Acupuncture is the Western name for a technique involving stimulation of particular anatomically mapped locations or palpable tender zones of the body by heat applications, mechanical stimulation, or the insertion of fine needles. Classical approaches to the theory and organization of this health care practice date back as many as 4000 to 5000 years. For contemporary practitioners, their practice styles of acupuncture are based on an understanding of several fundamental concepts, as discussed in the following subsections.

Yin/Yang Balance

Yin/yang balance is the central theory in the practice of acupuncture. It refers to relative biophysiological balance and can be clinically observed in neurological signaling or in cellular and organ metabolism as activation versus inhibition, in tissues as inflammation versus inflammation control, in thermoregulation as heating versus cooling, in autonomic activity as sympathetic versus parasympathetic tone, and in vascular tone as vasodilation versus vasoconstriction.

Qi, Blood, and Fluid

Qi, blood, and fluid can be clinically observed in the vascular system as oxygenated versus deoxygenated blood flow, as venous drainage versus venous congestion, in lymphatic flow as determined by tissue tension and by intravascular versus extravascular fluid exchange, and by physicochemical phase shifts in biological fluids between liquid, solid, and gel (traditionally translated as "phlegm") states.

Five Phases

The five phases (or five elements or five movements) are clinically observable patterns of genetically expressed physiological tendencies and body morphotypes, which resonate with personality strengths and weaknesses and with environmental and dietary preferences and susceptibilities. This approach can be clinically useful in determining which acu-stimulation targets could rebalance specific physiology or psychological factors that are promoting the yin/yang or qi, blood,

and fluid imbalances. This treatment approach varies from the TCM approach by being a more indirect or nonlinear approach to achieving healthier homeostasis. Five-element acupuncture is a refined form of constitutional acupuncture. Practitioners of this style will identify the deeper and lifelong biopsychosocial patterns underlying their patients' ailments. They attempt an artful rebalancing of the interwoven patterns of dysfunction using the special channel acupoints that classically have inherent nourishing and controlling relationships among the five-phase physiology of that particular person.

Zang Fu Organ Functional Metabolism Qualities

The Zang Fu are the Chinese "organs" and related physiological functions. There are five solid "Zang" yin organs (liver, heart, spleen/pancreas, kidneys, and lungs) and five hollow "Fu" yang organs (gallbladder, small intestines, stomach, large intestine, and urinary bladder). In addition, there are two "organs" that represent distributed physiological functions that the ancient Chinese associated with a related body anatomy. The *San Jiao* or "triple energizer" is a yang organ that roughly corresponds to the overall restorative and functional activities of all the organs in the upper, middle, and lower body cavities. In traditional teaching, it is considered to be a Fu organ with the function of transporting water. In modern thinking, it seems to correspond to the physiological function of the mitochondria, whose activities provide the metabolic energy of the internal organs. The paired yin "organ" is the *Xin-Bao,* or "heart protector," which has been poorly translated in English as "pericardium."

Depending solely on the Western name without a thorough understanding of the traditional Chinese meaning leads to much confusion clinically. In clinical practice, the heart-protector function often corresponds to the regulation of sympathetic tone. In practice, the Chinese term for urinary bladder function seems to correspond to the embryological and functional aspects associated with the entire cloacal region in comparative anatomy. The liver in the Chinese sense is much more a functional system with many body-wide interactions. Among other things, the Chinese *Gan* (liver) stores blood and qi and is responsible for the smooth transmission of qi and blood throughout the body. It also has a chief role in emotions; an unbalanced *Gan* (liver) results in anger, high blood pressure, and a general state of agitation. In the TCM diagnostic approach, the Zang Fu and yin/yang principles lead to poetic explanatory diagnoses. Clinical symptoms such as dizziness, vertigo, insomnia, dry throat, and lumbago could be ascribed to a deficiency of liver and kidney yin. Cold limbs, lumbago, diarrhea, and scanty urine could be ascribed to a deficiency of spleen and kidney yang.

Six-Channel Acupuncture *(Jing Luo)*

Six-channel acupuncture *(Jing Luo)* is explained in the classical text *Sang Han Lung*. This approach facilitates interactions among organs, tissues, nerves, and blood vessels via electromechanical needle stimulation of the semiconductive connective tissue web that permeates the body but can be accessed by major acupoints.

Neuroanatomical Acupuncture

Neuroanatomical acupuncture is a style of practice inclusive of recent biomedical studies in animals of electroacupuncture effects on the central and peripheral nervous system[27] and anecdotal clinical experience with myofascial "trigger-point" mechanisms.[24,26,28,29-37]

The treatment of tender knots in muscles by intramuscular stimulation is a "non–channel-based acupuncture. It was termed "Ashi" or "ouch point" acupuncture by the ancients and was probably the first form of acupuncture practiced in the West from the time of the Dutch physician Willem Ten Rhyne, who visited Japan sometime in the early 17th century.[38] Dr. Franklin Bache (Benjamin Franklin's great-grandson) described his clinical trials utilizing acupuncture on prisoners with various conditions in an 1825 article in the *North American Medical and Surgical Journal.* The descriptions of his empirical needling intervention suggest he knew nothing about classical point, channel, or related theories.[39]

This form of acupuncture was essentially rediscovered by Dr. Janet Travell, who, along with Dr. David Simon, published texts for the treatment of myofascial pain with trigger-point therapy. They discovered that the stimulation of these palpable points with hydremic needles was effective even if they did not inject local anesthetics. Over the intervening several decades, this has led to the promotion of a simplified "dry-needling" style of acupuncture among U.S. physical therapists and some chiropractic physicians. Conversely, basic research done in modern China with electroacupuncture has contributed to the broader neuroanatomical style of acupuncture by demonstrating that different frequencies of electronic stimulation via acupoints and myotome and sclerotome regions can boost specific types of endorphins and enkephalins, achieving a level of pain relief not seen with simple trigger-point releases or channel-based manipulation with needles and moxibustion.[27]

Modern research has found a high degree of overlap between the mapped trigger points of Travell and Simons and the classical acupoints that are related to the anatomy of the connective tissue major and auxiliary channels[37]:

Microsytem acupuncture
Ear (auricular) acupuncture
Korean hand acupuncture
Scalp acupuncture: Chinese, YNSA (Yamamoto New Scalp Acupuncture)

SCOPE OF PRACTICE

Similar to the challenges in universal acceptance of an exact definition of the term *acupuncture,* the clinical practice of acupuncture also varies across the world and in different U.S. jurisdictions. As noted, there were acupuncture practice acts in 47 U.S. states and the District of Columbia as of early 2018. Although there is a core of therapeutic acceptance from state to state, there are wide variations in expanded scopes. Although most states use the designation "LAc," a few have begun to use other credentials, such as "doctor of acupuncture" in Rhode Island, "doctor of Oriental medicine" in a few other states, and "East Asian medicine practitioner" in Washington State.[40]

New Mexico is a good example of perhaps the broadest acupuncture scope in the United States. In New Mexico, the practice of "Oriental medicine" includes homeopathy, prescriptive drug authority (with expanded practice certification), laser therapy, injection, and intravenous (IV) therapy within its doctor of Oriental medicine (DOM) designation.[41]

Although California law has in many ways set the pace for the profession through the years, with a scope that now defines acupuncturists as primary health care professionals with a practice inclusive of Asian massage, acupuncture, herbal medicine, exercises, breathing techniques, and dietary supplements, among others, it is the Washington State law that forged entirely new ground for acupuncturists in the United States.

The stage was set for the renaming and overhaul of the state acupuncture law for a number of reasons, including the strong desire by a Korean Washington State legislator to rid the Western world of the term *Oriental,* an upcoming sunset review, and several confusing and deficient parts of current acupuncture law. What resulted was the insertion of the term *Asian* in place of *Oriental* in the Washington State acupuncture regulations. "East Asian medicine means a health care service utilizing East Asian medicine diagnosis and treatment to

promote health and treat organic or functional disorders and includes the following: Acupuncture (or lancets), electrical, mechanical, magnetic devices, moxibustion, acupressure, cupping, dermal friction technique, infrared, sonopuncture, laserpuncture, point injection therapy (aquapuncture), dietary advice (including recommendation and sale of herbs, vitamins, minerals), breathing, relaxation and East Asian exercise, Qi Gong, East Asian massage and Tui na, and superficial heat and cold therapies."[42]

Acupuncturists in the state of Washington are now licensed under the EAMP credential.[43]

SAFETY

Acupuncture therapy is generally regarded as a safe and relatively pain-free procedure. There are many forms and styles of acupuncture therapy practiced; some have a reputation for potentially being more painful at times, but generally the procedure in the United States is accompanied by very little reporting of adverse effects. The treatment provided by most licensed acupuncturists is painless. Millions of treatments have been performed by licensed acupuncturists in the United States who have taken "clean needle" training as part of their basic acupuncture training. For the past 15 years, it has been the standard of care in acupuncture practice that single-use disposable needles are used in all treatments.

Recently, there has been renewed discussion about the safety of acupuncture, sparked by a *British Medical Journal (BMJ)* editorial piece that put a cautionary spin on the view that acupuncture needling is entirely safe or at least has virtually no side effects.

The article, "Acupuncture Transmitted Infections," although highlighting the skin infection risk of acupuncture needling, also identified only "more than 50 cases" to date (2010) worldwide. Nevertheless, the authors' main opinion stated that these types of infections were underreported.[44] An older report also published in the *BMJ* by Vincent seems appropriately titled: "The Safety of Acupuncture; Acupuncture Is Safe in the Hands of Competent Practitioners." Vincent stated, "The conclusion that acupuncture is a very safe intervention in the hands of a competent practitioner seems justified on the evidence available."[45] A large review study published in 2008 focused on acupuncture safety and efficacy in pediatrics. The authors "found evidence of some efficacy and low risk associated with acupuncture in pediatrics." They stated some caution as well, noting "the safety of acupuncture is a serious concern, particularly in pediatrics. Because acupuncture's mechanism is not known, the use of needles in children becomes questionable." They also stated, "nevertheless, it seems acupuncture is a safe complementary/alternative medicine modality for pediatric patients on the basis of the data we reviewed."[46]

The NCCAOM and the AAAOM jointly authored a response to the *BMJ* editorial, stating that "the article neglected to mention that the incident of infections is drastically reduced when a consumer seeks a qualified practitioner who has met the rigorous standards of the NCCAOM certification which includes passing of the Council of Colleges of Acupuncture and Oriental Medicine (CCAOM) clean needle technique course, a prerequisite to becoming an NCCAOM certified practitioner."[47] They stated in another article that "while acupuncture is a highly effective and valuable form of healthcare, it is not an entirely risk-free medical procedure, and should be administered by practitioners with the proper training who follow accepted guidelines of practice."[48]

Acupuncture has a low relative risk. The NIH Consensus Statement on Acupuncture published in 1998 found that the incidence of adverse effects is substantially lower than that of many drugs or other accepted procedures for the same conditions.[49] Systematic reviews and surveys have clarified that acupuncture is safe when performed by appropriately trained practitioners, with infrequent minor side effects, such as feeling relaxed, elated, tired, or having sensation or itching at the point of insertion. Rare, serious complications, such as infection or pneumothorax, are directly related to insufficient training. Safe use of acupuncture has also been established in pediatrics and for women who are pregnant.[49]

EVIDENCE-BASED AND EVIDENCE-INFORMED ACUPUNCTURE

Acupuncture practice has steadily increased across the world since the 1970s. Although it was once viewed as a strictly Asian practice, acupuncture is now practiced by a wide variety of medical and nonmedical practitioners. Each type of health care discipline has at least some of its members practicing acupuncture. Of course, the popularity and spread of the practice do not mean acupuncture has become mainstream or effective. Where is the evidence proving or disapproving the practice? Skeptics abound within established medical practice. At the same time, there is an increasing body of acupuncture research to consider, review, and evaluate. According to the Society for Acupuncture Research, "every month, an average of 100 acupuncture-related articles are published in more than 50 journals."[50] Although this may not seem impressive in the greater context of evidence-based medicine as a whole, it does represent a great increase over the years in research focused on the field.

A defining moment in acupuncture research in the West came with the conclusion of the NIH Consensus Conference in 1997. For the first time, a Western panel of medical experts gathered to review, critique, and set guidelines for the use of acupuncture in the medical field in the United States. Before this conference, research in acupuncture was acknowledged by some Western doctors but largely dismissed. The view of Asian studies and of studies from other countries in general did not make an effect on the U.S. radar. The conference helped focus the attention, collect what research had been completed to date, and concluded that there was merit in the use of acupuncture for certain conditions and, most importantly, that there was a real need and demand that acupuncture be better studied and used. Acupuncture was finally "on the map" in the West.[51]

Progress was made in the 10 years after the NIH conference, as was detailed by the 2007 Society for Acupuncture Research (SAR) International Symposium.[52] The symposium detailed a number of important research conclusions, highlighting growing evidence for the effectiveness of acupuncture treatment for chronic pain while detailing the issues concerning sham acupuncture in trials and a number of basic science trials demonstrating the physiological effects of needling.

Conventional medical practice has grown within a system of great scrutiny and self-analysis. A massive research culture spins off studies by the thousands. The double-blinded, placebo-controlled trial has become the hallmark of the "appropriately conducted research trial." Acupuncture evolved in a completely different culture, that of China, where, ironically, as we were "discovering" the Chinese traditional system of acupuncture, not so many years ago, the Chinese began a wholesale discovery of traditional Western medicine. Acupuncture and all that is TCM have been extensively researched in China. The quality and breadth of acupuncture research in China and Asia in general have increased greatly since the first edition of this textbook.

Large research academies, such as the China Academy of Traditional Chinese Medicine in Beijing, and numerous universities and schools of TCM have greatly improved the research culture in China since the 1970s. Although there is considerable emphasis on herbal research, there is still quite a lot of research examining the other areas of TCM, including acupuncture.[53-56]

In 2014, the Veterans Administration (VA) published an evidence map of acupuncture.[57,66-81] This document is a broad overview of the evidence base for acupuncture and is based on 183 systemic reviews from 2005 through 2013. The map estimated the research volume and effectiveness of acupuncture on the basis of the published reviews. According to the document, assessments to evaluate the value of acupuncture need to take into account multiple factors, including the following:

- Clinical efficiency
- Risk and benefits compared with standard treatment
- Costs and cost-effectiveness
- Patient satisfaction
- Patient preferences for a particular diagnosis

The evidence map of acupuncture for pain summarizes the clinical indication of pain. The bubble plot summarizes the results of 59 systematic reviews for 21 distinct indications relevant to the outcome of pain.

Evidence of a positive effect with high confidence was found for dysmenorrhea, cancer pain, and labor pain. The wellness-relevant indications and outcomes bubble plot summarize 43 systematic reviews and 3 large randomized controlled trials (RCTs) with 20 distinct indications. Evidence of a potential positive effect with high confidence was found for insomnia, smoking cessation, and restless leg syndrome. Results for the mental health bubble map represented 17 systematic reviews with summary effects for 9 clinical indications. There was a potential positive effect with high confidence for depression and schizophrenia. Medium confidence was found for the treatment of anxiety and posttraumatic stress disorder (PTSD).[57]

An excellent source of current research studies regarding integrative medicine including acupuncture is the Academic Consortium for Integrative Medicine and Health. The organization's website notes the following: "The Consortium was founded in 1999 by eight academic health centers including Duke University, Harvard University, Stanford University, University of California, San Francisco, University of Arizona, University of Maryland, University of Massachusetts, and the University of Minnesota. Now with 72 institutional members, the Consortium continues to grow and represents thousands of scientists, educators, clinicians and other health professionals who share an interest in the field of Integrative Medicine and Health."[58]

One of the topic areas within the Consortium is "moving beyond medications" to an area of collected information on evidence-based nonpharmacological pain approaches. Available for review is a white paper on strategies for comprehensive pain care. Also included in this section are evidence summaries for treating pain, as follows:

- Acupuncture in the management of cancer pain
- Acupuncture therapy for chronic pain
- Acupuncture therapy for postoperative pain with opioid sparing
- Acupuncture therapy acute pain (not perioperative)[58]

One of the studies highlighted included a review of several studies performed in emergency departments (EDs) in the United States between 2014 and 2016 and provided evidence of the effective use of acupuncture for acute nonperioperative pain.

A randomized study involved 300 ED patients who received either IV morphine or acupuncture. Acupuncture proved better than morphine in pain relief by 14%. Acupuncture also provided pain relief in a shorter time frame, by 6 to 18 minutes. There were also far fewer side effects, only 4 compared with 86 in the morphine group.[59]

In another summarized study, this one of feasibility and acceptability, 182 ED patients who received only acupuncture had a decrease in pain comparable to that of patients who had received analgesics. In addition, the acupuncture-only group had a reduction in anxiety levels.[60] The 2017 Clinical Guidelines of the American College of Physicians for acute, subacute, and chronic low back pain recommend that patients should select nonpharmacologic treatment with superficial heat, massage, acupuncture, or spinal manipulation.[59]

In multiple systematic reviews with meta-analyses, acupuncture was found to be effective in reducing postsurgical pain compared with sham acupuncture, controls, and usual care, with a reduction in opioid need (21% opioid reduction at 8 hours, 23% at 24 hours, and 29% at 72 hours postsurgery) and with lowered incidence of opioid-related side effects such as nausea, dizziness, sedation, pruritus, and urinary retention.[60-65]

SUMMARY

By most accounts, acupuncture has been around for approximately 5000 years. The basic practice of placing needles (made of metal, stone, bone, wood, or other materials) into select points on the body to effect change, be it pain relief or the calming of anxiety, has not really changed much. As we have briefly touched on in this chapter, the history of acupuncture is rich. Standards of practice vary widely, and critical areas of study have yet to be adequately delineated. Yet here we are in 2018 with a much larger and richer database of study—from RCTs to therapeutic outcomes—at our fingertips to discuss than we had in 1985 when this text was first published.

Ayurveda: The Science of Life and Mother of the Healing Arts

Virender Sodhi, MD (Ayurveda), ND

OUTLINE

INTRODUCTION

Ayurveda is one of the most ancient systems of medicine known today. The origins of this science of life (*Ayu,* "life," and *Veda,* "knowledge"), although difficult to pinpoint, have been placed by scholars of ancient Indian Ayurvedic literature somewhere around 6000 BC.[1]

Ayurveda is a holistic science of health and a balance in lifestyle. Disease is seen as an imbalance, and its treatment involves diverse strategies to restore optimal function and balance. Using dietary alterations, yoga, and exercise, along with elaborate surgical techniques and complex, integrated herbal formulas, the Ayurvedic physician treats the whole person, removing disease completely by ending the imbalance that created it.

HISTORY

In ancient India, it was custom for a teacher's instruction to be recorded by his students, who would eventually repeat the same information orally to their own disciples. Thus according to the different interpretations given by various disciples of Ayurveda, a number of treatises were written. Although specific instructions differed, the basic principles remained the same.

Ayurvedic teachings were orally transmitted for thousands of years and then written down in melodious Sanskrit poetry. The contents of a number of Sanskrit verses, or *shlokas,* although written many centuries ago, still sound a note of familiarity in today's scientific environment. Ayurveda, in its first recorded form (*vedas:* the world's oldest literature), is specifically called *Atharveda.*

The Development of Ayurvedic Medicine

Hindu legend holds that after seeing the suffering of human beings, Lord Brahma, the god of creation, elaborated ways to ease that suffering to Daksha, who, in turn, taught them to the Ashwin twins. Fig. 33.1 presents the chronology of Ayurveda's development.

Dhanvantari and Bhardwaj separately developed the surgical and medical aspects of Ayurveda around the 9th century BC. Their students recorded these principles in great detail in compendia that are called *Samhitas.*

The *Sushruta Samhita,* one of the most widely accepted Ayurvedic texts, emphasizes the surgical aspects of therapy. Its author, Sushruta, is considered the father of surgery (particularly of plastic and reconstructive surgery). The medical teachings of Charak were a synthesis of earlier work. His material has become a classic text of the nonsurgical medical wisdom of Ayurveda. Successive generations have modified his work, the *Samhita.*

The Major Schools and Specialties

School of Physicians *(Atreya Sampradaya)*

Charak wrote a complete text on Ayurvedic medicine in which he revised the work of Agnivesh. Charak's text described the *Tridosh* physiology (*Vat, Pit,* and *Kaph*), seven *Dhatus* (tissues), and three *Malas* (excretions). His text covered the pathophysiology and treatment of diseases, human constitution *(Prakriti),* classifications and preparations of drugs, diet, "right conduct," medical ethics, and many other aspects of medicine.

School of Surgeons *(Dhanvantari Sampradaya)*

Sushruta wrote the first comprehensive works on surgery. These were later revised by Nagarjuna in the 2nd century AD. The major subjects in his texts were the following:

- Injections
- Preoperative care

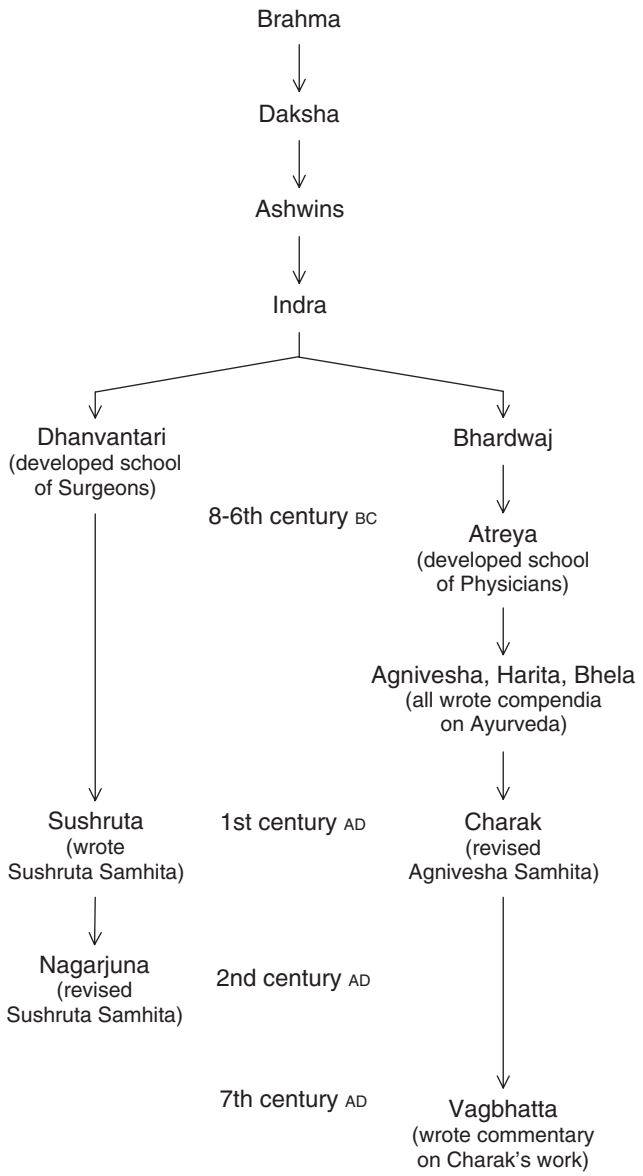

Fig. 33.1 The chronology of Ayurveda.

- Postoperative care
- Suturing
- Asepsis
- Sterilization
- Operation theaters
- Hospitals

Sushruta described 141 types of instruments and listed 40 types of surgeries and surgical techniques for treating cataracts, hemorrhoids, hernias, and bone problems, for cosmetic and plastic purposes, and for the removal of kidney stones and gallstones.

BRANCHES OF AYURVEDA

Ayurveda encompasses eight specialties or branches. They comprise a system developed to prevent and cure disease and also to achieve and maintain excellent health. Table 33.1 lists the branches.

Philosophy

Ayurvedic philosophy is based on the Samkhya philosophy of creation. It has influenced major strains of philosophy in both Eastern and Western civilizations. The word *Samkhya* is derived from the Sanskrit words *Sat* ("truth") and *Khya* ("to know"). The Rishi Kapila (*Rishi* means "realized beings" or "seers of truth") realized the Samkhya philosophy of creation. They perceived the following:

- The close relationship between humans and the universe: humans are a microcosm, a universe within themselves, whereas the external environment is the macrocosm.
- The source of all existence is cosmic consciousness, manifest as male (*Shiva* or *Purusha*) and female (*Shakti* or *Prakriti*) energy.

Purusha is formless, colorless, and "beyond" attribute. *Prakriti* has form, color, awareness, and choice. *Prakriti* creates all the forms of the universe and has three attributes *(Gunas): Satva* (essence), *Rajas* (movement), and *Tamas* (inertia). It is also represented by *Brahma* (the god of creation), *Vishnu* (the god of protection), and *Shiva* (the god of destruction), which together comprise a cycle active in this universe.

In *Prakriti,* the three attributes are in balance. Whenever this balance is disturbed, the attributes interact to bring about the evolution of the universe, yielding the cosmic vibration of *Aum.* The cosmic intellect (the *Mahad*) manifests itself as ego *(Ahamkar),* which, through the help of *Satva,* manifests the five senses and five motor organs, which together constitute the "organic universe." Ego further manifests into the five basic elements (space, air, fire, water, and earth), which, under the influence of *Tamas,* create the "inorganic universe."

Satva is a creative potential *(Brahma), Rajas* is a kinetic protective force *(Vishnu),* and *Tamas* is a potentially destructive force *(Shiva).* These three—*Brahma, Vishnu,* and *Shiva*—are constantly operating in the universe.

TABLE 33.1 Specialties in Ayurveda

Ayurvedic Name	English Name
Shalya Tantra	General surgery
Shalkya	Ophthalmology and otorhinolaryngology
Kaya Chikitsa	Medicine
Bhutvidya	Psychiatry
Kumar-Bhritya	Pediatrics, obstetrics, and gynecology
Agada Tantra	Toxicology and jurisprudence
Rasayana	Geriatrics
Vajikaran	Fertility and sterility

Five Basic Elements and the Universe (Panchbhuta Philosophy)

The Rishis perceived that consciousness consists of five basic elements: ether (space), air, fire, water, and earth. At the beginning of the world, consciousness was without form, existing as the subtle vibration of the cosmic "soundless" sound *Aum.*

Within these vibrations appeared the element ether. Ether started to move, creating air. The movement of ether also produced friction and, through friction, generated heat, then fire. From the heat of the fire, ethereal elements dissolved and liquefied into water. Water then solidified to form molecules of earth. Thus all matter was born from the five elements. These five elements exist in energy forms.

Five Elements and the Senses

The five elements also connect with the five senses: ether—hearing, air—touch, fire—vision, water—taste, and earth—smell, and they are present in certain physiological functions. Expressing the functions of the sensory organs are five actions (Table 33.2). In this manner, the

TABLE 33.2 The Five Elements and the Senses

Element	Sense	Organ	Action	Vehicle of Action
Ether	Hearing	Ear	Speech	Mouth
Air	Touch	Skin	Holding, giving, receiving	Hand
Fire	Vision	Eye	Walking	Feet
Water	Taste	Tongue	Procreation	Genitals
Earth	Smell	Nose	Excretion	Anus

BOX 33.1 Properties of *Dosha*

Vat	*Pit*	*Kaph*
Dry	Oily	Oily
Light	Light	Heavy
Cold	Hot	Cold
Rough	Liquid	Slimy
Subtle	Penetrating	Soft
Mobile	Mobile	Static
Clear		Dense
Dispersing		Slow
Smells sour		

elements are directly related to humans' abilities both to perceive the external environment in which they live and to respond to it:

- Ether is the medium through which sound travels. The ear is the organ of hearing, expressing its action through the organ of speech, which creates meaningful sound.
- Air is related to skin and the sense of touch. Its organ of action is the hand, which is especially sensitive. The hand performs the actions of holding, giving, and receiving.
- Fire produces light, heat, and color and is thus related to vision and direction. Its organ is the eye.
- Water relates to the organ of taste. The tongue is also related to the action of the genitals, the penis and clitoris. In Ayurveda, the penis and clitoris are called the lower tongues. By controlling the upper tongue, one naturally controls the lower tongue.
- The earth element relates to the sense of smell, and the nose is its organ.

Physiology

The five elements manifest within the body as the Tridosha (*Dosha* means "protective" or, when out of balance, "disease producing"). The Tridosha are the three humors, or basic principles, described earlier—*Vat, Pit,* and *Kaph.*

From the bodily combination of ether and air comes the bodily air principle, *Vat Dosha.* Likewise, fire and water combine as *Pit Dosha,* or fire principle, and earth and water produce the *Kaph Dosha,* or water principle.

These three control all biological, psychological, and physiopathologic functions of the body, mind, and consciousness. They produce natural urges and individual tastes in food, flavor, and temperature. They govern the maintenance and destruction of bodily tissue and the elimination of waste products. They also are responsible for psychological phenomena, including the emotions of fear, anger, greed, and the highest order of emotions: understanding, compassion, and love.

Properties of *Dosha*

Vat, Pit, and *Kaph* control all human biological, psychological, and physiopathologic functions and have subtle properties, as shown in Box 33.1.

The *Doshas* increase by similar properties and are diminished by opposite properties. For example, *Vat* is dry, light, and cold, so any food, medicine, lifestyle, or behavior that increases these qualities increases *Vat* within the body. Conversely, oily, heavy, or hot factors decrease *Vat.*

Functions of *Tridosha*

Each humor has a specific action. *Vat* is the principle of movement and may be called the bodily air principle, as opposed to the environmental air principle. *Vat* is a subtle energy governing all biological movement—breathing, blinking, muscle and joint movement, heartbeat, and all nerve and membrane contractions and expansions. In addition, it controls the psychological functions governing the emotions of fear and anxiety. *Vat* also controls pain, tremors, and spasms. Broadly speaking, the whole nervous system can be labeled as *Vat* function. The large intestine, pelvic cavity, bones, skin, ears, and thighs are the places of *Vat*. Any excess of *Vat* accumulates in these areas.

Pit, or bodily fire, governs digestion, absorption, assimilation, nutrition, temperature, skin color, luster of the eye, intelligence, and understanding. It arouses anger, hate, and jealousy. The small intestine, stomach, blood, sweat glands, fat, eyes, and skin are the places of *Pit;* all metabolism is governed by *Pit.*

Kaph, biological water, is the cement of the body, providing for physical structure. It is responsible for body resistance and biological strength. It lubricates the joints; provides moisture to skin; and promotes wound healing, strength, vigor, and stability. It supports memory, gives energy to the heart and lungs, and maintains immunity. *Kaph* is present within the throat, chest, head, sinuses, nose, mouth, stomach, joints, cytoplasm, plasma, and liquid secretions. Psychologically, *Kaph* governs attachment, greed, long-standing envy, calmness, forgiveness, and love.

A balance of the *Dosha* is necessary for optimal health. Together, they govern all metabolic activities: anabolism *(Kaph),* catabolism *(Vat),* and metabolism *(Pit).*

Individual Psychosomatic Constitutions—*Prakriti*

Prakriti, a Sanskrit word composed of *pra* ("before") and *akriti* ("creativity"), denotes the constitution of each individual as determined at conception. At the time of fertilization, permutations of *Vat, Pit,* and *Kaph* determine the constitution of the new individual, with maleness or femaleness dominating other traits. These basic traits are also shaped by other important factors, such as diet, lifestyle, behavior, emotions, and seasons.

As illustrated in Box 33.2, up to seven different constitutions can exist depending on the permutation and combination of *Vat, Pit,* and *Kaph. Prakriti* is genetically determined; the basic constitution, the combination of the three humors, remains unchanged throughout an individual's lifetime. The combination can, however, respond to environmental changes.

Life is considered a sacred path in Ayurveda, a ceaseless interaction between the internal *(Tridosha)* environment and the external environment, or the sum of cosmic forces. To counteract external change, an individual may create a balance in the internal forces by altering diet, lifestyle, and behavior. The characteristics of the corresponding psychosomatic constitutions are listed in Table 33.3.

Mental Constitutions

On the mental and astral planes, three *Gunas* (attributes of female energy or *Prakriti*) correspond to the three humors that make up the physical constitution. In the Ayurvedic system, the *Gunas* are *Satva, Rajas,* and *Tamas*. They provide the basis for the distinctions in human temperament and individual differences in psychological and moral dispositions. These attributes are further subdivided, but that is beyond the scope of this chapter.

Satva

The *Satva* type of mind expresses essence, understanding, purity, clarity, compassion, and love. People of Satvic psyche (*Satva* temperament) have healthy bodies and pure behavior and consciousness. They believe in the existence of God, are religious, and are often holy persons.

Rajas

The *Raja* type of mind operates on the sensual level. Such persons are interested in business, prosperity, power, prestige, and position. They enjoy wealth, are generally extroverted, and are politically minded.

