes are certain long-term complications, described as follows. The main four areas of the body affected most by diabetic complications are the eyes, kidneys, nerves, and endothelial lining. These four areas do not require insulin to absorb glucose into their cells, as do the liver, muscle, and fat cells, so when glucose levels are elevated in uncontrolled diabetes, unregulated glucose floods those cells and causes significant damage. Thus they are the key sites for diabetic complications.

Atherosclerosis

Atherosclerosis and other vascular lesions are the underlying factors in the development of many chronic complications of diabetes. Individuals with diabetes have a four- to sixfold higher risk of dying prematurely of heart disease or stroke than do nondiabetic individuals, and 55% of deaths among patients with diabetes are caused by cardiovascular disease. The majority of those with T2DM have hypertension, and many of the diet and lifestyle habits of patients with diabetes—such as eating poorly and not exercising—combined with nutrient deficiencies can accelerate the risk of developing cardiovascular disease.

Retinopathy

Diabetic retinopathy is the leading cause of blindness in the United States for people between the ages of 20 and 64. In this condition, the retina is damaged by microhemorrhages, scarring, and the attachment of glucose molecules (glycosylation) to structural proteins in the retina. Studies have shown that 20 years after a diagnosis of diabetes, 80% of those with T1DM and 20% of those with T2DM have significant retinopathy. Diabetic patients are also prone to developing cataracts—opacities that occur in the lens of the eye as a result of oxidative damage to the delicate protein structures of the lens.

Neuropathy

Neuropathy usually involves the loss of peripheral nerve function and is characterized by tingling sensations, numbness, and a characteristic burning pain (neuropathic pain). It commonly occurs noticeably in the feet but can also spread elsewhere in the body, such as to the autonomic nerves of the gastrointestinal tract, causing diarrhea, constipation, and/or gastroparesis. If it progresses, it can affect deeper nerves of the autonomic nervous system, resulting in disturbances in stomach emptying and, later, impaired cardiac function, alternating bouts of diarrhea and constipation, and an inability to empty the bladder. Impotence is a common occurrence and is caused by damage to the small blood vessels of the penis as well as neuropathy of the autonomic nerves controlling blood flow into the penis. Approximately 60% of all people with diabetes eventually develop neuropathy. The main problem of peripheral neuropathy is that lack of feeling in the feet can lead patients to develop sores and lesions that they do not notice. These may then ulcerate, leading to gangrene and amputation.

Nephropathy

Nephropathy due to diabetes accounts for 40% of the cases of severe kidney disease and, in the United States, is the most common reason for end-stage renal disease, hemodialysis, and kidney transplantation. In addition to monitoring blood glucose levels, it is important to monitor kidney function with various laboratory measurements (random microalbuminuria, 24-hour urine protein, blood urea nitrogen, uric acid, creatinine and creatinine clearance, and glomerular filtration rate). Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) are part of standard care because they have been shown to protect the kidneys from diabetic damage.

Poor Wound Healing and Foot Ulcers

Poor wound healing is common in patients with diabetes for several reasons, such as the microvascular changes leading to poor circulation and the functional deficiency of nutrients. Foot ulcers are common in individuals with diabetes because of microvasculature changes leading to a poor blood supply, peripheral neuropathy, poor wound healing, poor nutrition, and immune system dysfunction, all of which can promote chronic infections in the feet. Apart from trauma, diabetic wounds are the leading cause of limb amputations in the United States. More than 50% of lower-limb amputations in the United States (70,000 each year) are due to diabetic foot ulcers.

Immune System Dysfunction

Immune system dysfunction often begins long before a diagnosis of diabetes is made. In fact, in many cases, a recurrent yeast infection of the vagina or skin is the first clue leading to the detection of diabetes. Immune system problems are made worse by poor glucose control, which puts the diabetic patient at risk for serious infections or complications of simple infections. Susceptibility to chronic, hidden infections in the oral cavity, blood, or respiratory tract may be a primary underlying cause of the increased risk for cardiovascular disease among diabetic patients.

Depression and Cognitive Difficulties

Depression and cognitive difficulties are common among those with diabetes. In fact, depression may begin to occur when the individual first starts to develop insulin resistance, decades before the onset of T2DM. The brain is more sensitive to its need for glucose than any other organ, and it appears that brain cells may suffer from some degree of glucose deprivation when insulin resistance occurs.[88] Depression is also much more common among overweight and obese individuals, probably owing to the combined effect of insulin resistance and diminished self-esteem. Cognitive changes begin to occur after the first severe hypoglycemic episode in people with diabetes. Hypoglycemia is profoundly stressful to the brain and, if severe hypoglycemia occurs many times, significant cognitive impairment can ensue. Uncontrolled diabetes is also associated with an increased risk of developing Alzheimer's disease.

Contributors to the Long-Term Complications of Diabetes

The major contributors to the long-term complications of diabetes are listed here, followed by a brief description of each factor along with coping measures:

- Poor glucose control
- Glycosylation of proteins
- Intracellular accumulation of sorbitol
- Increased oxidative damage
- Nutrient deficiency
- Elevated levels of homocysteine
- Hypertension
- Endothelial cell dysfunction

Poor Glucose Control

A large body of evidence indicates that good blood glucose control significantly reduces the development of complications. The largest and most extensive study to date in T1DM is the Diabetes Control and Complications Trial, whereas the largest and longest study on patients with T2DM is the United Kingdom Prospective Diabetes Study. Both

studies conclusively demonstrated that improved blood glucose control reduces the risk of developing long-term complications of diabetes, especially retinopathy, nephropathy, and neuropathy. Maintaining $HgbA_{1c}$ levels near normal (equal to or less than 7%) can dramatically help reduce the risk of eye problems (up to 76%), nerve damage (up to 60%), and kidney disease (up to 56%).

Glycosylation of Proteins

As described previously, the term *glycosylation* refers to the binding of glucose to proteins. The poorer the glucose control, the greater the binding of glucose molecules to proteins. This binding leads to changes in the structure and function of the protein. Among the adverse effects of excessive glycosylation are inactivation of enzymes, inhibition of regulatory molecule binding, and the formation of abnormal protein structures. For example, when glucose molecules bind to cholesterol-carrying low-density lipoprotein (LDL) molecules, they block LDL from binding to receptors on the liver that tell the liver to cease manufacturing cholesterol. As a result, the liver "thinks" that there is a shortage of cholesterol in the body and continues to produce more and to release it into the blood. This is one reason why diabetes is almost always associated with high cholesterol levels.

In addition to keeping blood glucose levels as close to ideal as possible, high intakes of antioxidants—especially vitamins C and E, flavonoids, and alpha-lipoic acid (discussed later)—help reduce glycosylation.

Intracellular Accumulation of Sorbitol

Sorbitol is a sugar molecule formed from glucose within cells. In people without diabetes, once sorbitol is formed, it is quickly broken down into fructose. This conversion to fructose is critical because it allows any excess sorbitol to be excreted from the cell, and sorbitol cannot exit the cell once it is formed. If sorbitol levels continue to increase within cells, they create an osmotic effect.

When there is an increase in the concentration of soluble compounds (e.g., sorbitol) that the cell cannot get rid of, the cell leaks small molecules like amino acids, inositol, glutathione, niacin, vitamin C, magnesium, and potassium to maintain osmotic balance. Because these compounds function to protect cells from damage, their loss results in increased susceptibility to damage.

Intracellular accumulation of sorbitol is a major factor in the development of most complications of diabetes, as evidenced by the fact that elevated sorbitol levels are found in high concentrations in the tissues commonly involved in the major diabetic complications: the lens of the eye, nerve cells, kidney cells, and the cells that line blood vessels.

In addition to controlling blood glucose levels, vitamin C and flavonoids like quercetin, grape seed extract, and bilberry extract can help lower intracellular sorbitol levels. Sorbitol accumulation, by the way, has nothing to do with eating foods that contain sorbitol.

Increased Oxidative Damage

Increased oxidative stress is a major factor in the development of the chronic complications of diabetes. As previously stated, individuals with diabetes typically have elevated levels of free radicals and oxidative compounds.[89] These highly reactive compounds bind to and destroy cellular compounds, cause damage all over the body, and increase insulin resistance. They also greatly increase the inflammatory process by adding fuel to their destructive fire via the increased formation of inflammatory mediators like C-reactive protein, interleukin-6, and tumor necrosis factor-alpha. One of the critical goals in diabetes prevention and treatment is to flood the body with a high level of antioxidant compounds to counteract the negative effects of free radicals and prooxidants. Implementation of this goal is achieved by following the dietary and supplementary strategies given, which promote weight loss, establish better glucose control, and replete antioxidants in the body. In addition to the basic supplementation program, supplementing the diet with super antioxidants like alpha-lipoic acid and flavonoid-rich extracts is often useful in further boosting antioxidant protection.

Nutrient Deficiency

A deficiency of any one of several nutrients has been shown to contribute to several chronic complications of diabetes. Studies have found that nutrient supplementation helps patients with diabetes control their glucose levels; it can also lower their blood pressure and protect their bodies from diabetic complications. In general, the risk of long-term complications of diabetes is inversely proportional to micronutrient status. Sometimes the symptoms of nutrient deficiency can closely mimic those of a chronic complication of diabetes. For example, vitamin B_{12} deficiency is characterized by numbness, "pins and needles" sensations, or a burning feeling in the hands or feet—symptoms virtually identical to diabetic neuropathy. Although vitamin B_{12} supplementation has been used with some success in treating diabetic neuropathy, it is not clear whether this success is due to correction of a vitamin B_{12} deficiency state or the normalization of the deranged vitamin B_{12} metabolism seen in diabetic patients.

High-potency multivitamin/multimineral supplementation is critical to the management of diabetes. Supplying the diabetic patient with additional key nutrients improves blood glucose control and reduces the development of the major long-term complications of diabetes.

Elevated Levels of Homocysteine

Elevated homocysteine levels constitute an independent risk factor for heart attack, stroke, and peripheral vascular disease. In addition, recent research has implicated elevations of homocysteine in the development of long-term complications of diabetes, especially diabetic retinopathy.[90]

Hypertension

Blood pressure control is essential in preventing the complications of diabetes, especially renal disease, retinopathy, and stroke. Maintaining blood pressure in the normal range (120/80–140/80 mm Hg) can reduce the risk of heart disease and stroke by approximately 33% to 50% and can reduce microvascular disease (eye, kidney, and nerve disease) by approximately 33%.

Endothelial Cell Dysfunction

A single layer of endothelial cells lines all the body's blood vessels, serving as a metabolically active interface between the components of blood and the blood vessel. These cells regulate many important aspects of blood flow: coagulation, clot formation, and the formation of key regulatory compounds, including those that control blood pressure. Endothelial cells are susceptible to damage by oxidized LDL cholesterol (LDL-C) and other free radicals—hence the importance of a high dietary intake of antioxidants, flavonoids, key supplemental antioxidants like vitamins C and E, and alpha-lipoic acid. All of these factors have been shown to improve endothelial cell function and are critical in the battle against vascular disease in diabetes.[91–94]

THERAPEUTIC CONSIDERATIONS

Diet Therapy in Managing Diabetes

The optimal diet for the treatment of diabetes is virtually the same as the program presented in Chapter 44. The difference is that there must often be an even stricter avoidance of foods with a high carbohydrate

concentration (see Appendix 7). The strictness of the diet with regard to the intake of carbohydrates must be based on the patient's ability to maintain satisfactory blood glucose measurements and $HgbA_{1c}$ levels and to achieve/maintain ideal body weight. Obviously, the poorer the control, the more the carbohydrate intake must be restricted. Initially, some people with diabetes—especially those who have poorly controlled blood glucose levels—may have to avoid meals with a total GL of more than 20 and space these meals at least 3 hours apart. Higher-GL meals can be consumed if one of the special natural products designed to slow gastric emptying and blunt after-meal blood glucose levels is used (these compounds are discussed later in the chapter).

Clinical Studies With Diet Therapy in Type 1 Diabetes

Numerous clinical studies have shown impressive results in improving blood glucose control when diets high in fiber and low in GL are followed. This holds true in both adults and children as well as in both T1DM and T2DM. In a study involving children, 8- to 13-year-olds in Melbourne, Australia were divided into two groups: one group followed the ADA's exchange-program diet, and the other was instructed to eat low-GI foods.[95] Although there was no change in A_{1c} in the exchange diet (8.6%), the group eating the low-GI diet dropped from 8.6% to 8%—an acceptable value in children. Rates of excessive blood glucose levels were 66% for the exchange diet versus 35% for those eating low-GI foods. Although these results are good, what the study really highlighted was the effect of eating a low-GI diet on the quality of life. There were significantly fewer family conflicts, fewer limitations placed on family activities, and fewer difficulties in meal selections. Furthermore, parents and children alike showed a clear preference for the low-GI diet.

Similar results have been seen in adults, including pregnant women, with T1DM following a high-fiber, low-GI diet.[96–99] What these studies and others indicate is that low-GI and low-GL diets are emerging as the most scientifically proved dietary support for T1DM. We have taken the proved diet to a much higher level by also considering the role of fats on insulin action.