BOX 33.2 The Seven Types of Constitution

- *Vat*
- *Pit*
- *Kaph*
- *Vat-Pit*
- *Pit-Kaph*
- *Kaph-Vat*
- *Vat-Pit-Kaph*

Tamas

The *Tamas* type is distinguished by its ignorance, inertia, heaviness, and dullness. Tamasic people are lazy, selfish, and destructive by nature. They show little respect to others. All their activities are egocentric. The Satvic person attains self-realization without much effort, whereas those of Rajasic or Tamasic mind have difficulty. These three subtle mental energies are responsible for behavior patterns that may be altered and improved through practice and spiritual discipline, such as yoga and meditation.

HEALTH AND DISEASE

Health is defined in Ayurveda as the soundness of body *(Shrira)*, mind *(Manas)*, and soul *(Atma)*. Each part of this tripod of life should receive equal attention to ensure that the individual achieves sound health. Ayurvedic medicine stresses that psychic influences strongly affect the body in health and disease, a fact that must also be taken into account in modern therapeutics.

Modern science takes pride in its understanding of physiology but, in doing so, has emphasized fragmentation, isolation, and disunity. Instead of wholeness and interaction, this modern view accepts only physical objects as causes of disease, whereas these objects are merely the agents of disease, able to cause specific symptoms but only in a susceptible host. Disease is the result of a disruption of the spontaneous flow of nature's intelligence within physiology. When people violate nature's laws and cannot adequately rid themselves of the results of this action, they acquire diseases.

Ayurveda conceives the body as being composed of three principal divisions: three *Doshas* (humors), seven *Dhatus* (tissues), and three *Malas* (excretions).

The three *Doshas* regulate cell functions. *Pit* gives energy and is responsible for cellular, enzymatic, and metabolic functions; *Kaph*

TABLE 33.3 Psychosomatic Constitutions *(Prakriti)*

Characteristic	*Vat*	*Pit*	*Kaph*
Body frame	Tall or small, thin, ill-nourished, hard, dry, cold	Medium, many moles, well nourished, pimples, patches of freckles, pigment, tender appearance	Stout, well-nourished, big, oily, greasy, cold, beautiful
Skin	Dry, cracked, tough, broken, brownish, black	Soft, thin, yellow, red, pink	Greasy, soft, yellow, white
Hair on head	Brown, scanty, coarse, curved, wavy, wrinkled	Pinkish, yellow, moderate, soft, baldness, premature graying	Black, plentiful, firm, wavy, curved
Head	Small size	Moderate in size	Big and steady
Eyes	Small, dry, thin, muddy brown, unsteady gaze, not pleasant looking	Thin, yellow, pink coppery, quickly become inflamed, pleasant looking	Big, white, pink, pleasant looking, thick, fixed, greasy
Body weight	Less	Moderate	Heavy
Action of body	Quick and unsteady walk, quick actions and movements	Moderate, intelligent actions	Steady walk, slow and dignified
Eliminations	Less, constipated	Copious, watery	Moderate, solid
Strength	Less, tires quickly	Moderate	Strong, hard worker, can withstand strains
Body odor	No smell, less sweating	Heavy sweating, bad smell	Less sweating, pleasant smell
Voice	Feeble, broken, hidden, hoarse, unpleasant	High pitch	Pleasant, deep bass voice, good tone
Speech	Quick, very talkative	Moderate	Slow, definite
Sleep	Less sleep, wakeful at night	Moderate	Sleeps a good deal
Dreams	Moving in sky, action	Cold, flowers, sun, fire, lightning, red, frightful dreams	Ponds, lakes, flowers, swans, beautiful sights
Sex	Less sex capacity, less semen/menses, few children	Less sex capacity, few children	Great sex capacity
Life expectancy	Short	Moderate	Long-lived
Reaction to disease	Quick to get diseases, usually nervous disorders	Moderate, usually inflammations	Good resistance, usually cold and phlegm type
Reaction to drugs	Minimum doses required	Intolerance to drugs	Slow, tolerates high doses

helps in synthesizing blocks of cells; and *Vat* controls the other two. A balance of these *Doshas,* good-quality tissues (the seven *Dhatus*), and a certain character of excretions are essential for maintaining health.

As explained earlier, an individual is born with a particular *Dosha* predominating in his or her constitution *(Prakriti).* This predominant *Dosha,* quite apart from genetic, age, environment, and dietary factors, may make an individual susceptible to a certain disease. For example, *Pit Prakriti* individuals are more prone to develop a disease syndrome with symptoms similar to a peptic ulcer. This is a result of hyperactivity of the *Pit Dosha,* which regulates enzymatic activity. Hyperpepsinogenemic individuals are more susceptible to duodenal ulcer formation.[2]

Ayurveda teaches that the origin of most diseases is found either in an exogenous or endogenous *Dosha* imbalance or in an inherent or acquired weakness of the tissues. Therefore, the successful treatment or prevention of disease consists of normalizing cellular functions by correcting any *Dosha* imbalance or improving inherent tissue vitality. For example, in the treatment of cancer, the use of agents cytotoxic to the cancer cells is important. However, equally important is potentiation of the immune system and stimulation of the body's own healing mechanisms.

MODES OF THERAPY

Once a diagnosis is made, Ayurveda offers various modes of therapy. The treatment is chosen according to patient constitution and the disease process. Modalities include dietary alterations, botanical medicines, minerals, animal products, exercise, yoga, meditation, counseling, and surgery.

Diet

Ayurveda places great emphasis on diet, for both its direct effect on the individual's physiological state and its influence on the action of medicines. Proper assimilation of dietary constituents is essential for the maintenance of good health. Improper assimilation results in the formation of intermediary products of digestion that have toxic properties and are therefore treated as foreign by the body. Such toxic products are called *Ama* (this leads to the concepts of immune and autoimmune disorders).

Arthritic diseases such as rheumatoid arthritis are attributed to an accumulation of *Ama.* Could these toxic intermediates—macromolecules absorbed transmucosally from the intestine (in nutritionally insignificant amounts)—provoke strong immune reactions? The human gut has a complex system to control the continuous onslaught of antigenic substances derived from food, microorganisms, and toxins.[3] It has been suggested that absorption of such compounds could underlie the pathogenesis of disease in the gut and in distant sites such as the liver and spleen.[4]

Ayurveda stresses prevention of the formation and accumulation of *Ama* through appropriate diet and the use of therapies to improve digestion. It also considers various dietary factors that trigger or eliminate certain diseases.[5] That is why Ayurveda places emphasis on diet according to the patient's psychosomatic constitution *(Prakriti),* time of day *(Dincharya),* and season *(Ritucharya).* For example, a person with the *Pit* psychosomatic constitution should not eat foods that are hot, pungent, or spicy at noon in the summer because this tends to increase diseases of inflammation.

Ayurveda prescribes specific diets for several psychiatric disorders. Recent research supports this approach. Brain levels of the neurotransmitters 5-hydroxytryptamine, catecholamine, and acetylcholine have been found to be influenced by dietary constituents. Consequently, it has been suggested that normal brain functions and mental disease can be altered by diet.[6] Recent exciting developments include the successful treatment of mental depression with neurotransmitter precursors.[7,8]

Ayurveda also prescribes certain diets *(Pathya)* during drug therapies because dietary constituents are believed to influence drug action.

BOX 33.3 Host- and Drug-Related Factors

Drug Factors	
Prakriti	Constitution of the drug
Guna	Properties
Prabhava	Activity (potency)
Desh	Place
Ritu	Season
Grahan	Storage
Nihit	Transport
Sanskar	Refinement
Matra	Dose
Sanyog	Combination
Adhishthan	Ability to reach site of action
Host Factors	
Prakriti	Constitution of host
Vayam	Age
Vikriti	Pathological condition
Sar	System strength
Satamya	Tolerability
Satva	Psychological state
Ahar Shakti	Digestive capacity
Vyayam Shakti	Exercise tolerance
Balam	Strength of host

Individualization of Medicinal Therapy

Medicinal therapy is highly individualized in Ayurveda.[9] The choice and dose of medicine are influenced not only by disease but by the individual's constitution and the environmental conditions likely to affect that individual's *Doshas.*

For example, *Piper rotudum* (black pepper) and *Zingiber officinale* (ginger), which increase *Pit* (increasing stomach acid and pepsin secretion), are used cautiously in individuals with a *Pit* constitution. Another example is in the treatment of the patient with hypertension. Ayurveda prescribes *Terminalia chebula* for the treatment of hypertensive patients who have *Vat Prakriti,* whereas for the patient with *Pit Prakriti,* one uses *Terminalia arjuna.*

In the *Vimanastrana,* Charak presented an interesting discussion of host- and drug-related factors that help in the determination of the drug and dosage (Box 33.3).

Ayurveda also emphasizes proper timing for the administration of medicines. Considering that chronopharmacology (the study of the timing of drug administration in relation to physiological function) has only recently been developed as a branch of modern therapeutics, it seems remarkable that such astute observations about the timing of medicaments were made so many centuries ago.

Pharmacy in Ayurveda

In Ayurveda, pharmacy is highly developed. Almost 70 books contain more than 8000 recipes for the preparation of different medicines, most of which are derived from minerals and plants. Many formulations are available, including simple distillates *(Arka),* decoctions *(Kwatha),* tinctures *(Avleha),* powders *(Churna),* pills (*Vati, Goti,* and

Modak), fermented products *(Asva),* and medicated oils (*Taila* and *Ghrita*). The oil preparations are particularly useful because they help target the sites of action.

Detailed descriptions of the methods are recommended to ensure a medicine is suitable for human use.[10] One pharmaceutic technique, *Samskara* ("refinement"), is known as *Shudhi* ("purification"), a process that eliminates the toxicity of some minerals and plants. Another practice is the administration of drugs in combination *(Samyoga)* to reduce toxicity and increase efficacy.

RESEARCH

Considerable modern research has proven the efficacy of Ayurvedic herbal preparations, and research has now moved to elucidating their mechanisms and sites of action.[11] Recent studies demonstrated probable genomic bases for metabolic differences as predicted by *Prakriti*. This genetic variant may provide newer approaches to pharmacogenomics. Extensive studies on *Prakriti* subtypes and genome mapping, especially of other important drug-metabolizing enzyme polymorphisms (e.g., CYP2C19, CYP2D6, CYP2C9, CYP3A4, TPMT), would be useful to understand a possible *Prakriti* pharmacogenomics relationship to its correlating genotype, *Prakriti,* and drug metabolism.[12]

Curcumin, the active principle of *Curcuma longa,* has been found to exert a powerful anti-inflammatory effect by blocking many inflammatory pathways, reversing insulin resistance, and reversing cancer by repairing defective genes.[13] Further, it has been shown to selectively inhibit platelet prostaglandin production while sparing vascular endothelial prostaglandin synthesis.

Many plant preparations have been used to strengthen general host resistance. *Rasayna, Jeevaniya,* and *Balya* increase tissue resistance to disease, a concept similar to "prohost therapy" as put forward by Hadden.[14] Prohost therapy claims to augment cellular responses and, consequently, ameliorate disease states.[15]

A paper published in *Phytotherapy Research* in May 2011 found that aqueous extract of *Withania somnifera* root had an ability to inhibit the formation of mature amyloid-β fibrils in vitro. Amyloid plaques in the brain cause Alzheimer's disease. This is an exciting discovery and may help many people prevent Alzheimer's disease.[16] Perhaps most exciting, however, is the current research demonstrating the efficacy of Ayurvedic herbal preparations in conditions for which modern medicine has had limited or no success. For example, animal studies showed that *Withania somnifera (Ashwagandha)* can reverse the immunosuppression of cyclophosphamide, azathioprine, and prednisolone, and a 50% alcoholic extract of *Phyllanthus emblica* protects the liver from paracetamol.[17,18] Recent human studies found that patients with acne vulgaris demonstrated substantial improvement, with no significant side effects, after using *Sunder vati* compared with placebo. Interestingly, the study found three other Ayurvedic formulas ineffective. Patients with osteoarthritis experienced substantial, highly significant improvement in pain and disability with no significant side effects (however, the radiological findings did not improve).[19]

AYURVEDIC AND MODERN MEDICINE

In evaluating Ayurvedic medicine by modern standards, one encounters a number of difficulties. First, there is a wide variation in the quantity of pharmacologically active substances in plants. In addition, many findings are more subjective than objective. The modern scientist has difficulty recognizing subjective experiences because no reliable methodology has been developed to measure and reproduce such experiences. Yet totally objective experience, which completely disregards the subjective, may be wrong and even dangerous.

There is no such thing as complete objectivity. What people claim as such is merely agreement among many minds. Subjective experience is limited. Senses vary in ability, and reality for one is unreality for another. When using the tools of quantitative, technical science to describe biological and living systems phenomena, one soon encounters limits. Artificial distinctions must be imposed to reduce variables and interpret nonlinear events intelligibly.

Science has often confused the map for the actual reality. Take the example of color vision in bees. The eye of a bee is more sensitive to blue, violet, and ultraviolet light, whereas receptors in the human eye more readily detect red, green, and blue wavelengths. Thus bees are nearly blind to red light, and humans are quite blind to ultraviolet light. These differing characteristics result in members of each species forming a completely different perception of the same object. Color, rather than being a part of the "reality" of a perceived object, is an expression of sensory apparatus, determined by each species' or individual's unique pattern of interneural connections. Even more interesting is the fact that, within the same species, perception may vary considerably.

Ayurvedic philosophy may strike the contemporary reader as unnecessarily complex for the conceptual territory it addresses. However, it is actually quite succinct and relevant to modern life. Its precepts have influenced many systems of healing, including naturopathic medicine, through several paths of its root traditions. It emerged alongside systems known to early Persians, Greeks, and the Chinese. Modern medicine is itself a distillation of these same rich traditions. When one compares Ayurvedic concepts with those of preindustrial Europe, much similarity becomes apparent.

Ayurgenomics

Understanding Ayurvedic Insights Toward Individualized Genomic Medicine

Individualized medicine is the core essence of Ayurveda. The *Tridosha* system in Ayurveda is used to guide the individualization of treatments. The Ayurvedic physicians observe the patient's body type, mental activity, emotional tendencies, and physiological functions to make an assessment of the unique combination of *Tridosha,* called *Prakriti.* The *Prakriti* of the individual is like the expression of the individual's genome today.

A unique, integrative "Ayurgenomics" medicine approach can be used to reinforce the essence of Ayurveda with the modern science of genomics. Ayurveda follows an approach that has noteworthy parallels with modern-day personalized genomic medicine advances in the understanding and management of health and disease. Every individual is born with a specific proportion of *Tridosha,* which is partially determined genetically but also affected by the environment during fetal development. In Ayurvedic medicine, diseases are believed to originate based on the imbalances in *Doshas,* and the primary goal of Ayurveda is to make sure that the *Doshas* maintain their homeostatic state.

The individuation explained by *Dosha* balance is a precursor to the modern genomic individuation. Even when the modern technology did not exist, ancient Vedic sages used the power of observation to determine the constitution of an individual. The Vedic sages gave complete attention to the patient by interviewing the patient and examining the patient. Old Ayurvedic texts give an immense amount of details about symptoms, disease progression, and physical examination, and these details were translated into the language of *Tridosha.* This knowledge informs the practitioner about the genomic individuality (i.e., *Prakriti*) of the person. In the contemporary world, the *Prakriti* or constitution of the individual is the sum expression of the individual's genome. This individual genomic signature is expressed by the

individual's symptoms, likes and dislikes, mental and emotional tendencies, and modern physiological measures.

Recently, the field of Ayurgenomics has emerged to test the validation of the works of traditional Ayurvedic physicians. In one study, researchers performed genetic testing of individuals with three unique constitutions: *Vat, Pit,* or *Kaph.*[20] The genetic study was matched with the constitution, and genetic patterns were observed. The *Vat* individuals had more active transport components. The *Pit* individuals had greater activity and responsiveness of blood components such as various blood cells, platelets, and immune cells. The *Kaph* individuals had a larger share of lipid components, such as cholesterol, triglycerides, and structural proteins. These results clearly demonstrated the qualities of *Doshas* seen in Ayurvedic texts: *Vat*—movement, *Pit*—metabolism, *Kaph*—structure and stability.

In another investigation, the constitutional expression of individuals from distinct climates was tested.[21] The scientists looked at the *EGLN1* gene, an oxygen sensor that activates other genes in the body to adapt to low oxygen concentrations. It was hypothesized that expression of the *EGLN1* gene would be greater in high-altitude populations. Because this gene is linked to adapting and oxygen metabolism, it was also thought that this population might have more *Pit* individuals. They found both hypotheses to be true: individuals in higher altitudes had greater expression of the *EGLN1* gene, and there was a higher number of *Pit* individuals in this population.

Another Ayurgenomics research study looked at rheumatoid arthritis.[22] Rheumatoid arthritis involves inflammation and joint pain. Hence, there is an increased activation of inflammatory pathways. According to Ayurveda, the fundamental characteristics between *Vat*-dominant and *Pit*-dominant individuals suffering from rheumatoid arthritis are unique. The study reaffirms constitutional-based individuality. The *Vat* individuals had greater expression of inflammatory markers, interleukin-1-beta (IL-1β) and tumor necrosis factor-alpha (TNF-α), whereas the *Pit* individuals had greater expression of oxidative stress markers SOD3 and PON1. *Kaph* individuals did not demonstrate either inflammatory or oxidative pathways. Overall, Ayurgenomics established some underlying mechanisms of the destructive process of rheumatoid arthritis based on *Prakriti.*

The idea of *Prakriti* in Ayurveda and its correlation with genomics was observed more than a decade ago. Some studies did find the relationship between *Prakriti* classification with genetic information and the link of single-nucleotide polymorphisms (SNPs) in *HLA-DRB1, CYP2C19, EGLN1,* genes related to inflammatory and oxidative stress, cardiovascular disease markers for various blood cells, DNA methylation alterations, and risk factors for cardiovascular and inflammatory diseases. Perhaps these studies have demonstrated the association of specific genes with the phenotype of a particular *Prakriti,* but the first attempt to organize the *Prakritis* using genome-wide SNP markers and find a scientific basis for *Prakriti* classification was made in 2015.[23]

The investigators performed genome-wide SNP analysis of 262 male individuals belonging to three different *Prakritis.* They discovered that 52 SNPs were significantly different between *Prakritis.* The scientists also analyzed 297 Indian population samples with known ancestry. They found out that the *PGM1* gene correlates with the phenotype of *Pit.* We know that in Ayurveda, characteristics of Pitta include digestion, metabolism, and energy production. Interestingly, the *PGM1* gene is in the center of many metabolic pathways, such as glycolysis and gluconeogenesis. Research shows that the function of the gene directly correlates with the role of *Pit* in metabolism as described in ancient Ayurvedic literature, *Charak Samhita*. This provides evidence that the phenotypic classification of Ayurveda has a genetic basis, and its *Prakriti*-based practice complements personalized medicine.

SUMMARY

Only some glimpses of Ayurveda are presented here. This ancient system of medicine, developed over centuries, has a consistent and logical framework. Ayurveda gives detailed instructions for the preservation of health and the treatment of disease. The ancient system faced a setback when modern medicine subjected all knowledge to experimental and statistical verification, which, although useful, is limited by the tools available and the perceptions underlying the questions asked. Furthermore, modern medicine finds human bodies to have no variability within studies, creating the inability to study a pattern in differences in body types. Now that considerable knowledge of cellular physiology has accumulated and more sensitive modern biomedical research tools exist, we may be able to evaluate the concepts of Ayurveda more effectively. Ayurgenomics is already being practiced in Ayurvedic clinics all over the globe, filling in gaps present in modern medical science and creating a platform for integrative medicine.

Botanical Medicine—A Modern Perspective

Michael T. Murray, ND

OUTLINE

INTRODUCTION

The term *herb* refers to a plant used for medicinal purposes. Are herbs effective medicinal agents, or is their use merely a reflection of folklore, outdated theories, and myth? To the uninformed, herbs are generally thought of as ineffective medicines used before the advent of more effective synthetic drugs. To others, herbs are simply sources of compounds to isolate and then market as drugs. However, to some, herbs and crude plant extracts are effective medicines to be respected and appreciated.

For many people of the world, it is still the case that herbal medicines are the only therapeutic agents available. In the late 1990s, the World Health Organization estimated that about 80% of the world's population relies on herbs for primary healthcare needs.[1] This widespread use of herbal medicines is not restricted to developing countries; it has been estimated that 70% of all medical doctors in France and Germany regularly prescribe herbal preparations. And there is no question that herbal medicine is also flourishing in the United States.

Although herbal medicine has existed since the dawn of time, knowledge of how plants affect human physiology remains largely unexplored. Many individuals formulate their view of herbal medicine based on opinion, philosophy, and ideology. This chapter seeks to facilitate an informed view of herbal medicine. The past and future of herbal medicines are discussed. We believe that the continued evolution of the tradition of herbal medicine can only be accomplished within the context of continued scientific investigation.

Throughout the world, but especially in Europe, the United States, Canada, Australia, and Japan, a tremendous renaissance in the use and appreciation of herbal medicine occurred in the latter part of the 20th century. For example, in the United States, the sale of herbal products skyrocketed from $200 million in 1988 to more than $3.5 billion in 1997 before steadily growing to more than $8 billion in sales in 2017.[2]

The rebirth of herbal medicine, especially in developed countries, is largely based on a renewed interest by the public and scientific researchers. During the past 30 to 40 years, there has been a huge increase in scientific information concerning plants, crude plant extracts, and various substances from plants as medicinal agents. For example, a PubMed search of the term "herbal medicine" yielded more than 38,000 hits in 2018. Combine the term with "clinical trial" and the number is more than 2600. There had been more than 350 clinical trials with *Ginkgo biloba* alone as of 2018.

THE ROLE OF HERBS IN MODERN PHARMACY

Plants still play a major role in modern pharmacy. For the past 70 years, about 25% of all prescription drugs in the United States and other developed countries have contained active constituents obtained from plants. Digoxin, codeine, colchicine, morphine, vincristine, and yohimbine are some popular examples (see Table 34.1 for more). Many over-the-counter (OTC) preparations are also composed of plant compounds. Pharmacognosy, the study of natural drugs and their constituents, plays a major role in current drug development. Unfortunately, the standard path of the approval of a drug is a process that typically takes 10 to 18 years at a total cost somewhere between $350 million and $5 billion.

Because a plant cannot be patented, plants are screened for biological activity, and then the so-called "active" constituents (compounds) are isolated and typically chemically modified to produce unique substances. If the compound is powerful enough, the drug company begins the process to procure U.S. Food and Drug Administration (FDA) approval. Of 520 new drugs approved by the FDA or comparable entities in developed countries, 30 came directly from natural product sources, and another 173 were either semisynthetic from a natural source or modeled after a naturally occurring compound.[1]

Because of the expense and lack of patent protection, few clinical evaluations were done before 1980 on whole plants or crude plant extracts as medicinal agents per se. A key factor in contributing to more research into herbal medicines after this time was the development

in Europe of regulatory policies and practices that made it economically feasible for companies to do research. For example, in Germany, beginning in 1978, regulations were instituted that allowed herbal products to be marketed with drug claims if they are proven to be safe and effective through a special monograph system.[3] A special commission (Commission E) authored the initial series of 400 monographs on herbal products similar to the over-the-counter (OTC) monographs in the United States. Whether the herbal product was made available by prescription or OTC was based on its application and safety of use based on its monograph. If a manufacturer of an herbal product meets the quality requirements of the monograph or produces additional evidence of safety and effectiveness, which can include data from existing literature, anecdotal information from practicing physicians, and limited clinical studies, it is viewed as safe and effective. Herbal products sold in pharmacies are also reimbursed by insurance if they are prescribed by a physician.

In contrast, in the United States, extracts identical to those approved in Germany and other countries as drugs are available as "dietary supplements," and manufacturers are prohibited from making any therapeutic claims for their products. No medicinal claims are allowed for most herbal products in the United States because the FDA requires the same standard of absolute proof as required for new drugs. For decades, the FDA has rejected the idea of establishing an independent "expert advisory panel" for the development of monographs similar to Germany's Commission E monographs, as well as other ideas to create a suitable framework for the marketing of herbal products in the United States.

The monograph system in Germany allows companies to market their products according to the guidelines of Commission E. With the ability to make appropriate claims, many companies have achieved success with their products, enabling them to fund the necessary research to gain greater acceptance within mainstream, conventional medicine. The use of St. John's wort extract in the treatment of depression is a perfect case in point to illustrate how Commission E monographs led to significant documentation of the efficacy of plants with a long history of folk use for depression.

When the Commission E monograph for St. John's wort came out in 1984, it identified the constituent hypericin as the active constituent and permitted the medicinal use of the herb (in average doses of 2 to 4 g of herb, or 0.2 to1 mg total hypericin) for depression, anxiety, or nervous excitement.

Originally, it was thought that hypericin acted as an inhibitor of the enzyme monoamine oxidase, thereby resulting in the increase of central nervous system monoamines such as serotonin and dopamine. However, it was later shown that St. John's wort does not inhibit monoamine oxidase in vivo.[4] The antidepressant activities appear to be related more to serotonin-reuptake inhibition as occurs with the drugs Prozac, Paxil, and Zoloft; modulation of neuroendocrine function; downregulation of β-adrenergic receptors; and upregulation of serotonin receptors in the brain areas that are implicated in depression.[4,5] In addition, it appears that although hypericin is an important marker, other compounds such as flavonoids are also thought to play a major role in the pharmacology of St. John's wort. The key point here is that the further understanding and documentation of the clinical effectiveness of St. John's wort extract was largely the direct result of a commercial incentive created by the existence of Commission E.[6]

Science Fueled the "Herbal Renaissance"

Improvements in analytic techniques and modern pharmacology gave researchers the tools and understanding necessary to better evaluate herbal medicines. Improvements in plant cultivation techniques and the quality of herbal extracts (quality control and standardization) have also led to the development of some effective plant medicines. These advances have created a renaissance in the appreciation and use of herbal medicine. It seems that science and medicine have finally advanced to a level where nature can be appreciated rather than discounted. The scientific investigation of plant medicines is replacing some of the mystery and romance of herbalism with a greater understanding of the ways in which herbs work. Thirty years ago, it was impossible to determine exactly how herbs promoted their healing effects because analytic science had not advanced to a sufficient level of sophistication. This point is well illustrated by the fact that the main mechanism of action responsible for aspirin's anti-inflammatory effect was not understood until the early 1970s, and its mechanism of action for pain relief has yet to be fully understood.

Because the mechanism of therapeutic action of a particular herb or its constituents could not be fully elicited, many effective plant medicines were erroneously labeled as possessing no pharmacological activity. Now, researchers equipped with greater understanding and more sophisticated technology are rediscovering the wonder of plants as medicinal agents. Much of the increased understanding is, interestingly, a result of synthetic drug research.

For example, one of the modern classes of drugs is calcium channel blockers. These agents block the entry of calcium into smooth muscle cells, thereby inhibiting contraction and promoting muscular relaxation. Calcium-channel-blocking drugs are currently being used in the treatment of high blood pressure, angina, asthma, and other conditions associated with smooth muscle contraction. They represent a highly evolved stage of modern drug pharmacy. After calcium channel drugs became better understood, it was discovered that many herbs contain components that possess calcium-channel-blocking activity. In most cases, the historical use of these herbs corresponded to their calcium-channel-blocking activity.

In addition to possessing currently understood pharmacological activity, many herbs possess pharmacological actions that are not consistent with modern pharmacological understanding. For example, an herb often appears to affect homeostatic control mechanisms to aid normalization of many bodily processes. When there is a hyperstate, the herb has a lowering effect, and when there is a hypostate, it has a heightening effect. This action is totally baffling to orthodox pharmacologists but not to experienced herbalists, who have used terms such as *alterative, amphoteric, adaptogen,* or *tonic* to describe this effect.

The Advantages of Herbal Medicines

In general, herbal preparations are thought to have three major advantages: lower cost, fewer side effects, and medicinal effects that tend to normalize physiological function. When used most effectively, the mechanism of action of an herb often corrects the underlying cause of a disorder. In contrast, synthetic drugs are often designed to alleviate the symptom or effect without addressing the underlying cause. They generally act as specific agonists or inhibitors of enzymes or receptor sites. Interestingly, research has often shown that for many plants, the whole plant or crude extract is much more effective than isolated constituents. In many instances, multiple components produce multiple pharmacological actions. This is a key concept because, in general, most drugs poison a specific enzyme. In contrast, herbal medicines, with their multiple constituents, work broadly, modulating multiple enzyme systems.

Herbal medicine will certainly play a major role in future medicine. As modern medicine gains more knowledge and understanding about health and disease, it is adopting therapies that are more natural and less toxic. Lifestyle modification, stress reduction, exercise, meditation, dietary changes, and many other traditional naturopathic therapies are becoming much more popular in standard medical circles. This illustrates the paradigm shift that is occurring in medicine.

With the continuing advancement in science and technology, there has been a great improvement in the quality of herbal medicines available and in the understanding of their optimal clinical use. Improvements in cultivation techniques coupled with improvements in quality control and standardization of potency will continue to increase the effectiveness of herbal medicines.

THE STUDY OF HERBAL MEDICINE

The study of herbal medicine spans the breadth of pharmacology, the study of the history, source, physical and chemical properties, mechanisms of action, absorption, distribution, biotransformation, excretion, and therapeutic uses of "drugs." In many respects, the pharmacological investigation of herbal medicine is just beginning. This textbook is replete with examples of herbs whose historical use is being justified by new investigations into their pharmacology.

The History of Herbal Medicine

The history of the use of plants as medicines is full of interesting stories and fascinating facts. The evolution that occurred in herbal medicine over the centuries is only beginning to be recognized as more natural medicines gain acceptance. Interestingly, this acceptance is largely a result of increased scientific investigation.

A trend exists toward using natural substances, including compounds found in the human body, such as interferon, interleukin, insulin, and human growth hormone, as well as foods, food components, herbs, and herbal compounds. More and more researchers are discovering the tremendous healing properties of these natural compounds and their advantages over synthetic medicines and surgery in the treatment of many health conditions. Through these scientific investigations, a trend toward natural medicine is emerging. To better appreciate this evolutionary trend, this section presents some of the historical aspects of herbal medicine. Much of the following discussion is derived from Barbara Griggs's *Green Pharmacy: A History of Herbal Medicine.*[7]

In the Beginning

Plants have been used as medicines since the dawn of animal life. The initial use of plants as medicines by humans is thought to have been a result of "instinctive" dowsing. Animals in the wild still provide evidence that this phenomenon occurs. Animals, with a few notable exceptions, eat plants that heal them and avoid plants that do them harm. Presumably humans also possessed this instinct at one time.

As civilizations developed, medicine men and women were responsible for transmitting the information on herbs to their successors. Before the advent of written language, this information was handed down by verbal and experiential means.

Besides instinctive dowsing, it was commonly believed that plants had been signed by the "creator" with some visible or other clue that would indicate its therapeutic use. This concept is commonly referred to as the "doctrine of signatures." Common examples of this doctrine are the following:

- *Panax ginseng* (ginseng): its roots bear a strong resemblance to a human figure, and its general use is as a tonic.
- *Caulophyllum thalictroides* (blue cohosh): its branches are arranged like limbs in spasm, indicating its usefulness in the treatment of muscular spasm.
- *Sanguinaria canadensis* (bloodroot): its roots and sap are a beautiful blood color, corresponding to its traditional use as a "blood purifier."
- *Lobelia inflata* (lobelia): its flowers are shaped like a stomach, corresponding to its emetic qualities.
- *Hydrastis canadensis* (goldenseal): its yellow-green root signifies its use in jaundice as well as infectious processes.

All of these uses have been confirmed by recent research.

Materia Medicas

With the development of written language, materia medicas (books containing prescribing information on herbs) became the vehicle of passing information about the medicinal use of herbs to future herbalists. Materia medicas were recorded in ancient China, Babylon, Egypt, India, Greece, and other parts of the world. From these materia medicas, it is quite obvious that herbal medicines were highly respected therapies in ancient times.

Galen's Influence

No system, rules, or classification of Western herbal materia medicas existed until the first century AD, when Galen, the Greek physician who founded experimental physiology, established his system of rules and classification. Galen's classification was based on Hippocratic medicine (i.e., balance of the four humors: blood, yellow and black bile, and phlegm) and a profound belief in a beneficent nature. Although his system is considered seriously flawed in the light of modern medical knowledge, Galen is historically considered to be the founder of scientific herbalism.

Galen evaluated and classified each plant according to its relation to Hippocratic medical theory. Although based initially in Hippocratic principles, Galen constructed his own elaborate, and rigid, system of medicine. Galen's work also signified the beginning of a clear division between the professional physician and the traditional healer. Because only the well educated could understand Galen's system, and even with the best schooling it remained a mystery to many, all challenges to the professional physician were effectively squelched by dogma.

Galen's system dominated European medical thinking for 1500 years. Perhaps if the Roman Empire had continued to flourish, others would have surfaced to develop alternative theories. Instead, Galenical medicine reigned unchallenged throughout the Middle Ages. By the 19th century, the "professional" physician, confident in his supposedly superior knowledge, took Galenical philosophy to an extreme probably never imagined by Galen, by the adoption of bloodletting, purging, and administering exotic medicines. This was in direct contrast to the traditional healer's patient use of traditional herbs and tremendous faith in the healing power of nature.

The Black Plague and Syphilis

Although Galenical medicine dominated the Middle Ages, herbal medicine was still deeply entrenched in European culture. The Black Plague of 1348 may have been the beginning of a change in medical thought because conventional medicine was totally useless. As nearly one third of Europeans died during this plague, the public began to lose faith in Galenical medicine. Nearly 150 years later, another blow was dealt to Galenical medicine, when syphilis became the major medical problem. Unlike the Black Death, patients with syphilis tended to survive longer, giving physicians more time to experiment with treatments. At this time, perhaps the greatest hoax in the history of medicine began. Mercury became the standard medical treatment for syphilis despite the fact that even Galen thought mercury too poisonous to use.

Syphilis did, however, open the door for the use of some new herbs from the Americas. A French physician, Nicholas Monardes, published a comprehensive account of sarsaparilla and several other "new" drugs in the treatment of syphilis in 1574. Many Europeans at the time believed that syphilis had come to Europe from the West Indies with Columbus's sailors, and because there was a general belief that whatever disease was native to a country might be cured by the medicinal

herbs growing in that region, it was only natural for sarsaparilla to become a popular remedy. Because the standard treatment for syphilis was the use of mercury, which often resulted in greater morbidity than did syphilis, sarsaparilla was a welcome alternative. Despite initial excitement, Monardes's sarsaparilla cure eventually lost favor, probably due to other components in the cure; specifically, patients were confined to a warm room for 30 days and for the following 40 days were required to abstain from both wine and sexual intercourse.

Although the public popularity of sarsaparilla waned, it continued to be used in the treatment of syphilis. During military operations in Portugal in 1812, a British Inspector General of Hospitals noted that the Portuguese soldiers suffering from syphilis who used sarsaparilla recovered much faster and more completely than their British counterparts who were treated with mercury.

Sarsaparilla was also used by the Chinese in the treatment of syphilis. Later clinical observations in China would demonstrate, through the use of blood tests, that sarsaparilla is effective in about 90% of cases of acute syphilis and 50% of cases of chronic syphilis.

Although sarsaparilla was clearly more beneficial than mercury in the treatment of syphilis, mercury was the standard medical treatment of choice for more than four and a half centuries. Some historians have stated that "the use of mercury in the treatment of syphilis may have been the most colossal hoax ever perpetrated" in the history of medicine. Mercury represented a new kind of medicine, one formulated and prepared in a laboratory using the new techniques of chemistry. It helped prepare the way for future synthetic and mineral drugs at the expense of herbal medicines.

Challenges to Galenical Medicine

The 1500s also saw a strong challenge to Galenical medicine from within the traditional circles. Specifically, Paracelsus, an alchemist who believed strongly in the doctrine of signatures, was responsible for founding modern pharmaceutical medicine. Paracelsus is probably most remembered for the development of laudanum (tincture of opium). After Paracelsus, Galenical preparations and treatments fell greatly out of favor.

In public circles, herbal medicine was regaining some respect as well. In the early 1600s, Culpepper, an English pharmacist, published his book *The English Physician.* Instead of requiring patients to purchase expensive exotic or imported drugs, Culpepper recommended the herbs his clients and readers had growing in their own backyards. Although Culpepper's herbal philosophy is based on astrological rationalizations, it reinforced a strong English tradition of domestic herbal medicine. This came at a time when professional physicians were beginning to become contemptuous of herbal medicine.

Meanwhile, in the Americas during the 1600s and 1700s, herbs used traditionally by Native Americans were becoming quite popular, especially in the treatment of malaria and scurvy. Herbal medicine continued to gain even greater respect in the late 1700s, as exemplified by English physician Withering's classic description of digitalis. However, mercury, bleeding, and purging were still the "standard" medical treatments, epitomized by George Washington's death from complications incurred during treatment of a sore throat (i.e., he was bled to death).

The Thomsonian and Eclectic Movements

During the early 1800s, standard medicine may have been ready to reconsider traditional herbal remedies, but then came the Thomsonian movement. Samuel Thomson (1769 to 1843) patented a system of herbal medicine that, in 1839, claimed more than 3 million faithful followers. Although Thomson brought back to medicine the vitalistic Hippocratic idea of *vis medicatrix naturae* and gained widespread public support for the use of herbal medicine, the Thomsonian movement was probably detrimental to medical reform.

Thomsonians became locked in prejudice and dogma and insisted that all medical knowledge was complete and could be found in Thomson's works. These and other claims roused scorn, indignation, rage, and resentment in the average North American doctor. Frequently based on purging through the use of herbal emetics, Thomson's treatments were often as harsh as the standard treatments of the times (for further discussion, see Chapter 4).

During the 1800s, the eclectic movement attempted to bridge the gaps among standard medical thought, Thomsonianism, and traditional herbal medicines. Rather than attack the existing medical system, the eclectic movement sought to bring about reform by educating physicians about the use of herbal medicines. Several eclectic medical colleges were established, and for a while it appeared that the eclectic movement was making headway in its attempt to reform the medical system from within.

The movement eventually failed, however. Several factors were probably responsible for this: a split in the ranks, which diluted the movement; harsh measures like mercury, calomel, and bloodletting were finally discarded by the conventional professional physician, due to a decrease in infectious disease as a result of improved sanitation and hygiene; and perhaps most important, the failure to establish and sustain quality medical schools.

The Flexner report on medical education in 1910 spelled doom for the eclectics; by 1920, seven of the eight schools that had existed before the report closed, with the last school closing in 1938. Meanwhile, the standard medical schools, aided by the Rockefeller Foundation, flourished, promoting the growth of the modern pharmaceutical industry and the current near-monopoly of the medical profession.

The Growth of the Pharmaceutical Industry

Because a plant cannot be patented, little research was done before the latter part of the 20th century. Instead, pharmaceutical firms and researchers screened plants for biological activity, and then the so-called active constituents were isolated and chemically modified to produce unique, patentable compounds. Much to the dismay of the researchers was the discovery that in many instances, the isolated constituents were less biologically active than the crude herb. Because the crude herb provided no economic reward to the American pharmaceutical firm, the crude herb or extract never reached the marketplace. In contrast, European policies on herbal medicines made it economically feasible for companies to research and develop phytopharmaceuticals. The policies in the United States contributed to the tremendous growth of the pharmaceutical industry and loss of appreciation and respect for herbal medicine.

The herbal industry further compounded the problem by failing to provide quality herbal products or take advantage of technological advances that allowed for the standardization of chemical constituents. The herb that best exemplifies the failure to adopt standardization techniques is digitalis. One batch of crude digitalis might have a low level of active constituents, making the crude herb ineffective, whereas the next batch might be unusually high in active constituents, resulting in toxicity or even death when standard amounts are used. The lack of standardization made it easier for U.S. pharmaceutical firms to rationalize their economic need to isolate, purify, and chemically modify the active constituents of digitalis so they could market these compounds as drugs. The problem with using the pure active constituent is that the safe dosage range is smaller: digitalis toxicity and death have increased dramatically as a result of purification. Toxicity was less of a factor when using the crude herb because overconsumption of potentially toxic doses resulted in vomiting or diarrhea, thus avoiding the severe heart disturbance and death that now occur with pure digitalis cardiac glycoside drugs.

Fortunately, several European and Asian pharmaceutical firms began specializing in phytopharmaceuticals in the latter half of the 20th century. These companies have played a prominent role in researching, developing, and promoting herbal medicines.

Research is demonstrating that crude extracts often have greater therapeutic benefit than the isolated "active" constituent. This occurrence has been long known in other parts of the world, but in this country, isolated plant drugs are still thought of as having the greatest therapeutic effect. This myth is gradually being eroded as our knowledge of herbal medicines increases.

If current standardization techniques had been available earlier in this century, it is possible that many current prescription drugs would be herbal extracts instead of isolated and modified active constituents or synthetic chemicals.

IMPORTANT NORTH AMERICAN HERBAL MEDICINE ORGANIZATIONS

The American Botanical Council

One of the critical entities in promoting the responsible use of botanical medicine in the United States has been the American Botanical Council (ABC), an independent, nonprofit research and education organization dedicated to providing accurate and reliable information on botanical medicine for consumers, health care practitioners, researchers, educators, industry, and the media. Founded by Mark Blumenthal in 1988, the ABC has a robust website and publishes *HerbalGram,* a peer-reviewed quarterly journal, along with providing other useful publications and services. For example, Blumenthal and the ABC were largely responsible for translating the entire Commission E monographs into English, and the complete expanded version is now provided on the ABC website.[8] ABC is also the publisher of four books, including *The ABC Clinical Guide to Herbs,* a continuing education and reference book, which contains extensive monographs on the safety and efficacy of 30 popular herbs.

In addition, the ABC provides proactive, science-based information about herbal medicine to the media through its Media Education program. The ABC also provides an internship program for students of pharmacy and dietetics, as well as other training and certification programs. For more information, go to http://www.herbalgram.org.

American Herbal Pharmacopoeia

The American Herbal Pharmacopoeia (AHP) was founded in 1995 by herbalist Roy Upton, with unrestricted funding initially provided by Planetary Herbals and now by many organizations. The AHP produces critically reviewed and scientifically validated monographs that provide an internationally recognized standard for herbal medicine identification, adulteration recognition, extraction, and quality control. These standards help ensure the identity, purity, and quality of botanical raw materials and manufactured products. Each monograph also presents a complete and critical review of the traditional and scientific literature regarding the efficacy and safety of herbal medicines. More information can be found at http://www.herbal-ahp.org.

FINAL COMMENTS

Although the future looks extremely promising for herbal medicine, its growth and continued success will ultimately be determined by the following:

- Continued scientific investigation and clinical research
- Adoption of recognized standards of quality by manufacturers
- Governmental regulations that allow meaningful therapeutic and health claims

TABLE 34.1 Classic Examples of Drugs From Plants With a Correlation to Their Traditional Use

Drug	Clinical Use	Botanical Source
Atropine	Anticholinergic	*Atropa belladonna*
Caffeine	Central nervous system stimulant	*Cola nitida*
Camphor	Rubefacient	*Cinnamomum camphora*
Cocaine	Local anesthetic	*Erythroxylon coca*
Codeine	Analgesic/antitussive	*Papaver somniferum*
Colchicine	Antigout	*Colchicum autumnale*
Digitoxin	Cardiotonic	*Digitalis purpurea*
Digoxin	Cardiotonic	*Digitalis lanata*
Emetine	Amebicide/emetic	*Cephaelis ipecacuanha*
Ephedrine	Sympathomimetic	*Ephedra sinica*
Gossypol	Male contraceptive	*Gossypium* spp.
Hyoscyamine	Anticholinergic	*Hyoscyamus niger*
Kawain	Tranquilizer	*Piper methysticum*
Methoxsalen	Psoriasis/vitiligo	*Ammi majus*
Morphine	Analgesic	*Papaver somniferum*
Noscapine	Antitussive	*Papaver somniferum*
Physostigmine	Cholinesterase inhibitor	*Physostigma venenosum*
Pilocarpine	Parasympathomimetic	*Pilocarpus jaborandi*
Podophyllotoxin	Topical wart remedy	*Podophyllum peltatum*
Quabain	Cardiotonic	*Strophanthus gratus*
Quinine	Antimalarial	*Cinchona ledgeriana*
Reserpine	Antihypertensive	*Rauwolfia serpentine*
Scopolamine	Sedative	*Datura metel*
Sennosides	Laxative	*Cassia* spp.
Theophylline	Bronchodilator	*Camellia sinensis*
Tubocurarine	Muscle relaxant	*Chondrodendron tomentosum*
Yohimbine	Male erectile dysfunction	*Pausinystalia yohimbe*

Environmental Medicine

Joseph E. Pizzorno, ND, and *Walter Crinnion*, BS, ND*

OUTLINE

ENVIRONMENTAL TOXIC LOAD

The 20th century, with its promise of "Better Living Through Chemistry," resulted in a host of chemical toxicant-related illnesses (referred to here as "environmental illnesses"). We are experiencing the relatively new medical diagnoses of sick (closed) building syndrome[1] and multiple chemical sensitivity,[2] both of which are known to be related to overexposure to environmental contaminants. The rates of asthma, allergy, autism spectrum disorder, and attention deficit hyperactivity disorder, as well as childhood brain tumors, obesity, and diabetes, are all skyrocketing in concert with the level of environmental pollution. Indeed, most of the primary chronic, noninfective health problems plaguing our modern world have been linked to the growing environmental burden found in all people. Included in this list are the most common cardiovascular, respiratory, neurological, immunological, and endocrine problems.

This chapter summarizes key aspects of environmental medicine every clinician should know. Clinicians wanting to delve into this important area more deeply will find this topic extensively addressed in *Clinical Environmental Medicine* (Crinnion and Pizzorno, Elsevier, St. Louis, MO, 2018).

The Toxic Burden

The main principle of environmental medicine (EM) is "total load."[3] Many patients want to point to the one chemical exposure predating their illness as *the* compound that made them ill. This approach coincides with the traditional approach of toxicology that focuses on a single toxicant, ignoring the fact that all people have multiple toxicants present. In most cases, the symptom-initiating exposure was merely the one that tipped the individual's total load "over the edge," leading to a health crisis. EM takes into account the possible synergism of the total load of all toxicants and toxins as a causative factor in illness.[4–7]

The U.S. Centers for Disease Control and Prevention (CDC) has been conducting ongoing laboratory assessment of samples gathered in the National Health and Nutrition Examination Survey (NHANES) trial to quantify the total load of xenobiotic compounds present in the average U.S. resident.[8] The overall purpose of this work is to "provide unique exposure information to scientists, physicians, and health officials to help prevent exposure to some environmental chemicals."

The goals of this survey include the following:

- To determine which chemicals are found in the U.S. population and at what concentrations
- For chemicals with known toxicity levels (as defined by the field of toxicology), to determine the prevalence of people with levels that exceed the safe limit (e.g., a blood lead level that is ≥10 mcg/dL)
- To establish reference values that can be used by physicians and scientists to determine whether a person or group has an unusually high exposure—especially helpful to identify population groups that merit further assessment of exposure sources or health effects

Before the CDC's publication of these reports, standard laboratory reference values for these compounds reflected industrial workplace standards. The new CDC values give us, instead, a population-based reference range, allowing identification of those with higher-than-normal burdens of these toxic compounds. To date, samples of urine, blood, and serum collected from the NHANES participants have been assessed for the presence of 246 environmental chemicals or their metabolites. Of these 246 compounds, 120 were ubiquitous enough to have mean values assigned (Table 35.1).

Exposure to these persistent and nonpersistent compounds begins during the fetal stage because they all appear to easily cross the placental barrier.[9] To this maternally transferred burden is added the daily exposures to xenobiotics in the air, food, water, and personal care products. Cord blood samples taken at birth offer an accurate reading of which xenobiotics the fetus is being exposed to. The Environmental Working Group (EWG) tested the cord blood of 10 babies born in US hospitals for the presence of 413 toxic compounds.[10] Of those, 287 were detected in the samples, with an average of 200 of these compounds present for each infant. Table 35.2 shows the compounds that were looked for in the cord blood samples and how many were found.

A number of compounds, including pharmaceutical agents, illegal drugs, heavy metals, and pesticides, have been found in meconium

TABLE 35.1 Ubiquitously Found Toxicants in U.S. NHANES Participants[8]

Compound	No. Tested	No. Found
Acrylamides	2	2
Benzophenone-3 (sunscreen)	2	1
Bisphenol A	1	1
Chlorinated pesticides	16	5
Cotinine, nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) (smoking)	2	2
Dichlorophenol	3	3
Dioxins/furans	17	2
Herbicides	23	2
Metals	26	16
Methyl tert-butyl ether (MTBE)	1	1
Nitrate	1	1
Organophosphate pesticide metabolites	16	4
Parabens	3	3
Perchlorate	1	1
Perfluorinated compounds	12	7
Phthalates	16	12
Polybrominated diphenyl ethers	11	5
Polychlorinated biphenyls (PCBs)	40	33
Polycyclic aromatic hydrocarbons (exhaust)	10	10
Pyrethroid pesticides	5	1
Solvents	28	6
Thiocyanate	1	1
Trihalomethanes (chlorination by-products)	4	2
Triclosan (disinfectant)	1	1

TABLE 35.2 Xenobiotics Found in the Cord Blood of 10 Children Born in U.S. Hospitals[10]

Compound	No. Tested	No. Found	Pollutant Source
Mercury	1	1	Seafood, dental amalgams
Polycyclic aromatic hydrocarbons (PAHs)	18	9	Combustion by-product (from tailpipes and cigarettes)
Polybrominated dioxins and furans (PBDDs/Fs)	12	7	Contaminants in brominated flame retardants
Polychlorinated dioxins and furans (PCDDs/Fs)	17	11	By-products of plastic production (PVC), industrial bleaching, and incineration
Perfluorinated chemicals (PFCs)	12	9	Teflon, Scotchgard, fabric and carpet protectors, food wrap coatings
Chlorinated pesticides	28	21	Maternal transfer, sardines, farmed salmon
Polybrominated diphenyl ethers (PBDEs)	46	32	Flame retardants; high in house dust and farmed salmon
Polychlorinated naphthalenes	70	50	Wood preservatives, varnishes
Polychlorinated biphenyls (PCBs)	209	147	High in farmed salmon and sardines

samples.[11] Included in the meconium toxicant assays were organophosphate pesticide (OP) metabolites that were not looked for in the EWG cord blood study. This is quite a load for each child to start out with, especially because the liver, brain, and endocrine and immune systems are all still developing, and many of these compounds are toxic to those tissues.

Table 35.3 shows a typical report from the CDC. As can be seen, the body load of this common metabolite of neurotoxic OPs has been increasing relentlessly in the general population.[12]

Other Factors Affecting Clinical Impact of Total Load

EM physicians also consider many other factors besides toxicant levels as part of the total load on an individual. Many of these factors will negatively affect the ability of the body to clear these toxicants from the blood or the tissue or to protect itself from the damage caused by these compounds. Such factors include the following:

- **Genetics.** Polymorphisms in liver Phase I and Phase II biotransformation enzymes can reduce the ability of the body to metabolize xenobiotic toxicants.[13]
- **Nutrient deficiencies.** Deficiencies of nutrients needed for biotransformation (Phases I and II), excretion (Phase III), and protection against toxicant damage can result in reduced clearance and increased oxidative damage.[14]
- **Dietary choices.** The amounts and ratios of proteins, fats, and carbohydrates can either enhance or inhibit the clearance of toxicants from the bloodstream.[15]
- **Emotional/mental/spiritual stressors.** Stresses from family, jobs, society, relationships, and other sources can directly affect health, toxin clearance, and clinical reaction to environmental toxicants.[16]
- **Lifestyle.** Daily choices can have a direct bearing on pollutant exposures and how well the body responds to its toxic burden. This includes the amount of sleep, exercise, and leisure time one gets.
- **Overall health and wellness.**
- **Infections, disease, organ function.** The health of organs, tissues, and cells has a profound influence on the ability to clear toxicants efficiently[17] and to resist toxic damage. The presence of pathogenic organisms that release their own toxins can be a decisive contributor to the total load.
- **Microbiome.** Especially if endotoxicity is present.
- **Electromagnetic field (EMF) exposure.**

Sources of Environmental Toxins

- Maternal-fetal transfer
- Air, indoor and outdoor
- Food
- Personal care products
- Water

In the previous section, the EWG newborn study[10] highlighted the fact that mothers unwittingly pass a host of toxic compounds to their children during gestation. After birth, the toxic exposures primarily come from indoor air (especially in one's residence) and the food that is consumed. The U.S. Environmental Protection Agency did a number of total exposure assessment methodology studies in the 1980s,

TABLE 35.3 Urinary Dimethylphosphate (DMP) (1999–2008): Metabolite of Several Organophosphorus Insecticides, Geometrical Mean and Selected Percentiles of Urine Concentrations (in µg/L) for the U.S. Population from the National Health and Nutrition Examination Survey

Categories	Survey Years	Geometrical mean (95% confidence interval [CI])	50th Percentile (95% CI)	75th Percentile (95% CI)	90th Percentile (95% CI)	95th Percentile (95% CI)	Sample Size

LOD, Limit of detection; *<LOD,* less than the limit of detection, which may vary for some chemicals by year and by individual sample.
The LOD for survey years 1999–2000, 2001–2002, 2003–2004, 2005–2006, and 2007–2008 was 0.58, 0.5, 0.5, 0.47, and 0.47, respectively.
[a]Not calculated: proportion of results below LOD was too high to provide a valid result.

which showed that indoor air typically contained higher levels of environmental chemicals than outdoor air (even in towns with multiple chemical plants). The majority of compounds found in the indoor air were solvents from smoking, dry-cleaned clothes, home furnishings, and home cleaning agents. Pesticide use in the home and garden is also a contributing factor to the burden of pollutants in indoor air and dust.[18,19]

Food is the other route through which the majority of our xenobiotic load is delivered. The U.S. Food and Drug Administration (FDA) has an ongoing Total Diet Study that measures a set list of foods for a variety of environmental contaminants, including heavy metals and plasticizer compounds.[20] The U.S. Department of Agriculture (USDA) has also been doing an ongoing measurement of pesticide residues on the most commonly consumed fruits and vegetables.[21] The data published in this USDA report form the basis for the "dirty dozen" list of the most toxic fruits and vegetables, which are published on the web by the EWG.[22] This listing gives the consumer information on how to avoid produce containing high levels of agricultural chemicals.

High levels of glyphosate residues are found in all Roundup Ready soybeans, whereas no residue was found in organically raised soybeans.[23] All soy protein isolates from genetically modified (GM) soy contained residues of glyphosate and its metabolite in levels up to 2.7 ug/g.[24] Fortunately, no residues were found in soy milk or soybean oil, nor were any found in corn oil, cow's milk, whole-milk powder, or breast milk. However, glyphosate residues have been found in wheat.[25]

High-molecular-weight phthalates (plasticizers) contaminate food based on the length of time food is stored in plastic wrapping, the fat content of the food, and whether or not heat is involved. Microwaving foods in plastic wrap increases phthalate migration.[26] Levels of plasticizers are high in store-wrapped meat, poultry, fish, and cheese, with cheese having the highest level of plasticizers. This is most likely due to the fat content of each of these foods. Contrary to an ongoing Internet myth, freezing food in plastic containers does not increase plastic levels in the food. Plastic levels in unheated plastic-wrapped foods only increased in those foods after they were heated.[27] Exposure to low-molecular-weight phthalates, however, comes primarily from fragrances and other personal care products.[28] On average, the consumption of one canned food item daily increased urinary bisphenol A (BPA) by 24%, and consuming two items increased urinary BPA by 54%.[29] However, not all canned foods increased urinary BPA to the same degree. Consumption of one canned soup increased urinary levels by 229%, canned pasta by 70%, and canned fruits and vegetables by 41%. Consuming one can of soup daily for 5 days has been shown to increase urinary BPA levels by more than 1000%.[30] Data from NHANES 2005–2006 revealed that drinking soda pop and consuming school lunches and meals prepared outside of the home were the most significant sources of BPA.[31]

Butter has been used as a sampling agent to assess the regional and global distribution of polychlorinated biphenyls (PCBs) and other persistent organic pollutants (POPs) around the globe. When butter was sampled for these compounds, the highest levels of PCBs were found in butter from Europe and North America.[32] For individuals living in North America, the greatest source of PCB exposure came from butter and fish.[33] Sardines have the highest concentration of the highly toxic PCBs 138, 153, and 180, followed closely by farmed salmon and then hamburger.[34]

In the 2004–2005 FDA Total Diet Study, 100% of the salmon samples were found to contain PCBs and dichlorodiphenyldichloroethylene (DDE). Currently 50% of world fish consumption comes from aquaculture,[35] and two thirds of all salmon consumed in North America is farmed.[36] Farmed salmon is estimated to be responsible for 97% of dietary POP exposure.[37] POP levels were assessed in 700+ salmon (totaling approximately 2 metric tons of farmed and wild salmon) from around the globe.[38] Fourteen persistent chlorinated compounds were found in significantly higher levels in farmed salmon than in wild salmon. The only compound that did not reach statistical significance was lindane, which was still higher in farmed versus wild salmon. The four compounds with the greatest differences were PCBs, dioxins, Toxaphene, and dieldrin. The PCB content in farmed salmon averaged 42.5 ng/g, whereas the wild Alaskan salmon averaged only 3.2 ng/g. Fish samples from farms off the coast of Washington State and Chile had lower PCB concentrations than salmon farmed by Scotland and the Faroe Islands. POP levels in the fish samples paralleled the POP levels in the fish pellets used in those areas.[39] Another study revealed the average PCB content in farm-raised Atlantic Salmon to be 28 to 38 ng/g, whereas total PCB content in wild Alaskan salmon averaged 2.8 to 13.7 ng/g.[40] The PCBs found in Atlantic salmon, dominated by highly toxic PCBs 138, 153, and 180, are different from those in Alaskan salmon, which have fewer chlorine molecules, have greater water solubility, and are far less toxic to humans. Some changes have been made to the fish pellets that are fed to farmed salmon, resulting in a decrease in some of the POPs present in the fish.[41] Unfortunately, the levels of PCBs 135, 153, and 180 have remained about the same. Farmed shrimp and tilapia, along with cod, are relatively free of the POPs found in farmed salmon, providing less toxic fish alternatives.

Lead and arsenic are common water contaminants that vary by geographical area as well as the age of the water pipes and the type of disinfection used.

Many areas, including much of the United States, have high levels of inorganic arsenic in the groundwater (Fig. 35.1).[42]

Other commonly found water pollutants are the gasoline additive methyl tert-butyl ether (MTBE),[43,44] hexavalent chromium,[45,46] perchlorate (rocket fuel),[47] perfluorocarbons (in areas where industry is using perfluorinated compounds [PFCs]),[48,49] and trichloroethylene (TCE),[50] along with fluoride,[51] trihalomethanes,[52] pesticides, solvents,[53] other industrial chemicals, and pharmaceuticals.[54–56] In contrast, commonly used personal care products contain low-molecular-weight phthalates[57] and parabens.[58]

ADVERSE HEALTH EFFECTS

Numerous studies have been published on the adverse health effects of individual xenobiotic pollutants. Although the areas of impact cover all the systems in the body, this chapter focuses on the documented immunotoxic, neurotoxic, and endocrinotoxic effects of these chemicals.

Immunotoxicity

Of the three major systems affected by xenobiotic burden (immune, neurological, and endocrine), the signs and symptoms of immunotoxicity are very often the first to occur in a patient's history. The classic picture of immunotoxicity is reduced cell-mediated immunity leading to chronic infections (reduced Th1 function), allergies and asthma (increased Th2 function), chemical sensitivity, and autoimmunity (overactive Th2 or Th17 activity).[59] The first manifestation of immunotoxicity often seen in a case history is the development of asthma and allergies. Multiple environmental toxicants are associated with increased incidences of allergic reactivity to the environment and to foods (Table 35.4). The chemicals that lead the way in causing atopic reactions include both OPs and chlorinated pesticides, solvents, and combustion by-products, including tobacco smoke and diesel exhaust.

Cell-Mediated Immune Dysfunction

Unfortunately, many of the xenobiotics that have been ubiquitously found are very potent suppressors of cell-mediated immune

TABLE 35.4 Common Environmental Pollutants Associated with Low Th1 and High Th2

Diesel exhaust particles (DEPs)[60,61]
Polycyclic aromatic hydrocarbons[62]
Particulate matter $(PM)_{2.5}$[63,64]
Lead[65,66]
Mercury (thimerosal and methylmercury)[67,68]
Tributyl tin[69]
Organophosphate pesticides[70]
Dichlorodiphenyltrichloroethane (DDT)/dichlorodiphenyldichloroethylene (DDE)[71]
Broadleaf chlorophenoxy herbicides[72]
Trichloroethylene in drinking water[73]
Polychlorinated biphenyl (PCB) 118[74]
Benzene[75]
Bisphenol A[76]
Bisphenol A (prenatal exposure)[77]
Phthalates[78]
Dioxin[79]
Toluene diisocyanate (from indoor building materials)[80]
Trimellitic anhydride (from indoor building materials)[39]
Perfluorooctanesulfonate (PFOS)[81]
Gas stove in the home[82]
Maternal agricultural work

responses. DDE (the main metabolite of dichlorodiphenyltrichloroethane [DDT]) causes apoptosis of peripheral blood mononuclear cells, resulting in fewer macrophages roaming the body to phagocytize invading pathogens and trigger an immune response.[83,84] Mercury, another commonly found xenobiotic, also increases apoptosis of both monocytes and lymphocytes and reduces the phagocytic ability of the monocytes. It has been demonstrated that workers occupationally exposed to mercury vapor exhibited a diminished capacity to produce both tumor necrosis factor-α (TNF-α) and interleukin-1.[85]

The chemicals produced by combustion, polyaromatic hydrocarbons (PAHs), have been shown to have similar depressing effects on the immune system, including decreased T-cell–dependent antibody response, decreased splenic activity, diminished T-cell effector functions, and suppression of T-cell cytotoxic induction, and they lower the activity of natural killer (NK) cells.[86] PAH exposure results in impaired systemic immunity and increased risk of allergy in humans.[87] The OPs, which are not as biologically persistent as chlorinated pesticides, are also toxic to the immune system. They have been found to cause decreased percentages of CD4 and CD5 cells, increased numbers and percentages of CD26 cells, increased incidence of atopy and antibiotic sensitivity, and high rates of autoimmunity. This elevation in autoimmunity is reflected by high levels of antibodies to smooth muscle, parietal cells, brush border, thyroid, and myelin and elevated antinuclear antibody (ANA).[88]

Allergy and Asthma

Traffic-related air pollutants increase the risk of 1-year-old children becoming allergic to both foods and airborne allergens.[89] As children

continue to be exposed to vehicular exhaust, their risk of developing food allergies by age 4 increases by 230%, far higher than their risk of having pollen allergies by that age (83% increase).[90] Multiple studies have demonstrated a clear association between vehicular exhaust and asthma in both children and adults.[91–93] Children living in areas with denser traffic were 250% more likely to present to a local emergency department with asthma.[94] The spikes of asthmatic symptoms in children rise with daily spikes of vehicular pollution and can persist for up to 2 days after a spike.[95] When exposure to high traffic was combined with mycotoxin (mold contamination) exposure in the home, the risk for asthma went from a 75% increase to 5.85-fold increase.[96]

Diesel vehicles, which are most closely associated with these immunological effects, comprised 70% of all new vehicle sales in France and 50% in the rest of Europe in 2010.[97] In the United States, the sale of diesel vehicles increased by almost 40% in 2010 alone. Diesel exhaust particles (DEPs) interfere with immune system regulation by suppressing nuclear factor kappa B (NF-κB), reducing NF-κB cytokine production.[98] DEPs reduce levels of the antiviral cytokine interferon-gamma (IFN-γ) and IFN-γ mRNA more potently than either dexamethasone or cyclosporine A.[99] DEP also dramatically diminishes NK cell function in human volunteers.[100,101] This reduction of Th1 function, resulting in diminished cell-mediated immunity, is the likely cause for DEP exposure also increasing the rates of respiratory infections.[102–105]

DEP exposure in animals results in increased allergen-specific Th2/TH17 cells in the lungs, which enhances allergic reactivity. Not surprisingly, when mice were exposed to egg albumin *after* DEP exposure, they produced more immunoglobulin E (IgE) to ovalbumin than mice that were not exposed to DEP.[106] In atopic individuals with null GSTT1 genotypes, DEP exposure resulted in even higher interleukin (IL)-5 production.[107] Other studies have confirmed the increase in Th2 cytokine production after DEP exposure and have shown that this exposure leads to increased reactivity to ragweed,[108] cedar pollen,[109] birch pollen,[110] and egg protein.[111] Simultaneous exposure to DEP and allergens leads to a more rapid development of allergic reactivity to those allergens than would occur without DEP presence.[112]

Autoimmunity

In the past 30 years, the incidence and prevalence of autoimmune diseases have been steadily rising.[113] Currently, rheumatic, endocrine, gastrointestinal, and neurological autoimmune diseases are increasing annually at a rate of 7.1%, 6.3%, 6.2%, and 3.7%, respectively. Comparing old rates with current rates, the greatest jumps are found in celiac disease, diabetes 1, and myasthenia gravis. These increases in autoimmunity have been linked to common environmental pollutants. The notion of chemically induced autoimmune states is, of course, not new because many chemicals are known to induce the onset of systemic lupus erythematosus. Some chemicals, like formaldehyde and other volatile organic compounds, may induce tissue-specific autoimmune reactions by acting as haptens.[114] These low-molecular-weight molecules bind to various tissues in the body, making a new antigenic combination. But the elevation of Th2 and Th17 cytokine pictures secondary to pollutant exposure is the clearest pathway for these autoimmune problems. Autoimmunity highlighted by connective tissue destruction is associated with an increased Th17 immune response. Published research has already shown that particulate matter, diesel exhaust, BPA, trichloroethylene, cigarette smoke, PCBs, and paraquat have been linked to conditions of increased Th17. Most of those have also been clearly linked to increased rates of autoimmune disorders. Although the findings have not yet been associated with increasing Th17 levels, women in the NHANES 1999–2004 study with the highest versus lowest levels of hair and blood mercury were either 410% or 232% more likely to have elevated ANA levels, respectively.[115] Individuals with higher levels of mercury exposure are also more likely to have elevated ANA levels.[116,117] In the 2003–2004 NHANES, those persons with the highest levels of PCBs were over four times more likely to have elevated ANA levels than those with a lower PCB burden.[118]

Twelve persons who were residentially exposed to the chlorpyrifos were found to have elevated antibody levels between 1 and 4.5 years after the exposure occurred.[119] The most common autoimmune antibodies found were anti–smooth muscle, causing autoimmune hepatitis (odds ratio [OR] 3.99), and anti–parietal cell, leading to diminished hydrochloric acid production (OR 9.7), along with antithyroid and antimyelin antibodies. Animals exposed simultaneously to mercury and trichloroethylene developed autoimmune hepatitis, whereas those exposed to only one of those two compounds for 8 weeks failed to show this pathology.[120] Four groups of patients with long-term formaldehyde exposure (mobile home dwellers, office workers in closed buildings, persons who had been removed from their formaldehyde exposure for 1 year, and persons with occupational exposure) demonstrated similar autoantibody production.[121] Mobile home dwellers had a 144-fold higher risk of having anti–parietal cell antibodies than nonmobile home dwellers, whereas office workers were 40.5-fold more likely to have anti–parietal cell antibodies. Levels of anti–smooth muscle, antimitochondrial, and anti–brush border were also higher in those with formaldehyde exposure.