Although ketogenic diets have become popular for T2DM, they should be used with caution in T1DM. In an observational study, 11 adults with type 1 diabetes following a ketogenic diet (<55 g carbohydrate per day) for a mean of 2.6 years showed excellent effects on HbA_{1c} levels (5.3 ± 0.4%), and participants spent 74% and 3% of their time in the euglycemic and hyperglycemic ranges, respectively, with little daily glycemic variability. They did spend about 3.6% of the time with blood sugar levels of greater than 3.0 mmol/L or 54 mg/dL, and participants experienced a median (range) of 0.9 (0.0–2.0) daily episodes of hypoglycemia. In addition, total cholesterol, LDL-C, total cholesterol/HDL-C ratio, and triglycerides were above the recommended range in 82%, 82%, 64%, and 27% of participants, respectively. These results indicate that ketogenic diets in adults with T1DM result in excellent HbA_{1c} levels and little glycemic variability but may also be associated with dyslipidemia and a high number of hypoglycemic episodes.[100]

Clinical Studies with Diet Therapy in Type 2 Diabetes

Diet alone can often be effective as the sole factor in treating and reversing T2DM. Other lifestyle factors and supplements are important, but the treatment of T2DM begins with diet. The critical dietary focus based on results from clinical trials is that the diet should be low in GI and GL. The actual composition of the macronutrients is less as important as the quality of the carbohydrates consumed. A low-GI and low-GL diet is the most scientifically proven approach, especially considering not only the diet's effect on blood glucose levels but also its effects in reducing the sequelae of diabetes, such as high cholesterol levels, cardiovascular disease, hypertension, and complications of diabetes.[101]

In addition to low GL, another key goal is to get the total fiber intake from foods to at least 40 g/day. In one study, the effects of two diets on blood glucose levels were compared,[102] because higher fiber intake is known to lower average daily glucose levels. One diet contained 24 g of dietary fiber as 8 g of soluble fiber and 16 g of insoluble fiber on the basis of ADA recommendations, whereas the other provided a total of 50 g as 25 g of soluble fiber and 25 g of insoluble fiber. Both diets had the same calorie level and percentages of fat, carbohydrate, and protein. After 6 weeks, the average daily blood glucose levels were 13 mg/dL lower in the group on the higher-fiber diet. Furthermore, a high-fiber diet has also been found to lower the total area under the curve for 24-hour blood glucose levels; in addition, it lowered insulin concentrations and reduced total cholesterol concentrations by 6.7%, triglyceride concentrations by 10.2%, and very low-density lipoprotein cholesterol (VLDL-C) concentrations by 12.5%. This study showed that a high intake of dietary fiber, particularly of the soluble type, above the level recommended by the ADA, improves glycemic control, decreases hyperinsulinemia, and lowers plasma lipid concentrations in patients with T2DM. Similar studies looking at a low- versus a high-GI diet have clearly shown the advantages of the former.[101,103]

As far as specific eating plans, the Mediterranean, Dietary Approaches to Stop Hypertension (DASH) and plant-based diets are examples of healthful eating patterns that have shown positive results in clinical research. The diabetes plate method can also be helpful. This method provides a visual guide showing how to control calories (by featuring a smaller plate) and carbohydrates (by limiting them to what fits in one-quarter of the plate) and puts an emphasis on low-carbohydrate (or nonstarchy) vegetables. The bottom line is that there is great flexibility for patients to construct a personalized, health-promoting diet that works.[104]

Because weight loss is often a major goal in T2DM, please consult Chapter 201, Obesity, for additional recommendations. Diet and exercise combinations have shown significant effects in promoting weight loss and improved blood sugar control in patients with T2DM.[104]

Psychological Support in Diabetes

Helping people with diabetes deal with their diagnosis, develop a sense of empowerment, and make important lifestyle changes is an extremely important aspect of proper medical care. It is imperative to analyze the emotional aspects of diabetes and manage any negativity or sense of being overwhelmed, which is very common in patients with diabetes and can impair their capacity to follow their protocols and maintain good blood sugar control. A book called *Diabetes Burnout: What to Do When You Can't Take It Anymore,* by William Polonsky, published by the ADA, is highly useful reading material for patients with diabetes when they are feeling stressed by their condition. Cognitive-behavioral therapy has proven to be especially effective in helping adolescents with T1DM deal with their disease, leading to improvements in both mood and blood glucose control.[105]

Dealing With Stress

Stress adversely affects blood glucose control because higher stress levels are associated with higher blood glucose levels in both T1DM and T2DM. There is a simple explanation for this. Exposure to stress—whether it be physical, mental, or emotional—leads to activation of the body's "stress response" and causes increased secretion of the adrenal gland hormones adrenaline and cortisol. Among other things, these hormones cause blood glucose levels to rise and also blunt the response to insulin. In addition, they have a negative effect on the immune system. Because stress seems to be an inevitable part of modern living, it is critical to develop effective methods to deal with it. Some studies

have shown that positive methods for dealing with stress, such as yoga and relaxation training, can improve blood glucose control, especially in individuals who are anxious or are experiencing significant stress in their lives.[104,106,107]

Exercise and Diabetes

Exercise is absolutely essential in the prevention and management of diabetes. Exercise directly improves insulin sensitivity and blood glucose control from a combination of increased lean muscle mass and an improvement in muscle cell metabolism.[108] Exercise also has profound benefits for the cardiovascular system, directly as well as indirectly through improvements in blood lipids (especially an improvement in HDL-C, the "good cholesterol"). Exercise also decreases symptoms of anxiety and depression, improves sexual functioning, and improves confidence and self-esteem. Importantly, exercise has been shown to help attain and sustain weight loss.[109] Three types of exercise are important for people with diabetes: aerobic, strength training, and stretching.

Aerobic Exercises

Aerobic exercises, such as walking, jogging, aerobic dance classes, cycling, and swimming, produce rises in heart and respiratory rates. These sorts of activities are foundational in both the prevention and treatment of diabetes. In its simplest form, an aerobic exercise program would consist of a schedule of regular walking combined with cycling, swimming, or the use of low-impact indoor exercise equipment such as an elliptical trainer. Patients should engage in at least 30 minutes of aerobic exercise five times a week.

Strength Training

Strength training is important for many reasons, including that it leads to increased production of secretory molecules, called myokines, from contracting muscle fibers. Myokines are beneficial modulators of obesity, metabolic syndrome, and type 2 diabetes.[40]

Strength training should occur for 15 to 30 minutes five times a week. Working initially with a trainer to learn proper technique and a rotating regimen of weights is the healthiest way to go. Anaerobic weight training can burn 19 times the amount of glucose as aerobic exercise and protects against the loss of lean body mass while also increasing its size. The loss of lean muscle mass means that there is less tissue to actively absorb glucose. The more muscle one has, the easier it becomes to control blood glucose. Also, patients with diabetes are particularly prone to developing chronic musculoskeletal complaints. Most of these problems are related to increased susceptibility to injuries of joints, ligaments, and muscles due to the loss of muscle mass.

Stretching Exercises

Stretching exercises should be done daily. Stretching is extremely important because most people with diabetes suffer from premature stiffening of the spine and joints. Stretching on a daily basis helps maintain flexibility and avoid the chronic pain problems that occur frequently in patients with diabetes due to stiff muscles and joints.

Nutritional Supplements

The proper treatment of diabetes with natural medicine involves trying to achieve ideal blood glucose control and to reach metabolic targets as well as to reduce the risk of complications by focusing on the following four areas:

1. Providing optimal nutrient status
2. Reducing after-meal elevations in blood glucose levels
3. Improving insulin function and sensitivity
4. Preventing nutritional and oxidative stress

Even though natural products can have significant effects on their own, the proper and effective treatment of diabetes requires the careful integration of diet and lifestyle changes along with any required medication and then natural medicines. Furthermore, all those with T1DM and many with T2DM also require conventional medical treatment (with oral drugs or insulin), depending on the adequacy of pancreatic insulin production (this can be determined by the C-peptide level) and the individual's response to dietary and lifestyle measures. The most important determining factor as to whether or not a patient will require the use of drugs or insulin is the adequacy of blood glucose control.

Providing Optimal Nutritional Status

In addition to eating a nutrient-dense diet, a high-potency multivitamin/multimineral (MV) supplement is an absolute must for people with diabetes. Follow the guidelines given in Appendix 9. The person with diabetes has such an increased need for many nutrients that supplementation is critical. Supplying him or her with additional key nutrients has been shown to improve blood glucose control as well as to help prevent or reduce the development of the major complications of diabetes. Taking an MV supplement has also been shown to boost immune function and reduce infections in patients with diabetes.[110] The best MV is not a "one a day" but instead a high-potency product recommended by a physician who specializes in alternative medicine. Specific examples of nutrients for which the patient with diabetes has increased requirements include chromium, vitamin C, vitamin E, certain B vitamins, manganese, magnesium, potassium, and zinc.

Whenever a patient with diabetes adds significant nutrient, fiber, or botanical medicines to his or her protocol, glucose monitoring is recommended because oral or injectable medicines may have to be reduced. A physician should be involved in all decisions regarding natural supplementation.

Chromium

Chromium is vital to proper blood glucose control because it functions in the body as a key constituent of what is referred to as the "glucose tolerance factor." Chromium works closely with insulin in facilitating the uptake of glucose into cells. Without chromium, insulin's action is blocked, and glucose levels are elevated. Evidence indicates that marginal chromium status is common in the United States. A chromium deficiency may be an underlying contributing factor to the tremendous number of Americans who have diabetes and hypoglycemia and are obese.

More than 20 clinical studies have focused on chromium supplementation in diabetes. In some of these studies in T2DM, supplementing the diet with chromium has been shown to decrease fasting glucose levels, improve glucose tolerance, lower insulin levels, and decrease total cholesterol and triglyceride levels while increasing HDL-C levels. Although there are also studies that have not shown chromium to exert much effect in improving glucose tolerance in diabetes, there is no argument that chromium is an important mineral in blood glucose metabolism. However, it appears that chromium supplementation is likely to produce meaningful improvements in glycemic control only in people who are deficient in this essential trace element.[111]

It appears to see benefits in people with diabetes, they must supplement between 400 and 600 mg per day. Chromium polynicotinate and chromium picolinate may offer the best results because chromium-rich yeast failed to produce any significant benefit in the most recent trials.[112] In contrast, several recent studies with chromium picolinate in combination with biotin at dosages of 600 mcg and 2 mg, respectively, showed considerable benefit in helping patients with T2DM improve blood sugar control: fasting glucose levels dropped 10

mg/dL, and $HgbA_{1c}$ levels dropped 0.54%.[113] Improvements in blood lipids and atherogenic indices were also noted in other studies.[114]

Vitamin C

Because the transport of vitamin C into cells is enhanced by insulin,[115] many people with diabetes suffer from a relative deficiency of vitamin C within their cells even if they consume an adequate amount of vitamin C in their diets, which many do not. For many reasons, people with diabetes must take extra vitamin C as well as increase the consumption of vitamin C–rich, low-GI foods.

In addition to its role as an antioxidant, vitamin C is required in immune functions and the manufacture of collagen, the main protein substance of the human body. Because collagen is such an important protein for the structures that hold the body together (e.g., connective tissue, cartilage, tendons), vitamin C is vital for wound repair, healthy gums, and the prevention of easy bruising. A chronic, latent vitamin C deficiency leads to a number of problems for the patient with diabetes, including increased capillary permeability, poor wound healing, elevated cholesterol levels, and a depressed immune system. Vitamin C supplementation has been shown to exert a mild effect in improving glucose control, as evident by a slightly lower $HgbA_{1c}$ in the vitamin C group (8.5%) compared with placebo (9.3%) in one double-blind study.[116] Probably more important than any significant effect on improving blood glucose control is the fact that vitamin C supplementation has been shown to reduce the formation of compounds linked to the development of diabetic complications.

In one study of vitamin C supplementation in T2DM, 30 patients who were 45 to 70 years old and had not only T2DM but also hypertension were randomly assigned in a double-blind manner to take either 500 mg of ascorbic acid by mouth or a placebo daily for 4 weeks. Vitamin C supplementation decreased systolic blood pressure from 142.1 to 132.3 mm Hg and diastolic blood pressure from 83.9 to 79.5 mm Hg. Additional analytic methods designed to measure vascular resistance also demonstrated significant improvements in arterial stiffness in the group taking vitamin C. These results indicate that vitamin C supplementation is effective in improving the elasticity and function of blood vessels in patients with T2DM.[117]

The attempt to prevent sorbitol accumulation with drugs has failed because of severe side effects. In contrast, vitamin C can accomplish what these drugs could not—provide safe and effective inhibition of sorbitol accumulation. In one study comprising young adults with T1DM, the baseline measurement of sorbitol in RBCs was nearly double in these patients compared with those without diabetes despite "adequate" dietary intakes of vitamin C. Vitamin C supplementation at a dose of either 100 or 600 mg normalized RBC sorbitol within 30 days. This correction was independent of changes in diabetic control as monitored by fasting glucose or $HgbA_{1c}$. In fact, overall diabetic control during the study was moderate to poor, indicating that vitamin C's effect was not dependent on glucose concentration.

Vitamin C inhibits the enzyme aldose reductase, which converts glucose to sorbitol.[118] At concentrations higher than 100 µmol, vitamin C reduced sorbitol production by about 30%. Levels between 600 and 900 µmol reduced sorbitol production by about 50%. These concentrations are attainable with vitamin C supplementation. In fact, the normal level of vitamin C in plasma and RBCs is 40 to 120 µmol. Supplementing with 500 to 1500 mg of vitamin C a day boosts blood levels into the higher range required to inhibit sorbitol production.

Although vitamin C supplementation is necessary, patients should not rely exclusively on it to meet all their vitamin C requirements. Vitamin C–rich foods are also rich in compounds such as flavonoids and carotenes, which work to enhance the effects of vitamin C while also exerting favorable effects of their own.

Vitamin E

Vitamin E functions primarily as an antioxidant in protecting against damage to cell membranes. Nerve cells are particularly vulnerable when vitamin E levels are low. Compounding the matter is that diabetic patients appear to have an increased requirement for vitamin E. At higher dosages in the range of 400 to 800 IU, vitamin E improves the action of insulin and has a number of beneficial effects that may aid in preventing the long-term complications of diabetes. Actions of vitamin E:

- Prevents free radical damage to LDL-C and the vascular lining[119–121]
- Improves the functioning of blood vessels and the cells that line them[122,123]
- Increases the concentration of magnesium within cells[124,125]
- Decreases the level of C-reactive protein and other inflammatory compounds[126,127]
- Increases the level of glutathione—an important intracellular antioxidant—within cells[128]
- Improves the rate of conduction of electrical impulses through the nervous system[129]
- Improves blood flow to the eye and mitigates diabetic retinopathy[130]
- In diabetic nephropathy, it improves kidney function and leads to a significant decrease in urine protein and protein-to-creatinine ratio, serum tumor necrosis factor-α, lipid peroxides, advanced glycation end products, and insulin concentrations[131]

Vitamin E supplementation may be particularly helpful for patients with the haptoglobin (Hp) 2-2 genotype, a subgroup that comprises 2% to 3% of the general population. Hp, a major antioxidant protein, is a determinant of cardiovascular events in patients with T2DM. The Hp gene is polymorphic, with two common alleles, 1 and 2. The Hp 2 allelic protein product provides inferior antioxidant protection compared with the Hp 1 product. In a large study of more than 1400 patients with diabetes 55 years of age or older with the Hp 2-2 genotype randomized to vitamin E (400 IU a day) or placebo, the rates of myocardial infarction, stroke, and cardiovascular death 18 months after initiating the study were significantly reduced in those receiving vitamin E (2.2%) compared with placebo (4.7%), a greater than 50% reduction.[132]

It should be noted that in one study in patients with T2DM, treatment with either 500 mg of α-tocopherol or mixed tocopherols significantly increased systolic blood pressure (approximately 6–7 mm Hg) versus placebo, indicating that some patients may have a hypertensive reaction.[133] Patients should be monitored to rule out this negative effect.

Niacin and Niacinamide

Enzymes that contain niacin (vitamin B_3) play an important role in energy production; fat, cholesterol, and carbohydrate metabolism; and the manufacture of many body compounds, including sex and adrenal hormones. Niacin, like chromium, is an essential component of the glucose tolerance factor, making it a key nutrient for hypoglycemia and diabetes.

In addition to offering possible benefits in T1DM, niacinamide may also help in T2DM. Eighteen patients with T2DM of normal body weight who failed to respond to oral antihyperglycemic drugs were randomly assigned to one of three treatments for 6 months: (1) insulin plus nicotinamide (500 mg three times daily), (2) insulin plus placebo, or (3) an oral antihyperglycemic drug plus niacinamide (500 mg three times daily). The parameters assessed included C-peptide, $HgbA_{1c}$, and both fasting and mean daily blood glucose levels. With detailed analysis, niacinamide administration was the only significant factor accounting for the improvement of C-peptide release. The data indicated that niacinamide improves C-peptide release and blood glucose control in patients with T2DM who had previously failed to respond to oral antihyperglycemic drugs alone.[134]

Vitamin B_6

Vitamin B_6 supplementation appears to offer significant protection against the development of diabetic neuropathy.[135] Patients with diabetes with neuropathy have been shown to be deficient in vitamin B_6 and to benefit from supplementation.[136] The neuropathy of a vitamin B_6 deficiency is indistinguishable from diabetic neuropathy. Individuals with long-standing diabetes or who are developing signs of peripheral nerve abnormalities should definitely supplement their diets with vitamin B_6, which is also important in preventing other diabetic complications.

Vitamin B_6 supplementation can be a safe and effective treatment for gestational diabetes. When 14 women with gestational diabetes were given 100 mg of vitamin B_6 daily for 2 weeks in one study, the diagnosis was eliminated in 12 of the 14 women.[137]

Magnesium

Like manganese and chromium, magnesium is also involved in glucose metabolism. Considerable evidence indicates that patients with diabetes should eat foods rich in magnesium as well as take supplemental magnesium—the reasons being that more than one half of all people with diabetes show evidence of magnesium deficiency, and magnesium may prevent some of the complications of diabetes, such as retinopathy and heart disease. Magnesium levels are usually low in patients with diabetes and lowest in those with diabetic complications like retinopathy and neuropathy. Clinical studies have shown that magnesium supplementation (usually 400–500 mg/day) improves insulin response and action, glucose tolerance, and the fluidity of the RBC membrane in patients with diabetes.[138,139] Higher magnesium intake is also associated with a reduced risk of progression from prediabetes to diabetes.[140]

Magnesium supplementation is especially helpful for gestational diabetes as well as preterm labor, preeclampsia, and small for gestational age or intrauterine growth restriction. In a double-blind study of 70 women aged 24 to 34 with gestational diabetes, the subjects were given either 250 mg of magnesium (oxide) or placebo daily for 6 weeks. Results demonstrated significant improvements in several blood parameters beyond blood sugar, including homeostatic model assessment of insulin resistance (HOMA-IR), high-sensitivity C-reactive protein (hs-CRP), and malonaldehyde (MDA). In addition, only 3 of the 35 newborns from mothers taking magnesium were afflicted with hyperbilirubinemia (8.8%) compared with 10 in the placebo group (29.4%).[141]

Effects of Magnesium Supplementation in Gestational Diabetes[141]

	Magnesium Group	Placebo Group	*p*-Value
Fasting blood sugar (mg/dL)	9.8% decrease (95.1–85.8)	2.5% increase (91.4–93.7)	<0.001
HOMA-IR	13% decrease (3.1–2.7)	46.8% increase (3.2–4.7)	<0.001
Triglycerides (mg/dL)	1.2% decrease (173–171)	21% increase (166.5–201.5)	0.005
Very low-density cholesterol (mg/dL)	0.6% decrease (34.1–33.9)	28.3% increase (33.1–39.9)	0.005
hs-CRP (nanograms/dL)	7.5% decrease (5731–5305)	12.8% increase (6101.1–6881.1)	0.03
MDA (micrograms/Liter)	12.5% decrease (4.0–3.5)	8.8% increase (3.4–3.7)	0.01

Because the study consisted of women with hypomagnesemia (i.e., serum levels below 1.82 mg/dL), results with magnesium supplementation may be more apparent in those with lower magnesium levels. However, in a follow-up analysis in these same patients, quantitative results of reverse-transcription polymerase chain reaction (RT-PCR) demonstrated that compared with the placebo, magnesium supplementation upregulated gene expression of peroxisome proliferator-activated receptor-gamma (PPAR-γ) and glucose transporter 1 (GLUT-1) and downregulated gene expression of oxidized low-density lipoprotein receptor (LDLR). These results would indicate possible beneficial effects are not limited to either hypomagnesia or in only those with gestational diabetes.[142]

The recommended dietary intake (RDI) for magnesium is 400 to 420 mg/day for adult males and 300 to 320 mg/day for adult females. Patients with diabetes may need as much as twice this amount because they tend to lose excessive magnesium through their kidneys.[139] Most of the magnesium should be derived from the diet. The average intake of magnesium by healthy U.S. adults ranges from 143 to 266 mg/day. This is obviously far below the RDI. Food choices are the main reason. Although magnesium occurs abundantly in whole foods, food processing refines out a large portion of it. The best dietary sources of magnesium are tofu, seeds, nuts, and green leafy vegetables. Fish, meat, milk, and the most commonly eaten fruits are low in magnesium. Most Americans consume a low-magnesium diet because they eat a lot of refined foods, meat, and dairy products.

In addition to favoring a diet rich in magnesium, patients with diabetes should supplement it with 300 to 500 mg of magnesium. For best results, highly absorbable sources of magnesium like magnesium aspartate or citrate should be taken. Diabetic patients should also be sure to get at least 25 mg of vitamin B_6 per day because the level of vitamin B_6 within body cells appears to be intricately linked to the cells' magnesium content. In other words, without vitamin B_6 (as well as vitamin E), magnesium will not get inside the cells and will therefore be useless.

Zinc

Zinc deficiency, like chromium deficiency, has also been suggested to play a role in the development of diabetes.[143] Although severe zinc deficiency is rare in developed countries, many individuals in the United States have marginal zinc deficiency. This is particularly common in the elderly population as well as in people with diabetes. Zinc is involved in virtually all aspects of insulin metabolism: synthesis, secretion, and utilization. Zinc also has a protective effect against beta-cell destruction and has well-known antiviral effects. Patients with diabetes typically excrete too much zinc in the urine and therefore require supplementation (e.g., 30 mg of zinc daily). Zinc is also found in good amounts in nuts and seeds.

Manganese

Manganese functions in many enzyme systems, including those involved in blood glucose control, energy metabolism, and thyroid hormone function. Manganese also functions in the antioxidant enzyme superoxide dismutase (SOD). Patients with diabetes have been shown to have only one-half the manganese of normal individuals. In a large epidemiological study, dietary manganese intake was inversely proportional to type 2 diabetes incidence.[144] A good daily dose of manganese for a patient with diabetes is 1.5 to 3 mg.

Biotin

Biotin is a member of the B-vitamin family; it functions in the manufacture and utilization of carbohydrates, fats, and amino acids. Without biotin, sugar metabolism is severely impaired. Biotin supplementation

has been shown to enhance insulin sensitivity and increase the activity of the enzyme glucokinase—which is responsible for the first step in the utilization of glucose by the liver. Glucokinase concentrations in patients with diabetes are low. Evidently, supplementing the diet with high doses of biotin improves glucokinase activity and glucose metabolism. In one study, 16 mg of biotin daily resulted in a significant lowering of fasting blood glucose levels and improvements in blood glucose control in patients with T1DM. In another study in patients with T2DM, similar effects were noted with 9 mg of biotin daily. Biotin therapy has also been shown to be helpful in the treatment of diabetic neuropathy.[145,146]

Omega-3 Fatty Acids From Fish Oil Supplements

Omega-3 fatty acids are vital supplements for patients with diabetes. They offer significant protection against heart disease in patients with diabetes, helping lower lipids and blood pressure. They are anti-inflammatory and promote insulin sensitivity. Omega-3 oils are usually almost completely lacking in the basic diet of patients with diabetes. Foods that contain these oils include oily fish such as wild salmon, sardines, herring, trout, and mackerel; walnuts; grass-fed beef; wild game; omega-3 eggs; and ground flax, hemp, and chia seeds.

Initially, there were concerns that omega-3 fatty acid supplementation might adversely affect blood glucose control based on earlier studies, but many of these studies were conducted with lower-quality fish oil products that contained significant amounts of cholesterol and lipid peroxides. Two intensive investigations, one conducted at Oxford University and the other at the Mayo Clinic, analyzed data from 18 double-blind clinical trials involving 823 participants followed for an average of 12 weeks.[147,148] Dosages of fish oil (18% eicosapentaenoic acid [EPA] and 12% docosahexanoic acid [DHA]) ranged from 3 to 18 g/day. Both evaluations came to the same conclusions. Fish oil supplementation has no adverse effect on glycemic control, but it does appear to offer the same protection against cardiovascular disease in people with diabetes that it does in people without diabetes. A more recent analysis of 45 randomized controlled trials involving 2674 people with T2DM, omega-3 fatty acid supplementation was associated with significant reductions in LDL-C, VLDL-C, triglycerides, and HbA_{1c}.[149] The researchers did note the heterogeneity in the studies, however, that is likely explained by the poorer quality of products used in many of the early studies. It is important for patients with diabetes to ingest a high-quality fish oil product that is guaranteed not to be rancid or to contain mercury, solvents, polychlorinated biphenyls (PCBs), or other toxins. The combined total EPA + DHA level should be approximately 1000 mg daily.

Reducing After-Meal Elevations in Blood Glucose Levels

Elevations of blood glucose levels after a meal can wreak biochemical havoc in any patient with diabetes. In fact, an elevation in postprandial blood glucose levels is the major contributor to the development of diabetic complications, especially cardiovascular disease and diseases of the microvasculature (retinopathy, neuropathy, and nephropathy). For example, patients who have a normal fasting blood glucose measurement but an average 2-hour postprandial glucose level greater than 200 mg/dL (11 mmol/L) have a threefold increase in the incidence of diabetic retinopathy.[150] Therefore blunting of the after-meal increase in blood glucose levels is an important goal.

In addition to following low-carbohydrate dietary guidelines to reduce postprandial blood glucose levels (eating low-GI/low-GL meals), several natural products can be used. The best supplements in this regard are fiber supplements and natural glucosidase inhibitors.

Fiber Supplements

Fiber supplements have been shown to enhance blood glucose control, decrease insulin levels, and reduce the number of calories absorbed by the body. The best fiber sources for reducing postprandial blood glucose levels, lowering cholesterol levels, and promoting weight loss are those that are rich in water-soluble fibers, such as glucomannan (from konjac root), psyllium, guar gum, defatted fenugreek seed powder or fiber, seaweed fibers (alginate and carrageenan), and pectin.

Clinical studies have repeatedly shown that after-meal blood glucose levels decrease as soluble fiber viscosity increases. This relationship has also been shown to hold true for the other physiological benefits produced by soluble fibers, including increased insulin sensitivity, diminished appetite, significant weight control, improved bowel movements, and decreased serum cholesterol.[151,152]

When taken with water before meals, these types of fiber bind to the water in the stomach and small intestine to form a gelatinous, viscous mass that not only slows down the absorption of glucose but also induces a sense of satiety (fullness) and reduces the absorption of calories.

One of the most viscous naturally occurring dietary fibers is glucomannan, a soluble fiber obtained from grinding the root of konjac, a plant that has been used as a food and remedy for thousands of years in Asia. Highly refined and uniquely processed glucomannan possesses the greatest viscosity of any single dietary fiber. It is three times more viscous than guar and approximately seven times more viscous than psyllium. Konjac fiber is now easily available in the form of noodles made with konjac root.

PGX is a novel natural polysaccharide matrix composed of three natural compounds (glucomannan, alginate, and xanthan gum) combined in a proprietary process that leads them to coalesce and form an entirely new matrix that is one of the most viscous fibers ever discovered.[153,154] By binding glucomannan with alginate and xanthan gum, the viscosity of glucomannan can be amplified to a viscosity three to five times higher than that of glucomannan alone. PGX reduces the glycemic index of any food or beverage by 15% to 70% and also reduces postprandial glucose levels when added to or taken with foods.[155,156] In a double-blind study with an earlier version of PGX, 3 weeks of supplementation with meals was shown to lower postprandial blood glucose by approximately 20% and insulin secretion by approximately 40%, producing a whole-body insulin-sensitivity index improvement of nearly 50%.[157] It was also shown to reduce total cholesterol (12.4%), LDL-C (22.3%), the LDL-C:HDL-C ratio (15%), and serum fructosamine (5%). The typical dosage for PGX is 2.5 to 5 grams before meals. PGX is discussed further in Chapter 201, Obesity.

Natural Glucosidase Inhibitors

Starches, complex carbohydrates, and even simple sugars (disaccharides) like sucrose are broken down in the digestive tract into glucose by the action of certain enzymes. Among the most important of these are the α-glucosidases that line the intestines. Because these enzymes are essential for the breakdown of starches, complex carbohydrates, maltose, and sucrose into absorbable glucose molecules, their inhibition can diminish the after-meal rise in both glucose and insulin.

Acarbose (Precose) and miglitol (Glyset) are approved drugs for treating diabetes by inhibiting α-glucosidase. Although clinical studies have shown them to be effective, they are also characterized by a high frequency of mild to moderate gastrointestinal side effects, such as flatulence, diarrhea, and abdominal discomfort. Although these side effects generally diminish in frequency and intensity with time, few patients are willing to deal with them. Natural alternatives include berberine and mulberry extract.