Elevated levels of particulate matter $(PM)_{2.5}$-containing traffic-related air pollution have been associated with circulating levels of anti-dsDNA, a classic marker for systemic lupus erythematosus (SLE).[122] Persons exposed to higher levels of $PM_{2.5}$ in Quebec were more likely to have SLE or one of the other autoimmune connective tissue disorders (Sjogren's syndrome, scleroderma, polymyositis, or dermatomyositis).[123] PM_{10}, NO_2, and CO have all been shown to be risk factors for juvenile-onset SLE, with each increase of 13.4 ug/m^3 in PM_{10} increasing disease risk by 34%.[124]

Chemical Sensitivity

Chemical sensitivity (CS), also termed multiple chemical sensitivity (MCS), idiopathic environmental intolerance (IEI),[125] and toxicant-induced loss of tolerance (TILT),[126,127] is a modern medical phenomenon that is now present in up to 30% of the population.[128] Individuals with CS experience adverse physical, mental, or emotional symptoms after being exposed to ambient levels of common environmental chemicals. Individuals with chemical sensitivity often show the same cytokine imbalances already discussed in this section.[129] However, CS may not be a manifestation of only immunotoxicity—there is also evidence of limbic kindling or neural sensitization in persons with this problem.[130,131]

Neurotoxicity

The neurological system is also a frequent target for xenobiotic compounds. Some patients will present primarily with neurotoxicity symptoms, whereas others may exhibit immunotoxicity signs and symptoms first. The most common neurotoxicity symptoms include reduced cognitive functioning (often referred to by the patient as "brain fog" or "crooked brain"), headache, memory problems, and mood disorders. Tremors, balance problems, and anxiety can also be present (Box 35.1).

The nervous system is a unique target for toxic agents in several ways:

1. The adult neuron does not divide, and therefore, replacement of lost neurons is not possible. Nerve cells killed by toxins cannot regenerate.
2. The blood–brain barrier does not block nonpolar substances or items that are actively transported.

BOX 35.1 Neurotoxicity Presentations

- Organophosphates
  - Poor cognition
  - Poor attention
  - Depression
  - Fatigue
  - Headache

  - Headache

3. Because the normal function of the nervous system requires the action of a complex, integrated network, damage to even a small portion of the nervous system sometimes can result in marked effects on function.
4. Neurons are dependent on glucose and oxygen, and some cell bodies exist at borderline levels of oxygen. If high energy demands are placed on the system and the delivery of oxygen is reduced, then cell death may occur.
5. Because of the high lipid content (myelin), there is an accumulation and storage of lipophilic xenobiotics.
6. Neurons have high surface areas and, therefore, increased exposure to toxic compounds.
7. Neuroinflammation is fairly easy to start and very difficult to alleviate.

Unfortunately, a great many of the common toxic xenobiotics in our bodies are potent neurotoxins. All of the major classes of pesticides kill pests by virtue of their neurotoxic actions. Chlorinated pesticides and pyrethroids disrupt the ion flow along the axon, whereas OPs (developed in Germany between the First and Second World Wars for use in warfare[132]) and carbamates are potent acetylcholinesterase inhibitors (resulting in excessive acetylcholine levels in the synaptic clefts). Solvents, some of which were originally used as anesthetics, dampen the propagation and transmission of electrical impulses along the nerve axons. All of these agents produce various forms of toxic encephalopathy (acute or chronic, selective, or diffuse toxic encephalopathies). Many environmentally ill patients present to their physicians with chief complaints that fit this diagnostic category.

Other common pollutants are indirect neurotoxins and affect the neurological system adversely by causing neuroinflammation, resulting in cognitive decline, mood imbalances, pain disorders, and chronic neurological diseases.

Pesticide Neurotoxicity

Organophosphates. The average clinician will rarely see an individual with acute organophosphate poisoning. Instead, they will see persons presenting with depression, headache, fatigue, cognitive issues, and other problems that could tend to be attributed to other issues of aging. The following OP worker studies highlight these problems.

Greenhouse workers who were exposed to OPs exhibited higher incidences of depression, headache, tremors, and paresthesias.[133] Polish female greenhouse workers exposed to OPs exhibited longer reaction time and reduced motor steadiness than unexposed workers. They also reported increased tension, depression, and fatigue more often than controls.[134] Dutch farmers and gardeners who used OPs frequently had a much higher risk of developing mild cognitive dysfunction than others.[135] Farmers repeatedly exposed to OPs from sheep dip showed much greater vulnerability to psychiatric disorders than controls (quarry workers). They also performed worse than controls on cognitive testing that assessed attention span and how fast they processed information.[136] None of the persons in any of these studies fit the definition of acute OP poisoning as set by the field of toxicology, including no evidence of low acetylcholinesterase levels.

A study of persons previously poisoned by OPs revealed that OP-induced neurotoxicity can persist after the incident, manifesting as problems with memory, abstraction, intellectual functioning, mood, and motor reflexes. They also had greater distress and complaints of disability.[137]

Chlorinated pesticides. The use of chlorinated pesticides was almost completely banned in the United States by the 1980s, and thus the symptomatic picture of acute organochlorine poisoning is rarely seen. Instead, low-level organochlorine neurotoxicity presents with generalized neurological dysfunction very similar to what is found with OPs.

Early controlled trials of airborne exposure to low levels of DDT revealed that exposed subjects would experience neurological symptoms, including dimming of vision, a drawing sensation at the base of the nose or behind the eyes, a sense of fullness deep inside the skull, headache, slowness of thought, inability to concentrate, and short-term memory loss.[138] Various muscle symptoms also occurred, including weakness, fatigue, dysphagia, and ataxia.

A study of retired malaria control workers and non-DDT-exposed controls revealed that the exposed group had significantly poorer performance on cognitive, sensory, and motor testing that persisted long after exposure ended.[139] They did particularly poorly on the cognitive testing (verbal attention, visuomotor speed, and sequencing) and reported significantly more psychiatric symptoms than controls reported. Additionally, children who were exposed to "background, low-level concentrations" of DDT while in utero revealed decreases of up to 7.86 (standard error, 3.21) points in the verbal scale and 10.86 (standard error, 4.33) points in the memory scale compared with children whose concentrations were <0.05 ng/mL.[140]

The neurological effects of chlordane exposure were studied in a group of persons who lived in an apartment complex where chlordane was used. Seven years after the application occurred, residents and former residents of the complex were assessed with neuropsychiatric testing.[141] Significant changes were found in the exposed persons, including reduced reaction time; balance dysfunction (shown by increased sway speed); and reductions in cognitive function, perceptual motor speed, and immediate and delayed verbal recall. They also had worse scores for mood, including increased tension, depression, anger, and fatigue.

Solvents. Chronic toxic encephalopathy (CTE) from solvent exposure will often gradually improve in 50% of cases with the elimination of solvent exposure (Box 35.2). However, 50% will not improve from mere avoidance in the time frame of 6 to 42 months after initial assessment, far longer than the clearance of solvents would suggest. It is interesting to note that in one study, persons on

BOX 35.2 Chronic Toxic Encephalopathy: Designations of Solvent-Induced Neurotoxicity

1. Affective syndrome: neuropsychiatric symptoms, no signs of impairment, reversible
2. Mild chronic toxic encephalopathy: neuropsychiatric symptoms, proven impairments, uncertain reversibility
3. Severe chronic toxic encephalopathy: more severe neuropsychiatric symptoms, more pronounced impairments, usually irreversible

Data from World Health Organization meeting on Organic Solvents, Copenhagen, Denmark, 1985.

antidepressants were nearly four times more likely to have persistent solvent-induced CTE than those not on the medications.[142] Although the study failed to list which antidepressants were used, many of the commonly used antidepressant medications are known inhibitors of the CYP system in the liver, thereby prolonging the half-life of xenobiotics. Workers with a genetic polymorphism affecting glutathione conjugation also had a dramatically increased risk for the development of CTE.[143]

White-collar employees with low-level toluene exposure have exhibited significant deficiencies in continuous performances tests and tests measuring processing speed and memory.[144] Additionally, shipyard painters were found to have significantly higher scores for neurotic behaviors than controls.[145] They were also found to have significantly greater problems with short-term memory, concentration, fatigue, dizziness, and insomnia and noted more trouble with a feeling of pressure in the chest and perspiration without work. One of the questions most frequently answered affirmatively by the group (in significantly higher levels than controls) was, "Do you often have to go back to check things that you have done, such as turned off the stove, locked the door, etc.?"[146]

Female workers exposed to toluene showed significantly more problems with manual dexterity, visual scanning, and verbal memory.[147] The authors of this study noted that the workers who exhibited these changes on neurobehavioral testing showed absolutely no clinical signs of toxicity!

Heavy Metal Neurotoxicity

Lead. Lead is a well-recognized neurotoxin that causes multiple problems in exposed children, including reduced IQ scores[148] and attention and behavioral problems.[149] Parents of children with lead burdens have reported that their children experienced more somatic complaints and delinquent, aggressive, internalizing, and externalizing behavior.[150] Their teachers have reported that the children had more problems with anxious/depressed behavior; social problems; attention problems; and delinquent, aggressive, internalizing, and externalizing behavior. Such findings contributed to the removal of lead from gasoline and paint in the United States in 1978.

When persons who were exposed to lead in childhood were studied 20 years later, neurological deficits were still found. In this group, significant adverse central and peripheral neurological effects were present. Peripheral nerve function was altered, as were measures of coordination, reaction time, dexterity, learning, and mood.[151] When bone lead burden was measured in older individuals, none of whom had industrial exposures to lead, a clear association was correlated with mental function. As the total bone lead (measured by fluoroscopy of the tibia) increased, cognitive function decreased in a group of older individuals from Baltimore.[152] The cumulative lifetime lead burden has been associated with increased risk for the development of parkinsonism.[153,154]

Even though blood lead levels (BLLs) have been steadily dropping in the past few decades, these lower lead levels are still associated with neurological deficits in children, leading some to propose that there is not a safe BLL. Approximately 7.4 IQ points were lost in children with a BLL of <10 ug/dL versus 4.6 IQ points in those with a per-unit increase in BLL of >10 ug/dL.[155] The IQ losses in children with a BLL of <10 ug/dL were confirmed in a subsequent study of 6-year-old children[156] and in children in seven international population studies.[157] IQ loss with BLLs above 1.71 ug/dL has also been found in a study of Italian adolescents. In this study, a doubling of the BLL equated to a 2.4-pt reduction in IQ. The researchers stated that for each 0.19-ug/dL increase in BLL, 1 IQ point was lost.[158] In a North Carolina study, BLLs as low as 2 ug/dL were associated with poorer performance in the classroom for school-aged children.[159]

Mercury-Induced Neurotoxicity. Mercury in both organic and elemental forms is neurotoxic, and methylmercury (organic) is the most well-known neurotoxin. The widespread pollution of Minamata Bay, Japan, by methylmercury in the 1950s provided researchers with a clear picture of methylmercury poisoning through daily fish consumption. Known as Minamata disease, the neurotoxic signs included ataxia, speech impairment, constriction of visual fields, hypoesthesia, dysarthria, hearing impairment, and sensory disturbances. These neurological problems persisted and were found in other areas of Japan as the mercury contamination spread through fish consumption.[160] Follow-up studies in the Minamata area almost 40 years after the spill and almost 30 years since a fishing ban was enacted for the area showed the persistence of mercury neurotoxicity. Male residents in fishing villages in the area in 1995 reported significantly higher prevalence than town-resident controls for the following complaints: stiffness, dysesthesia, hand tremor, dizziness, loss of pain sensation, cramping, atrophy of the upper arm musculature, arthralgia, insomnia, and lumbago. Female residents of the fishing villages had significantly higher incidents of complaints of leg tremor, tinnitus, loss of touch sensation, leg muscular atrophy, and muscular weakness.[161]

Fish-eating Amazonian children with hair mercury levels above 10 mcg/g showed deficits in neuropsychological tests for motor function, attention, and visuospatial performance that correlated with their hair mercury concentrations.[162] Patients in an internal medicine practice in San Francisco who consumed large fish regularly and had mercury blood levels above 5 mcg/L were most likely to present with fatigue, hair loss, trouble thinking, memory loss, muscle aches, headaches, and a metallic taste in the mouth.[163]

The majority of individuals who had their amalgam fillings removed noted psychological improvements, including a reduction in anger outbursts, depression, irritability, and fatigue.[164]

Indirect Neurotoxicity—Neuroinflammation

All of the environmental pollutants have demonstrated powerful prooxidant activity; in addition, they deplete the levels of reduced glutathione in the brain tissue and inhibit the function of the antioxidant enzymes. Neurons and their supporting glial cells are directly affected by this oxidative stress and diminished antioxidant protective ability. Oxidative stress activates the glial cells, leading to increased production and release of the proinflammatory chemicals interleukin 1β (IL-1β), interleukin 6 (IL-6), interleukin 10 (IL-10), IFN-γ, and TNF-α.

The resulting neuroinflammation is a key component in the pathobiology of headaches and chronic pain,[165] cognitive decline,[166,167] mood disorders,[168] traumatic brain injury,[169] and neurodegenerative diseases such as Alzheimer's disease,[170] attention deficit hyperactivity disorder (ADHD),[171] amyotrophic lateral sclerosis (ALS),[172] autism,[173]

multiple sclerosis,[174] bipolarity,[175] seizures,[176] and parkinsonism.[177] Neuroinflammation has been shown to be present in parkinsonism and appears to be responsible for all the non–dopamine-depletion-related manifestations.[178]

Neuroinflammation is triggered by traumatic brain injury,[179] endotoxicity (circulating levels of lipopolysaccharides from gram-negative bacterial cell walls),[180] elevated blood sugar (glycation end products),[181] stress,[182] and a host of environmental toxicants such as air pollutants,[183] heavy metals,[184] and OPs.[185] Vehicular exhaust produces particulate matter in a range of sizes, all of which carry a variety of polycyclic aromatic hydrocarbons.

Endocrine Toxicity

The most common endocrine diagnoses associated with xenobiotic burden include the following:

1. Infertility (both male and female)
2. Low testosterone in males less than 55 years of age
3. Hypothyroidism (especially autoimmune)
4. Adult-onset diabetes
5. Obesity

Infertility

Herbicides and organophosphate pesticides. Ontario women who used pesticides were 3.8-fold more likely to be infertile.[186] Five compounds reduced females' fecundity rates to between 24% and 49%: dicamba (0.51), glyphosate (0.61), 2,4-D (0.71), organophosphates (0.75), and thiocarbamates (0.76). Spanish greenhouse sprayers exposed to OPs had higher rates of spontaneous abortion rates, along with higher rates of depression and headaches.[187] Although these health problems were clearly evident, no significant decrease in erythrocyte acetylcholinesterase was found. This reproduced the findings of other studies showing apparent adverse neurological organophosphate health effects without markers of acute OP toxicity. A study in California farming counties showed a clear association with pesticide spraying and fetal death due to congenital anomalies.[188] In this study, when an OP or carbamate pesticide was sprayed in one of 8 adjacent square miles of women's residences during the third to eighth week of pregnancy, the OR of fetal death was 1.4. When the spraying occurred within 1 square mile of a residence, the OR increased to 2.2.

Chlorinated pesticides and polychlorinated biphenyls. Hexachlorocyclohexane (HCH) serum levels were significantly associated with miscarriage history and uterine fibroid presence among patients in a German reproductive clinic.[189] Higher HCH and PCB levels were also noted more frequently in women with antithyroid and antinuclear antibodies. PCB exposure and elevated antithyroid antibodies have also been reported elsewhere.[190] PCB serum levels were significantly associated with endometriosis, and increasing DDT levels with reduced conception. Pentachlorophenol (PCP) levels were also found to be associated with increased miscarriage rates and levels of ANA.

A noncontrolled study in Canada looked for the presence of certain xenobiotics in the serum and follicular fluid from infertile females and seminal plasma from their male partners.[191] These 18 couples all attended an in vitro fertilization program in hopes of becoming parents. The researchers found DDE, mirex, HCH, trichlorobenzene, and three different PCBs in more than 50% of all follicular fluid samples. Four different PCBs, DDE, and endosulfan were also found in over 50% of all serum samples. DDE was the most frequently found contaminant, had the highest residue, and was negatively associated with fertilization. Of the couples tested, those who failed to achieve pregnancy with in vitro fertilization methods generally had higher toxic levels than successful couples. It is unfortunate that these authors did not get a matched control group of fertile couples to compare the toxic burden.

In the same Canadian study, women with higher DDE levels had greater trouble conceiving. This finding was also noted in the previously mentioned German study and was recently redocumented as a generational effect as well in a group of women from Oakland, California.[192] In this study, serum levels of DDT/DDE were measured from maternal samples at the time of birth. The time it took their daughters to conceive was then followed for 28 to 31 years. Differing generational effects were found for both DDT and DDE. Maternal levels of DDT were associated with reduced fecundity (32% less) in their daughters, whereas DDE levels were associated with increased fecundity (16% greater).

Solvents. Reduced fecundity has also been shown in female toluene workers (fecundity rate [FR] 0.47) and in laboratory workers exposed to organic solvents (FR 0.79).[193,194] Wives of men who worked around organic solvents also showed decreased fecundity (FR 0.36).[195] Occupational exposure to organic solvents is associated with both longer time to pregnancy and increased risk for spontaneous abortion once conception occurs.[196] Chinese female chemical plant workers exposed to organic solvents experienced a very high risk for spontaneous abortions (OR 2.9).[197] Of the myriad of petrochemicals they were exposed to, benzene (OR 2.5), gasoline (OR 1.8), and hydrogen sulfide (OR 2.3) all showed independent significant association with miscarriages. Solvent-exposed pharmaceutical factory workers also showed increased spontaneous abortion risk from multiple solvent exposures that increased along with the number of solvents they were exposed to.[198]

Air pollutants. Smoking more than 10 cigarettes daily has been associated with reduced fertility in women (FR 0.66), with the OR for infertility being 1.64.[199] Because tobacco smoke contains high benzene and styrene levels, along with heavy metals and polycyclic aromatic hydrocarbons, it is difficult to say which xenobiotic would have the greatest effect on fertility. Female smokers also experience higher rates of ectopic pregnancies and spontaneous abortions,[200] along with greater rates of stillbirths (OR 2.0) and infant mortality (OR 1.8).[201] Mothers who quit smoking in the first trimester showed the same rates of stillbirth and infant mortality as nonsmoking women. When Ireland banned smoking in the workplace, rates of preterm births dropped by 25%.[202]

Women living closest to busy roadways have slightly higher rates of infertility than those living further away.[203,204] Brief exposure to elevated levels of PM_{10} has been shown to increase the rates of miscarriage by up to 2.6 times.[205] Mothers exposed to higher ambient air pollution were found to have significantly higher levels of polycyclic aromatic hydrocarbon (PAH)-DNA adducts in the white blood cells of their cord blood.[206] The PAH-DNA adducts were also significantly higher in infertile men than in fertile men.

Hypothyroidism

PCBs have been closely studied for their possible adverse effects on thyroid hormonal status and function. Both PCBs and thyroxine are made of two connected benzene rings with attached halogens, with PCBs having chlorine molecules and thyroxine having iodine. Interestingly, the common human contaminant BPA is also structurally similar, with two bromine molecules on each of the rings. PCBs have demonstrated in vitro activity in binding transthyretin, a transport protein mechanism for thyroxine.[207] POPs also appear to adversely affect the thyroid hormone–metabolizing enzymes (uridine-diphosphate-glucuronyltransferases, iodothyronine deiodinases, and sulfotransferases) found in the liver and brain.[208]

Elevated levels of both antiperoxidase and antithyroglobulin were found in workers in a PCB manufacturing plant.[209] This is reflective of the earlier noted study,[188] in which PCBs and HCH were frequently found in infertile German women with antithyroid and antinuclear antibodies. Surprisingly, no difference was found in the levels of T4 and thyroid-stimulating hormone (TSH) in these 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) workers versus the control group.

PCB serum levels of consumers of fish from the Baltic Sea were found to have a significant inverse correlation between PCB levels and TT3, along with a nonstatistically significant inverse correlation with TT4.[210] German children showed a significant positive correlation between PCB serum levels and elevation of TSH,[211] and they also exhibited a significant inverse correlation between serum PCB levels and FT4, as one would expect with increasing TSH levels.

Chlorinated pesticides have also been associated with hypothyroidism. A study of Indian women looked for any association between DDT and dieldrin in women with elevated TSH and depleted T4. DDT was found to be higher in all of the hypothyroid women, although not significantly, but dieldrin was significantly associated with low T4 levels.[212]

Adult-Onset Diabetes

The incidence of adult-onset diabetes has risen in the past decade at rates much higher than previously recorded.[213] Although type 2 diabetes mellitus (T2DM) has long been associated with a variety of lifestyle choices, new information is powerfully pointing to a number of common pollutants as major risk factors.[214] Inorganic arsenic, naturally present in groundwater throughout the world, has been clearly linked to the development of T2DM, whereas arsenic from food-based sources has not.[215,216] The presence of persistent organic pollutants has also been linked to the development of diabetes. The NHANES participants with the lowest levels of PCB 153 in their blood were 2.5 times more likely to develop diabetes than persons without PCB 153, whereas those individuals in the highest quartiles of this toxicant were 6.8 times more likely to have this disorder.[217] The termiticides transnonachlor and oxychlordane each increased the risk of T2DM from 2.7-fold, for those with the lowest blood levels of these chlordane residues, to 11.8- and 6.5-fold, respectively, for those with the highest blood levels. When the sums of all six bioaccumulative toxins were combined, the odds of developing diabetes went from a low of fourteenfold to a high of 37.7-fold for those with the greatest fat-soluble burden. Evidence of the increased risk for T2DM from a variety of POPs continues to mount.[218,219]

Not all persons are living in areas with higher groundwater arsenic, and exposure to POPs is not as common as it was several decades ago. But all persons are exposed to various levels of air pollution, which is strongly associated with the development of both obesity and diabetes. Ambient nitrogen dioxide has been positively linked to reduced B-cell function and reduced insulin sensitivity in Latino youth living in Los Angeles, in whom it was also found to contribute to increased weight.[220] Additionally, ambient levels of $PM_{2.5}$ have been positively associated with the incidence of T2DM.[221,222]

Urinary phthalate and BPA levels have also been associated with increased diabetes risk, although not all BPA studies demonstrate a significant risk.[223–226] Urinary phthalate levels are also positively associated with increased weight and waist circumference.[227,228]

ASSESSMENT

History

A comprehensive history is the cornerstone of detecting xenobiotic-induced health problems. When taking a history, attention should be paid to both occupational and nonoccupational chemical exposures. Occupational exposures can be the ones the client is most aware of and should always be followed up with a request for the Material Safety Data Sheet on each chemical from the employer. Nonoccupational exposures are harder to document, but in a family practice they are often found to be the main culprit. Specific questions should be asked about the history of residences: where the patient lived, how new the structure is, age of carpeting, time of remodel, type of heating, use of indoor or outdoor pesticides, attached garage, and so forth. The presence of environmentally induced illnesses will often become very clear when the clinician compares the chronological history of all the client's health complaints with the client's residential and occupational exposures.

However, because of the ubiquitous nature of the chemicals in question, a history may not always give a clear picture of which chemical caused the illness in question.

Laboratory Tests

Laboratory tests may be helpful in cases where the history is not. A standard complete blood count and general blood chemistry test is usually nonremarkable in cases of chronic low-level exposures (although Crinnion often finds leukopenia present in his population of toxic patients). In his patient population, the author (Crinnion) has rarely found elevated levels of liver enzymes, even when solvents and pesticides are present in the serum. This has also been reported in the literature with persons occupationally exposed to solvents.[229]

Serum tests for the most commonly found PCBs, chlorinated pesticides, and aromatic solvents are currently available. Urine assays for the metabolites of organophosphate pesticides, glyphosate (from Roundup), low- and high-molecular-weight phthalates, and other common chemical pollutants are also currently available to the clinician. The publication of the CDC's national reports provides national reference values for many of these compounds that the clinician can use when interpreting the laboratory reports. For the biologically persistent PCBs and chlorinated pesticides, the CDC gives levels both in parts per billion and as lipid-adjusted (nanogram per gram lipid) values. These fat-soluble toxins are released from adipose tissue along with triglycerides and cholesterol.[230] Previously published research actually found that quantifying the fat-soluble xenobiotics according to the amount of lipids in the blood corresponded well with the concentration of xenobiotics present in adipose biopsies of the same person.[231] These findings are the reason why the CDC presented lipid-adjusted levels for these specific POPs. Lipid-adjusted values offer a glimpse of the POP adipose burden and allow the clinician an opportunity to monitor the effectiveness of depuration treatments.

Current OP exposure can be identified by the presence of OP metabolites in the urine. Similar testing can be done for phthalate (plasticizers) metabolites, BPA, and parabens. All of these compounds are nonpersistent, and their presence indicates regular, ongoing exposure. These tests can be highly useful in helping people attain a diet and lifestyle that are free from several serious toxic families.

Heavy metals can be measured in the hair, blood, urine, and stool. Blood levels are mostly indicative of current exposure levels and are still considered by many physicians to be the only valid method of heavy-metal assessment. Unfortunately, the blood reference values for heavy metals are typically based on industrial medicine standards for toxicity in the workplace. Fortunately, the CDC national reports again provide the national normal ranges for most of the heavy metals in blood and in urine (given as microgram per liter and microgram per gram creatinine). A nonchallenged random or first-morning urine test will provide information on total body cadmium levels and current exposures to mercury, lead, and arsenic.[232,233]

An estimation of the body burden of mercury and lead can be derived from a metal-mobilization test (MMT). MMTs use urine metal assessment before and after the administration of a metal-mobilizing agent. The total amount of metal in the pre- and postchallenge urine samples needs to be calculated as part of this method (ug/sample). Intravenous calcium edetate (CaEDTA) and oral 2,3-dimercaptosuccinic acid (DMSA) have both been used for lead-mobilization testing.[234–238] DMPS has been used for mercury-mobilization testing, and DMSA can also be used.[239]

TREATMENT

Effective treatment for chemically induced illnesses begins with avoidance of further exposures, which is the major step for all nonpersistent pollutants. Supplementation to support xenobiotic elimination and antioxidant protection is always beneficial. For persistent compounds, depuration techniques are necessary to reduce their body burden.

Avoidance of Further Chemical Exposure

This step is critical, although it is often the most difficult step in terms of compliance. In cases of multiple chemical sensitivities, simply having a chemically safe dwelling can bring improvement.[240] Compounds to be avoided include solvents, paints, exhaust fumes, perfumes, hair sprays, new furniture, carpeting, cabinetry, plastics, and gas or oil heat, among others. Because the home is the environment that is most in one's control, the home must be made a "safe oasis." If there are building materials that are off-gassing chemicals and these materials cannot be removed, they should be sealed. There are a number of good books available to help with these issues.[241]

The single greatest source of solvent exposure in the home comes from smoking inside, which also provides combustion by-products, cancer-causing chemicals, and heavy metals. After smoking, the next greatest sources are carpeting, new cabinetry, and new paint. Cleaning supplies, including tile cleaners, perfumes, air fresheners, and the presence of dry-cleaned clothing, complete the rest of the top indoor polluters. Exposure to all of these can be reduced with simple lifestyle choices, such as the following:

- Do not wear shoes indoors.
- Replace furnace filters every 6 weeks with high-quality pleated filters (rated minimum efficiency reporting value [MERV] 7–9).
- Air out dry-cleaned clothing in the garage or car trunk for a week before bringing it into the house.
- Do not smoke indoors.
- Consider replacing carpet with tile or stone flooring.
- Use nonscented laundry detergent and fabric softener.
- Consider getting an air purifier that has both charcoal and high-efficiency particulate air (HEPA) filters (e.g., IQAir and Blue Air). Make sure to get one with enough cubic feet of air purified each minute to clear the air in the bedroom at least once every 30 minutes.

In addition to avoiding environmental chemicals, any foods that cause adverse reactions should be avoided (see Chapter 14 on food hypersensitivities). Organic foods should be chosen wherever possible, as well as purified water. Avoiding the "dirty dozen" fruits and vegetables (www.foodnews.org), along with all farmed salmon, high-mercury fish, and nonorganic dairy products, will significantly reduce toxin exposures through the diet.

Dietary Support

The best macrodiet choice (in addition to organic foods) is to consume a high-protein, low-carbohydrate, and low-fat diet. Such a diet helps Phase I biotransformation significantly.

Protein

The metabolism of toxic chemicals and drugs has been shown to be impaired by protein deprivation. Increased toxicity of chemical compounds and drugs has been reported with protein deficiency. Protein deficiency decreases the activity of liver mixed-function oxidase (MFO) systems, which increases the half-life of numerous toxic chemicals and drugs and potentiates drug action and toxicity. The quantity and quality of protein in the diet alters both Phase I and Phase II reactions in drug metabolism (a gelatin diet induces very low MFO activity). The toxicity of organochlorinated compounds (OCCs), acetylcholinesterase inhibitors, herbicides, and fungicides have all been shown to be increased severalfold by protein deficiency. Reduced clearance of antipyrine and increased half-life of antipyrine have been found in Asian vegetarians with low dietary protein intake. This was not found in white vegetarians with adequate protein intake.

Although protein deficiency clearly reduces the ability of the body to adequately metabolize chemicals,[242] the opposite also appears to be true. Isocalorically increasing the ratio of dietary protein to carbohydrate ratio in well-nourished volunteers was shown to enhance the clearance of antipyrine and theophylline. Although it is not clear if the effect of the protein was due to the amino acid content alone, it is known that methionine and cysteine deficiency led to a reduction of intestinal and hepatic Phase I enzyme activity. Hepatic Phase I activity can also be suppressed by folic acid and choline deficiency. Low methionine intake also affects selenium metabolism by making less selenium available for glutathione-peroxidase biosynthesis. High sugar intake is also known to reduce the clearance of certain chemicals from the liver.