Berberine

Berberine is an alkaloid found in many plants (see Chapter 86, *Hydrastis canadensis* (Goldenseal) and Other Berberine-Containing Botanicals). In the early 1900s, purified berberine also emerged as a popular natural medicine in China. Berberine exerts a number of

TABLE 165.5 Influence of Mulberry and Glyburide Treatments on Blood Glucose, Glycosylated Hemoglobin, and Serum Lipids of Patients With Type 2 Diabetes

	GLYBURIDE			MULBERRY		
Parameter	**Before**	**After**	**Change (%)**	**Before**	**After**	**Change (%)**
Fasting blood glucose (mg/dL)	154.4	141.8	–8	152.7	110.5	–27
$HgbA_{1c}$ (%)	12.5	12.4	0	12.5	11.2	–10
Cholesterol (mg/dL)	190	182	–4	193.7	170.3	–12
LDL cholesterol (mg/dL)	102.5	95.5	–7	102.1	78.7	–23
HDL cholesterol (mg/dL)	49.8	51.3	+3	50.1	59.2	+18
Triglycerides (mg/dL)	199.5	180	–10	200.4	168	–16
Free fatty acids (pmol/dL)	589.8	580	–2	590.1	520	–12

HDL, high-density lipoprotein; *LDL*, low-density lipoprotein.

interesting effects beneficial in T2DM, including inhibition of glucosidase. A meta-analysis of 27 published clinical trials using berberine as a therapeutic agent in T2DM, elevated blood lipids, and high blood pressure showed quite convincingly that in the treatment of T2DM, berberine along with lifestyle intervention lowered the level of fasting blood sugar levels, after-meal blood sugar levels, and glycosylated hemoglobin (HbA_{1c}) more than lifestyle intervention alone or placebo. When berberine was compared with oral hypoglycemic drugs used in T2DM, there was no statistical significance between treatment with berberine and these drugs. In other words, the clinical results seen with berberine were on par with those of the drugs.[158]

Much of berberine's health benefits in T2DM may be the result of modulating the gut microbiota. One of the easy links to this line of thought is that berberine has a very low oral bioavailability. The gut absorption rate of berberine is about 9%, and systemic oral bioavailability is only about 1% of an administered dosage. With so many double-blind studies showing clinical effects, it is thought to work via the microbiome specifically by increasing level of *Akkermansia muciniphila* because its colonization in the gut is inversely associated with diabetes, obesity metabolic syndrome, and low-grade chronic inflammation.[159]

Morus indica

The mulberry plant *(Morus indica)* is probably best known as food for silkworms, but it has also been highly regarded in traditional Chinese and Japanese medicine for human use. It has been shown to possess significant hypoglycemic effects in animal studies, and it contains an effective α-glucosidase inhibitor along with other compounds that appear to improve blood glucose control.[160] Mulberry extract has been studied in T2DM, and the results are excellent. In one study, researchers decided to investigate its effect on blood and RBC lipids as well as to compare its blood glucose–lowering actions with those of the oral antihyperglycemic drug glyburide.[161] Patients were given either dried mulberry leaves at a dosage of 3 g/day or one tablet of glyburide (5 mg/day) for 4 weeks. Mulberry therapy significantly improved diabetic control in patients with T2DM (Table 165.5). The results clearly show that fasting blood glucose concentrations were significantly lowered with mulberry therapy, suggesting that it is effective in controlling diabetes. Compared with glyburide treatment, mulberry therapy significantly reduced the fasting blood glucose concentrations of patients with diabetes (27%; $P < 0.01$). However, no significant differences were observed in blood glucose concentrations between pretreatments and posttreatments with glyburide (P 0.05). Mulberry extract was also superior to the approved drug in its ability to decrease $HgbA_{1c}$, total cholesterol, LDL-C, and triglycerides. It also resulted in an increase in HDL-C (the "good cholesterol"). Although these changes were not statistically significant ($P > 0.05$), there are strong suggestions that this natural product is clearly superior to an established pharmaceutical agent (see Table 165.5).

In addition to the benefits for blood glucose levels and blood lipids, mulberry therapy was also shown to reduce the amount of lipid peroxidation to the cell membranes of RBCs, indicating a significant antioxidant effect. Additionally, mulberry therapy significantly decreased membrane cholesterol in patients with T2DM.

Improving Insulin Function and Sensitivity

The first step in improving insulin function and sensitivity is achieving ideal body weight and following the dietary and lifestyle recommendations given earlier, including taking a high-potency multivitamin/multimineral supplement to make sure that the body has all essential vitamins and minerals required for proper insulin sensitivity. If additional support is necessary to bring blood glucose levels under control, we would recommend using in isolation or in scientifically formulated combinations one or more of the following: *Gymnema sylvestre* extract, bitter melon, *P. quinquefolius* (American ginseng) or *Panax ginseng*, and fenugreek seed extract. We also recommend increasing the intake of onions and garlic.

Gymnema sylvestre

Gymnema is a plant from India that has long been used as a treatment for diabetes. Recent scientific investigation has upheld its effectiveness in both T1DM and T2DM. Gymnema extracts have been shown to enhance glucose control in diabetic dogs and rabbits. Interestingly, in animals that have their pancreas removed, gymnema has no apparent effects, suggesting that it enhances the production or activity of insulin. There is evidence in animal studies that gymnema promotes the regeneration of insulin-producing beta cells in the pancreas. Studies in humans also seem to support the possibility of pancreatic regeneration.[162]

An extract of the leaves of *G. sylvestre* given to 27 patients with T1DM on insulin therapy was shown to reduce insulin requirements and fasting blood glucose levels as well as to improve blood glucose control.[163] These results indicate that gymnema enhances the action of insulin because these patients with diabetes were not recently diagnosed. Clinical experience also shows that gymnema has a significant benefit in decreasing cravings for carbohydrates and enabling patients to follow a lower-carbohydrate diet.

With regard to T2DM, gymnema extract appears to work by enhancing the action of insulin. In one study, 22 patients with T2DM were given gymnema extract along with their oral antihyperglycemic drugs.[164] All demonstrated improved blood glucose control, 21 of the 22 were able to reduce their drug dosage considerably, and 5 were able to discontinue their medication and maintain blood glucose control with the gymnema extract alone.

The dosage for gymnema extract (standardized to contain 24% gymnemic acid) can range from 200 mg twice a day to 2400 mg/day. No side effects have been reported from gymnema extract.

Momordica charantia

In addition to being eaten as a vegetable in Asia, unripe bitter melon has been used extensively in folk medicine as a remedy for diabetes. The blood glucose–lowering action of the fresh juice or extract of the unripe fruit has been clearly established in modern scientific studies in both T1DM and T2DM.

Bitter melon is composed of several compounds with confirmed blood glucose–lowering properties. Charantin, extracted by alcohol, is a hypoglycemic agent composed of mixed steroids that is more potent than the oral hypoglycemic drug tolbutamide. Bitter melon also contains an insulin-like polypeptide, polypeptide-P, which lowers blood glucose levels when injected like insulin into patients with T1DM. Because it appears to have fewer side effects than insulin, bitter melon has been suggested as a replacement therapy for some patients, although there is little likelihood of this application ever being developed. Fortunately, drinking as little as 2 oz of the juice has shown good results in clinical trials.[165,166]

Unripe bitter melon is available primarily at Asian grocery stores. Health food stores may have bitter melon extracts, but the fresh juice is probably the best to use because this was what was used in the studies. Bitter melon juice is difficult to make palatable. As its name implies, it is quite bitter, so it is recommended that patients plug their noses and take a 2-oz shot of the juice. The dosage of other forms should approximate this dose.

Panax quinquefolium and *Panax ginseng*

Research conducted at the University of Toronto's Risk Factor Modification Center has uncovered important properties of some ancient natural medicines. In their first studies and published reports, the group used whole powdered American ginseng root *(Panax quinquefolium)* and found that a dose of about 3 g before each meal reduced postprandial blood glucose significantly in patients with T2DM.[167–170]

P. ginseng can also be helpful. In a double-blind controlled study, 36 patients with non–insulin-dependent diabetes were treated for 8 weeks with ginseng extract at 100 or 200 mg or with a placebo. Ginseng elevated mood, improved psychophysiological performance, and reduced fasting blood glucose and body weight. The 200-mg dose improved glycated hemoglobin, serum aminoterminalpropetide concentrations, and physical activity.[171]

Fenugreek

Fenugreek seeds have demonstrated significant antidiabetic effects in experimental and clinical studies. The active principles are the special soluble fiber of fenugreek along with the alkaloid trigonelline and 4-hydroxyisoleucine. Fenugreek appears to be helpful in both types of diabetes. Defatted fenugreek seed powder given twice daily at a 50-g dose to patients with T1DM led to a significant reduction in fasting blood glucose and improved the results of glucose tolerance tests.[172] A 54% reduction in 24-hour urinary glucose excretion and significant reductions in LDL-C and VLDL-C and triglyceride values also occurred. In patients with T2DM, the addition of 15 g of powdered fenugreek seeds soaked in water significantly reduced postprandial glucose levels during the meal tolerance test.[173] However, that is a very large dose and impractical for daily supplementation. In another study, 25 patients with T2DM randomly received 1 g/day of fenugreek seed extract or placebo capsules for 2 months.[174] Complex analysis of the data found that the group taking the fenugreek seed extract had improved blood glucose measurements (e.g., fasting blood glucose levels dropped from 148.3–119.9 mg/dL), but there was also a significant decrease in insulin output. This finding indicates that there was a significant improvement in insulin sensitivity, an effect that is most likely due to the 4-hydroxyleucine.

Allium cepa and *Allium sativum*

Onions and garlic appear to have significant blood glucose–lowering action. The active principles are believed to be the sulfur-containing compounds allyl propyl disulfide and diallyl disulfide oxide (allicin), respectively, although other constituents such as flavonoids may play a role as well.

Although garlic generally has more potent effects, onions can be given at higher doses, and the active compounds appear to be more stable than allicin. Graded doses of onion extracts (1 mL of extract = 1 g of whole onion) at levels sometimes found in the diet (i.e., 1–7 oz of onion) reduced blood glucose levels during an oral glucose tolerance test in a dose-dependent manner. The effects are similar in both raw and boiled onion extracts, indicating that the active components are probably stable.[175]

Garlic has a wide range of additional well-documented effects that are useful for patients with diabetes, including helping improve blood glucose control, lower cholesterol and blood pressure, and inhibit some of the factors associated with increased risk for vascular complications of diabetes, such as increased fibrinogen levels.

Preventing Nutritional and Oxidative Stress

Diabetes is characterized by increased nutritional and oxidative stress. Because individuals with diabetes typically have elevated levels of free radicals and oxidative compounds, they are much more likely to experience damage. These highly reactive compounds bind to and destroy cellular compounds. They also greatly increase the inflammatory process by adding fuel to their destructive fire via increased formation of inflammatory mediators like C-reactive protein.

One of the critical goals in nutritionally supporting individuals with diabetes is to flood the body with a high level of antioxidant compounds to counteract the negative effects of free radicals and prooxidants. This goal is implemented by using the recommendations given earlier, along with taking a flavonoid-rich extract and alpha-lipoic acid.

Flavonoids

Flavonoids are extremely important considerations in both T1DM and T2DM, both in terms of possibly improving glycemic control and definitely in the prevention of diabetes complications. A variety of individual flavonoids, like quercetin, as well as flavonoid-rich extracts such as extracts of proanthocyanidolic oligomers (see Chapter 106), *Silybum marianum* (see Chapter 113), *Vaccinium myrtillus* (see Chapter 122), and *Craetagus oxyacantha* (see Chapter 71), have shown favorable mechanisms in blood sugar control, insulin secretion, prevention of oxidative damage, and inhibition of glycosylation and sorbitol accumulation.

In individuals with diabetes who are already showing signs of long-term complications, it is extremely important to take a flavonoid-rich extract. Because certain flavonoids concentrate in specific tissues, it is possible to take flavonoids that target those tissues. For example, because the flavonoids of bilberry *(V. myrtillus)* have an affinity for the eye, including the retina, bilberry is probably the best choice in a patient with diabetes who is already exhibiting signs of diabetic retinopathy. The point is to identify which flavonoid or flavonoid-rich extract is most appropriate for the patient and then to direct the patient to take it according to the recommended dosage. There is tremendous overlap among the mechanisms of action and benefits of flavonoid-rich extracts; it is important to take the one that is most specific to the individual's needs (Table 165.6).

TABLE 165.6 Flavonoids Used in the Treatment of Diabetes and Diabetic Complications

Flavonoid-Rich Extract	Daily Dose	Indication
Bilberry extract (25% anthocyanidins)	160–320 mg	Best choice in diabetic retinopathy or cataracts.
Ginkgo biloba extract (24% Ginkgo flavonglycosides)	120–240 mg	Best choice for most people > age 50. Protects the brain and vascular lining. Very important in improving blood flow to the extremities in treating neuropathy and foot ulcers.
Grape seed or pine-bark extract (95% procyanidolic oligomers)	150–300 mg	Systemic antioxidant; best choice for most people < age 50, especially if retinopathy, hypertension, easy bruising, and poor wound healing exist. Also specific for the lungs, varicose veins, and protection against cardiovascular disease.
Green tea extract (60%–70% total polyphenols)	150–300 mg	Best choice in the early stage of type 1 diabetes or if there is a family history of cancer.
Hawthorn extract (10% procyanidins)	150–300 mg	Best choice in cardiovascular disease or hypertension.
Milk thistle extract (70% silymarin)	100–300 mg	Best choice if there are signs of impaired liver function.
Mixed citrus flavonoids	1000–2000 mg	Least expensive choice but may not provide same level of benefit; use if no complication is present.
Quercetin	150–300 mg	Good choice if allergies, symptoms of prostate enlargement or bladder irritation, or eczema are also present.

Alpha-Lipoic Acid

Alpha-lipoic acid is a vitamin-like substance that is often described as "nature's perfect antioxidant." Alpha-lipoic acid is a small molecule that is efficiently absorbed and easily crosses cell membranes. Unlike vitamin E, which is primarily fat soluble, and vitamin C, which is water soluble, α-lipoic acid can quench either water- or fat-soluble free radicals both inside the cell and in the intracellular spaces. Furthermore, α-lipoic acid extends the biochemical lives of vitamins C and E as well as other antioxidants.

Although α-lipoic acid's primary benefit is as an antioxidant, it has also been shown to lead to an improvement in blood glucose metabolism as well as blood flow to peripheral nerves and even to stimulate the regeneration of nerve fibers.[176] Alpha-lipoic acid is an approved drug in Germany for the treatment of diabetic neuropathy. In fact, it has been successfully used in Germany for more than 40 years. The beneficial effects of α-lipoic acid in diabetic neuropathy at a dosage of 400 to 600 mg daily have been confirmed in several double-blind studies.[177,178]

Recommendations for Specific Chronic Complications

Following are additional recommendations for dealing with the specific complications of diabetes. The most important method for reducing the risk of these complications is achieving optimal blood glucose control.

Elevated Cholesterol

Key natural products used to lower cholesterol levels in diabetes are soluble fiber, garlic, berberine, and niacin. These agents are also discussed in Chapter 149. Berberine may yield the best results because it also addresses blood sugar control and hypertension. Regarding niacin, because taking niacin at higher doses (e.g., 3000 mg or more) can impair glucose tolerance, many physicians have avoided niacin therapy in patients with diabetes. However, studies with slightly lower doses (1000–2000 mg) have not shown that niacin affects the regulation of blood glucose adversely.[179] For example, during a 16-week double-blind placebo-controlled trial, 148 patients with T2DM were randomized to placebo or 1000 or 1500 mg/day of niacin; in the niacin-treated groups, there was no significant loss of glycemic control, and the favorable effects on blood lipids were still apparent.[180] Other studies have actually shown $HgbA_{1c}$ to drop, indicating improved glycemic control.[181]

The most common blood lipid abnormality in patients with T2DM is elevated triglyceride levels; decreased HDL cholesterol levels; and a preponderance of smaller, denser LDL particles. Niacin has been shown to address all of these areas much more significantly than statins or other lipid-lowering drugs. However, one reason that niacin may not be as popular as it should be is the side effect of skin flushing—rather like a prickly heat rash—which typically occurs 20 to 30 minutes after the niacin is taken and disappears within about the same time frame. Other occasional side effects include gastric irritation, nausea, and liver damage. The risk of liver damage is especially pertinent. Patients with diabetes who are overweight often develop fatty livers, which are now considered to be as damaging as livers injured by alcoholism and hepatitis C. Moreover, a fatty liver may facilitate the development of fibrosis and cirrhosis. Giving niacin to a patient with a fatty liver may put extra stress on that vital organ. Therefore in an overweight patient with diabetes, high-dose niacin is to be used only under a physician's supervision. To reduce the side effect of skin flushing, an intermediate-release niacin may be prescribed, one that is identical in its dissolution pattern to the prescription product Niaspan. This product is best taken just before going to bed because most people sleep right through any flushing reaction that might occur.