Fiber

Rice bran fiber (RBF), which can be found in a diet high in brown rice or using RBF as a fiber supplement, has been shown to have a high binding ability for PCBs and other toxins, including the combustion by-product benzo(a)pyrene, in a laboratory setting.[243] When measured against other fibers, RBF demonstrated the ability to dramatically reduce the reabsorption (termed "hepatic recycling") of PCBs from the intestines in animals.[244] Hepatic recycling occurs after the liver dumps some of these toxins into the intestines with bile, but when these compounds make it to the intestine, they are reabsorbed into the bloodstream and sent back to the liver—a process facilitated by low fiber and deconjugating bacteria in the gut. This recycling pattern is the main reason why such a minute amount of these toxicants actually makes it out of the body. Although RBF helps break this recycling and gets more toxic xenobiotics to leave, wheat bran showed absolutely no benefit in this regard.[245] A study using either spinach fiber or RBF in PCB-exposed animals showed that RBF increased fecal PCB excretion by 6.6 times and spinach fiber by 4.1 times.[246] In another animal study, 10% RBF in the diet increased the excretion of toxic furans by 4.5 times that of placebo.[247] A study of PCB-burdened patients who consumed 7 to 10 g of a fermented RBF product (which is available as a food item in Japan) three times daily (after each meal) for a year found that they had twice the amount of dioxin excretion as controls.[248] While bran fiber has shown many benefits, as much of rice is contaminated with arsenic. The prescriber must ensure the recommended product is not contaminated.

Chlorophyll, Seaweed, Chlorella

Chlorophyll has long been thought of as a blood purifier, and recent studies have documented its effectiveness at helping clear POPs, but not toxic metals, from the body. As previously mentioned, both

chlorophyll-containing spinach fiber and matcha green tea increase the excretion of POPs. The seaweed nori, which also contains chlorophyll, was tested in rats to measure its power in helping clear dioxins. Rats fed a diet of 10% nori had an increase in fecal excretion of two different dioxins at levels 5.5 and 6.0 times more than the control group.[249] Chlorella, long a popular "detoxification" agent, was also tried with dioxin-contaminated rats. The group of rats given chlorella had increased dioxin excretion that varied from 30% to over 300% higher than the control group.[250] Postulating that it was the chlorophyll content of the chlorella that was the active ingredient, this group of researchers then set out to measure that hypothesis.

The effectiveness of chlorophyll alone on the excretion of dioxins and furans from rats was quickly established. The higher the content of chlorophyll in the diet, the greater the excretion of these persistent fat-soluble toxins in the feces. The ranges of chlorophyll went from a low of 0.1% to a high of 0.5% in the diet. A diet with 0.1% chlorophyll is roughly equivalent to consuming 10% of your diet as spinach or 20% as seaweed. In the 0.1% group, the fecal excretion of the various toxins ranged from 40% to 80% greater than that of the control group. At the end of the study, all of the animals that were given chlorophyll had a lower total body burden of these persistent toxins than their counterparts.[250]

Similar results were found with chlorophyll-containing vegetables. When POP-burdened rats were fed a diet with or without 10% dioxin and furan, elimination occurred in proportion to the chlorophyll content of the vegetables.[251] The vegetables with the smallest increase in fecal dioxin excretion (60% to 300% increase) were Chinese cabbage, broccoli, onion, Welsh onion, cabbage, and celery. Kale, Chinese chive, Shungiku, Chingensai, green lettuce, and sweet peppers increased dioxin excretion by 330% to 480%. Topping the charts with an increased dioxin excretion of 760% to 1160% were Komatsuna, mitsuba, spinach, and perilla.

Nutritional Supplementation

In cases of toxic overload, supplementation can be tricky because some persons with severe chemical reactivity can react to many of the nutrients that are normally needed. In his four-volume treatise *Chemical Sensitivity,* Rea stated that his chemically burdened patients were typically deficient in magnesium, selenium, and vitamin B_6 (whether or not they were taking oral supplements of these).[3,4] Supplementation with high levels of antioxidants is typically recommended because all of these xenobiotics have been shown to cause oxidative damage.

Depuration (Cleansing)

The removal of impurities from the body is known as depuration. Colonic irrigations and sauna have been used for depuration in addition to the use of RBF and chlorophyll.

The earliest articles on the use of saunas for depuration came from clinics associated with the Church of Scientology, using the "Hubbard Purification Rundown." Designed by L. Ron Hubbard, the protocol uses exercise, high-temperature saunas, increasing doses of niacin, and electrolyte replacement.[252] This protocol has been used to reduce levels of PCBs, polybrominated biphenyls (PBBs), and hexachlorobenzene.[253] More recently, Genuis et al. have published studies on the effectiveness of sweating for depuration. A small group of patients with chronic illness along with an equal number of healthy controls provided serum, urine, and sweat samples. Far-infrared (FIR) saunas were used by 10, standard Finnish steam saunas by 7, and exercise alone by 3. Both BPA and phthalates were documented in the sweat and urine from individuals in the study who used either FIR or Finnish saunas.[254,255] BPA and di(2-ethylhexyl)phthalate (DEHP) were both found to be present in the sweat of individuals who did not have these toxicants present in their serum, indicating that both have some degree of storage in the subcutaneous fat pads. Mono-(2-ethylhexyl) phthalate (MEHP) was found in the sweat at concentrations double that in the urine. Five polybrominated diphenyl ether (PBDE) flame retardants found in the serum of these individuals were also mobilized into their sweat with sauna use.[256] As with both BPA and phthalates, some PBDE cogeners were present in the sweat while not being present in the serum.

A comprehensive naturopathic protocol of diet, supplements, hydrotherapy, colonic irrigations, and sauna for treating environmentally poisoned individuals was developed by the author (Crinnion) and has been in use for more than 20 years. An outcome study on persons using this protocol for a variety of chemically induced ills revealed it to be surprisingly effective. Of all the various problems treated with the depuration protocol, 83% of the participants rated their results as good or great. The two conditions in which 100% of the participants reported great results were asthma ($n = 3$), and addiction recovery ($n = 1$). There were several problem (chief complaint) categories in which 100% of the participants rated their results as moderate/good or great. Those categories were autoimmune, dermatological, gastrointestinal, and/or liver. The categories with the next highest ratings of moderate/good and great were fatigue, with 92% improvement; allergies, with 85% improvement; and chemical sensitivities, with 84% improvement.[257]

The Crinnion Depuration Protocol

The Crinnion Depuration Protocol consists of the following components:

1. **Daily exercise.** Exercise usually consists of using an exercycle, rebounder, or brisk walking to begin lipolysis and diaphoresis.
2. **Thermal chambers.** Up to three 60-minute "sauna" sessions, with temperatures at a range of 120°F to 135°F, followed by 10- to 15-minute cool-down periods. Glass-bottled spring water was given along with electrolyte replacement. Although the Hubbard clinics use higher temperatures, it was observed that lower temperatures reduced the frequency of adverse effects and increased the release of chemicals in the sweat.
3. **Constitutional hydrotherapy.** This uses alternating hot and cold towels with sine-wave stimulation as done by O. G. Carrol, ND, and Harold Dick, ND.[258] This therapy has been used for decades to stimulate the body's own self-healing activity. We found that it also increased the amount of toxin-laden bile dumped from the liver into the intestines. Also assisting the choleretic and cholagogue action on the liver is an herbal capsule taken daily consisting of *Chelidonium, Chionanthus, Taraxacum, Arctium lappa, Silybum* mar., and *Urtica dioca.*
4. **Colonic irrigation.** Gravity-fed machines are used to gently introduce triple-filtered water into the large intestines, providing an avenue for toxic bile to rapidly leave the body. Individuals will routinely have "liver dumps" of bile that range in color from yellow to red, with occasional gray or brown. The color of bile normally ranges from green to yellow to orange to red, depending on the amount of time of exposure to bacterial action in the bowel. However, in this situation, we believe that it is dumped from the liver and rapidly passed through the small intestines, similar to what is seen in "gastric dumping" syndrome. We are therefore unable to account for the differences in the color of this effluent. In some patients with heavy agricultural exposure, we have seen higher amounts of fluorescent yellow bile. Hence, the color of the bile may be more attributable to the chemical compounds in the bile than the bacterial action upon the bile. We have documented that chlorinated pesticides are present in the effluent, which we refer to as "bile dumps."
5. **Constitutional homeopathy.** This has been used primarily as a stand-alone treatment, with the use of any other supplemental and treatments prohibited. However, we have found it to be a valuable component of this protocol and completely

compatible with all the other treatment methods involved. It appears most beneficial in those individuals who need a boost for their vital force to get them moving toward healing and for those who are stuck in emotional issues that they have not been willing to look at.

6. **Body therapies (massage, Shiatsu, craniosacral, visceral, chiropractic).** These are done as needed for the individual to treat specific musculoskeletal problems and to assist in mobilizing toxins that are stored in the tissues.
7. **Counseling.** Mental and emotional toxins are as big of a problem as physical and/or chemical toxicants. When people are exposed to powerful emotional toxins (abuse, etc.) that they have no outlet for handling, they end up "stuffing" the emotional toxins. When this emotional stuffing occurs, any physical toxins that they are exposed to at that time are also stuffed (stored) rather than being eliminated. Because of this, when they start to mobilize the physical toxins, the old emotional issues will come back into consciousness. When individuals choose to again suppress the emotional issues (rather than facing them), their physical cleansing will also stop. This is evidenced by the observations that they will stop sweating in the thermal chambers, stop heating the cold towels in the hydrotherapy, and stop having good liver releases in the colonic therapy. When the emotional "toxins" are faced and released, then these cleansing parameters are returned to former levels. Assisting all of the individuals going through this depuration protocol with their emotional issues helps them cleanse physically.

This protocol is run on a daily basis that usually lasts between 4 and 8 weeks (five sessions weekly). This protocol begins the depuration process, which then must be continued once the individual returns home. Most individuals will need to continue regular cleansing (use of home saunas, hydrotherapy, and colon therapy) for at least 12 months after completing their intensive in-office cleansing. When testing for serum levels of chlorinated pesticides, PCBs, and solvents is repeated along with immune parameters after 12 months, improvements are routinely seen. In addition to symptomatic relief, improvements in the laboratory reports (decrease in serum xenobiotics and reduction in autoantibodies, etc.) are clearly evident.

SUMMARY

Environmental chemicals and toxic metals are ubiquitous in our environment and in all humans at varying levels. Damage by these xenobiotics can be found in virtually every cell, tissue, and organ system in the human body. The most susceptible systems appear to be the immune, neurological, and hormonal systems. Many of the chronic health problems caused by toxic xenobiotics in these systems often present as classic degenerations that are considered to be the result of aging. Classic immunotoxicity manifestations include the development of allergies and asthma, chemical reactivity, chronic infections, and autoimmunity. Neurotoxicity typically presents with decreased cognition, headache, fatigue, short-term memory loss, and mood disorders. Endocrine toxicity can result in hypothyroidism, obesity, infertility, and diabetes.

Exposure to many of the ubiquitous xenobiotic toxicants can be easily eliminated by simple lifestyle choices (Box 33.3), although the burden of fat-stored pollutants can be reduced by depuration techniques that often can be handled through dietary changes. The diagnosis of xenobiotic-induced damage can be elucidated by a comprehensive history, along with the presence of pollutant-specific biomarkers.

BOX 35.3 Treatment

Avoiding toxic exposures is mostly in one's control.

Diet and Home Air:

1. Avoid the 12 most toxic fruits and vegetables (peaches, apples, bell peppers, celery, blueberries, kale, nectarines, strawberries, cherries, pears, imported grapes, spinach, lettuce, potatoes); use organic varieties of these instead.
2. Freely eat all of the 15 least toxic fruits and vegetables (onions, avocado, sweet corn, pineapples, mango, asparagus, sweet peas, kiwi fruit, cabbage, eggplant, cantaloupe, watermelon, grapefruit, sweet potato, honeydew melon).
3. Do not eat any farmed or Atlantic salmon.
4. Freely eat Alaskan salmon (available fresh only from June until October; canned and frozen Alaskan salmon available year-round).
   a. Alaskan/Pacific salmon will always be labeled as King (Chinook), Red (Sockeye), or Silver (Coho) Salmon. If that distinction is not given, it is farmed salmon being passed off as Alaskan.
5. Avoid the fish with the highest mercury content (shark, swordfish, king mackerel, tuna, orange roughy, marlin, Chilean bass, lobster, halibut, snapper).
6. Freely eat the fish with the lowest mercury content (clam, ocean perch, Alaskan salmon, tilapia, flounder, sole, catfish).
7. Avoid all sugar—sugar reduces the ability of the liver to clear toxic compounds out of the bloodstream.
8. Begin to reduce the toxicity of the air inside the home:
   a. Don't wear shoes indoors.
   b. Replace the furnace filters every 6 weeks with high-quality pleated filters (rated minimum efficiency reporting value [MERV] 7–9).
   c. Air out dry-cleaned clothing in the garage or car trunk for a week before bringing it into the house.
   d. Do not smoke indoors.
   e. Consider replacing the carpet with tile or stone flooring.
   f. Use nonscented laundry detergent and fabric softener.
   g. Consider getting an air purifier—the best are IQAir and Blue Air. Make sure you get one with enough cubic feet of air purified each minute to clear the air in your bedroom at least once every 30 minutes.
   h. Follow the directions for step-by-step reduction of indoor air pollution sources in *Clean, Green and Lean* (New York: Wiley).

Dietary Things to Do:

1. Consume broccoli and other members of the *Brassica* family daily.
2. Consume green tea daily.
3. Increase intake of green foods (green leafy vegetables) daily.
4. Consume brown rice daily, or take a rice-fiber supplement.

Basic Supplementation:

1. Multivitamin/multimineral—take a quality product daily.
2. Vitamin C—begin with 3000 mg/day; for cases of high toxicity, a total of at least 9000 mg/day may be needed (unless this causes diarrhea).
3. N-acetyl cysteine—1500 to 1800 mg/day. This nutrient helps increase the amount of glutathione in the body.
4. Magnesium citrate—1 capsule (140 mg) up to three times daily.
5. A good probiotic—1/day.
6. Rice bran fiber—1 tablespoon in water or juice after each meal.
7. Whey protein powder—2 scoops daily in water or organic juice—high-quality whey protein will help boost glutathione levels and increase the ability of the liver to clear toxins out of the blood.

Cleansing:

1. Begin doing colonic irrigations. This is the best way to reduce the total toxic burden. It works best to do five colonics in the first 2 weeks, which will typically reduce the circulating toxic load enough for both the patient and the clinician to notice the difference.

The Exercise Prescription

Keoni Teta, ND, Jade Teta, ND, and *Ralph Esposito, ND, LAc*

OUTLINE

INTRODUCTION

Movement has been inextricably linked to health, well-being, and survival throughout human existence. It served as the means to procure food and was the key tool in protecting ourselves in times of danger. The ability to fight, flee, migrate, and forage was at the very core of life. Today, movement is no longer required for survival, and food is easily available with little need to expend energy. Yet the ancient connection between movement and metabolism remains permanently imprinted into our physiological function. Combating the diseases of the modern day is impossible without restoring movement as a permanent way of life.

Because a full discussion of movement and exercise physiology is beyond the scope of this chapter, this chapter will instead focus on movement as medicine for the most common diseases, with a special focus on the overlapping mechanisms that account for exercise's beneficial effect. A strong emphasis is given to newer understandings of exercise physiology and metabolism and how this information relates to the practice of medicine and the historical human condition.

The obesity epidemic, by most estimates, is the greatest health challenge of this century. It already represents one of the largest modifiable risk factors for increased morbidity and mortality, with close to 66% of the U.S. population being overweight or obese.[1–3] Because of the huge challenges obesity represents and the powerful role exercise can play, this chapter is framed in the context of weight management. Other related health issues, such as exercise approaches for inflammation, cardiovascular disease, cancer, mood, sexual dysfunction, and the brain, are also discussed.

EXERCISE IN HISTORICAL CONTEXT

Human movement patterns have always necessitated multiple parameters of fitness. Understanding these historical movement patterns provides a guiding context in which to view exercise. Although research in exercise is essential to understand, without a guiding context, it can be difficult to provide an appropriate exercise prescription. Viewing movement through the lens of human evolution, we believe, provides the frame of reference necessary to understand how to use movement as medicine.

Longer-duration, lower-intensity exercise made up the majority of early human activity.[4–6] Walking was the chief means of movement for millions of years. Early humans walked most of the day and did this every day. Their survival was dependent on it. Research suggests that early *Homo sapiens* foraging on the plains of Africa covered a range of over 10 miles daily, hauling weapons, game, and tools.[4–7] Analysis of modern-day hunter–gatherers confirms this degree of walking activity.

In addition to this lower-intensity activity, survival also depended on higher-intensity, shorter-duration activity. Sprinting away from danger or after wild game and lifting and hauling were essential. Both women and men engaged in these more anaerobic bouts of exercise. Although in most cultures women did not participate in the hunt, they did lift and haul wood, help construct shelters, and carry babies. The average baby was carried almost 1000 miles in the first 2 years of life in more traditional cultures.[5] The more intense activities of hunting, hauling, and foraging were done in what is termed the "paleolithic rhythm," where more intense activities were spaced out over 2 to 4 nonconsecutive days per week.[5,7]

Moderate-intensity exercise, much like aerobic exercise today, was also a part of life. However, this exercise did not take the shape of going for a jog or leisure run. Aerobic exercise was mostly in the form of sporadic running after food and dancing, which occupied an important place in the culture of ancient peoples and still does in modern-day hunter–gatherer societies. These dances can last from one to a few hours and take place several times during the week.[5–7]

The movement patterns of our historical ancestors were a necessary part of life and were fully integrated into the lifestyle. This movement was what could be best described as "cross-training," with elements of lifting, jumping, running, walking, throwing, climbing, hauling, hiking, or whatever movement pattern was required to procure food, stay protected from the elements, and defend territory. Our species is adapted from an environment where food was not guaranteed and a nomadic hunter–gatherer way of living dominated. This understanding is essential for the appropriate prescription of exercise. Hunter–gatherer societies in the past and present have been analyzed through a number of different scientific tools, which show that they do not experience the same degenerative and chronic diseases of modern, Westernized peoples.[4,8,9]

After taking into account body weight, the modern-day human energy expenditure is estimated to be only 38% of that of our hunter–gatherer ancestors.[5] It has been shown that for modern-day humans to approximate the level of activity of hunter–gatherers, they would have to walk 12 miles/day in addition to other activity. [5] Policy leaders on appropriate levels of human activity, such as the American College of Sports Medicine, recommend movement patterns estimated to be 44% less than that of our prehistoric ancestors and modern-day hunter–gatherers.[5]

Several studies have shown that total energy consumption from exercise may be the primary health-promoting property of movement.[5,10,11] Given the drastically different environment in which humans now reside, we are left with a serious dilemma. How do we get people to do an activity not required for their survival, that takes time, and is not an enjoyable activity for many? It is useful to remember that the number-one reason given for not participating in exercise is time.[12] These facts, and the historical frame of reference provided by evolutionary movement patterns, create a problem. Exercise prescriptions must deliver acceptable caloric expenditure, should mimic the cross-training attributes of our ancestors, but must also be time conscious and "doable" for the average population.

A NEW PERSPECTIVE ON MOVEMENT

It is easy to look at the data presented and quickly move to a "more is better" approach to exercise. However, movement quality is an important consideration before simply instructing more exercise. Quality in this segment is discussed in terms of more functional and efficient movement. In other words, movement that provides the perfect balance of range of motion and stability leads to more efficient animation of the body. The body is a chain of parts that are completely integrated. Individual exercises, although viewed in isolation by us, are actually complex and highly entrained patterns of neurological connections translated into muscular action. These "movement patterns" are the building blocks on which all exercise is constructed. Without a strong foundation, the benefits of exercise can sometimes become a liability, increasing the risk of injury, pain, and dysfunction.

It is both irresponsible and shortsighted to focus exercise prescriptions solely on delivering greater metabolic stimulus if there is not a strong and appropriate base of mobility and stability through basic movement patterns. In other words, doing more activity may not be beneficial if it simply reinforces poor movement mechanics. We must keep in mind that our ancestors were able to move more because they also moved better.

Human development and survival from infancy to adulthood required mastery of movement. The neurological and muscular systems are built as a unit and cannot be separated. Movement should not be thought of in terms of isolated anatomy but rather as an integrated system that moves in patterns. A squat, for example, is not simply a matter of contracting certain muscles that move joints. It is instead a coded and rehearsed pattern of neurological firing translated into physical movement.

Gray Cook, physical therapist and the foremost expert on functional movement, is the author of two of the most foundational pieces of work in movement science. In his books *Athletic Body in Balance: Optimal Movement Skills* and *Conditioning for Performance* and *Movement: Functional Movement Systems,* Cook described movement science as analogous to the relationship between computer software and hardware.[13,14] The muscles and joints act as the hardware, but the neuromuscular firing pattern is the software. Software obviously is what controls and informs the computer, and so it is with the nervous system controlling the muscle. To address movement, he rightly pointed out that we need to work movement patterns and not simply isolate parts.

The brain does not view exercise as individual muscles working. Instead, the brain has a code or a pattern for each movement. This pattern consists of thousands of different neurons firing in very specific ways to elicit a coordinated action, resulting in a movement. Each movement is to the brain like a computer software program; movement science calls this a motor program. It is these motor programs that need to be attended to in terms of movement quality.

Although exercise science has developed core principles and protocols to be followed, movement has not developed such protocols. Up until very recently, there has been no standardized understanding of what constitutes normal functional movement. This gap has now been filled by the work of Gray Cook and his colleagues. They have put together a system of screening and analyzing movement so that it can be objectively measured, tracked, and corrected. If we are to use movement as medicine and stay true to the natural medicine axiom of "first, do no harm," we must establish a standard of practice in movement medicine.

STANDARDS OF MOVEMENT

The Functional Movement Screen and Selective Functional Movement Assessment

The Functional Movement Screen, or FMS, as it is popularly known, is "a ranking and grading system that documents movement patterns that are key to normal function." By acting as a screen for movement, the FMS pinpoints movement dysfunctions that may predispose to injury and/or inefficiency.

The FMS has a scoring system that allows for a hierarchical ranking of the most limiting patterns or asymmetries unique to an individual. This in turn provides direction to clinicians as to what corrective strategies should be implemented and when. The FMS score can then be used to systematically address underlying movement dysfunctions and restore a base of movement from which conditioning can be built.

The FMS is complimented by the Selective Functional Movement Assessment (SFMA). The SFMA is the diagnostic system of functional movement. For the clinician concerned with movement, the two work hand-in-hand. The FMS is both the precursor to and the follow-up from the SFMA. The FMS looks at seven key movement patterns, including a squat, lunge, and hurdle step. Its purpose is to ascertain a baseline of mobility and stability and to determine whether movement

is pain-free. The SFMA is the clinician's tool for the diagnostic determination of when pain is present. Together, the screen and the assessment provide a movement system that allows tailored movement plans that can find, address, and track changes in movement from pain and dysfunction to recovery and optimal movement.

The FMS is a screening tool for the clinician; it is not diagnostic but rather prognostic. The SFMA is diagnostic and helps the clinician pinpoint the issue and further prioritize treatment. Once a patient has been discharged from treatment and no longer has pain with movement, movement quality must still be measured. This is where again the FMS is used.

Several recent studies showed the FMS to be a reliable and repeatable screening tool for movement quality, but they also proved its ability to predict injury in several high-population groups. Minick et al.[15] showed that the FMS demonstrated substantial interrater reliability by both novice and expert users. This demonstrates an important quality of any clinical tool, that of repeatability and objective evaluation in the hands of different users.

When the FMS was put to the test in very active population groups, its usefulness became clear. American football players were analyzed in a 2009 study in the *Scandinavian Journal of Medicine, Science and Sports;* they demonstrated reliable improvements in FMS scores from a standardized intervention based on the screening examination and established an FMS score cutoff predictive of increased injuries.[16]

Firefighters benefitted from an FMS-guided functional exercise program.[16]The FMS-guided intervention resulted in a 62% reduction in time off of work because of injuries and reduced injuries by 42% during a 12-month period.

Movement pattern performance is an important precursor to increased exercise participation and is an important addition to the exercise world. The FMS and SFMA are new and essential tools for the use of exercise as medicine. They provide a much-needed "standard operating procedure" for movement quality. Gray Cook and colleagues have a clinical website (http://www.functionalmovement.com) that teaches and instructs on movement systems and provides valuable clinical tools for clinicians.

New Insights on Exercise for Weight Loss

Once movement quality is attended to, exercise quality needs to be addressed. The current approaches of exercise for weight loss and health are still centered on the low-intensity, "aerobic-zone," calorie-burning paradigms. Recent understanding is redefining this narrow approach to health and fitness. A caloric-focused model of metabolism may not be the most useful way to view exercise. If we look at track athletes, both elite marathoners and sprinters have very low percentages of body fat. Sprinters, however, have less body fat and higher amounts of muscle mass, yet they exercise in a very different way.[17–19] Sprinters engage in short bursts of anaerobic effort lasting seconds, whereas marathoners run in an "aerobic zone" for hours and use large amounts of caloric energy. If the aerobic model of exercise truly is the best way to gain fitness and fat loss, why is there a discrepancy between these two groups of athletes? In analyzing recent data, we can see that anaerobic contributions to energy expenditure now need to be considered in exercise prescription.[20–22]

There is a common misunderstanding of fat-burning percentages in exercise. Many still perceive exercise done in the aerobic zone, usually defined as between 65% and 80% of maximum heart rate (MHR), as burning the most fat per unit time. This is not the case. Lower exercise intensities burn a higher proportion of fat compared with sugar, relatively speaking. However, exercise beyond the aerobic training zone burns more total energy and fat because it is a higher intensity.

Suppose two people exercise for 30 minutes. Person A jogs at an intensity of 60% MHR, whereas person B jogs at an intensity of 60% MHR and then, every few minutes, sprints for a short period, reaching over 90% MHR before returning to a lower intensity. Assume person A burned 200 calories, 60% coming from fat and 40% from sugar. Person A therefore used 120 total units of fat and 80 units of sugar (200 calories × 0.60 = 120 fat calories). Person B exercised at a higher intensity, burning a lower percentage of fat. Assume Person B used 50% fat and 50% sugar but burned 100 more calories because of the higher workload. Person B therefore burned 150 units of fat and 150 units of sugar (300 × 0.50 = 150 fat calories). When the energy burned is totaled, person B burns more energy (300 calories) and more total fat (150 units compared with 120 units) than person A, despite using a lower percentage of the energy as fat. This example shows that higher-intensity exercise of the same duration surpasses lower-intensity exercise in fat calorie use. There are further metabolic consequences created through higher-intensity exercise that make its application in exercise prescription for fitness and fat loss more intriguing.

Does Aerobic Exercise Work for Weight Loss?

A 2009 review by Melanson et al.[23] looked at the effect exercise had on metabolic stimulation. The study primarily looked at moderate-intensity aerobic exercises like jogging, biking, or swimming while including a small sample of anaerobic exercise studies. It showed that aerobic exercise of moderate intensity did not provide a metabolic advantage aside from the calories burned during activity. A previous meta-analysis done over a 25-year period came to a similar conclusion.[24] This study analyzed the data from over 400 studies comparing the effects of diet alone, aerobic exercise alone, or diet plus aerobic exercise on weight loss. The results showed that aerobic exercise did not provide a significant advantage to weight loss over diet by itself. Although aerobic exercise has been shown to be a reliable tool in the maintenance of weight loss,[22,23] these studies suggest it may not be enough to elicit significant fat-loss effects.[24–27]

At the same time, new lines of research show potentially promising effects from more anaerobic modalities. High-intensity interval training (HIIT) is a method of alternating highly anaerobic activity with more relaxed aerobic movement. This method allows the benefits of intense exertion under more tolerable conditions. Rest is required to sustain intense activity for any length of time. Weight training is another anaerobic-centered activity. These more anaerobic-dominated exercise approaches have unique benefits that may complement the calorie-burning effects of aerobic exercise.

Aerobic Versus Anaerobic Exercise

In very simple terms, aerobic metabolism takes place in the mitochondria and requires the use of oxygen. Anaerobic metabolism proceeds through a different pathway and requires neither the involvement of the electron transport chain nor oxygen. It is well known that as exercise intensity increases, anaerobic metabolism dominates; unfortunately, the exact anaerobic contribution to energy production is exceedingly difficult to measure. The standard way to approximate calorie expenditure and substrate utilization during exercise is through the measure of respiratory gases. The ratio of carbon dioxide expelled to oxygen consumed can give a predictable evaluation of not only energy use but also fuel utilization—glucose versus fat.

However, this method is only valid at lower exercise intensities. At higher intensities, the relationship is less clear. To help address this error, researchers also measure excess postexercise oxygen consumption (EPOC). This is a measure of the recovery energy expenditure after exercise, and it has been thought to consist of anaerobic contributions to exercise as well. There is

some argument as to how meaningful this EPOC effect can be. Many researchers claim the effect does not last long, only several hours, and amounts to, at best, 15% of total calories burned.[28–30] However, these approximations come largely from studies with lower exercise intensities involving standard aerobic exercise protocols.

Studies using highly anaerobic protocols including cardiovascular interval protocols and weight training showed a much different picture. In 2001 Schuenke et al.[31] showed that circuit resistance training, using heavy weights and short rest periods lasting only 31 minutes, were able to generate an EPOC that persisted for 48 hours. The results showed that metabolism 24 and 48 hours after the exercise session was increased by 21% and 19%, respectively. The researchers pointed out that for a typical 180-lb individual, "this equates to 773 calories expended post exercise" while resting and as a result of the workout. This is far from insignificant and greatly exceeds the 15% many researchers quote for EPOC. Similar findings were shown in women using a similar resistance-training protocol. In women, the elevation in metabolic rate lasted 16 hours.[32–34] The same findings were seen with HIIT protocols, with significant EPOC values lasting up to 24 hours.[33–35]

Exercise Burn and "After-Burn"

Dr. Christopher Scott of the University of Southern Maine published extensively in this area and is the author of one of the authoritative textbooks in this field, *A Primer for Exercise and Nutritional Sciences: Thermodynamics, Bioenergetics, and Metabolism*.[36] In his works, Dr. Scott points out that EPOC does not fully explain anaerobic energy use and that the anaerobic contributions to exercise might be even greater than originally thought, especially where lactic acid production is concerned. Dr. Scott emphasized that to fully account for calories burned during exercise, three components must be measured: (1) calories burned aerobically during exercise, (2) calories burned aerobically after exercise (EPOC), and (3) anaerobic calories burned from exercise.[37–41] EPOC and the anaerobic lactic acid measurements for exercise should be considered separately according to Dr. Scott.

A 2005 study by Dr. Scott demonstrated the potential ramifications of anaerobic exercise. This study compared a 3.5-minute aerobic exercise challenge with three work-equivalent 15-second sprints.[42] Calorie use during the exercise bout was calculated to be 29 kcal for the aerobic exercise and approximately 4 kcal for the sprinting. However, when the EPOC contribution was added to the two exercise bouts, energy use rose to 36 kcal for the aerobic bout and 39 kcal for the sprint exercise. Finally, when the purely anaerobic contribution was added to the calorie totals, the numbers for the anaerobic sprint exercise rose significantly. The final tally was 39 kcal for the aerobic exercise compared with 65 kcal for the sprint exercise. By adding both EPOC and the anaerobic contribution to the original calorie total, the sprint exercise was shown to far surpass the aerobic exercise in calories burned. This is interesting when one considers the aerobic exercise session took over four times longer to complete (210 vs. 45 seconds). Without including both the EPOC and anaerobic energy use, a full 94% of the calories used during the sprinting would go uncounted.

In studies published in 2006 and 2009 in the *Journal of Strength and Conditioning Research,* the same researchers quantified anaerobic energy use during weight lifting.[37,41] Using the method of measuring and quantifying all three components of calorie burn (aerobic metabolism during exercise, EPOC, and anaerobic contributions), these studies showed that weight-training exercise burned 70% more calories than originally thought.

Hormonal Versus Caloric Exercise

To understand the full ramifications of this new exercise science, the discussion must move to hormonal metabolism. Hormones as we describe them in this chapter refer to all signaling molecules in the body, including steroid hormones, muscle-derived cytokines (myokines), and other signaling molecules. Hormonal messengers directly influence the fat-burning stimulus during exercise and may be responsible for part of the EPOC after-burn as well.

Brief bouts of anaerobic exercise appear to adjust hormones for greater caloric burn during and after exercise.[43] This increased energy use is partly explained by EPOC. This is a measure of how much oxygen the body consumes in the hours and days after a workout. An example of EPOC in the acute sense is climbing a long flight of stairs. While walking up the stairs, breathing is labored, but respiration becomes most difficult after reaching the top. The body does this to recover the "debt" of oxygen used during activity. The EPOC created by climbing a flight of steps is an example of the much larger metabolic effect created from intense movement.

Exercise of sufficient intensity elevates stress hormones like adrenaline, noradrenaline, and cortisol. Together these hormones ensure the switch to glucose metabolism, which historically supplied the energy to fight or flee. As exercise intensity is elevated further, anaerobic contributions to metabolism increase. This produces lactate (lactic acid), which, contrary to common belief, is not a waste product, but a physiological buffer and signaling molecule.[44–46] As lactate rises, it is correlated with, and some studies suggest actually induces, the anabolic steroids testosterone and human growth hormone (HGH).[47–49] This "hormonal soup," catecholamines along with cortisol, HGH, and testosterone, acts synergistically to increase postexercise fat loss and lean muscle tissue production, thus creating a more fit and functional physiology.

Aerobic and anaerobic exercise have different hormonal effects. Hormones do not work in isolation, and like people, they behave differently depending on the social environment. Interestingly, the hormone cortisol, often seen as a fat-storing hormone because of its insulin-desensitizing effect, behaves differently when combined with growth hormone and testosterone.[46,50,51] When cortisol is "socializing" with testosterone and growth hormone, its catabolic action on muscle is blocked, fat storing at the belly is attenuated, and the three may synergistically enhance fat burning.[51–54] Attempting to blunt the cortisol response to high-intensity exercise may be counterproductive for fat burning and not necessary in the context of growth hormones.[55–58]

Long-duration, lower-intensity cardiovascular exercise behaves differently in regard to cortisol. There are also key changes in hunger hormones that are different between lower-intensity aerobic exercises compared with higher-intensity anaerobic workouts. With aerobic-zone exercise, there is a danger of cortisol increasing unopposed by the growth-promoting hormones.[50] This, along with a lowering of leptin and an increase in ghrelin, can lead to compensatory eating with specific cravings for fatty, sugary, and salty foods.[59–65] Higher-intensity, shorter-duration activity has the opposite effect on ghrelin, with a more balanced ratio of catabolic versus anabolic hormones.[62,63] This may explain why standard aerobic prescriptions have not been shown to be as effective for optimal body composition.[23,24,66–69]

Aerobic Zone Versus Interval Training

A 2001 study compared standard aerobic-zone training and anaerobic-interval exercise in women.[70] The anaerobic-interval group exercised for 2 minutes at a highly intense 97% of MHR. They then rested by doing 3 minutes of low-intensity activity. The more aerobic group performed moderately intense activity at close to 70% of MHR. The researchers made sure that each group burned 300 calories. Despite

exercising longer and burning the same amount of calories, the aerobic group lost less body fat at the end of the study compared with the interval group. In addition, fitness in the interval group was substantially greater than in the aerobic group.

A similar study published in the same journal in 1996 showed that an anaerobic-interval group burned significantly more fat than their aerobically trained counterparts.[71] Not only did the interval group burn greater amounts of fat during exercise, but they also exhibited increased fat-burning effects that persisted for 24 hours after the exercise had stopped. The interval group was able to accomplish this with an exercise session that was a full 15 minutes shorter than the aerobic group.

A 1994 study[35] tracked two groups of people, one group doing aerobic training for a period of 20 weeks, whereas a second group was followed for 15 weeks and engaged in HIIT. The researchers wanted to see how each program would affect body composition. The aerobic group burned 48% more calories than the interval group (120.4 vs. 57.9 MJ) during exercise. The interval group, however, enjoyed a ninefold greater loss in subcutaneous fat. At the conclusion of the study, muscle biopsy analysis showed that resting levels of 3-hydroxyacyl coenzyme A dehydrogenase, a marker of fatty acid oxidation, were significantly elevated in the interval group but not in the aerobic group.[35]

A 2008 study looked at intense intermittent exercise compared with steady-state aerobics.[72] Forty-five healthy women between the ages of 18 and 30 were recruited for the study, divided into three groups, and studied for 15 weeks. One group did HIIT, where they sprinted on a bike for 8 seconds followed by a 12-second rest. This was repeated for 20 minutes. Another group did moderately intense peddling that was sustained for 40 minutes. The final group did no exercise. At the end of the 15 weeks, the high-intensity interval group lost 2.5 lb of fat, whereas the aerobic group actually gained 0.6 lb of fat. A measure of the fat-related hormones leptin and insulin were also positively affected in the HIIT group compared with the steady-state group. This was accomplished with a workout that was half as long (20 vs. 40 minutes) as the steady-state's group.

Resistance Training Studies

Research hints that resistance training may also provide unique benefits for fat loss and fitness. Recent analyses showed that the clear distinctions once set for aerobic exercise and resistance training are no longer delineated so clearly. Circuit training routines have been shown to provide an aerobic stimulus great enough for cardiovascular benefit while providing strength-training benefits.[73,74] Resistance training may also have great applicability for not just fitness and fat loss but also diseases of insulin resistance.[75,76] Weight training, compared with aerobic exercise, greatly attenuates the natural loss of muscle mass that occurs with aging and dieting[77] and improves body composition and self-esteem better than aerobic exercise modalities.[78–80]

Resistance training may also have a much greater effect on EPOC. Two studies already discussed[32] showed significant metabolic elevations in men lasting up to 48 hours and in women lasting up to 16 hours. These workouts used exercise regimens that were more intense than most studied resistance-training programs, but they were also shorter. Combining the benefits of resistance training with cardiovascular exercise seems to have the most benefit.[81] This type of training is called concurrent exercise and involves resistance-training workouts that are followed immediately by aerobic exercise or vice versa. Studies showed that these approaches afforded the benefits of both aerobic and resistance-training workouts.[82–85] This "cross-training" approach falls in line with historical movement patterns and saves time.

Concurrent exercise approaches follow two patterns, serial concurrent exercise (SCE) and integrated concurrent exercise (ICE). In SCE, the two modalities (aerobic and resistance training) are done one right after the other, whereas in the integrated format, the two modalities are alternated; a weight-training movement is done, followed by a cardiovascular "burst" of exercise. Based on studies, it appears the benefits of this type of approach can be amplified further using the ICE approach. In a series of three studies in 2008, all published in the *Journal of Strength and Conditioning Research,* Davis et al.[86–88] showed the potential benefit of ICE protocols. An ICE workout consisted of brief 60-second bursts of "cardio-acceleration" placed between traditional weight-training sets. This protocol was able to dramatically amplify multiple fitness parameters over and above the same workout volume done in an SCE format.[87] Fat loss in the ICE group was close to 10 times greater than in the SCE group over an 11-week period. This constituted a time commitment of just over 4 h/week. Because the work was equivalent in both groups, it was the combination of exercises that made the difference. This same workout protocol showed the ability to improve cardiorespiratory and cardiovascular parameters even in well-trained athletes.[86] It also decreased the delayed-onset muscle soreness, the feeling of soreness lasting 24 to 48 hours after the workout, in the ICE group.[88] Similar protocols showed the same promising results in body composition change and cardiovascular benefits.[89,90]

Safety of Interval Exercise

HIIT, and intense weight training, can be used effectively and safely when combined with the appropriate use of heart rate (HR) monitoring, perceived exertion rate (PER), and the use of intervals: periods of exertion followed by rest. Studies show that this type of activity is manageable in several illness models, including chronic obstructive pulmonary disease,[91,92] post–coronary artery bypass patients,[93] congestive heart failure,[93] and heart transplantation patients.[94] This type of anaerobic stimulus more realistically mimics real-world challenge and allows for self-paced exercise that is safe, tolerable, and more beneficial for many heart and lung patients.[91–98] Cardiac patients also may have less risk with this type of activity because it has more favorable effects on ST-segment changes and heart rate variability (HRV).[96–98]

Monitoring HR is useful for any health care provider prescribing exercise. It is important to understand that HR equations are merely estimates based on age; there is much variability. HR equations, in general, underestimate HRs in the very fit. The old HR equation of 220 − age is an inferior HR equation that underestimates HR in the old and overestimates in the young.[99] Newer equations allow for better predictive value. Based on current understanding, women and men should use separate equations for predicted HR percentages. For men, the MHR equation should be 208 − age (0.7).[99] For women, this equation should be 206 − age (0.88).[100] It is also useful to know the equation for translating percent of MHR to percent of oxygen uptake (VO_2), and vice versa. That equation is %MHR = (0.64) %VO_2 + 37.

Because multiple drugs and disease states can interfere with HR, exertion ratings used alone or combined with HR are a more useful clinical tool. In exercise research, a 16-point exertion scale called the Borg scale is used. It is a cumbersome tool to use and teach in clinical practice. A simple 1 to 10, with 10 being maximum exertion and 1 being at rest, is a far more useful tool clinically. It is easy to teach and implement. Traditional aerobic exercise scores between 6 and 8 on the 1 to 10 scale. HIIT will reach between 8 and 10 on the work phase and between 1 and 4 on the rest phase. In clinical practice, this is a useful aid in working with exercise intensity. Combining HR percent monitoring with PERs and heart rate recovery (HRR) allows for tight control of workout safety.

Two other useful clinical tools for health care practitioners are the "talk test" and HRR. Exertion and respiration are closely linked. The ability of a person to talk during exercise is a direct indication

of whether they have crossed into the anaerobic zone.[101] For the unfit, this usually occurs around 55% of VO_2 max, and for the very fit, it occurs around 85% VO_2 max. This corresponds to 72% MHR and 91% MHR, respectively, leaving the average healthy exerciser right around 80% of MHR for the anaerobic threshold, at which point the ability to talk will be compromised. Correlating this "talk test" with an individual's HR allows practitioners to closely monitor exercise. HRR is a measure of how fast the heart recovers from exertion and is an indication of sympathetic and parasympathetic tone. A healthy heart should recover at least 25 beats/min or more within 1 minute after exertion. A heart that recovers 10 or fewer beats in 1 minute is a concern that should constitute a referral to a cardiologist.[102]

Muscle–Body Messengers and Inflammation

If we were able to see, in real-time, the molecular interactions occurring within muscles and fat tissue, we would see a unique interaction of muscle communication via myokines. Every time the body moves, muscles release signaling molecules that communicate to the rest of the body. The endocrine properties of muscle, like fat, have been confirmed.[103–105] We are now learning that myokines, cytokines derived specifically from muscle, give instructions to the body about how to function and adapt and may very well hold the key to controlling chronic inflammation.

Interleukin-6: The Exercise Factor

Of the numerous myokines, interleukin-6 (IL-6) is one of the most important in understanding the inflammatory response. IL-6 is generally known as a proinflammatory cytokine and a member of the inflammatory triad: tumor necrosis factor-alpha (TNF-α), IL-1, and IL-6. When all three of these molecules are released in the bloodstream, we find a proinflammatory effect, typically found with infection and sepsis. However, when released during exercise, IL-6 can have protective effects.[106,107] Skeletal muscle contraction induces increases in IL-6 while keeping TNF-alpha and IL-1 levels at bay via IL-1 receptor antagonist (IL-1ra) and soluble TNF receptors (sTNFRs).[108–110] IL-1ra inhibits interleukin-1-beta (IL-1β), a major proinflammatory cytokine, but also induces IL-10, which is not only anti-inflammatory itself but sets off a cascade stimulating other anti-inflammatory cytokines while concurrently inhibiting proinflammatory cytokines such as TNF-α. [106,109,110]

The IL-6 effect implicates exercise as a first-line defense against inflammation and thus suggests the benefits of resistance training in chronic illness and inflammatory conditions such as rheumatoid arthritis, heart disease, diabetes, and cancer.[111–115] Increasing exercise intensity, full-body muscle contraction, and muscle glycogen depletion are the major exercise elements enhancing IL-6 release from muscle.[104,116–118] These factors together can induce an increase of plasma IL-6 that is 20- to 100-fold over resting levels.[104,118] At these levels, IL-6 begins to exert influence over the body, relaying messages about the metabolic needs of the muscle. In this way, IL-6 acts more like a hormone than a cytokine by sending communications from muscle to adipose tissue, immune cells, and the liver instructing the body to burn fat via adenosine monophosphate kinase (AMPK) [116,119] and hormone-sensitive lipase (LPL),[113] control glucose regulation by improving insulin sensitivity,[120] and inhibit the production of the proinflammatory cytokines.[121,122]

Interleukin-15: The Arnold Cytokine

A potent antiobesity and anti-inflammatory myokine, IL-15 has gained the title the "Arnold cytokine" after the famous bodybuilder Arnold Schwarzenegger. This myokine is a potent anabolic factor[123] that is upregulated in trained skeletal muscle, particularly type 2 muscle fibers, which are most activated in resistance training over endurance exercise.[124,125] Furthermore, IL-15 decreases fat deposition, reduces white adipose tissue, lowers visceral adiposity, and possibly may inhibit TNF-α, thus promoting an anti-inflammatory benefit. These effects are desirable because muscle mass is frequently lost along with fat in aerobic-centered exercise programs.

We do know that an accumulation of adipose tissue, particularly visceral adipose tissue, induces chronic systemic inflammation via macrophage infiltration, thus leading to many downstream effects, such as insulin resistance, cardiovascular disease, diabetes, and neurodegenerative disease. IL-15, like IL-6, crosses over, having hormone-like action affecting the body systemically, thus explaining the important role these myokines play in the anti-inflammatory benefits of exercise.[126]

Lactate

Lactate has been correlated with several positive benefits to exercise. It is now believed that lactate is directly related to some of these beneficial changes through hormone-like action. As exercise intensity escalates, there is a large surge in catecholamine production. This occurs to supply the body with much-needed blood sugar to fuel intense exercise. As the exercise intensity increases, aerobic physiology becomes "maxed out," forcing the body to become more anaerobic. This switch, believed in the past to be caused by an oxygen deficit, is currently understood to indicate mitochondrial shuttle saturation. When this occurs, pyruvate and hydrogen ions begin to accumulate in the cytosol. It is the accumulation of hydrogen ions that lowers the pH of the cell, causing fatigue and the familiar muscle burn of intense exercise. In this situation, lactate is quickly formed. Lactate can then be recycled back to glucose via gluconeogenesis, be burned directly by conversion back to pyruvate and entry into the Krebs cycle, and/or engage cellular machinery as a signaling molecule.

The major signal sent by lactate during exercise seems to be an "adaptation signal." Analysis of this action shows that lactate has two major functions: first, it increases cellular events, leading to mitochondrial generation,[127,128] and second, it stimulates the release of growth-promoting hormones, including HGH and testosterone.[46,129–131]

The major action on cellular signaling seems to be the upregulation of MCT-1.[128] MCT-1 is an embedded protein in the mitochondrial membrane that speeds the formation of pyruvate from lactate, thus making existing mitochondria more efficient. In addition, research by Hashimoto et al.[127] in 2007 elucidated a complex mechanism whereby lactate interacts directly with key genes involved in mitochondrial biogenesis. Taken together, this opens a whole new understanding for improving metabolic efficiency. By harnessing the power of lactate, mitochondrial levels can be increased and enhanced, resulting in many beneficial effects on total physiology.

The idea of lactate as a hormone is a novel concept. However, it has been made clear through several studies over the past few years that lactate is a key signaling molecule in exercise metabolism. Interestingly, a lactate receptor called GPR81 was recently isolated in rats, confirming it does act like a hormone.[132] Other studies have shown that lactate can directly stimulate the release of testosterone, progesterone, and HGH.[44,129,133–135] This lends further credibility to lactate's role in helping the body adapt and grow.[136]

Testosterone and Human Growth Hormone

Testosterone and HGH, in particular, are key players in human metabolism, especially as they pertain to physique development, combating obesity, and antiaging effects. Testosterone and HGH, in addition to

other effects, increase lean muscle tissue and decrease fat mass. Both of these anabolic hormones are more pronounced with anaerobic exercise.

Exercise Approaches to Inflammation

IL-6's release from muscle cells is not a nervous system phenomenon and is not based on muscle injury. It seems the impetus for IL-6 release is mechanical.[105,118] In other words, just the act of movement is all that is required. However, there are ways to amplify IL-6 production during exercise. The science of exercise metabolism now goes far beyond simple calories. The ability to harness the far-ranging hormonal and cytokine effects of exercise can be accomplished through the use of short-duration, high-intensity exercise techniques used in athletic populations for decades. Although the term *high intensity* has the tendency to cause reservation, these tools and techniques can be adapted for use in even the least fit and most populations with inflammation.[32,112,137]

Before discussing the techniques in this approach to exercise, it is important to define why short, intense exercise may be more useful than traditional approaches. The damage associated with chronic inflammation is compounded by a lack of offsetting growth factors. The body produces these growth factors in response to intense exercise. Testosterone and especially growth hormone are known to be factors linked closely with intensity. The word *intense* as used here means exercise that is glycogen depleting—that is, it significantly reduces the body's muscle and liver sugar stores. Only two types of exercise are likely to produce these effects, long-duration exercise lasting hours or short, intense, sprint-type exercise. There are obvious constraints to prescribing hour-long exercise sessions because lack of time is the number-one reason cited for lack of exercise participation, making short, intense exercise more realistic. In addition, the overall hormonal response to long-duration exercise is counterproductive because it raises cortisol levels above the body's ability to compensate with growth promoters.[51–57,138]

This type of exercise also makes sense because it creates a hormonal environment that produces sustained fat burning and muscle growth.[32,58,70] The amount of glycogen reduction is directly correlated with IL-6 release, and high-intensity exercise is shown to increase IL-6 and catecholamines together.[105,109,117,118] Catecholamines have their own independent effect in lowering TNF-α and IL-1, synergistically enhancing IL-6. Combining these known effects with techniques that can deliver the same benefit in less time presents the opportunity to supply these anti-inflammatory effects in short time periods.[109,122,139]

EXERCISE PROTOCOLS

Holistic Fitness Prescription

Based on the research reviewed in this chapter of the new understandings emerging from exercise research, it seems a cross-training approach in line with our historic movement patterns would provide the most benefit. This approach would include walking, aerobic-zone exercise, resistance training, and cardiovascular interval training. However, realizing exercise prescription needs to be feasible and time consciousness necessitates combining elements to generate the most health benefit.

Putting this information in the historical context, it would appear that daily walking should be done as much as feasible. Walking should be viewed as a necessity rather than exercise. Based on historical information, walking constituted the predominant activity of our ancestors. Walking not only burns calories but also has restorative and relaxing effects. Because walking and eating are generally incompatible, it may be a suitable replacement for eating behavior. Walking may best be done in the evening and for hormonal benefit; walking in a natural setting may be more beneficial than walking in more urban settings.[140] Studies have shown positive effects on lowering cortisol.[141]

In addition to walking, aerobic-zone training should be instituted as well. Based on most data, an aerobic program lasting between 20 and 60 minutes 3 to 5 days/week seems optimal. Based on new information, aerobic exercise may be best for weight maintenance and not the most optimal for attaining weight loss. Given the new data on HIIT, the time spent doing aerobic exercise may be able to be cut in half. A HIIT program done 3 times/week for 20 to 40 minutes could save considerable time[72] and provide the same cardiovascular benefit and perhaps better weight-loss results without the compensatory food behaviors.[59–65]

Recommendations capitalizing on the concept of non–exercise-associated thermogenesis (NEAT)[142] and burst training[140-143] may have special applicability in today's time-starved world. NEAT involves accumulating as much non–exercise-related activity as possible and includes everything from washing the dishes to fidgeting with a pencil, to nervously bouncing a leg up and down and even nonsitting time. Burst training is a concept popularized by Mark Smith, PhD, and involves accumulating several 1-minute anaerobic bouts of activity throughout the day. Several interesting studies showed this approach was able to generate clinically meaningful weight-loss results with only minutes of exercise per day.[142,143] Instituting behavioral changes that involve parking further away, doing a burst of activity by running up the steps, standing rather than sitting, and even fidgeting when standing or sitting still can all have a significant effect on total energy expenditure.[144]

Weight-training programs should also be a center point of health, fitness, and fat loss.[145] Resistance exercise excels at maintaining muscle mass and helps attenuate rebound weight gain.[146] Three full-body workouts per week, using moderately heavy weights in the 8 to 12 repetition range for 3 to 5 sets appears optimal. Again, because time is an increasingly limiting factor, integrating resistance training with interval training into one workout 3 to 5 times/week for 30 to 60 minutes can save considerable time yet still yield significant caloric expenditure and fat loss.

Rest-Based Training Method for Exercise Prescription

Rest and movement are often seen as opposites, but they are actually complementary and dependent on each other. Exercisers told to run as fast as possible for 10 minutes will necessarily regulate intensity to complete the task. If they were instead told to run as fast as possible for 10 seconds, the intensity could be dramatically elevated. True high-intensity exercise is impossible to achieve without rest. Quality rest leads to quality work, and vice versa.

HIIT and intense weight lifting have always coupled work with rest. One issue with these workouts is the rigid structure. The work/rest ratios "force" individuals of varying fitness levels to work at mandated levels. This works to lower intensity, inducing the same pacing effect seen in traditional aerobic exercise. These types of workouts are often too intense for many and can create psychological resistance to participating.

Rest-based training (RBT) uses rest, autonomy, and time manipulation to optimize intensity for all fitness levels. It combines the latest in exercise science and motivational psychology. RBT enjoys the same physiological benefits of intense interval exercise and weight training but with key psychological benefits.

RBT differs in the application of rest. Although interval training and weight training have clearly defined work and rest ratios, RBT leaves the exerciser in charge of the duration of rest. The language employed in this type of training is "push until you can't, rest until you can." This shift in paradigm acts as reverse psychology for exercisers.

The motivational psychology of exercise is an important consideration regarding exercise consistency, frequency, and intensity. The primary goal or purpose of interval training is to maximize work effort across all work bouts and employ the shortest recovery time possible to maximize the training stimulus. Contrary to popular belief, research has shown that exercisers who have autonomy over their workout parameters will often work harder and are able to self-regulate to an optimal work/rest ratio for their physiology.[146,147]

There are four key attributes in our RBT system. All are geared toward maximizing work effort in a safe and scalable way. The key tenets of rest-based exercise are represented by the acronym REST.

Rest Based

Pushing to the point of rest is actually the goal of a rest-based workout. By putting the focus on rest as opposed to work, RBT not only automatically increases the quality of work but also makes exercise psychologically easier.[146–148] When exercisers know they have permission to rest, they may voluntarily work harder without even being consciously aware they are doing so.

Interestingly, animal research showed that intermittent exercise is inherent and may be an evolutionary adaptation to maximize distances covered per unit time.[147] Animals naturally engage in sporadic work/rest ratios during movement and self-regulate exercise to optimize both performance and recovery. Research showed that humans have the same capability.[146]

Extrinsic Focus

A major inhibitor of intensity is exercisers' focus on intrinsic sensations such as breathlessness, burning, and other uncomfortable feelings.[146,148] RBT uses strategies that focus participants away from these intrinsic sensations to more extrinsic factors. Workout parameters change quickly, monotony is minimized, circuits are used, exercise timing is limited, and different movement strategies are incorporated in the same workout. All of this is designed almost as a distraction technique so that the exercisers focus more on what they are doing versus what they are feeling. This helps them work harder and therefore rest more often.

Self-Determined

In psychology research, self-determination theory posits that when people are given control and choice over their options, internal motivation automatically increases.[149–151] With RBT, there is structure in the workout, but the exerciser is left in complete control over how hard to work, when to rest, and for how long and even has flexibility regarding exercise choice and modifications. These factors not only serve to increase the quality of work within a session[146] but can also improve exercise adherence from session to session.[146,149–153]

Time Conscious

Given that time and intensity are so closely linked, harder workouts by necessity must be shorter. RBT workouts can be as short as a 1-minute burst repeated multiple times throughout the day to as long as 40 minutes of continuous exercise employing start-and-stop working and resting. Workouts lasting over 40 minutes suffer in intensity and may have negative hormonal consequences.[62,63,72]

Work/rest ratios employed by traditional interval and weight-lifting workouts work for some but can be imperfect for most. By focusing on rest in a workout and allowing exercisers control over when they rest and for how long, optimal intensity for results can be achieved in a safe, scalable way. A 96-year-old grandfather would be able to use the same workout approach to deliver optimal intensity for him, whereas a 24-year-old elite athlete could use the concept to deliver an optimal intensity as well. Rest-based exercise can be seen as a new functional model for fitness and fat loss.

CLINICAL APPLICATIONS

Exercise and the Heart

Aerobic-zone exercise is a well-known preventive and treatment strategy for cardiovascular disease. Virtually all health care providers are aware of the aerobic exercise prescription advocated by most policy-making organizations as "20 to 60 minutes of aerobic exercise done at an intensity of 65% to 80% of MHR on all or most days."[156] Given that these recommendations are well established and universally accepted, we will focus our attention here on new research related to the heart.

Since the publication of the book *Aerobics* by Kenneth Cooper in 1968, participation in activities such as jogging, biking, swimming, marathons, and triathlon training has steadily risen. Newer research suggests, however, that this approach can be taken too far and that exercise for health, fitness, and fat loss should not be so one-dimensional. Dr. Cooper himself has conceded "In that book I said, 'The more exercise, the better.' But by 1982, after too many telephone calls from distraught widows whose 55-year-old, overweight smoker husbands had died jogging, I realized I had made a mistake. … Exercise wasn't a panacea that could fix everything, it had risks.… There may be a point of diminishing returns."[157] To improve our return on exercise investment, there must be adequate rest between sessions. Resting may also include active resting such as walking, restorative yoga, meditation, and tai qi. However, sleep is certainly the most important aspect of restoration, with 8 to 10 hours being necessary to reap the most from exercise. Of note is that the older the age, the more rest that may be needed between exercise sessions.

The risks of excessive aerobic exercise are now better understood. Ultra-endurance exercise, such as marathon running and triathlons, can have a negative effect on heart function. Intense, long-duration aerobic activity dramatically elevates oxidative stress in the heart, alters left and right ventricle function, and causes damage in otherwise normal hearts.[158–160] This is not to say aerobic exercise is dangerous but rather to highlight the potential downside of an aerobically dominated exercise prescription.

Research studying ultramarathon runners has found that these athletes experience significant detrimental changes in their immunological, hematological, and biochemical parameters. Ultra-endurance training in cold conditions may significantly impair immune function via changes in neutrophils, immature neutrophils, and monocytes, suggesting an increased risk of infection.[154] Furthermore, cardiovascular illness and renal dysfunction are evident with increases in blood viscosity,[155] postexercise anemia, increased creatine kinase (CK) and brain natriuretic peptide (BNP), and increased copeptin.[156,157]

On the other hand, there is some research suggesting that at least at the cellular level, certain biochemical processes are put into play with ultra-endurance athletes that suggest such exercise may impart longevity. One of the ways this can be assessed is via telomere length and cellular senescence. Aerobic exercise prolongs and prevents shortening of leukocyte telomeres and promotes telomere homeostasis by the action of human telomerase reverse transcriptase (TERT), the shelterin complex (or telosome), and miRNA.[158,159] Cellular senescence appears to be slowed in endurance athletes compared with their sedentary counterparts, with reductions in DNA damage, inflammatory markers, and induction of telomerase, which is associated with longer telomere length and longevity.[160]

Obesity may actually be a better target for exercise therapy because it is so closely related to heart disease. Any exercise approach that helps lower body fat can be viewed as a heart-healthy plan. Because

so many view exercise as a time-consuming chore and because lack of time is the number-one reason cited for lack of participation in exercise, interval-training exercise prescriptions may be better suited to heart protection. High-intensity interval training, as evident in several studies, provides both the cardiovascular and aerobic benefits of endurance and moderate-intensity training while providing the benefits of weight-resistance exercise. Improvements in insulin sensitivity, VO_2 max, and cardiac function[161] and increased muscular irisin are seen with high-intensity training over moderate intensity.[162] Yet a key limiting factor in exercise is actually physically exercising, but compared with moderate continuous exercise, high-intensity exercise with short bursts of action is more enjoyable and improves patient compliance.[163,164]

Interval Training and the Heart and Vascular System

The theory behind interval training is that the heart, like all muscles, needs to be challenged to repair and grow stronger. Theoretically, interval training allows the advantage of a harder challenge with less risk because each high-intensity bout is followed by recovery. If done correctly, the heart is forced to alternate between sympathetic stimulation and parasympathetic recovery. This, it is argued, is a more functional way to exercise because it trains HRR and heart stimulation. Because many cardiac events come from sudden unexpected anaerobic challenges, like shoveling the first winter snow, running through an airport to catch a plane, or walking up a large flight of steps, HIIT is believed to help the body prepare for these challenges by teaching the heart to work and recover quickly.

HRV and spontaneous cardiac baroreflex provide functional measures of cardiac parasympathetic activity. A study in April 2005 showed the effect of interval training on both.[96] Eleven healthy elderly men, mean age 74 years, underwent an intensive 14-week interval training program involving nine 1-minute bouts of exercise at 85% MHR followed by 4 minutes of recovery at 65% MHR. Aerobic capacity increased 18.6%, whereas HRV showed a significant parasympathetic shift at night from pre- to posttraining. The cardiac baroreflex response also improved, with 10 of the 11 participants showing a favorable response.

Benefits of HIIT may be good for peripheral vascular disease and cardiovascular disease. A 2006 study reported an observational study on the effect of HIIT on intermittent claudication.[165] A total of 47 patients were included in the study. Patients were asked to walk on a treadmill to maximal claudication pain six times in each exercise session with 3 minutes of rest in between. Once a patient could walk continuously for 6 minutes without reaching maximal pain, the speed and/or grade was increased. A rehabilitation score was calculated as the product of speed and grade achieved by the participants. Results showed that HIIT led to clinical improvement in symptoms and a higher tolerable workload by patients. No adverse effects were seen from the treatment, suggesting those with peripheral arterial disease could both tolerate and benefit from HIIT.

In 2007, Wisløff et al.[166] shed some light on the cardiovascular effects of HIIT versus traditional aerobic training for heart failure patients. Twenty-seven patients with stable postinfarction heart failure were randomized to either aerobic exercise (70% MHR) or HIIT (95% MHR for 4 minutes separated by 3 minutes at 50%–70% MHR) 3 times/week for 12 weeks or to a control group. The control group was told to follow the exercise advice of their family doctor and met for 47 minutes of walking at 70% MHR every third week. All groups did exercise on a treadmill. The major finding was that HIIT was superior to traditional aerobic training with regard to reversal of left ventricular (LV) remodeling, aerobic capacity, endothelial function, and quality of life. With respect to LV remodeling, in the HIIT group, the LV diastolic and systolic diameters decreased by 12% and 15%, and estimated LV end-diastolic and end-systolic volumes dropped by 18% and 25%, respectively. Prohormone BNP, a marker of hypertrophy and severity of heart failure, declined by 40% in the HIIT group. There was no change in the traditional aerobic group or control group in LV remodeling, pointing to a rather profound effect of HIIT on traditional aerobic exercise in this patient population.

As mentioned, HIIT has been shown to be safe and well tolerated in chronic obstructive pulmonary disease,[91,92] postbypass patients,[93] congestive heart failure,[93] and even heart transplantation patients.[94] As discussed, HIIT may realistically mimic real-world challenges. It can also be tailored into a self-paced format that is safe, tolerable, and beneficial for many cardiovascular conditions.[95–97] It was shown in one study to have more favorable effects on ST-segment changes than traditional aerobic exercise, in addition to the positive effects on HRV.[96–98,100]

Obviously, physicians prescribing exercise for high-risk patients will not want to completely abandon traditional aerobic exercise in favor of HIIT. Traditional aerobic exercise is well established to both treat and prevent cardiovascular diseases. More studies need to be done on HIIT, but it appears it may have some unique cardiovascular benefits. There are some considerations when prescribing this form of exercise. Work/rest ratios should be larger for the more fit and smaller for the less fit or more frail. A beginning exercise protocol for a younger fit person wanting to optimize cardiac prevention would be a work/rest ratio of 1:2. More frail and less fit clients will want to start with a work/rest ratio of 1:4 or greater. The RBT approach highlighted previously may provide increased benefit and safety when using intervals.