If regular niacin is being used, a dosage of 500 mg a night may be tried for 1 week. The dose can then be increased to 1000 mg the next week and 1500 mg the following week. The 1500-mg dose should be given for 2 months before checking the response, and the dose can then be adjusted up or down as needed. Time-release niacin products like Niaspan can be used at the full dosage of 1000 to 2000 mg at night from the beginning. Regardless of the form of niacin being used, periodic checking (at least every 3 months) of cholesterol, $HgbA_{1c}$, and liver function is strongly indicated.

Retinopathy and Cataracts

Diabetic retinopathy has two forms: (1) "simple" retinopathy consisting of burst blood vessels, hemorrhages, and swelling and (2) proliferative retinopathy with newly formed vessels, scarring, more serious hemorrhage, and retinal detachment. Laser photocoagulation therapy is an important treatment for the more severe type of proliferative retinopathy but is still not indicated in milder forms because of the risk of vision loss. That is, there is a risk that the side effects of this treatment may outweigh the benefits.

As with other complications of diabetes, prevention is the best treatment, with the key factor being the maintenance of optimal blood glucose control. $HgbA_{1c}$ should be monitored frequently.

Extremely important in the battle against retinopathy are flavonoid-rich extracts, especially bilberry, pine bark, and grape seed extracts.

The flavonoids in these extracts exert many benefits in diabetes, including an ability to increase intracellular vitamin C levels, decrease the leakiness and breakage of capillaries, prevent easy bruising, and serve as potent antioxidants. These effects are of particular value in dealing with the microvascular abnormalities of diabetes. Because the flavonoids in bilberry, pine bark, and grape seed extract have an affinity for the blood vessels of the eye and improve circulation to the retina, they are particularly helpful in slowing the progression of diabetic retinopathy, as evidenced by positive results in more than a dozen clinical trials (see Chapters 106 and 122).

Neuropathy

In addition to α-lipoic acid and the basic supplementation program, three additional natural medicines, along with acupuncture, deserve mention here.

Gamma-linolenic acid (GLA) has been shown to improve and prevent diabetic neuropathy. Diabetes is associated with a substantial disturbance in EFA metabolism. One of the key disturbances is the impairment in the process of converting linoleic acid to GLA. As a result, providing GLA in the form of borage, evening primrose, or black currant oil can bypass some of this disturbance. In the GLA Multicenter Trial, 111 patients with mild diabetic neuropathy were given either GLA at a dose of 480 mg/day or a placebo for 1 year. Sixteen parameters were assessed, including conduction velocities, hot and cold thresholds, sensation, tendon reflexes, and muscle strength. After 1 year, all 16 parameters improved, 13 of them to a statistically significant degree. Treatment was more effective in patients with diabetes who were relatively well controlled than in those who were poorly controlled. The latter finding highlights the need for a comprehensive approach in controlling blood glucose levels rather than expecting a single physiological aid (i.e., GLA) to compensate for poor control.[182]

Benfotiamine is a fat-soluble form of thiamine, or vitamin B_1, that is more effective in raising blood thiamine levels (up to 120%–240% vs. regular thiamine). In studies in patients with diabetes, benfotiamine decreased advanced glycosylated end-product formation, decreased the aldose reductase pathway, and reduced oxidative cellular damage.[183] However, results in the treatment of diabetic neuropathy and nephropathy in small clinical trials with benfotiamine alone have shown modest to no benefit.[184,185] It is possible that benfotiamine can be usefully combined with α-lipoic acid. In a small study in patients with T1DM, treatment with 600 mg of benfotiamine plus 300 mg of α-lipoic acid produced better results in reducing the effects of hyperglycemia than benfotiamine alone.[186]

Capsaicin is the active component of cayenne pepper *(Capsicum frutescens),* which stimulates and then blocks the small nerve fibers that transmit the pain impulse by depleting these fibers of a transmitting substance known as substance P. In numerous double-blind studies, topically applied capsaicin has been shown to be of considerable benefit in relieving the pain of diabetic neuropathy. Roughly 80% of people with diabetic neuropathy experience great relief in this way. Commercial ointments containing 0.025% or 0.075% capsaicin are available over the counter. The patient should apply the 0.075% cream twice daily to the affected area (the first covering his or her hand with plastic wrap to prevent the capsaicin from coming in contact with the eyes or mucous membranes). It may take a few days for the cream to start working, and it will continue to work only with regular application.

Acupuncture can also be helpful in improving neuropathy. The scientific investigation of acupuncture in diabetes includes both experimental and clinical studies. For example, animal experiments have shown that acupuncture can act on the pancreas to enhance insulin synthesis, increase the number of receptors on target cells, and accelerate the utilization of glucose, resulting in the lowering of blood glucose.[187] However, the best documentation for the clinical application of acupuncture is in treating chronic painful diabetic neuropathy. In one clinical study, 77% of patients treated with acupuncture noted a significant improvement in their symptoms, with 21% noting that their symptoms were completely eliminated.[188] That success rate is excellent considering the long-standing nature of the condition in most of the cases and the fact that no side effects were observed.

Nephropathy

Many of the previous recommendations also apply to preventing diabetic nephropathy. In fact, a strong reason for adhering to the dietary principles outlined previously is to protect the diabetic kidneys. Especially important, again, is dietary fiber. Dietary fibers (especially the water-soluble type) are fermented in the colon to produce short-chain fatty acids. These by-products are the primary fuel for colonic cells and, if present in high amounts, greatly increase the colon's waste-removal capabilities. It has been shown that in the presence of a diet high in fermentable fiber, the colon turns into the "second kidney" as it collects nitrogenous wastes out of the blood and disposes of them via the feces. This has been shown to greatly reduce the workload and stress on the kidneys themselves.[189]

Highlighting just how important some basic supplement recommendations are in halting the progression of diabetic nephropathy are the results of a study of 30 patients with T2DM with elevated albumin in their urine. These patients received vitamin C (1250 mg) and vitamin E (680 IU) daily or a matching placebo for 4 weeks, followed by a 3-week washout period before being switched to the other arm.[190] The results were that the vitamins were successful in reducing urinary albumin levels by an average of nearly 20%, indicating that antioxidant therapy may halt or slow down the progression of kidney disease in patients with diabetes.

If a patient has developed serious kidney failure, then following the low-protein, low-potassium standard diet becomes necessary; unfortunately, that does not promote good glucose control, which can then worsen kidney function. The main goal is to prevent end-stage renal disease from developing in the first place.

If drugs are necessary, the ACE inhibitors and ACE receptor blockers offer the greatest benefits in dealing with diabetic nephropathy.[191] They are now often prescribed in low doses to help prevent nephropathy even in the absence of high blood pressure. Alternatively, a special preparation of bonito peptides has been shown to exert anti-ACE activity (see Chapter 179 for more information) and may prevent the need for ACE-inhibitor drugs.

Poor Wound Healing

A deficiency of virtually any essential nutrient can lead to impaired wound healing. Key nutrients include vitamin C and zinc, both of which are often deficient in patients with diabetes. Taking a high-potency multivitamin/multimineral formula should improve nutritional status and promote proper wound healing. For topical application, pure (100%) *Aloe vera* gel can be used. The wound-healing effects of *Aloe vera* are well known. It contains a number of compounds that promote wound healing, including vitamin C, vitamin E, and zinc. It has been shown to stimulate many factors important to wound repair and should be applied to affected areas (not open wounds) two to three times daily. Another option is a topical ointment called Amerigel, featuring an oak extract *(Quercus rubra)*, which contains tannins, including quercitannic acid, catechin, ellagitannin, and proanthocyanidin, that are readily absorbed into damaged skin.

Foot Ulcers

Lack of blood supply, poor wound healing, and peripheral neuropathy are key factors in the development of diabetic foot ulcers. Key strategies

in prevention and treatment are proper foot care (including professional care of nails and calluses), preferably by a podiatrist; regular physician's examination of the feet; avoidance of injury; avoidance of tobacco in any form; and the use of methods to improve the local circulation. Proper foot care includes keeping the feet clean, dry, and warm and wearing well-fitting shoes. Tobacco use in any form constricts the peripheral blood vessels and can lead to more serious peripheral vascular disease, including severe arterial blockages. Diabetes and smoking are like nitro plus glycerin—a sure recipe for catastrophe. Circulation can be improved by exercising regularly, avoiding sitting cross-legged or in other positions that compromise circulation, and massaging the feet lightly upward. *Ginkgo biloba* or grape seed extract can also be used to support optimal circulation.

THERAPEUTIC APPROACH

Effective treatment of patients with diabetes requires the careful integration of wide-ranging therapies and patients who are willing to substantially improve their lifestyles. T2DM is usually the result of many years of chronic metabolic insult and, although treatable with the natural metabolic approach presented here, requires persistence for its ultimate resolution. Although much of the information presented in this chapter focuses on T2DM, it is equally appropriate for T1DM, with the exception that, according to current information, the patient with T1DM will always require insulin.

The first step in the therapy of either T1DM or T2DM is a thorough diagnostic workup. Of particular importance is identifying any of the complications of diabetes. The patient's diet, environment, and lifestyle should be carefully studied to rule out any exposure to agents that may be inducing his or her glucose intolerance.

A diet, exercise, and supplement program that meets the patient's individual needs and his or her current level of glucose tolerance should be developed. For maximum efficacy, the patient's ideal body weight must be achieved (see Chapter 201 for additional recommendations).

In treating patients with severe or uncontrolled diabetes, a high level of awareness of the acute diabetic complications must be maintained. If the patient is on insulin, the physician should be adept at using, changing, and adapting insulin types and doses according to the individual's particular needs.

Finally, the patient must be monitored carefully, particularly if he or she is on insulin or has relatively uncontrolled diabetes. Patient symptomatology, home glucose monitoring, and the $HgbA_{1c}$ test are at present the best ways to monitor progress. It is important to recognize that as these therapies take effect, the patient's drug dosages must be altered and that a good working relationship with the physician will greatly aid the healing process. The ultimate goal is to reestablish normal glycemia and prevent the development of (or ameliorate) the complications of diabetes.

Diet

The optimal healthy diet detailed in Chapter 44 is clearly the diet of choice. All simple, processed, and concentrated carbohydrates must be avoided. A low-GI diet rich in high-fiber foods should be stressed, and sources of healthy fats should be ingested. Low-GI vegetables, particularly onions and garlic, are useful, and their liberal ingestion should be encouraged.

Supplementation for Type 1 Diabetes

The recommended supplementation program depends on the degree of blood glucose control, as evidenced by self-monitored blood glucose and $HgbA_{1c}$ levels.

Recently diagnosed T1DM

- Foundation supplements
  - High-potency multivitamin/multimineral supplement
  - Fish oils: 1000 mg of EPA and DHA (combined total) a day
  - Vitamin C: 500 to 1500 mg a day
  - Vitamin E (mixed tocopherols): 400 to 800 IU a day
- Vitamin D: 4000 to 8000 IU a day (vitamin K_2 should always be used with vitamin D)
- Niacinamide: 25 to 50 mg/kg a day
- Green tea extract: The recommended dosage for children 6 years of age or younger is 50 to 150 mg; for children 6 to 12 years old, 100 to 200 mg; for children older than 12 years of age and adults, 150 to 300 mg. The green tea extract should have a polyphenol content of 80% and be decaffeinated.

Level 1: Achievement of targeted blood glucose levels, $HgbA_{1c}$ levels less than 7%, no lipid abnormalities, no signs of complications

- High-potency multivitamin/multimineral supplement
- Fish oils: 600 mg each of EPA and DHA a day
- Vitamin C: 500 to 1500 mg a day
- Vitamin E (mixed tocopherols): 400 to 800 IU a day
- Alpha-lipoic acid: 400 to 600 mg a day
- Grape seed, pine bark, or green tea extract (or other appropriate flavonoid-rich extract): 100 to 300 mg a day

Level 2: Failure to achieve targeted blood glucose levels, $HgbA_{1c}$ above 7%

- Level 1 supplements plus:
  - *G. sylvestre* extract (24% gymnemic acid): 200 mg twice a day
  - Biotin: 8 mg twice a day
- Optional:
  - Bitter melon juice: 2 to 4 oz a day

Supplementation for Type 2 Diabetes

The recommended supplementation program depends on the degree of blood glucose control, as evidenced by self-monitored blood glucose and $HgbA_{1c}$ levels.

Level 1: Achievement of targeted blood glucose and $HgbA_{1c}$ levels less than 7%, no lipid abnormalities, no signs of complications

- High-potency multivitamin/multimineral supplement
- Greens drink: one serving a day
- Fish oils: 600 mg each of EPA and DHA a day
- Vitamin C: 500 to 1500 mg a day
- Vitamin E (mixed tocopherols): 400 to 800 IU a day
- Grape seed, pine bark, or green tea extract (or other appropriate flavonoid-rich extract): 100 to 150 mg a day
- Alpha-lipoic acid: 400 to 600 mg a day
- PGX (glucomannan, or other soluble source at equivalent dosage to PGX): 2500 to 5000 mg before meals

Level 2: Failure to achieve targeted blood glucose levels, $HgbA_{1c}$ above 7%

- Level 1 support plusOne of the following:
  - Berberine: 500 mg two or three times daily just before meals
  - Mulberry extract: equivalent to 1000 mg dried leaf three times a day
  - *G. sylvestre* extract (24% gymnemic acid): 200 mg twice a day
  - Fenugreek extract: 1 g a day
  - Garlic: minimum of 4000 mcg of allicin per day

If self-monitored blood glucose levels do not improve after 4 weeks of following the recommendations for the current level, move to the next highest level. For example, if the patient starts out having an $HgbA_{1c}$ level of 8.2% and a fasting blood glucose level of 130 mg/dL, he or she should start on level 2 support. After 4 weeks, if the average reading has not dropped to less than 110 mg/dL, a prescription medication (either an oral hypoglycemic drug or insulin) will be required.

Additional Supplements for the Prevention and Treatment of Diabetic Complications

For high cholesterol levels and other cardiovascular risk factors
Total cholesterol greater than 200 mg/dL or LDL-C greater than 135 mg (100 mg if history of heart attack); HDL-C below 45 mg/dL; lipoprotein(a) above 40 mg/dL; or triglycerides above 150 mg/dL

- Berberine: 500 mg two or three times daily just before meals
- Niacin (intermediate release): 1000 to 2000 mg at bedtime
- Garlic: minimum of 4000 mcg of allicin a day

For hypertension

- Choose one of the following:
  - Berberine: 500 mg two or three times daily just before meals
  - Garlic: minimum of 4000 mcg of allicin a day
  - Coenzyme Q10: 100 to 200 mg a day
  - Anti-ACE peptides from bonito: 1500 mg/day
- Choose one of the following:
  - Hawthorn extract (10% procyanidins or 1.8% vitexin with 4% rhamnoside): 100 to 250 mg three times a day
  - Olive leaf extract (17%–23% oleuropein content): 500 mg twice a day
  - Hibiscus: three 240-mL servings a day or an extract providing 10 to 20 mg anthocyanidins a day

For diabetic retinopathy

- Bilberry extract: 160 to 320 mg daily or grape seed extract 150 to 300 mg a day

For diabetic neuropathy

- Gamma-linolenic acid from borage, evening primrose, or blackcurrant oil: 480 mg a day
- Benfotiamine: 600 mg a day
- Capsaicin (0.075%) cream: applied to affected area twice a day

For diabetic nephropathy

- Follow previous recommendations for high blood pressure unless kidney function falls below 40% of normal. Be cautious in recommending magnesium and potassium supplements.
- Benfotiamine: 600 mg a day

For poor wound healing

- *A. vera* gel: Applied to affected areas twice a day

For diabetic foot ulcers

- *G. biloba* extract: 120 to 240 mg a day or grape seed extract 150 to 300 mg a day

Endometriosis

Bethany Montgomery Hays, MD, and *Tori Hudson*, ND*

OUTLINE

DIAGNOSTIC SUMMARY

- Endometriosis, the presence of endometroid tissue outside the uterus, is a heterogeneous condition characterized by a triad of symptoms: dysmenorrhea (pain with menses), dyspareunia (pain with intercourse), and infertility. It is now separated into superficial peritoneal endometriosis, ovarian endometriomas or "chocolate cysts" (hemorrhagic cysts with endometrial lining containing old blood and debris), and deeply infiltrating endometriosis. Some consider these to be different but closely related diseases.[1]
- Physical examination reveals one or more of the following: tenderness of the pelvic organs, cul-de-sac, or both; enlarged or tender ovaries (although endometriomas are often soft and therefore not palpable); a uterus that is tipped or flexed backward and may lack mobility; and other fixed pelvic structures.
- Pelvic ultrasound, although useful in the detection and differentiation of endometriomas from other types of cysts, is often unhelpful or negative in cases absent significant ovarian disease.
- Definitive diagnosis requires laparoscopy or laparotomy, visualizing endometrial implants within the pelvic cavity, and/or confirmatory biopsy of implants.

GENERAL CONSIDERATIONS

Endometriosis affects 10% to 15% of menstruating women of childbearing age. Although published estimates of the incidence vary depending on the methodology of diagnosis and the geographical location of the study, the exact incidence is unknown because most women undergoing the laparoscopic evaluation needed for a reliable diagnosis have pain and/or infertility, and as many as half of these (high-risk) women are found to have endometriosis.[2]

*Previous edition contributor

Genetics

A common risk factor for endometriosis is heredity. A woman with a mother or a sister who has endometriosis is at increased risk,[3] and "risk genes" such as aromatase, which converts androgens to estrogens), and 17-beta HSD type 2, which converts estrone to the more powerful estradiol (but not type 1, which does the reverse), have been identified. Common low-penetrance genes such as GSTM1, GSTT1, and CYP1B1 strongly involved in detoxification and protection of DNA are associated with increased susceptibility.[4] Additionally, the genetics of COMT may affect both estrogen metabolism[5] and pain perception in patients with endometriosis. Patients with low-activity COMT have higher adrenaline/noradrenaline levels, have more anxiety, and are more susceptible to nociceptive pain.[6] It is likely that heredity interacting with the environment creates a greater likelihood for developing endometriosis and its symptoms.

Menstrual History and Lifestyle Factors

Women with shorter menstrual cycles and a longer duration of flow, more painful periods, and the use of intrauterine devices have been found to be at higher risk for having endometriosis. Lack of exercise from an early age, a high-fat diet, and increased or unbalanced estrogen levels have been suggested as factors in the development of endometriosis. These factors have in common higher levels of estrogen and xenoestrogens, as well as poorer ability to detoxify them.

Personal History and Stress

A greater number of women with adhesions, endometriosis, or both have reported abuse histories.[7] This may be mediated through stress

effects on the immune system functions, which we will explore next, or epigenetic changes in relevant genes.

Immune System

A growing body of information implicates the immune system in the pathophysiology of endometriosis. Abnormalities of cytokines and adhesion molecules, increased numbers and activation of peritoneal macrophages, changes in T cells and natural killer (NK) cells (which normally remove cellular debris from retrograde menstruation), and the presence of increased autoimmunity are notable findings in endometriosis. It is not known whether the immune system changes are primary (causative) in the transformation of totipotent cells of the pelvic peritoneum or the failure to remove viable cells from retrograde menstrual effluent, or if its aberrations are secondary, that is, in response to the development and invasion of the endometrial implant.

Estrogen Levels (Production and Metabolism) and Xenoestrogens

Endometriosis has long been known to be an estrogen-related disease. Men don't get it. Women don't get it premenarche. It occurs during the reproductive period, and the incidence increases in perimenopause, during the period of increased estrogen and decreased progesterone. It regresses at menopause or with oophorectomy. It responds to estrogen-lowering agents such as gonadotropin-releasing hormone (GNRH) agonists, danazol, and aromatase inhibitors.[8] However, none of these drugs, although they may improve symptoms, improves fertility. Endometriosis may return in menopausal women put on hormone replacement therapy, although many tolerate low-dose therapy. Because endometrial implants make their own estrogen, as many as one third of implants are out of sync with the eutopic endometrium,[9–11] suggesting that the hormonal signals from the ovary are being overridden by the production of local estrogens. More recently, aromatase has been found to be present in endometrial implants but not in eutopic endometrium.[12] However, aromatase inhibitors have not been found as helpful in managing disease as it was once thought they would be.[13] The benefits of oral contraceptives, long thought to prevent endometriosis and ameliorate its symptoms,[14] are currently in debate. A meta-analysis in 2011 found that the apparent protective effect may have been due to the postponement of surgical evaluation and suggested that this treatment was "not sufficiently substantiated."[15]

Numerous lines of research have confirmed the association of endometriosis with higher levels of endogenous, exogenous, and xenoestrogens (polychlorinated biphenyls [PCBs], weed killers, plastics, detergents, household cleaners, tin can liners) and altered estrogen metabolism. Prenatal factors such as exposure to xenoestrogens have also been seen in these women.[16]

ETIOLOGICAL THEORIES

The origin of endometriosis remains a mystery. Many theories have been proposed, but none fits all the findings in patients with endometriosis. Establishing a correct hypothesis leads to targeted research, which benefits patients. Following an incorrect hypothesis leads to confusion, expensive and misleading research, and incorrect results, which do not benefit or only partially benefit patients.[17] It is possible that part of the confusion regarding the origin of endometriosis is that, as noted before, different locations of endometriosis and depth of disease may represent entirely different diseases.[18] It is also likely that the origin of endometriosis is multifactorial.

Retrograde Flow

Retrograde flow, the predominant theory, first proposed in 1927 by Sampson, proposes that during menses, menstrual effluent flows backward through the fallopian tubes, and living endometrial cells implant in the pelvic cavity. The problem with this theory is that more than 90% of menstruating women without endometriosis have retrograde flow as well. Women get endometriosis after tubal ligation and, rarely, after menopause. Finally, eutopic endometrial cells are genetically different from endometriosis cells. Thus this theory has been challenged, and questions have been raised regarding the biochemical and immunological factors causing the implantation of endometrial tissue within the pelvic environment.[19] The persistence of this theory, however, suggests that there may be factors in the menstrual effluent, such as inflammatory cytokines or autoantibodies, that stimulate or support endometriosis in nearby pelvic tissues. Finally, the eutopic endometrium of these women appears to be different from the endometrium of normal women.[12] Alterations in apoptosis, proliferation, adhesive and invasive behavior, angiogenesis, neurogenesis, lymphangiogenesis, hormone production and responsiveness, and immunological regulation differ between women with and without endometriosis.[20] Implants found in odd locations, such as the brain, nose, and lungs, suggest the transportation of endometrial tissue through lymphatic channels and/or blood vessels.[20]

Cellular Transformation

Another theory suggests that that "totipotent" (stem) cells are somehow triggered to transform. Some researchers believe the implants to be of embryological origin. Indeed, genetics specific to stem cells have been identified in endometriosis.[21,22] A closely related theory suggests that pieces of the embryonic female reproductive tract (Mullerian cells) were left behind during developmental migration and that these cells, when activated, transform in some way to become endometriosis. The growing understanding of the genetics of these aberrant cells is likely to shed light on the true origin of endometriosis in the near future.

Environmental Toxins

A recurring question is whether environmental toxins, many of which are estrogen mimics, are involved or even causative in endometriosis. Research on endometriosis in baboons suggests activation by environmental toxins that mimic estrogens.[23] Exposure to radiation and dioxin has been associated with a higher frequency of endometriosis.[24,25] The highest incidence of endometriosis appears to be in Belgium, which is also the home to the highest level of dioxin pollution in the world.[26] Two studies, however, one in Belgium, found no significantly increased risk associated with dioxins or polychlorinated biphenyls (PCBs).[27] The other study, in Italy, found no significantly increased risk of endometriosis in women who had high levels of dioxin in their blood.[28] These studies also point out the difficulty of studying a fat-soluble chemical that may not show up in the blood. Although there is currently no widely accepted epidemiological evidence linking any one class of chemicals to the risk of endometriosis, there does appear to be some link with estrogen-like compounds in the environment,[29] called xenoestrogens, which can interact with the estrogen receptor and disrupt estrogen metabolism.

In addition to estrogen mimetics, there are a number of environmental toxins that have strong associations but for which there is no clear mechanism. For example, women with endometriosis have significantly higher levels (median 0.57 micro g/mL vs. median 0.18 micro g/mL) of high-molecular-weight Di-(2-ethylhexyl)-phthalate (DEHP) than controls.[30] However, the levels do not correlate with severity. Several studies also show a correlation with perfluorocarbon levels.[31]

Immune Origins

Immunological alterations may exist in women with endometriosis. Lack of proper immune surveillance in the pelvis following menstrual retrograde flow may allow endometrial cells to implant rather than be phagocytized and removed.[32] Alteration of the inflammatory response to the implanted tissue is then involved in progression and

severity of disease. These alterations may be generational and begin in utero.[33] Women with endometriosis have been found to have suppressed NK-cell activity in their peritoneal fluid,[34,35] high levels of immunoglobulins (Igs) IgG and IgM,[36] and high levels of autoantibodies against ovary and endometrial cells.[37,38] Macrophages, cytokines, T lymphocytes, and tumor necrosis factor-alpha (TNF-α) are all found in greater numbers in the peritoneal fluid in early stages of endometriosis.[39] Both types of immunity, cell-mediated and humoral, have been implicated in endometriosis, with immunological defects present with even minimal disease.[40] Growth factors, angiogenic factors, and lipid peroxidation in the peritoneal fluid may stimulate endometrial cell growth.[41–43] Targeting of these proinflammatory compounds and blocking their action with anti-inflammatory antioxidants and natural compounds are being investigated as new treatment strategies.

Oxidative Stress

The presence of high levels of iron from retrograde flow creates oxidative stress, another factor linked to causation in endometriosis. The contents of endometriotic cysts, especially the high concentration of free iron, are a possible cause of carcinogenesis in the cysts through the iron-induced persistent oxidative stress.[44]

Genetic Origins

Endometriosis is now considered to be of multifactorial origin by most researchers.[45] Grouping of endometriosis cases within families has long been found in clinical studies,[46,47] population-based studies,[48] and studies of twins,[49-51] all of which suggest the importance of genetics in the origins of endometriosis. Several abnormalities in detoxification enzymes, tumor-suppressor genes, and antioxidant genes, interacting in multistep fashion, may be involved in both the development and the progression of the disease,[52] but no single genes that are primarily responsible have been identified. Epigenetic influences from the gut and the environment and prenatal influences also underline the importance of genetics, regardless of the theory of origins we ultimately accept.

Gut Dysfunction and Pathology

The search for a unifying theory of the origins of endometriosis that explains all the research quickly leads to the gastrointestinal tract.[53] Its close proximity to the most common sites of endometriosis; the frequent involvement of large and small bowel; dietary approaches that ameliorate symptoms; the inflammatory nature of the disease; and the effect of higher levels of endogenous estrogens, xenoestrogens, and other toxins ingested orally make looking to the gut for origins and to find preventive and curative measures a necessity. Let's look at the evidence implicating the gut:

1. Because family genetics is an important association, we must remember that family members share their microbiome as well as their genes.
2. The amount of pain is not proportional to the amount of disease, suggesting that both the disease and the pain come from a third cause: the gut.
3. Although associated with endometriosis, the cause or causes of infertility are not known. One theory linked tubal transport of the fertilized egg to dysbiosis.
4. Dietary interventions improve endometriosis symptoms.[54]
5. One of the most frequent sites of endometrial implants is the cul-de-sac between the uterus and rectum. One of the most common extraperitoneal sites is the rectovaginal septum just below the cul-de-sac. These sites, in close proximity to the rectum, would share the highest levels of toxins and toxic bacteria.
6. The gut microbiota is not only essential for physiological gastrointestinal function but also acts as a central regulator of a variety of inflammatory and proliferative conditions. "[W]e hypothesize that the gut microbiota may be involved crucially in the onset and progression of endometriosis."[55]
7. Alterations in gut bacteria and the gut-associated immune system in inflammatory bowel diseases produce an exudate that closely approximates the peritoneal fluid in early endometriosis (i.e., high levels of cytokines and macrophages).
8. Women with endometriosis are more likely to be diagnosed with pelvic inflammatory disease (altered bacteria likely sourced from the gut) and irritable bowel syndrome (IBS), both of which are associated with dysbiosis.[51]
9. Inflammation produces adhesions, a common finding in patients with endometriosis.
10. Eighty percent of the immune system is found in the gut. The immune response to altered contents in the gut (food, toxins, and the microbiome) produce many if not all of the altered immune system findings in endometriosis. Endometriosis and IBS share a picture of chronic inflammation.[51]
11. TNF-α has been shown to be in higher quantities in the peritoneal fluid of women with endometriosis. TNF-α has been shown to induce accelerated differentiation of stem cells. TNF-α is thought to be a critical factor in the induction and maintenance of endometrial implants.[56,57]
12. Autoimmunity is now both seen in patients with endometriosis and closely linked to gut pathology.
13. The pelvic peritoneum can be altered by benign and malignant forms of any of the three cell types of the female genital tract: serous (tubal) cells, endometrial cells, and mucinous (cervical) cells. These diseases are called endosalpingosis, endometriosis, and pseudomyxoma peritonei when benign and are called epithelial ovarian cancer (serous, endometrioid, and mucinous) when malignant. Although tubal cells might flow retrograde, cervical cells are not likely to go "upstream," making the transformation of peritoneal cells more likely than retrograde flow as an etiology. Thus we must look for reasons for the transformation of the peritoneal "totipotential cells."
14. Epithelial ovarian cancer of all three types (serous/tubal, endometrioid/endometrial, and mucinous/cervical) occurs more often in patients with endometriosis. This disease (epithelial ovarian cancer) is deadly because it is rarely found "early." In fact, the ovarian disease may start in multiple locations on the peritoneal surface and simply predominate in the epithelium of the ovary because the peritoneal surface reflected over the ovary is more richly supplied with estrogen, allowing what may start as peritoneal disease to progress more rapidly in that location.
15. Patients with endometriosis are more likely to develop endometrioid ovarian cancer and perhaps ovarian cancer of other types, suggesting cellular transformation and issues of altered environment.
16. The cells that become endometriosis are stem cells.[22]
17. Peritoneal stem cells are responding to something that is going on in the pelvis. Gastrointestinal immune activation is a likely candidate.