Exercise and Bone

When prescribing exercise for bone, there are several important considerations: the mechanostat theory, the concept of osteogenic shear forces, and most importantly, knowing that bone density does not necessarily equal bone strength. A strong bone is both dense and flexible, whereas a weak bone has only one or neither of those qualities.[167]

The mechanostat theory states that bone has set points of minimum effective strain (MES) that determine whether or not bone will be gained or lost.[168–170] If forces on bone increase more than what the bone is accustomed to (i.e., relative MES), mineral flux into bone increases. This, along with compensatory structural changes, helps bone become competent enough to deal with increased functional demand. Likewise, if demands on bone decrease and fall below the MES threshold, bone metabolism changes result in weaker bone.[170] The latter scenario often prevails in age and illness and can happen very quickly. During periods of immobilization, bone mineral density can decline as fast as 1% per month.[171,172]

To understand the concept of osteogenic shear forces, one must have some idea of the bone's anatomy. Cortical bone contains lacunae (hollowed-out areas) that are connected via canals (canaliculi). These lacunae house osteocytes that extend dendritic arms through the canaliculi to communicate with other osteocytes. Osteocytes act as mechanoreceptors. The osteocyte and its dendritic arms are bathed in fluid. The movement of this fluid is believed to be "sensed" by the osteocytes. The degree of intensity of this fluid movement dictates the degree of bone-building stimulation. Research hints that exercise that creates large "shear forces," such as jumping, creates the most potent stimuli for bone growth. Another key factor in this physiology is that small jostling forces have a much weaker effect, and continuous exercise may work against bone building by causing desensitization of osteocytes. Optimal bone-building exercise therefore is sporadic in nature, alternating work and rest, and creates large strain and shear forces. Multidirectional jumps and hops seem to be most ideal.

Measuring bone density alone does not provide an adequate measure of bone strength.[167] To determine the full effect of exercise, all bone parameters should be assessed. To properly ascertain bone strength, cortical thickness and bone diameter are equally important compared with bone mass. Cortical bone, the outer portion of bone, is responsible for 80% of bone strength. Thicker bones are also stronger bones. By measuring density, cortical bone, and thickness, we get a much more accurate picture of how much force a bone can handle. Effective exercise should address all these areas. In addition, bone-building exercise should be aimed at developing functional parameters that prevent a fall in the first place.[17,173] This means that exercise modalities that build strength, flexibility, balance, and reaction speed should not be ignored.

Exercise and Cancer

Yoga therapy has been shown to predict survivability in breast cancer,[174] is correlated with better outcomes in cancers of the head and neck,[175] and allays anxiety- and stress-related dysfunction in cancer treatment.[176,177] The research on yoga and its use in cancer is gaining ground. A report by Brauer et al.[178] in 2010 looked at the leading cancer treatment hospitals in America. This study showed that 56% of these centers incorporated yoga into their clinic offerings.

The wasting of cancer, cachexia, is a difficult condition to treat, with few therapeutic options. Resistance training has several unique mechanisms that seem to address several of the underlying mechanisms of cachexia.[179] Resistance exercise is able to increase phosphorylation of mammalian target of rapamycin (mTOR) substrates and p70S6 k.[180] This suggests it has the potential to induce mTOR, a major contributor to decreased muscle synthesis.[181] Resistance training is also a powerful modulator of adenosine triphosphate–dependent ubiquitin-proteasome system (UPS) activity by way of inflammatory cytokine modulation. Two review articles in 2007 by Pajak et al.[182] and Al Majid et al.[183] showed several complicated mechanisms of how resistance exercise works. Resistance exercise can release IL-6, which is anti-inflammatory when released by muscle,[85] and IL-15, which is strongly anabolic. Muscle-derived IL-6 suppresses TNF-α and IL-1. This action strongly decreases the overactivity of adenosine triphosphate–dependent UPS, which may be the most important component of cancer cachexia. IL-15 also will increase the type II muscle fibers that seem to be selectively lost in cachexia.

Exercise and Brain Neuroplasticity

Conditions of the brain that cause, or have the potential to cause, dementia-like illnesses are at epidemic proportions, with some experts suggesting that by 2050, upwards of 130 million people worldwide will have dementia.[184] With recent studies showing the strong connection and mechanism by which blood glucose and insulin resistance worsen neurocognitive health,[185] it would also be legitimate to suggest exercise to be a protective tool against neurocognitive disorders; the research is surely in agreement.

If there is one medication that outperforms any other drug in improving outcomes in Parkinson's disease (PD), Alzheimer's disease (AD), stroke recovery, depression, anxiety, attention deficit hyperactive disorder (ADHD), age-related cognitive decline, and multiple sclerosis, then exercise is it.

The mechanism by which exercise exhibits these significant benefits is via induction of neuroplasticity, neurogenesis, and neurotrophy. The ability of the brain to reorganize, create new neural pathways, induce neuronal activity, and enhance the growth and survival of neuronal tissue is influenced by exercise.

Neurotrophic factors such as BDNF, IGF-1, and VEGF play an intricate role as neuroprotective agents, with BDNF seeming to be the most potent.[186] Exercise induces the production of BDNF, which freely crosses the blood–brain barrier (BBB),[187] resulting in hippocampal neurogenesis, dendritic complexity, and synaptic plasticity.[188,189] One mechanism through which environmental toxins induce dementia is by impairing the production of BDNF. Increased BDNF levels may be responsible for enhancing hippocampal volume and improving cognitive function, whereas decreased levels of BDNF, along with IGF-1, are associated with Alzheimer's disease.[190] It is suspected that the benefits of BDNF are derived from its ability to induce hippocampal and cortical neuronal growth and mitochondrial biogenesis and reduce neuroinflammation.[191]

Vascular endothelial growth factor (VEGF), induced by exercise, is known for improving vascular circulation, and its role in inducing hippocampal neurogenesis is evident in humans.[192] Additionally, IGF-1, which is positively correlated with exercise intensity, is released into the blood postexercise and can, like BDNF, bypass the BBB and affect neuroprotective actions in the brain.[193] IGF-1 works in tandem with BDNF to improve neuroplasticity, and furthermore, it provides protection against oxidative damage and neuro-excitotoxicity.[194,195]

These mechanistic pathways explain the ability of exercise to attenuate cognitive decline. These mechanisms then translate to actual outcomes in human trials. Physical activity and exercise have been shown to improve learning capacity[196] in adults and offspring[197]; enhance recovery from traumatic brain injuries[198]; improve gait and function in PD; and improve memory,[199] language ability, attention, and other cognitive parameters in AD.[200,201]

Exercise and physical activity not only spare brain volume, which slowly declines with age, but also increase gray and white matter in various areas of the brain in older adults.[202] The volume of gray and white matter in the prefrontal cortex (involved with working memory and executive functions) and temporal lobe (involved with long-term memory) has been shown to be preserved with physical activity, along with attenuation of hippocampal volume, which is a predictor of time to progression in AD.[203] Increases in gray matter were shown in as early as 6 months and lasting up to 13 years, suggesting exercise has a prolonged benefit on neuroplasticity.[204] Furthermore, increased gray matter not only reduces the risk of cognitive impairment but improves cognitive function and prevents dementia in the elderly.[204,205]

Overall, exercise, whether it is aerobic or resistance training, is beneficial for neuroplasticity and cognitive health. However, most benefits have been observed with high-intensity training, exceeding 30 minutes daily and done for more than 6 months.[206] Including resistance exercise not only provides neurological benefits but also tackles many of the comorbidities of aging as discussed in this chapter, such as frailty, sarcopenia, and cardiometabolic disease.

Exercise for the Brain and Mood

Exercise increases cerebral blood flow and metabolism and therefore affects both mood and cognitive function. Exercise has been shown to have many positive benefits on mood, especially in the realm of depression, anxiety, and self-esteem.[207] In one depression study, 50 adults classified with depressed mood on the Profile of Mood States-Short Form Depression Scale (POMS) were studied over 10 weeks.[208] The treatment consisted of moderate-intensity aerobic exercise for 30 minutes three times per week. At the end of the study, 62% of the exercise group was classified as normal on the POMS compared with 29% in the control group. Another study in the elderly showed comparable results.[209] Several mood parameters were assessed, including both depression and anxiety. The study group had decreased scores for depression and anxiety and showed significant improvement in quality-of-life scores.

Two other studies on depression showed exercise as a potential primary therapy in major depression and among patients refractory to

drug therapy. A study published in 2001 showed that a small group of subjects with major depression who underwent a daily 30-minute walking program had a clinically relevant and statistically significant benefit from exercise in as little as 12 days.[210] The program was a moderate-intensity interval-walking program alternating from "somewhat hard" to half that pace on the rest phase. Even subjects refractive to drug therapy were able to improve with the exercise program. Considering the well-known response delay of 2 to 4 weeks with the use of medications, this study showed aerobic exercise as a more immediate fix and a smart integrative approach with drug treatment.

Direct comparisons of exercise versus drug therapy (sertraline) for major depression showed exercise as a powerful mood enhancer.[211] Subjects performed aerobic exercise on a treadmill three times per week and were followed over a 12-month period with respect to Zoloft therapy, exercise and Zoloft therapy, and exercise alone. The exercise-alone group had significantly better outcomes in terms of treatment effect, remission, and relapse than either the Zoloft group or the Zoloft group plus exercise. Although it is not completely understood, the mechanism by which exercise improves depression and mood-related disorders is multifactorial but does show similar mechanisms to antidepressant medications, but it also surpasses the palliative effects of medications and improves neurocognitive markers.[212] Exercise has been shown to inhibit GSK-3-beta, improve hippocampal neurogenesis, increase brain-derived neurotrophic factor (BDNF), and increase regulation of mTOR.[213,214]

Exercise and Anxiety

Exercise has favorable effects on anxiety. Past studies have shown exercise to be an anxiolytic in symptoms induced by caffeine and carbon dioxide,[215,216] but these compounds did not result in panic. One study showed that direct treatment of patients with panic disorder with aerobic exercise led to significant improvement compared with placebo.[217] The study was over a 10-week period, and the maximum effect was seen toward the end of the study. This points to exercise as both a preventative and alternative treatment strategy for anxiety. The acute effects of exercise may even be able to allay panic attacks. A recent study used exercise as a treatment against induced panic attacks.[218] Cholecystokinin tetrapeptide (CCK-4) is a reliable inducer of panic attacks in humans and mimics the mechanisms associated with anxiety-induced panic attacks. Fifteen subjects were studied in a crossover design. Exercise for 30 minutes at 70% of maximum oxygen consumption was compared against no exercise. The next day, subjects received a bolus of CCK-4 and were monitored for signs and symptoms of panic attack. Previous exercise the day before produced half as many panic attacks, 6 compared with 12. This appears to indicate exercise as a modifier of anxiety-induced panic attacks.

Exercise and Memory

Exercise also affects memory and has shown benefit in multiple brain parameters.[219] Even weight lifting can improve brain function in the elderly.[220] Exercise is known to increase neurotransmission and myelin synthesis. Taken together, this can increase both the speed and quality of mental activity. Studies have shown that exercise positively affects attention deficit disorder/ADHD, dementia, AD, and other mental disorders.[192–195] Recent studies also showed that exercise has the potential to create new neurons.[221,222]

SUMMARY

This chapter illustrated the vast potential of exercise to both prevent and treat multiple medical issues, from obesity to mental and emotional dysfunction. There are many aspects of exercise and health that were not covered or were only discussed briefly. However, the key concepts covered should allow smart manipulation of exercise parameters to fit many conditions. It is our hope that understanding the new science of exercise, and the historical construct in which movement evolved, will allow health practitioners to move beyond one-dimensional exercise models focused solely on aerobic exercise to a more holistic and functional model of prescriptive movement.

Fasting

Toshia R. Myers, BS, MA, MPhil, PhD, and *Alan Goldhamer, DC*

OUTLINE

INTRODUCTION

Fasting is broadly defined as the voluntary practice of partially or completely abstaining from caloric foods and beverages.[1] Fasting methods differ based on the amount and type of calories consumed daily, time period for daily caloric consumption, fasting duration, as well as rationale.[1-6] Therapeutic prolonged water-only fasting is the protracted (i.e., ≥2 days) consumption of only water for purposes of health promotion.[1,2,7] Most humans have sufficient nutrient reserves to safely undergo a prolonged water-only fast (herein called "fast") for 40 days[8-10] depending on body mass index, fat and muscle percentages, activity levels, and state of health. Human survival during fasting is supported by the ability to enter ketosis and utilize ketone bodies as an alternate energy source for the brain and other organs.[11] Ketone bodies potentially modulate some of the molecular and cellular adaptations observed during nutrient deprivation.[12] Preliminary evidence correlating beneficial clinical outcomes with fasting[13-17] supports the continued research and clinical application of this method.

This chapter reviews various aspects of therapeutic fasting in humans including historical context, physiological responses, clinical research, and clinical application. Caloric restriction and intermittent fasting in humans and other organisms are reviewed in depth elsewhere.[3,4,6,18]

HISTORICAL CONTEXT

Evolutionary biologists speculate that *Homo sapiens* evolved with unpredictable access to food resources, which likely became more unpredictable after the advent of agriculture.[19] Several evolutionary theories attempt to explain how periodic food scarcity shaped our fat storage capacity,[20] but there are fewer theories on how it contributed to our efficient utilization of ketone bodies as an alternate fuel. There is also limited understanding of how periodic food scarcity influenced our long-standing therapeutic, spiritual, and sociological relationship with fasting.[1] Historical texts indicate that, for millennia, people of nearly all cultures and religions have practiced various fasting methods.[21-23] Over the past 200 years, therapeutic fasting has gone in and out of fashion with both allopathic and alternative health practitioners. Therapeutic fasting has once again emerged as a potential tool to treat the pandemic of degenerative diseases largely caused by the overconsumption of highly processed foods.[1-4] The type of therapeutic fasting currently practiced is based on the tenets of Natural Hygiene, which was founded by Isaac Jennings, MD (1788–1874)[24] and later popularized by Herbert M. Shelton, ND (1895–1985).[25-32]

PHYSIOLOGY

Humans gradually transition from the fed state through the fasted state, ultimately terminating in starvation. This transition is regulated by metabolic, endocrine, and neuronal adaptations that ensure whole-body energy requirements are continuously met[8,11] and appear to modulate molecular and cellular mechanisms associated with retardation of aging processes, at least in studied organisms.[3,4,12,33,34] Early reports on human fasting physiology[9,35-37] as well as research by Cahill and colleagues[11,38-86] contributed substantially to our knowledge of

TABLE 37.1 Metabolic Phases of Fasting

Phase	Predominant Metabolic State	Duration (Post Final Caloric Intake)	Primary Tissue/ Organ Involvement	Main Features
I	Glycolysis	Approximately 4–6 hours	Blood Liver	• Food is digested • Glucose, amino acids, and TAG absorbed into the blood • Glucose converted to glycogen via glycogenesis for storage in the liver
II	Glycogenolysis	Approximately 6–24 hours	Liver	• Decreased blood glucose levels stimulates glucagon secretion • Glucagon stimulates glycogenolysis of hepatic glycogen reserves to glucose • Glycogenolysis supplies 75% of glucose requirements, remaining 25% from gluconeogenesis
III	Gluconeogenesis	Approximately 24–48 hours	Liver	• Gluconeogenesis meets the majority of glucose requirements • Blood glucose levels decline but are still utilized by all tissue except liver
IV	Gluconeogenesis > Ketogenesis	Approximately 48 hours until 5–7 days	Kidneys Fatty tissue Liver	• Renal gluconeogenesis increases • Lipolysis of TAGs into glycerol and fatty acids are converted to glucose and ketone bodies, respectively • Ketone bodies in urine steadily increase
V	Ketogenesis > Gluconeogenesis	Approximately 5–7 days until starvation	Fatty tissue Liver	• Energy requirements primarily met through fat metabolism • Starvation begins when essential protein is catabolized to meet energy requirements

TAG, Triacylglycerol.

human physiological responses to fasting. Metabolic processes were described in five phases based on the transition through the postabsorptive state and near-steady state of prolonged fasting (Table 37.1).[11] Throughout this transition, metabolic states are often concurrent and have variable rates depending on an individual's age, sex, and nutrient reserves.[87] It should be noted that there appear to be marked differences between the metabolism of lean and obese individuals.[73,74,88,89] For example, lean individuals have increased concentrations of ketone bodies and an increased percentage of energy derived from protein oxidation while fasting.[73]

Metabolic Phase I (0–4/6 Hours)

Phase I begins immediately after caloric ingestion, when carbohydrates, proteins, and fats are digested into sugars (primarily glucose), amino acids (single or peptides), and fatty acids (triacylglycerol, TAG), respectively.[11] All macronutrients are absorbed into the blood, transported to the liver for processing and/or storage, and transported back to the blood to maintain physiological processes. Glucose and amino acids are absorbed directly into the bloodstream through the small intestine. TAGs are broken down into glycerols and free fatty acids, which form micelles that enter enterocytes where they are reconverted to TAGs and packaged in chylomicrons. Chylomicrons are absorbed into the lymphoid system through the small intestine and then released into the bloodstream. In this phase, high blood glucose levels stimulate the pancreatic β cells to secrete insulin above basal levels. Insulin regulates the uptake and metabolism of glucose, amino acids, and fatty acids. At this phase, all tissues preferentially utilize glucose as fuel, except the liver and heart, which prefer α-ketoacids and fatty acids, respectively. Glucose is transported into cells where it is catabolized through glycolysis. During glycolysis, glucose is converted to pyruvate that is oxidized to acetyl-coenzyme A (CoA) that enters the tricarboxylic (TCA) cycle, ultimately producing adenosine tri-phosphate (ATP). Increased glycolysis in the liver results in an excess of acetyl-CoA that is used to synthesize TAGs, which are packaged into very-low-density lipoproteins for storage and secretion when blood glucose is low. Insulin also regulates the uptake of glucose by adipocytes, where it is converted through glycolysis to glycerol 3-phosphate and acetyl-CoA, which are then synthesized into TAG. High levels of blood glucose enable hepatocytes and muscle cells to convert glucose to glycogen—the storage form of glucose—through glycogenesis. The liver and muscles store approximately 100 and 300 grams of glycogen, respectively.[8]

Metabolic Stage Phase II (4–6 hours)

Phase II begins approximately 4 to 6 hours after final caloric intake.[11] Decreased blood glucose levels stimulate pancreatic α cells to secrete glucagon above basal levels. Glucagon is an insulin antagonist that stimulates glycogenolysis of hepatic glycogen to glucose. Hepatic glycogen reserves are depleted within approximately 24 hours of fasting. Glycogenolysis also converts muscle glycogen to glucose 6-phosphate. However, muscle cells lack the enzyme glucose 6-phosphatase that is required to release glucose; therefore muscle glycogen is not used to meet whole-body glucose requirements. During this early fasted phase, hepatic glycogenolysis provides about 75% and gluconeogenesis accounts for the other 25% of daily glucose requirements of all tissue except the liver.[8]

Metabolic Phase III (1–2 days)

Phase III lasts from approximately 24 to 48 hours after final caloric intake.[11] During this time, gluconeogenesis is the primary metabolic pathway supplying daily glucose requirements.[38-40,90] Gluconeogenesis, primarily in the liver, produces glucose from the noncarbohydrate carbon substrates glycerol, lactate, and amino acids.[8,91] TAG hydrolysis forms glycerol and fatty acids in adipose tissue. Glycerol is converted to dihydroxyacetone phosphate, which is used to produce glucose in the liver, after which it is exported to extrahepatic tissue. In skeletal muscle, when rates of glycolysis exceed the TCA cycle, excess lactate is produced and transported to the liver where it is converted to pyruvate and then to glucose through the Cori cycle. Glucose is then transported back to muscle cells or used to meet whole-body glucose requirements.[85] Amino acids are primarily used to make protein, but when glucose is

TABLE 37.2 Energy Reserves in Typical 70 kg Human[186-190]

	GLUCOSE/GLYCOGEN		PROTEIN		TRIGLYCERIDE

low, the breakdown of digestive and glycolytic enzymes, skeletal muscle, and other connective tissue provides amino acids for gluconeogenesis. In skeletal muscle, ammonium is produced as a by-product of protein catabolism, but it is unable to be converted to urea for removal through urine, as in the liver. Excess ammonium results in transamination of surplus pyruvate to ultimately form alanine. The glucose-alanine or Cahill cycle transports the glucogenic amino acid, alanine, from skeletal muscle to the liver to produce glucose that can then be used by extrahepatic tissue. Although all amino acids, with the exception of lysine and leucine, are glucogenic, alanine and glutamine are the predominate amino acids used in gluconeogenesis in the liver and kidneys, respectively.[92,93] Eventually, the renal cortex synthesizes more glucose through gluconeogenesis than does the liver.[64] During this phase, blood glucose begins to decline, but glucose is still utilized by all tissue except the liver.[8,91] In the fasted state, blood glucose levels routinely drop down to 40 mg/dL or lower.[11,90,94,95]

Metabolic Phase IV (2–5/7 days)

Phase IV begins approximately 48 hours after final caloric intake and lasts until approximately day 5 to 7.[11] At this phase, renal gluconeogenesis becomes progressively more important in the maintenance of blood glucose levels. Additionally, reduced blood glucose and increased glucagon levels induce adipocytes to increase lipolysis of TAGs into fatty acids and glycerol. Glycerol is converted to glucose through gluconeogenesis as described previously. Fatty acids bound to albumin are transported to the liver, muscle, and other tissues. Fatty acids in the liver are broken down by β oxidation to form acetyl-CoA. When acetyl-CoA exceeds the capacity of the TCA cycle because of reduced oxaloacetate availability, it is used to synthesize the ketone bodies acetoacetic acid (AcAc), acetone, and β-hydroxybutyric acid (βOHB) through ketogenesis.[8] The liver is unable to utilize ketone bodies for fuel, which results in large quantities of ketones, primarily AcAc and βOHB, to be secreted into the bloodstream. Within the mitochondria of extrahepatic tissue, βOHB is further oxidized to AcAc that is then transported to the TCA cycle. Increased ketones are typically identified through urinalysis by day three of the fasted state.[90] Except for red blood cells, the renal medulla, and the liver, all tissues, including the brain, is able to utilize ketone bodies for energy. By the end of Phase IV, the brain's energy requirements are met primarily by ketone bodies.[8,11]

Metabolic Phase V (Until Nutrient Depletion Begins)

Phase V begins when rates of ketogenesis exceed gluconeogenesis and continues until starvation begins.[11] The length of this phase depends on an individual's body mass index, fat and muscle percentages, physical activity levels, and state of health. Studies on respiratory quotient and urinary nitrogen have demonstrated that adipose TAG stores meet the majority of whole-body energy requirements during prolonged fasting.[35,49,51,56,85] Meeting energy requirements through fat metabolism decreases dependency on gluconeogenesis, thus sparing protein.[86,96] The brain begins utilizing ketone bodies, primarily βOHB, after approximately 4 days. This adaption is essential because brain glycogen content is very low (0.1%). The brain (40 g/day) and other tissues (40 g/day) still have an obligatory need for approximately 80 g/day of glucose, which is met through gluconeogenesis.[8,97] Starvation begins when essential proteins are catabolized to meet energy requirements.[8] Based on average nutrient reserves, a 70-kg human can fast for 2 to 3 months before entering starvation (Tables 37.2 and 37.3).[8,35,49,51,97,185-189]

TABLE 37.3 Utilization of Energy Reserves

Energy Source	Reserve[a]
Glucose	1 hour
Digestion	4–8 hours
Glycogen	12 hours
Amino acid	48 hours
Protein	3 weeks[b] 24 weeks (obligate use)
Triglycerides	8 weeks

[a]Based on 100% utilization in a 70-kg human.
[b]If protein were the only fuel used for gluconeogenesis.

PHYSIOLOGICAL EFFECTS

Although data in mammalian model organisms suggest that intermittent fasting has various effects on the neuroendocrine system, such as increased synaptic plasticity and parasympathetic tone,[98] data on neuronal and endocrine adaptations during prolonged water-only fasting in humans are lacking. Preliminary research has shown that during prolonged fasting human growth hormone, reverse T3, adrenaline, noradrenaline, dehydroepiandrosterone (DHEA), sex hormone-binding globulin, and cortisol increase,[94,95,99-102] whereas thyroid-stimulating hormone, T3, luteinizing hormone, follicle-stimulating hormone, and testosterone decrease.[94,95,99-101] Specific details on fluctuations over the course of a prolonged fast; differences between individuals based on age, sex, and nutrient reserves; and the downstream effects of these changes remain to be elucidated.

Weight decreases in response to caloric deprivation. During prolonged fasting, weight loss averages 0.9 kg/day during the first week and decreases to 0.3 kg/day by the third week.[90] Initial rapid weight loss

is primarily caused by water and sodium diuresis.[90,103] Other changes include decreased pulse rate[9,35] and blood pressure (BP),[9,35,37,104] as well as a transient small increase and then a slow drop in the basal metabolic rate by about 1% per day until stabilizing at about 75% of normal.[104] Electrocardiography often demonstrates cardiac adaptations, including sinus bradycardia, decreased QRS complex and T-wave amplitude, elongation of the QT interval, and shifts to the right of the QRS and T-wave axes, which normalize upon refeeding.[9,90,104,105] Physiological responses typically return to prefast levels upon caloric consumption.

CLINICAL RESEARCH

Research, primarily conducted in model organisms, has uncovered several potentially health-promoting cellular and molecular responses to nutrient deprivation, such as hormone modulation, reduced oxidative stress, and increased autophagy.[3,4] Additional research is needed to conclusively determine whether fasting produces similar mechanistic responses or how these responses might affect clinical outcomes in humans. A century of fasting literature[1,106] and limited clinical evidence[15,17,107-110] suggest that the method has beneficial health outcomes, but the substantial amount of data is largely inconclusive as a result of methodological limitations. For example, there are essentially no randomized controlled trials (RCTs) on the efficacy of fasting in the treatment of any disease.

There is an unsubstantiated perception that therapeutic fasting is unsafe.[5] The misconception is associated with a period during which an extreme form of water-only fasting was used to treat obesity.[111,112] During this period, there were several deaths[111,113-115] reported out of approximately 1000 documented fasting cases.[112,116-123] These deaths could likely have been prevented had unintentionally harmful fasting practices, such as arbitrarily long fasting lengths, uninformed electrolyte monitoring and refeeding practices, and fasting patients with contraindications,[114,120,124-129] not been used. Until recently, there were no peer-reviewed assessments of adverse events during fasting. A recent retrospective study describes the adverse events (AEs; classified according to the Common Terminology Criteria for Adverse Events and MedDRA terminology) that occurred during prolonged water-only fasting visits (2–40 days; n = 768) at a medically supervised fasting center.[7] The study found that the highest-grade AEs experienced during the majority visits (72%; n = 555) were mild to moderate in nature and are known to commonly occur during fasting (e.g., nausea, back pain, headache, and presyncope). There were two serious adverse events (grade 4 hyponatremia on fasting day 7 and grade 3 dehydration on fasting day 3), which resolved without further complication, and there were zero deaths. Overall, the data suggest that the method is safe, when conducted under medical supervision using the protocol described.

The following is a description of literature published on the effects of therapeutic fasting during which only water or, in some cases of early research, acaloric liquids and/or vitamin/mineral supplementation was administered. Unfortunately, in many early publications, the fasting method was not adequately described, and these studies are not included here.

CASE REPORTS

Case reports describe novel, informative clinical cases of 1 to 3 patients. They can inform clinicians and patients and guide the course of clinical research. In addition to the reports presented here, there are numerous case reports describing physiology and on the use of fasting to treat obesity.

Appendicitis

A 46-year-old male presented with abdominal pain that was progressively worsening and tenderness with an accompanying mass in the lower right quadrant. He had a normal white blood cell count and slightly elevated erythrocyte sedimentation rate. A retroperitoneal sonogram confirmed an enlarged appendix. The patient opted to undergo a medically supervised, water-only fast for 7 days with 4 days of refeeding rather than surgically remove his appendix. He fasted and refed for 7 and 4 days, respectively. There were no serious complications, and upon termination he had reduced abdominal swelling, no pain or fever, and a normal white blood count. He remained symptom-free at the 3-month, 1-year, and 2-year follow-up visits.[107]

Follicular Lymphoma

A 42-year-old woman with stage IIIa, low-grade follicular lymphoma was reported in *BMJ Case Reports*. After a 21-day water-only fast followed by 10 days of supervised refeeding, her enlarged lymph nodes were no longer palpable and computerized tomography (CT) scans confirmed the size reduction. She did not undergo standard cancer treatment, has maintained a healthy lifestyle, and was symptom-free at the 6-month follow-up visit.[15] At the 3-year follow-up visit, the patient remained symptom-free as indicated by CT/PET scans.

Chronic Posttraumatic Headache

A 52-year-old woman with a 16-year history of chronic posttraumatic headache presented with a constant headache that was described as "dull and achy" with a pain level of 6 to 8/10 that did not improve with standard pharmaceutical medications. She underwent two 40-day medically supervised, water-only fasts with a 6-month intervening period of an exclusively plant-foods diet. At the end of the second fast, she was free of headache symptoms with the exception of an occasional headache that lasted less than 10 minutes with a pain level 1/10. Her body mass index (BMI) reduced from 33.1 kg/m^2 to 18.8 kg/m^2. There were no serious complications, and her serological values remained normal with the exception of slightly increased liver enzymes, which resolved upon refeeding. At the 5-year follow-up visit, she was still symptom-free and had maintained a normal BMI.[110]

CLINICAL STUDIES

Studies on the clinical effects of fasting have been primarily observational in nature. Many studies lack the necessary sample size and controls to conclusively determine outcomes. RCTs are needed to draw conclusions about this method.

Cardiovascular Disease

Early studies suggest that fasting reduces serum triglycerides,[130] BP,[9,35,90,131] and symptoms of congestive heart failure.[125] More recently, medically supervised, water-only fasting was shown to reduce borderline and high hypertension.[14,109] In 68 consecutive patients with borderline high BP, an average of 13 days of water-only fasting reduced systolic BP by an average of 20 mm Hg, with 82% of patients achieving systolic BP below 120 mm Hg.[109] In 174 consecutive patients with high BP, an average of 10 days of water-only fasting resulted in more than 90% of patients becoming normotensive. In patients with systolic BP greater than 180 mm Hg, the average reduction in systolic BP exceeded 60 mm Hg.[108] Preliminary data also suggest that treatment of hypertension with a 14-day medically supervised, water-only fast could reduce combined medical and drug costs by almost $2700 per year per patient.[132]

Cancer and Chemotherapy

Preliminary research suggests that water-only fasting for approximately 2 to 3 days before and/or after chemotherapy ameliorated

commonly reported chemotherapy side effects.[17,133] There is currently a randomized trial being conducted on the effects of 72 hours of water-only fasting in conjunction with chemotherapy.[133]

Diabetes Mellitus

Reports, as early as 1912, suggest that prolonged water-only fasting improves diabetes.[9,134,135] In obese diabetic patients, prolonged water-only fasting substantially improved most parameters of insulin function independent of weight loss.[136]

Epilepsy

Therapeutic fasting has been used since the early 1900s to treat seizures.[135,137] Ketosis, initiated by fasting, decreased the duration, severity, and number of seizures.[138]

Autoimmune Disorders

Several reports suggest that fasting has a beneficial effect on autoimmune disorders, such as chronic urticaria.[139,140] It was found that fasting shortened the early stages of acute glomerulonephritis (reduced glomerular filtration rate, high BP, and edema) and improved prognosis.[141] Rheumatoid arthritis (RA) appears to respond particularly well to fasting. Studies have shown that fasting in arthritis patients results in decreased erythrocyte sedimentation rate (ESR), arthralgia, pain, stiffness, and need for medication.[142-149] Consistent with those findings, a study of 43 patients with definite or classic RA found that a water-only fast of 7 days significantly improved grip strength, pain, swelling of proximal interphalangeal joints, ESR, and functional activity.[150]

Obesity

Therapeutic fasting as a treatment for obesity was popularized in the 1960s.[81,111-114,117-119,121,122,125,131,151-153] In general, fasting results in an initial weight loss of approximately 0.9 kg/day with a gradual decrease to 0.3 kg per day over 30 days.[154] The initial weight lost is primarily that of water, glycogen, and sodium. A study monitoring 121 obese patients for approximately 7 years after fasting an average of 2 months found that after 2 to 3 years, 50% of patients returned to their prefast weights, and that by the end of the study, 90% weighed the same as before their fasts.[122]

CLINICAL APPLICATION

Although rigorous clinical research is lacking, there is substantial clinical anecdotal evidence supporting the use of medically supervised, therapeutic fasting as a safe and effective treatment for a variety of diseases. TrueNorth Health Center (TNHC), the only center in the United States that trains and certifies medical practitioners in water-only fasting,[155] has conducted more than 20,000 medically supervised fasts since 1984. The vast majority of these patients benefited from fasting; less than 1% experienced a serious adverse event and no patients died.[7] Clinicians at TNHC have observed improvement in diseases ranging from lupus to hyperhidrosis to follicular lymphoma. Additional therapeutic fasting centers now exist in the United States, Canada, England, and Australia. Like TNHC, these centers follow the standards of care and principles of ethics established by the International Association of Hygienic Physicians.[156]

Therapeutic fasting conducted under medical supervision at an inpatient facility minimizes adverse events that can arise during fasting because clinical staff can monitor symptoms, order and analyze necessary clinical laboratory tests and procedures, approve adjunctive therapies, appropriately terminate the fast, and supervise postfast recuperation. In most cases, fasting is therapeutically superior to a restricted diet because (1) hunger almost totally disappears,[9,131] (2) ketosis occurs more quickly and efficiently,[9,131] (3) famine edema does not occur,[9] (4) sodium diuresis is more pronounced,[112] (5) weight loss is greater and is typically from fat loss rather than protein catabolism, (6) healing time is shorter, and (7) patient strength may be greater.[31] Restricted diets of vegetable broth or fruit and vegetable juices do not initiate fasting metabolic processes because they contain carbohydrates, protein, and/or fat. Nonetheless, restricted diets are often useful before and after fasting, for patients in whom a healing crisis (i.e., where chronic conditions/symptoms become acute) develops during a fast, and when a fast is contraindicated.[30]

TABLE 37.4 Clinical Stages of Fasting

Stages	Duration	Main Features
I Early fasting	Up to 7 days	• Transient detox symptoms • Preoccupation with eating
II Balanced fasting	Weeks to months	• Acute healing crisis • Health gradually returns
III Starvation	Begins when body increases protein catabolism and can ultimately terminate in death	• Discontinue fasting before this phase • Risk of terminal tissue damage

Therapeutic fasting can be described in three clinical stages (Table 37.4). It should be noted that the clinical stages of fasting do not directly correspond with the metabolic phases described previously. This is because rates of metabolic change occur at a faster rate than patients typically transition through clinical symptoms. For example, clinical stage I can last up to 7 days, at which time metabolism has already progressed into Phase IV or possibly Phase V. There is also a lack of data on how clinical symptoms directly correlate with the metabolic changes that occur while fasting.