DIAGNOSIS

The clinical diagnosis of endometriosis is presumptive. A definitive diagnosis requires surgical evaluation and biopsy. Endometriosis is rarely seen before menarche. Although in some cases symptoms begin with the onset of menstruation, in most patients, symptoms

begin later and worsen progressively over time, suggesting the importance of stimulation of the disease by estrogens and/or the accumulation of xenoestrogens with time. It should be noted that pre-menarche girls with abdominal pain are usually diagnosed with gut problems, not gynecological problems, unless they have signs of infection. Although the triad of symptoms of endometriosis is dysmenorrhea, dyspareunia, and infertility, two of these—dyspareunia and infertility—may not be issues for young women having menstrual cramps, so the diagnosis may be missed. Acute pain may occur for only a few hours at the onset of menses or be present throughout the month. In some women, vomiting, diarrhea, and fainting can occur concurrently, suggesting a vagal component, with the intense pelvic/abdominal cramping and pains that are likened to contractions in childbirth. These are largely the symptoms of a heavy menstrual flow trying to pass through a small cervical outlet and autonomic stimulation from abdominal organs. In many women, these symptoms disappear after first childbirth (especially when the cervix is dilated by labor.) Because these symptoms also occur in conditions likely to produce retrograde flow, it is hard to state which comes first: heavy, painful periods or endometriosis. Other sensations include rectal pain producing a chronic bearing-down sensation, pressure in the lower back, and pain sometimes radiating down the legs, likely related to irritation of the psoas muscle, which attaches to the lower spine and courses retroperitoneally through the pelvis and down the front side of the leg, placing it immediately under the pelvic peritoneum, where implants may cause the muscle to tighten and spasm. The correlation between pain and the extent of disease is weak. Women with fixed ovaries and large endometriomas may report only mild discomfort, whereas those with visibly smaller lesions may report severe chronic pain. Pain therefore may be caused not by the endometriosis but by whatever causes endometriosis.[58] Some research suggests that the severity of symptoms is correlated with the depth of the lesions rather than the number or size of lesions.[59,60] Symptoms may also include pain with urination or bowel movements; bleeding from ectopic sites of endometrial implants, such as the nose or bowels; and fatigue.

Endometriomas, endometroid involvement of the epithelium reflected over the ovaries, are found in two of three patients with endometriosis. It is likely that endometriosis simply grows fastest on the peritoneal surface reflecting over the estrogen-producing ovary. This may also be true of epithelial ovarian cancer, leading the diagnosing surgeon to conclude that epithelial cancers *begin* in the ovary and spread to the peritoneum when, in fact, they may *begin* throughout the peritoneal cavity. (No wonder we don't "find them soon enough.") The association of endometriosis and ovarian cancer was first reported by Sampson in 1925. The origin of ovarian cancer is unknown, but both endometriosis and certain ovarian cancers share genetic changes (loss of p53 and PTEN and ARID1A).[61]

Endometriosis is associated with infertility and miscarriage and is often found in women at laparoscopic evaluation for infertility. The amount of endometriosis does not always correlate with infertility. Some women with small peritoneal implants are infertile, whereas some women with severe disease may become pregnant. Data suggest that excessive amounts of free radicals accompany endometriosis. Tubal scarring, adhesions, and unruptured follicles are common findings in women with endometriosis and concurrent infertility. Alterations of eutopic endometrium are also found in patients with endometriosis. Autoantibodies, including those to sperm, have been found. All of these as well as the inflammatory environment of the pelvis may contribute to poor ovulation, tubal transport, and implantation of the fertilized egg.

Physical Findings

Physical examination reveals one or more of the following: tenderness of the pelvic area, cul-de-sac, or both; enlarged or tender ovaries; a uterus that tips backward (and may be retroflexed as well as retroverted) and lacks mobility due to adhesions; and other fixed pelvic structures. Endometrial tissue can be visible in surgical scars, in the vagina, and on the cervix. Physical examination during the first or second day of menses may accentuate tender areas or nodules in the cul-de-sac or in the septum between the rectum and vagina.

An ultrasound examination of the pelvis can be useful in ruling out other pathology and tumors but is not a definitive tool in diagnosing endometriosis. It can detect a fluid-filled mass on the ovary and determine the size, characteristics, and consistency of the cyst, suggesting endometrioma, but it often fails to identify peritoneal disease.

Laboratory Findings

A blood test, CA-125, can have positive results in endometriosis but cannot differentiate among endometriosis, uterine fibroids, malignancies, and even normal tissue.

A definitive diagnosis of endometriosis can only be accomplished with laparoscopy or laparotomy. Endometrial implants, endometriomas, or both are then visualized, and a presumptive diagnosis is made. Only biopsy gives the definitive answer.

THERAPEUTIC CONSIDERATIONS

Endometriosis is a multifactorial disease. Therefore therapeutic approaches must be individualized for maximum benefit to each patient. Numerous drugs, surgical procedures, and integrative approaches have been tried. Most medical approaches to date have been only mildly to moderately successful in ameliorating symptoms and consist of hormone intervention aimed at lowering estrogen effects or nonsteroidal anti-inflammatory drugs (NSAIDs) aimed at decreasing inflammation. Only surgery has been successful in eradicating disease and stopping the feed-forward mechanisms that drive estrogen production, inflammatory cascades, and visceral hypersensitivity (pain).[62] And only surgery has proven effective in improving fertility. Recurrence rates are high, so surgical intervention should be timed to closely precede attempts at conception. These factors suggest that we are not getting at causes—that is, we are focusing our attention too far "downstream."

Therapeutic approaches should be aimed at the following:

a. Minimizing symptoms because there are significant quality-of-life issues for these women
b. Slowing or arresting the progression of disease, especially before desired childbearing, to preserve fertility and avoid or delay surgery
c. Improving fertility rates

A multifactorial approach to causes suggests the following areas to address therapeutically:

1. Lowering estrogen levels and improving estrogen metabolism
2. Decreasing xenoestrogens and toxic exposures
3. Improving gut health
4. Approaches that decrease inflammation

Approaches that have multiple effects will be starred (*).

Diet

Diet is the common denominator in a multifactorial approach to endometriosis.[63] Sadly, research on diet and endometriosis is sparse.[64]

Several dietary principles are key in a natural medicine approach to endometriosis, as discussed in the following subsections.

Reduce Inflammatory Foods and Increase Anti-inflammatory Foods

Perhaps the most inflammatory food is gluten*. Producing zonulin, which causes leaky gut, gluten increases the gut-associated immune system reactivity to intraluminal irritants and antigens, inducing inflammatory cytokines interleukin (IL)-6 and TNF-α. Additionally, removing gluten will often decrease carbohydrate consumption and help prevent insulin resistance (discussed later in the chapter). Consuming higher amounts of anti-inflammatory prostaglandin precursors (omega-3* and certain omega-6 fatty acids, discussed later in the chapter) and blocking leukotrienes (with omega-3 eicosapentaenoic acid [EPA]) may be more effective and safer than NSAIDs, the current first approach for pelvic pain. Decreasing "flesh foods"* (dairy, red meat, eggs), which contain high amounts of arachidonic acid (the inflammatory prostaglandin series 2 precursor), is also recommended. This approach may also limit toxins excreted in cow's milk and antigens in meat and dairy that drive the inflammatory process. Avoiding insulin resistance*, a diabetes precursor and major cause of inflammation and driver of obesity, with its accompanying increase in estrogen, is critical as well. Anti-inflammatory herbs and vegetables*, discussed later in the chapter, complete the four major parts of an anti-inflammatory diet: good fat, balanced carbohydrates, avoidance of gluten and inciting food antigens, and the addition of anti-inflammatory plants. Avoiding abdominal obesity (a stress-related disease) because of the inflammogenic properties of visceral adiposity may also be helpful.[65]

Enhance Detoxification Mechanisms, Especially Estrogen Metabolism

By increasing the intake of vegetables*, specifically those that enhance Phase I and Phase II detoxification in the liver, improving metabolism of estrogen and providing methylation factors, cell damage from toxins and estrogen metabolites can be limited. Methylation-supporting (lipotropic factors)[66] and detoxification-supporting vegetables to be increased include carrots, beets (carotene-containing vegetables; see later discussion), and cruciferous vegetables and green leafy vegetables. Indole-3-carbinol—found in broccoli, Brussels sprouts, cabbage, kale, and cauliflower—favors the production of less active 2OH metabolite of estrogen, thereby decreasing the more potent 16OH metabolite and the more dangerous DNA-damaging 4OH metabolite.[67] Other liver-supporting foods include artichokes, lemons, dandelion greens, watercress, and burdock root. Onions, garlic, and leeks contain organosulfur compounds, which enhance the immune system and induce enzymes that detoxify in the liver. They also provide the sulfate groups that modulate estrogen effects and are a major Phase II pathway for estrogens. In addition, they contain the bioflavonoid quercetin, which is known to stimulate the immune response, protect against oxidation, block the inflammatory response, and inhibit tumor growth by lowering aromatase.[68] Adding a tablespoon of milk thistle seeds that have been soaked and ground can also help liver function because silymarin is known to increase Phase I detoxification. Organically grown vegetables are expected to contain lower levels of pesticides and herbicides that may also mimic estrogen. In some studies, fruit was associated with increased risk (more than two servings/day). It is likely that the extra sugar is not helpful, whereas most studies show a significant benefit from vegetables. This may be mediated through beneficial effects on the microbiome.[69]

Increase Soy/Isoflavones and Lignans

The isoflavones in soy products and the lignans in flax seeds* may also be important in a dietary approach to endometriosis. Although some claim that these phytoestrogen compounds should be avoided, thinking that they would stimulate the growth of endometriotic implants, much as estrogen does, the evidence supports the conclusion that soy is beneficial in the diets of women with endometriosis.[70] A recent study in an endometriosis model in mice showed a dramatic lowering of estrogen receptors; inflammatory markers; and HIF-1a, a tumor marker, in mice given genistein in various doses.[71]

Improving Gut Function and the Microbiome

Foods high in fiber are associated with optimal transit time in the intestines and an optimal balance of friendly microorganisms within the large intestines (see Chapter 132). These microorganisms, better known as the microbiome, must remain healthy to crowd out flora that produces beta-glucuronidase, which deconjugates estrogens and allows them to recycle back through the body (called enterohepatic circulation). Freshly ground flax seeds*, high vegetable roughage (cellulose), and omega-3 fatty acids* all improve transit time in the large bowel, preventing absorption of some of the toxic load as well as feeding healthy bacteria. These "dual-use" foods are easily incorporated into the diet in smoothies, muffins, and dishes that combine fish and vegetables (fish tacos, for example). Magnesium*-rich foods, or magnesium taken as a supplement (see following discussion), are also useful for this purpose. Increased fiber content (24g/day) was shown in Women's Heath Initiative (WHI) to lower IL-6 and TNF-α.[72] Seasonings such as turmeric (curcumin) protect against environmental carcinogens, decrease inflammation, and increase bile secretion. Fresh flax seeds increase anti-inflammatory omega-6 fatty acids. Seasoning with *Fucus* (a seaweed) helps stimulate T-cell production and absorb toxins.[73] Studies suggest that a predominantly vegetarian diet emphasizing less protein and more fiber can lead to a decrease of biologically active unconjugated estrogens in the blood plasma.[74] Vegetarian diets are also of greater value owing to their lower fat content. Diets containing large amounts of animal protein, especially in the form of red meat, contain large amounts of arachidonic acid, which promotes inflammatory prostaglandins and thus inflammation and pain. Being higher on the food chain, the animals that produce red meat carry a greater burden of toxins from the environment. Adding vegetable protein, soy, nut butters (e.g., almond), and salmon to our diets tips the inflammatory pathway toward the anti-inflammatory prostaglandins that inhibit tumor growth—both benign and malignant.

Increase Omega-3 Fatty Acids and Reduce Trans Fats

Omega-3 fats, in addition to their anti-inflammatory function, improve membrane function, making membranes more fluid and accommodating to receptors. Omega-3 fats are precursors for series 3 anti-inflammatory prostaglandins and block the cyclooxygenase-2 (COX2) enzyme as well as the lipoxygenase enzyme. The arachidonic acid in flesh foods increases prostaglandin E 2 (PGE2) and the inflammatory series 2 prostaglandin, which increases aromatase, adding to the feed-forward production of estrogens in endometriosis.[75] Lowering fat and increasing essential fatty acids (EFAs) and short-chain polyunsaturated fatty acids (FAs)[76]; adding unfried, low-mercury, low-contamination fish to the diet[77]; and decreasing saturated fats[78] have all been shown to be beneficial.

The consumption of trans fats appears to increase the risk of endometriosis,[79] whereas long-chain omega-3 fats appear to be protective. Twelve years of prospective data from the Nurses' Health Study II, which began in 1989, were analyzed for dietary fat and its association with many health problems, including endometriosis.[80] Although there was no association with total fat consumption and endometriosis risk, those women with the highest consumption of long-chain omega-3 fatty acids were 22% less likely to be diagnosed with endometriosis compared with women who had the lowest intake of these fats. Those women who had the highest intake of trans unsaturated fats were 48% more likely to be diagnosed with endometriosis.