Stage I, or early fasting, lasts up to 7 days during which patients can present with common detoxification symptoms of malaise, headaches, and muscle aches that are typically transitory. Patients often express concern for their health and a preoccupation with eating, but any desire for food is likely psychological and has little to do with serious physiological need. Stage II, or balanced fasting, is the most clinically significant fasting stage and can last for weeks to months. This stage typically begins after the patient has entered into a near-steady state of ketosis and adjusted from their dietary habits before fasting. Patients often experience one or more "healing crises" and/or go through less significant detoxification reactions. Extending a fast beyond a notable healing crisis/detoxification reaction rather than stopping midcourse may result in more beneficial health outcomes. During this time, health should gradually return; if not, the patient should be given a thorough medical evaluation. Stage III, also called starvation, occurs when the body increases protein catabolism and can potentially damage essential tissue and, ultimately, terminate in death. Fasting should be discontinued before this stage begins. Predicting optimal fast length is difficult because it is based on many factors, including protein, fat, and electrolyte reserves, individual metabolism, mental health, financial limitations, work and family obligations, severity of disease, age, and sex. Overall, "[the] doctor will look for good practical recovery where the patient is symptom free and signs of regeneration are present."[157] "Fasting to completion" (i.e., exhaustion of nutrient reserves) is no longer practiced nor is it necessary, as consecutive fasting with intervening refeeding appears to be safer and as effective.[157]

Guidelines

The use of a whole plant-foods diet processed without added sugar, oil, and salt before and after fasting is beneficial for reducing symptom

severity during fasting and avoiding complications during refeeding. This diet also promotes prefast bowel movements, which should occur at least daily before fasting, as well as postfast bowel movements, which should quickly develop and pass without complication. It is necessary to adopt a health-promoting lifestyle, including a whole-plant-foods diet, postfast to maximize and maintain any benefits obtained while fasting.

Consumption of 64 to 96 oz/day of pure water (distilled, filtered, or reverse osmosis) is recommended,[31,158] but upwards of 160 oz is commonly ingested without affecting serum sodium levels. Increased water intake appears to reduce detoxification reactions, but excess consumption can cause electrolyte imbalances that are clinically significant and require refeeding. Physiologically, the body is able to modulate "available water" through reduced obligatory water excretion (caused by lower excretion of urea, the major osmotic solute) and by accessing water released from fat catabolism.[85] Upon refeeding there is a sudden shift from a low level of insulin and ketosis to a high level of insulin and glycolysis. As the plasma insulin rises, potassium, phosphate, and magnesium are driven intracellularly and sodium extracellularly, which dilutes the circulating concentrations.[159,160] Sodium restriction during refeeding should be emphasized to not precipitate dilution, edema, or acute heart failure.[78]

In addition to maintaining optimal hydration, rest is essential during fasting. Patients may nap throughout the day. It is also common to experience reduced sleep at night, possibly because of decreased daily activity and increased daytime rest. Brief walks or light stretching are permissible. Rigorous exercise while fasting is discouraged because fuel conservation is necessary to maximize healing and avoid unnecessary gluconeogenesis.[31,158] Even moderate activity can double caloric utilization.[59] In serious chronic disease, an excess of activity has been suspected as cause of death during fasting.[161] Sunlight is also important for general health during fasting, and patients should try to obtain 10 to 20 min/day. However, dehydration resulting from sun exposure can promote orthostatic hypotension and subsequent injury from falls. An increase in heart rate by 10 to 15 beats per minute may indicate excessive sun exposure.

LABORATORY VALUES

Assessment of a fasting patient's progress is not based on a single sign or symptom but on the total clinical picture. Therefore vital signs, including blood pressure and pulse, should be checked daily. Laboratory tests such as a complete blood count and serum chemistry panel and urinalysis are performed weekly and other tests are performed as necessary. Laboratory values during fasting are typically unique to the individual and disease process, but some general observations have been made.[121,154]

Complete Blood Count

Complete blood counts usually show no significant change. Low hemoglobin and hematocrit values[10,162] require that hemolysis or hemorrhage are ruled out, whereas elevations in hematocrit, hemoglobin, and red blood cell counts usually indicate reduced hydration.[78,163] White blood cell (WBC) counts are usually unchanged or decrease slightly with fasting. However, WBCs may increase if infection is present or if WBC counts are low before fasting.

Serum Electrolytes

Serum electrolyte levels are not good indicators of tissue stores, but they are considered the most important blood values during fasting because any significant change necessitates immediate clinical management. All electrolytes decrease over the course of a long fast as mobilized stores are lost, but stores appear to be redistributed even when distilled water is used during prolonged fasts. Serum calcium and chloride concentrations are usually stable but can decrease, especially if vomiting or diarrhea is present. There is a tendency for serum potassium concentrations to decrease, although they can also increase, and values less than 3 mmol/L or higher than 6 mmol/L often require the fast to be terminated. Similarly, serum sodium concentrations can decrease and values less than 130 mmol/L require immediate attention. The total body store of potassium is approximately 55 mEq/kg of body weight, of which 98% is intracellular.[164,165] The total body store of sodium is estimated at 50 mEq/kg, of which approximately 70% is exchangeable.[166,167] The typical daily dietary intake of potassium is 3 to 5 g and sodium is 3 to 7 g. During early fasting, each day the body loses 1.6 to 1.8 g (40–45 mEq) of potassium and 3.5 to 5.8 g (150–250 mEq) of sodium, and these values eventually drop to 0.4 to 0.6 g (10–15 mEq) and 0.02 to 0.35 g (1–15 mEq), respectively.

Liver Enzymes

During medically supervised fasting, the enzymes serum glutamic oxaloacetic transaminase (SGOT/AST) and serum glutamic pyruvic transaminase (SGPT/ALT) are used as biomarkers to assess liver function. These values typically remain in the normal range. However, the values may increase considerably if liver disease is present and may rise even if liver disease is not present. This is usually not a cause for concern as values typically return to normal postfast. For example, at the end of a 40-day fast, an obese patient with a history of chronic pharmaceutical use had a substantial increase in both SGOT and SGPT values. At the beginning of the patient's second fast (6 months later), the values of both enzymes had normalized and had increased only slightly at the end of the second 40-day fast. The enzyme values were at the low end of the reference range at 3-month and 5-year follow-up visits.[16]

Other Blood Values

Triglyceride, cholesterol, and uric acid levels usually rise during fasting,[168,169] indicating mobilization of tissue stores. Postfast values often show a decrease from prefast values,[168,170] but lipid panels may not normalize until 4 to 6 weeks postfast. Serum protein and pancreatic lipase and amylase values usually decline with fasting. A rise in blood urea nitrogen (BUN) value may occur, but a decrease has also been reported.[9,10] Serum creatinine levels can increase,[170] remain stable,[171] or decrease. In cases of increased levels, prompt retesting and/or fast termination are required. In cases of increased levels, prompt retesting and/or fast termination are required. Blood glucose values drop in most patients.[134,172] In some patients, values below 40 mg/dL have been observed and are not typically a cause for concern in the absence of additional signs of hypoglycemia. If the blood glucose value is low before fasting, it may rise after fasting. ESR and C-reactive protein usually drop after fasting, although they may rise during the fast.[148,149]

Urinalysis

Urinalysis is conducted weekly, but it might be difficult to interpret during fasting because the body discards considerable waste via the kidneys. It is not uncommon to see various types of casts, red blood cells, WBC, bilirubin (+1 to +2), protein (trace, +2), and ketones (+4) and, if liver disease is present, urobilinogen elevation. Trace leukocytes and blood are common incidental findings, particularly in women. Specific gravity is commonly elevated (possibly to 1.035), a finding that may reflect inadequate hydration.

Adjunctive Care

Dietary Supplements

During prolonged fasting, macro- and micronutrient imbalance is rare. Protein catabolism and vitamin and mineral excretion decreases as the fast progresses, and typically by day 10 is low enough to maintain homeostasis. Fast termination is preferred to supplementation. Problems such

as nausea and indigestion have been reported when vitamin and mineral supplements were taken during fasting.[122,171] In a report describing vitamin deficiency during fasting, the actual fasting protocol was not described; in addition, the patient's physical activity was not restricted and oral medication for intercurrent illness was maintained during fasting.[122]

Enemas

Enemas are generally not administered or necessary if the fasting patient has daily, healthy bowel movements before fasting begins. To help prevent constipation, a raw and cooked plant-foods diet free from any additives, animal products, or refined carbohydrates for at least 2 days will help promote bowel movement prefast and prevent postfast constipation. If bowel movements do not start early during refeeding, then precautionary methods to avoid fecal compaction should be considered, including stewed prunes, enema, and/or colon hydrotherapy.

Hydrotherapy

Constitutional hydrotherapy and sitz baths have been implemented with fasting. Strong treatments, both in frequency and/or temperature interval size, should be limited to early fasting.

Intravenous Therapy

Intravenous administration requires much care and is best avoided entirely, except for emergent conditions. Saline should be avoided as a result of plasma expansion and edema, which has precipitated acute heart failure. Glucose, in contrast, should be accompanied by vitamin B_1 and B_6 coadministration to avoid acute thiamine deficiency and lactic acidosis.[173-175]

Pharmaceuticals

Pharmaceutical use is contraindicated during prolonged fasting. The primary concern regarding fasting medicated patients is the potentiation of drug action during the fasted state, altered urinary/hepatic metabolism, and known drug side effects and adverse events. Appropriately removing pharmaceuticals allows for ease of clinical assessment while ensuring patient safety. Successful fasts have been administered while maintaining some hormonal medications including insulin, thyroid, and reproductive hormones, often at reduced dosage.

CONTRAINDICATIONS

Contraindications to fasting are few, and each case must be judged individually (Table 37.5). For example, an inexperienced practitioner may assume that emaciated patients should not fast, but in cases of extreme emaciation a short fast (1–3 days) or a series of such short fasts with longer periods of proper intervening feeding may be beneficial.[31] With regard to fasting contraindications Alec Burton stated:

> *I have found few health problems which are absolute contraindications to fasting. In my experience, if the need is evident, the only genuine contraindication is fear…. As for the other conditions often mentioned, e.g. kidney disease, heart impairment, [tuberculosis], etc., they merely require extreme caution, because of the limits imposed by pathology, but they are not inexorable contraindications.*[157]

Relative contraindications to fasting include severe anemia, porphyria, cachexia, anorexia, severe liver or kidney disease, medium-chain acyl-CoA dehydrogenase deficiency, advanced cerebral vascular insufficiency, higher-grade cardiac arrhythmias, certain cancers or psychological disorders, and active gastric ulcer disease.[176] Although fasting is contraindicated in severe renal insufficiency, patients with 65% renal function often normalize as a result of fasting and dietary management. Additionally, fasting pregnant women and children is controversial. Short, medically supervised fasts may be appropriate for pregnant women and children on an individual basis, but long fasts are typically strongly contraindicated and precaution is indicated. Doctors (e.g., Shelton, Benesh, Sidwha, and Burton) with considerable experience fasting pregnant women during all three trimesters have found no adverse effects with fasts of a few days to 2 to 3 weeks, but there are insufficient data to conclude if the practice is safe. Fasting during lactation is not generally advised because milk flow is halted by fasting and is difficult to resume.[31]

SIDE EFFECTS

Medically supervised, prolonged water-only fasting as a therapeutic procedure is generally safe.[7] Side effects of fasting are rarely serious, with the exception of rare electrolyte imbalance, but fasting may uncover disease and reveal weaknesses that were previously subclinical.[117,177] Discomfort during fasting may be due to withdrawal from stimulants, hypoglycemia, acidosis, elimination of wastes, and enhancement of repair. Patients may experience headaches, insomnia, nausea, back pain, dyspepsia, fatigue, skin irritations, presyncope, coated tongue, body odor, aching limbs, palpitations, mucus discharge, and visual and hearing disturbances. Hair growth is usually arrested, and skin may become dry and scaly. Most signs and symptoms are usually brief in duration. In certain cases, complications occur that may necessitate breaking the fast prematurely. Examples of such conditions are shown in Table 37.5.

Fasting also elevates serum uric acid values and uric acid excretion, and if fluid intake is insufficient, gout or renal stones may be precipitated.[178] A few reports have also discussed the development of Wernicke encephalopathy during prolonged fasting,[174,175] but this rarely occurs during therapeutic fasting. Therefore it is difficult to determine whether the condition is related to methodology. Furthermore, the incidence of death at fasting institutions is low, and there is no evidence in the scientific literature to suggest that fasting or starvation can be considered a cause of death. Death during fasting indicates that the remedial efforts of the body have been overpowered by the pathological process. This situation occurs in serious disease, whether the patient is eating or fasting. In examining the fallacy of attributing the cause of death to fasting, Stewart and Fleming wrote, "Fasting short of emaciation is not hazardous; if death results, reasons other than those of the fast should be considered before concluding that all supervised fasts should be discouraged."[179]

CONCLUSION

Prolonged water-only fasting conducted under medical supervision is increasingly recognized as a safe and effective therapy for a number of diseases, but the practice is not for everyone and postfast lifestyle modifications are necessary to maintain any health benefits obtained from fasting. Preliminary research indicates that there is at least some degree of overlap between the physiological responses induced by caloric restriction, intermittent fasting, prolonged fasting, and exercise, such as increased autophagy and insulin sensitivity.[3,180-184] Additional research is necessary to determine the extent to which these methods induce similar physiological responses in humans and if the responses result in clinical health outcomes. Nonetheless, used alone or in combination, these natural therapies could help reduce the overwhelming rates of chronic diseases that humans are experiencing globally. As it is more beneficial and cost effective to maintain rather than repair health, it will be important to determine the effect of these therapies on health span over the course of a life.

TABLE 37.5 Fasting Contraindications, Common Adverse Events, and Serious Complications

Contraindications	Common Adverse Events[a]	Complications[b]
• Severe anemia	• Headaches	• Sudden drop in BP
• Porphyria, cachexia, anorexia	• Insomnia	• Delirium
• Severe liver or kidney disease	• Nausea	• Prolonged hypothermia
• Medium-chain acyl-CoA dehydrogenase deficiency	• Back pain/aching limbs	• Rapid/slow/feeble/irregular pulse
• Advanced cerebral vascular insufficiency	• Dyspepsia	• Extreme weakness
• Higher-grade cardiac arrhythmias	• Fatigue	• Dyspnea
• Certain cancers	• Skin irritations	• Vomiting/diarrhea causing dehydration
• Pregnant women and children	• Presyncope	• Gastrointestinal tract bleeding
	• Coated tongue	• Hepatic decompensation
	• Body odor	• Renal insufficiency
	• Aching limbs	• Cardiac arrhythmias
	• Mucus discharge	• Severe electrolyte imbalance

[a]Common adverse events are typically mild to moderate in nature.
[b]Less common, potentially serious complications that typically require premature termination of fast.

Glandular Therapy

Michael T. Murray, ND

OUTLINE

INTRODUCTION

For almost as long as historical records have been kept, glandular therapy has been an important form of medicine. The basic concept underlying the medicinal use of glandular substances from animals is that "like heals like." For example, if the liver needs support or a patient is suffering from liver disease, then he or she may benefit from eating beef liver. Modern glandular therapy, however, primarily involves the use of concentrated glandular extracts.

A gland is defined as a secretory organ. The internal secretory organs of the body are called endocrine glands. These ductless glands secrete hormones directly into the bloodstream. The glands known to have endocrine function include the pineal, pituitary, thyroid, parathyroid, thymus, adrenal, pancreas, and gonads (testes or ovaries). Although not technically glands, it is common to refer to other organs of the body as glandulars when they are used in glandular therapy. For example, tissue extracts of heart, spleen, prostate, uterus, brain, and other tissues are often used in glandular or organotherapy.

Research has shown that certain glandular preparations and hormones are quite effective when taken orally. A number of glandular preparations are effective orally because of active hormone or enzyme content (e.g., thyroid, adrenal cortex, and pancreatin preparations). A good deal of literature supports pharmaceutical-grade liver, aorta, and thymus extracts, and some support exists for pituitary, spleen, orchic (testes), and ovarian extracts as well. However, despite this scientific support, many still question the effectiveness of glandular products in human health.

A key challenge to the use of glandulars is the lack of widely accepted standards for extraction and quantification. Each manufacturer of a glandular product claims its method of extraction is the most ideal. However, the majority of these contentions are based on theoretic or philosophical grounds, not on research or clinical results. No quality control procedures or standards are enforced in the glandular industry. It is left up to the individual company to adopt quality control and good manufacturing procedures. Nonetheless, many glandular preparations available in the U.S. marketplace appear to be effective.

METHODS OF MANUFACTURE OF GLANDULAR PREPARATIONS

It is critical that properly processed glandular material be used because the biologically active materials, such as enzymes, soluble proteins, natural lipid factors, vitamins, minerals, and hormone precursors, are destroyed or eliminated if the product is not prepared properly.

Most glandular products are derived from beef (bovine) sources, the exception being pancreatic extracts, which are most often derived from pork (porcine) sources. The four most widely known methods of processing are the azeotropic method, salt precipitation, freeze-drying, and predigestion.

The Azeotropic Method

The azeotropic method begins by quick freezing the material at well below 0°F, then washing the material with a solvent (e.g., ethylene dichloride) to remove the fatty tissue. The solvent is then distilled off, and the material is dried and ground into a powder so that it can be placed in tablets or capsules. Although the azeotropic method eliminates the problem of fat-stored toxins like pesticides and healthy metals, unfortunately, it also removes fat-soluble hormones, enzymes, essential fatty acids, and other potentially beneficial materials; in addition, traces of the solvent still remain.

The Salt Precipitation Method

The salt precipitation method involves the maceration of fresh glandular material in salt and water. Because the salt increases the density of the water-soluble material, when the mixture is centrifuged, the lighter fat-soluble material can be separated out. The material is then dried and powdered. The benefit with the salt

precipitation method is that no toxic solvents are used to separate the fatty material. The downside is the increased salt content of the product.

Freeze-Drying

The freeze-drying process involves quickly freezing the glandular material at temperatures of −40°F to −60°F and then placing the material into a vacuum chamber, which removes the water by direct vaporization from its frozen state (hence the term *freeze-drying*). The benefit of freeze-drying is that the product contains a higher concentration of unaltered protein, enzymes, and all of the fat-soluble components. Because the fat is not removed, it is critical that the glands are derived from livestock that have grazed on open ranges not sprayed with pesticides or herbicides. The animals must also be free from antibiotics, synthetic hormones, and infection.

Predigestion

The predigestion method employs plant and animal enzymes or some other method to partially digest or hydrolyze the glandular material. The partially digested material is then passed through a series of filtrations to separate out fat-soluble and large molecules. The purified material is then freeze-dried. This method of extraction is best for glandulars (e.g., liver and thymus) where the polypeptide and other water-soluble fractions are desired.

SPONGIFORM ENCEPHALOPATHY

Bovine spongiform encephalopathy (BSE), also known as mad cow disease, is a transmissible, slowly progressive, degenerative, fatal disease affecting the central nervous system of adult cattle. The transmissible agent in BSE is a modified form of a normal cell surface component known as a prion protein. Unlike infectious organisms, prions are resistant to common treatments, such as heat and digestive secretions. Eating the meat of an animal with BSE may lead to a disease similar to BSE in humans called variant Creutzfeldt–Jakob disease (CJD).

BSE was first reported among cattle in the United Kingdom in 1986 and has been a major concern since then. The outbreak in the United Kingdom may have started from the feeding of scrapie-contaminated sheep meat-and-bone meal to cattle. Scrapie is a disease of sheep that is related to BSE in cattle. The evidence is strong that the outbreak in cattle was amplified in the United Kingdom by feeding rendered bovine meat-and-bone meal to young calves.

BSE has been reported in cattle throughout Europe. There has been a single case in Canada and in the United States from a cow imported from Canada. Wild game in the United States, such as deer and elk, have been affected by a similar disease known as chronic wasting disease. The reason American cattle have been spared may be because of the active surveillance and import measures taken by the U.S. Food and Drug Administration (FDA) and the U.S. Department of Agriculture (USDA).

The USDA has restricted the importation of live ruminants, such as cows and sheep, and food products from these animals from BSE countries since 1989 and from all European countries since 1997. In addition, the FDA prohibits the use of most mammalian protein in the manufacture of animal feeds given to ruminants because this kind of feeding practice is believed to have initiated and amplified the outbreak of BSE in the United Kingdom.

To reduce the risk of ingesting beef with BSE, it is critical to use products manufactured under the following guidelines:

- The June 2000 European Commission Decision regulating the use of material presenting risks for BSE
- A "Certification of Suitability" by the European Directorate of Quality of Medicines to ensure that the highest-quality, pharmaceutic-grade material is being used
- The FDA's guidelines for sourcing and processing of bovine material

The incidence of all prion diseases (Kuru, CJD, Gerstmann–Sträussler–Scheinker syndrome, and fatal familial insomnia) worldwide is about 1 to 2 per million people per year.[1]

EVIDENCE FOR INTACT PROTEIN ABSORPTION

There is now considerable evidence that large macromolecules pass intact from the normal human gut into the bloodstream. In some instances, the body appears to recognize which molecules it needs to absorb intact and which molecules it needs to break down into smaller units. This phenomenon may help explain the effectiveness of glandular therapy.

Numerous whole proteins have been shown in human and animal studies to be absorbed intact into the bloodstream after oral administration.[2–8] These include human albumin and lactalbumin, bovine albumin, ovalbumin, lactoglobulin, ferritin (molecular weight 500,000), chymotrypsinogen, elastase, and other large molecules.

Furthermore, proteins and polypeptides, as well as various hormones that are absorbed intact from the gut, have been shown to exert effects in target tissues. For example, in addition to thyroxine or thyroid hormone and cortisone, several peptide hormones are known to be biologically active when administered orally, including luteinizing hormone–releasing factor and thyrotropin-releasing hormone.[9,10] Even insulin has been shown to be absorbed orally under certain circumstances (e.g., in the presence of protease inhibitors or hypertonic solutions in the intestines).[11,12]

These data indicate that at least some of the larger molecules in glandular products are absorbed intact to induce physiological effects, particularly polypeptides, which exert hormone or hormone-like action.

CLINICAL APPLICATIONS

An adequate body of research now exists to support the use of orally administered glandular extracts. The following is a brief discussion of several glandular preparations and their use. Table 38.1 lists the primary conditions responding to glandular therapy.

Adrenal Extracts

Oral adrenal extracts have been used in medicine since at least 1931.[13] Adrenal extracts may be made from the whole adrenal gland or just from the adrenal cortex. Whole adrenal extracts (usually in combination with essential nutrients for the adrenal gland) are most often used in cases of low adrenal function, presenting as fatigue, inability to cope with stress, and reduced resistance. Because extracts made from the adrenal cortex contain small amounts of corticosteroids, they are typically used as a "natural" cortisone in severe cases of allergy and inflammation (e.g., asthma, eczema, psoriasis, rheumatoid arthritis).

Dosage

The dosage of adrenal extract depends on the quality and potency of the product. The best measure of an effective dose for a preparation may be the level of stimulation (irritability, restlessness, and insomnia) the patient experiences. When prescribing adrenal extracts, start at one third of the recommended dosage on the label and slowly increase the dosage every 2 days until a stimulatory effect is noted. Once this effect is noticed, reduce the dosage to a level just below the level that produces stimulation.

TABLE 38.1 Therapeutic Uses of Glandular Extracts

Extract	Clinical applications
Adrenal extracts	Chronic fatigue
	Asthma
	Eczema
	Psoriasis
	Rheumatoid arthritis
Aortic glycosaminoglycans	Cerebral and peripheral arterial insufficiency
	Venous insufficiency and varicose veins
	Hemorrhoids
	Vascular retinopathies, including macular degeneration
	Postsurgical edema
Liver extracts	Chronic hepatitis
	Chronic liver disease
Pancreatic extracts	Pancreatic insufficiency
	Cystic fibrosis
	Inflammatory and autoimmune diseases such as rheumatoid arthritis, scleroderma, athletic injuries, and tendinitis
	Cancer
	Infections
Spleen extracts	After splenectomy
	Immune potentiation
	Infection
	Cancer
	Celiac disease
	Dermatitis herpetiformis
	Ulcerative colitis
	Rheumatoid arthritis
	Glomerulonephritis
	Systemic lupus erythematosus
	Vasculitis
	Low white blood cell counts
	Thrombocytopenia
Thymus extracts	Recurrent and chronic viral infections, such as chronic fatigue syndrome, respiratory infections, AIDS, acute hepatitis B infection
	Cancer patients with immune depression from chemotherapy or radiation
	Asthma, hay fever, eczema, and food allergies
	Autoimmune disorders, such as rheumatoid arthritis, lupus erythematosus, and scleroderma
Thyroid extracts	Hypothyroidism

AIDS, acquired immunodeficiency syndrome.

Aortic Glycosaminoglycans

A mixture of highly purified bovine-derived glycosaminoglycans (GAGs) is naturally present in the aorta, including dermatan sulfate, heparan sulfate, hyaluronic acid, and chondroitin sulfate; related hexosaminoglycans have been shown to protect and promote normal artery and vein function. More than 50 clinical studies have shown an orally administered complex of aortic GAGs to be effective in a number of vascular disorders, including the following:

- Cerebral and peripheral arterial insufficiency
- Venous insufficiency and varicose veins
- Hemorrhoids
- Vascular retinopathies, including macular degeneration postsurgical edema[14–23]

Significant improvements in both symptoms and blood flow have been noted.

In addition, aortic GAGs have many important effects that interfere with the progression of atherosclerosis, including prevention of damage to the surface of the artery, formation of damaging blood clots, migration of smooth muscle cells into the intima, formation of fat and cholesterol deposits, and lowering total cholesterol levels while raising high-density lipoprotein cholesterol.[24–28]

Dosage

The dosage of the mixture of highly purified bovine-derived GAGs naturally present in the aorta is 100 mg/day. Similar, but not nearly as impressive, results in the treatment of atherosclerosis have been noted with chondroitin sulfate at a daily dose of 3 g (1 g, three times daily).[29]

Liver Extracts

Beef (bovine) liver extracts and concentrates are a rich natural source of many vitamins and minerals, including iron. Liver extracts can contain as much as 3 to 4 mg of heme iron per gram. In addition to its use as a source of iron and other nutrients, hydrolyzed liver extracts have been used to treat chronic liver diseases since 1896. Numerous scientific investigations into the therapeutic efficacy of liver extracts demonstrated that these extracts improved fat utilization, promoted tissue regeneration, and prevented damage to the liver.[30–33] In short, clinical studies demonstrated that oral administration of hydrolyzed liver extracts can be quite effective in improving liver function.

For example, in one double-blind study, 556 patients with chronic hepatitis were given either 70 mg of liver hydrolysate or a placebo three times daily.[33] After 3 months of treatment, the group that received the liver extract had far lower serum liver enzyme levels. Because the level of liver enzymes in the blood reflects damage to the liver, it can be concluded that liver extract is effective in chronic hepatitis via an ability to improve the function of damaged liver cells, and to prevent further damage to the liver.

Dosage

The dosage is entirely dependent on the concentration, method of preparation, and quality of the liver extract. The highest-quality products are aqueous hydrolyzed extracts because they have the fat-soluble components removed and typically contain more than 20 times the nutritional content of raw liver, including 3 to 4 mg of heme iron per gram.

Contraindication

Liver extracts should not be used in patients experiencing an iron-storage disorder, such as hemochromatosis.

Pancreatic Extracts

Pancreatic enzymes are most often employed in the treatment of pancreatic insufficiency. Pancreatic insufficiency is characterized by impaired digestion, malabsorption, nutrient deficiencies, and abdominal discomfort. Pancreatic enzymes are also used by physicians in the treatment of the following:

- Cystic fibrosis
- Inflammatory and autoimmune diseases like rheumatoid arthritis, scleroderma, athletic injuries, and tendinitis
- Cancer
- Infections

For a full discussion of pancreatic enzymes, see Chapter 111.

Dosage

Full-strength products are preferred to lower-potency pancreatin products because lower-potency products are often diluted with salt, lactose, or galactose to achieve the desired strength (e.g., 4× or 1×). The dosage recommendation for a 10× U.S. Pharmacopoeia (USP) pancreatic enzyme product is 500 to 1000 mg three times a day immediately before meals when used as a digestive aid and at least 20 minutes before meals or on an empty stomach when anti-inflammatory effects are desired.

Pancreatic extracts are generally well tolerated and are not associated with any significant side effects.

Spleen Extracts

As early as the 1930s, orally administered bovine spleen extracts were shown to possess some physiological action in increasing white blood cell counts in patients with extreme deficiencies of white blood cells and being of some benefit in patients with malaria and typhoid fever.[34–36]

Like thymus extracts, pharmaceutical-grade bovine spleen extracts are currently quite popular in Germany for the treatment of infectious conditions and as immune-enhancing agents in cancer. Spleen tissue extracts may be of benefit in enhancing general immune function because many potent immune system–enhancing compounds secreted by the spleen are low-molecular-weight peptides. For example, the potent immunostimulants tuftsin and splenopentin are composed of only four and five amino acids, respectively.

Both tuftsin and splenopentin have been shown to exert profound immune-enhancing activity. Tuftsin stimulates macrophages that have taken up residence in specific tissues like the liver, spleen, and lymph nodes. Tuftsin also helps mobilize other white blood cells to fight against infection and cancer. A deficiency of tuftsin has been associated with signs and symptoms of frequent infections.[37]

Splenopentin, like tuftsin, has also demonstrated significant immune-enhancing effects. Its effects are primarily directed toward enhancing the immune system's response to regulating compounds such as colony-stimulating factors.[38] Colony-stimulating factors, such as interleukin-3, and granulocyte/macrophage colony–stimulating factors stimulate the production of white blood cells. Splenopentin is probably the factor responsible for the results noted in clinical studies during the 1930s in which spleen extracts were used in the treatment of depressed white blood cell counts.

Splenopentin has also been shown to enhance the activity of natural killer cells.[39] Natural killer cells destroy cells that have become cancerous or infected with viruses and are the body's first line of defense against cancer.

In addition to tuftsin and splenopentin, hydrolyzed (predigested) spleen extracts concentrated for peptides demonstrated impressive immune restorative properties in mice.[40] In one study, mice were exposed to radiation to significantly damage the immune system. Mice treated with the spleen extract recovered within 6 to 8 weeks. In contrast, those treated with a placebo recovered after 10 weeks at the earliest.

The primary clinical uses of spleen extracts are after removal of the spleen, and the conditions associated with low spleen function (hyposplenia) are shown in Table 38.2.

Spleen extracts may also be useful in the treatment of low white blood cell counts, bacterial infections, and as an adjunct in cancer therapy. Individuals who have had splenectomies or who have low tuftsin levels or autoimmune conditions linked to low activity of the reticuloendothelial system should use spleen extracts.

Because the spleen is difficult to repair, severe spleen trauma usually requires splenectomy to stop the severe hemorrhage. The spleen is also removed in the medical treatment of certain diseases, such as idiopathic thrombocytic purpura and to determine the extent of Hodgkin disease.

TABLE 38.2 Conditions Associated With Low Spleen