Foods to Avoid

Foods to decrease include sugar, caffeine, dairy, red meat, and alcohol. Sugar is known to increase estrogen levels.[81] A study of 50 women with endometriosis examined the effect of the reduction of higher glycemic carbohydrates, the addition of omega-3 and omega-9 fatty acids, and the elimination of foods containing caffeine and tyramine; after 8 weeks, there was a significant reduction in symptoms.[82] Endometriosis is found to be specifically correlated with caffeine consumption. Women consuming 5 to 7 g of caffeine monthly had a 1.2 times greater incidence of endometriosis, whereas those consuming more than 7 g had a 1.6 times greater increase.[83] The Environmental Protection Agency estimates that 90% of human dioxin exposure is through food, primarily meat and dairy products.[84] Cheese, particularly cottage cheese, and milk cause the lipid pathway to be tipped toward prostaglandins and leukotrienes, which cause inflammation, smooth muscle contraction, and vascular constriction. Alcohol consumption depletes stores of B vitamins in the liver and affects the metabolism of estrogen.

Nutritional Supplements

A number of nutritional supplements have been looked at related to the amelioration of symptoms, the development of endometriosis, and the preservation of fertility. The side effects of these supplements are minimal.

Estrogen Metabolism Facilitators

A number of supplements have been studied and found to be beneficial in lowering estrogen levels and improving estrogen metabolism. Because there is a clear benefit to lowering estrogen to slow the progression of disease, this same approach is helpful in patients with endometriosis. Important areas of estrogen production and metabolism to address are as follows: (1) aromatase, the main estrogen-producing enzyme; (2) 17OH dehydrogenase, the balance between the more potent estradiol and the less potent estrone; (3) Phase I detoxification, which involves directing the metabolites away from 16OH estrone (CPY3A4) and 4OH estrone (CYP1B1) to the least toxic 2OH estrogen (CYP1A1); and (4) Phase II detoxification, which involves methylation, sulfation, and glucuronidation to prevent DNA damage by oxidative intermediates and make the estrogens water soluble so that they can be excreted in urine or feces. There are numerous foods and natural substances that are effective in improving the overall estrogen picture in patients with endometriosis.

Aromatase Inhibitors

Because estrogen is being produced locally in the endometriosis implant, aromatase inhibitors (AIs) would seem to be an effective treatment. Pharmaceutical AIs have not been as successful as expected and are reserved for patients who do not respond to first-line therapies. A number of plant substances have been shown to be aromatase inhibitors. Because they have few if any side effects, and some do double duty (COX-2 inhibitors), they should be included in a comprehensive approach to endometriosis:

COX-2 inhibitors (see discussion of Essential Fatty Acids later in the chapter)

Essential fatty acids* (discussed later in the chapter)

Indole-3-Carbinol

Indole-3-carbinol (I3C) or DIM (a metabolic product of I3C in the gut) have been shown to improve Phase I detoxification of estrogens favoring the less potent 2OH estrone pathway. Although the 2OH estrone can also make DNA-damaging quinones, they are less adhesive to the DNA and therefore are probably only important when levels are very high (as can be seen with certain single-nucleotide polymorphisms [SNPs] of CYP1A1). These metabolites can be measured in the blood or urine to ensure that levels are low before starting I3C or DIM.

Calcium-D-Glucarate

Calcium-d-glucarate is a beta-glucuronidase inhibitor. By preventing the action of bacterially produced beta-glucuronidase in the gut, this supplement interrupts enterohepatic circulation of estrogen, allowing it to be removed in the stool and lowering the levels of estrogen in the system.

Sources of methyl groups, sulfate groups, and glucuronides are important to provide the Phase II substrates that make estrogens water soluble so that they can be excreted. Most patients can obtain these substrates from foods, as noted previously. Rarely, s-adenosyl methionine or NaSO4 will be needed as a supplement.

Methylation Factors

Methyl groups (functional single-carbon atoms) are involved in numerous biochemical reactions in the human body. They are critical to the reading of DNA and should be considered pertinent to the activation of pelvic peritoneal and immune cells in endometriosis.

As noted previously, B vitamins help the liver inactivate estrogen via the Phase II methylation pathway,[85] helping detoxify the DNA-damaging 4OH estrogen metabolite. Because it appears that changes in reading of the DNA in totipotent/stem cells may be critical to the development of endometriosis, attention to methylation in young women would seem to be important. Additionally, adequate methylation is critical for fertility and the developing embryo and could decrease the infertility and pregnancy losses seen in women with endometriosis. Because several enzymes are required to convert folic acid (an inexpensive, man-made folate) to 5-methyl folate (MTHF), the key folate for donating methyl groups to the methionine/homocysteine cycle, B-vitamin supplements containing 5-methyl folate are preferred. Pyridoxine as P5P, thiamine, riboflavin, and B_{12} as methyl or hydroxy cobalamine are also important in this process.

Lipotropic Factors

Supplements that contain choline, betaine, and methionine, the "lipotropic factors," promote the flow of fat and bile (containing estrogen metabolites) from the liver and facilitate excretion in the gut.[86] Because of their prominent role in methylation, making useable single-carbon CH3 molecules available, lipotropic factors may also play a role in the epigenetics of this disease.[87]

Vitamin C

A number of studies suggest that oxidative stress is a prominent feature of endometriosis.[88] Antioxidants are known to work in sequence, suggesting that they should be taken together in to fully reduce oxidants.

Studies with the use of vitamin C show increases in cellular immunity, decreases in autoimmune progression, and decreases in fatigue.[89] It is a potent antioxidant and is a cofactor for many biosynthetic and gene regulatory enzymes. It accumulates in phagocytic cells and enhances phagocytosis such as may be needed to "clean up" the peritoneal cavity after retrograde menstruation.[90] In addition, vitamin C enhances immunity and decreases capillary fragility and tumor growth, all of which are evident at varying levels in women with endometriosis. Studies on autoimmune progression point to the effectiveness of high levels of vitamin C.[90,91]

Beta-Carotene

Beta-carotene helps enhance immunity. Studies show that the use of beta-carotene increased T-cell levels after 7 days.[92] In addition, beta-carotene was shown to be protective against early stages of tumor growth.[91] Retinoids can moderate the effects of IL-6, which has been implicated in endometriosis.[94] Impairment of phagocytosis is seen in vitamin A–deficient states.[95] Although vitamin A was used in the latter

study, one third of beta-carotene is converted to retinol, the active form of vitamin A. Additional studies suggest that immune function is affected more by carotenoids than by vitamin A.[96] A significant portion of the population has genetics limiting the conversion of beta-carotene to vitamin A and therefore requires preformed vitamin A as a supplement (see Chapter 57) to ensure proper immune system function.

Vitamin E

Because parallels have been found between abnormal tumor growth in cancer and abnormal growth of lesions in endometriosis, vitamin E supplementation may be advantageous. Vitamin E helps correct abnormal progesterone:estradiol ratios in patients with mammary dysplasia (increased growth of cells).[97] Vitamin E has been shown to be of benefit in women with dysmenorrhea, a common complaint in patients with endometriosis.[98] When taken as a supplement, care should be taken to avoid synthetic d,l tocopherols, which could have a negative effect. Free radicals may contribute to the inflammation, damage to DNA, and excessive growth of endometrial tissue; vitamin E and N-acetyl cysteine, another antioxidant, can act to inhibit this proliferation.[99,100]

Selenium

Selenium aids in the synthesis of antioxidant enzymes responsible for detoxification reactions within the liver. In addition, selenium stimulates white blood cells and thymic function.[101,102]

In a mouse model, decreased selenium levels are associated with suboptimal cell-mediated immunity, decreased T cells, and associated inflammation.[103] Individuals with low selenium are also vulnerable to yeast infections,[104] a common clinical finding in patients with endometriosis.

N-Acetylcysteine

The rate-limiting precursor for glutathione, the number one antioxidant and detoxification molecule in cells, is N-acetylcysteine (NAC). It has been shown to limit the damage of estrogen quinones and serves as an important addition to an antioxidant regimen. Additionally, many women have glutathione transferase (GSTM1) null status and are not able to use glutathione as well for detoxification. These women need higher levels to ensure utilization of alternative transferases.

Resveratrol

Recently studies have shown that resveratrol, a property of red grapes in juice or wine, may have beneficial effects in endometriosis.[105] Most studies to date have been in animal models, however.[106] Resveratrol interacts with estrogen receptor (ER)-beta to slow growth and upregulates MnSOD, both of which may be helpful in endometriosis.[107]

Pine Bark (Pycnogenol)

Pycnogenol is a special standardized extract from the bark of the French maritime pine. It is composed of polyphenols, several phenolic acids, catechins, taxifolin, and procyanidins. In laboratory research, Pycnogenol was found to selectively inhibit matrix metalloproteinases and inflammatory cells and inhibit cyclooxygenases 1 and 2. Its role in endometriosis was evaluated in a study of 58 women who were surgically diagnosed with endometriosis. After confirming regular menstruation and ovulation for 3 months, they were randomized to receive either Pycnogenol 30 mg twice daily for 48 weeks or a GNRH agonist, leuprorelin acetate depot, 3.75 mg intramuscularly (IM) every 4 weeks for 24 weeks. After 4 weeks on Pycnogenol, patients slowly but steadily improved, experiencing a 33% reduction in symptoms (from severe to moderate). The leuprorelin group had a greater response within the treatment period but relapsed after 24 weeks posttreatment. The Pycnogenol group had the added benefit of maintaining regular menses and normal estrogen levels during treatment, whereas the leuprorelin group had suppressed menstruation and drastically lowered estrogen levels during treatment. Five of the women taking Pycnogenol became pregnant.[108]

Essential Fatty Acids

A number of studies have looked at the fat content in the diet and found that saturated and trans fats are detrimental in endometriosis, whereas long-chain unsaturated fats are beneficial. Long-chain unsaturated FAs provide the precursors for prostaglandins, a group of highly potent pro- and anti-inflammatory molecules. Two main groups of FAs are particularly important: the omega-6 group and the omega-3 group (named for the first carbon atom containing an unsaturated or double bond at the omega end of the molecule). Omega-6 fatty acids (from flaxseed, canola, pumpkin, soy, and walnuts) are precursors for gamma-linolenic acid (GLA; found in borage, black currant, and evening primrose oils), leading to either the series 1 prostaglandins, which are anti-inflammatory, or to arachidonic acid (AA), which, via the COX-2 enzyme, becomes the highly inflammatory series 2 prostaglandins. Another source of AA is animal fats via the enzyme phospholipase A2. Numerous supplements, including *Glycyrrhiza glabra* and quercetin, affect phospholipase A2, blocking the release of AA from membranes. AA, via lipoxygenase, can also be a precursor for leukotrienes, which are known to increase pelvic pain during menses. The omega-3 alpha-linolenic acid (from flaxseed, canola, pumpkin, soy, and walnuts) provides the precursor for EPA and the series 3 prostaglandins, which are anti-inflammatory. EPA is both a COX-2 inhibitor and a lipoxygenase inhibitor, which might be especially effective in endometriosis. Many botanical supplements act as COX-2 inhibitors, including *Zingiber officinale, Curcuma longa,* quercetin , *Boswellia serrata,* and *Withania somnifera.* Lipoxygenase inhibitors include quercetin, *Allium cepa, Allium staivum, Curcuma longa, Silybum marianum,* and *Boswellia serrata.*

In a 2001 study looking at the role of EFA ratios on the viability of endometrial cells and their production of inflammatory cytokines, endometrial cells from women with and without endometriosis attending an infertility clinic were studied in vitro. The culture media was supplemented with various ratios of omega-3 and omega-6 polyunsaturated fatty acids. The investigators found that the higher the ratio of inflammatory omega-6 to anti-inflammatory omega-3 fatty acids, the longer was the survival time and secretion of IL-8 in cells from women with and without endometriosis.[109]

Prostaglandins can be prospasmodic or antispasmodic, depending on the prostaglandins that are being produced; can inhibit or promote tumor growth; and as noted earlier, can stimulate estrogen production via upregulation of aromatase.[110] (See Chapter 57 for a more complete discussion of this complex topic.)

Long-chain FAs, saturated fats, and trans fats make up a large percentage of the lipid bilayer of cells. Polyunsaturated FAs, because of their "bent" configuration in space, allow more fluidity in the membrane. This facilitates the insertion of proteins such as receptors in the membrane, making it more functional. Whereas long-chain unsaturated FAs are "bent," trans fats and saturated fats are "straight." This allows them to stack tightly in the lipid bilayer, excluding proteins and receptors.

Castor oil packs to the abdomen have been used successfully by many women. They are usually applied by soaking a flannel sheet in organic castor oil and applying it to the lower abdomen with a plastic covering topped with a heating pad for 15 to 30 minutes. It is postulated that the castor oil may provide alterations of prostaglandin metabolism in the pelvis. In any event, the 15 to 30 minutes of "quiet time" and relaxation are beneficial to many women.

Botanical Medicines

The herbs appropriate for acute pain relief in endometriosis are the same herbs commonly used for menstrual cramps, such as valerian, crampbark, and black cohosh, in addition to other traditional herbs that might be helpful, such as wild yam, chamomile, blue cohosh, ginger, passion flower, and false unicorn root.

Vitex Agnus Castus

Vitex agnus castus, also known as chaste tree, has traditionally been used as a treatment for hormonal imbalances in women. Through its action on the pituitary gland, chaste tree increases progesterone production via an increase in luteinizing hormone. This herb is useful for fibroids, premenstrual syndrome, and perimenopausal times of increased estrogen. With its use, less estrogen is available to stimulate endometrial tissue.[111]

Taraxacum Officinale

Taraxacum officinale, also known as dandelion root, is one of the most detoxifying herbs. It works principally on the liver and gallbladder to help remove waste products. By supporting the liver, excessive estrogens and toxins can be deactivated. Researchers in Japan have found a link between dandelion and antitumor activity.[112] Additionally, dandelion leaf contains vitamins A, C, and K; calcium; and choline.

Xanthoxylum Americanum

Xanthoxylum americanum, or prickly ash, is known for its specific effects on capillary engorgement and sluggish circulation. Prickly ash stimulates blood flow throughout the body and enhances the transport of oxygen and nutrients, in addition to removing cellular waste products. For women with pelvic congestion, this herb enhances circulation throughout the pelvis.

Leonorus Cardiaca

Leonorus, or motherwort, is antispasmodic and gently soothes the nerves. Because women with endometriosis generally experience uterine cramps and pain, motherwort is useful in promoting relaxation during times of extreme "bearing-down" pain in the uterus and other regions.[62] As a mild sedative, motherwort helps women get needed rest during their menstrual periods.

Turska's Formula
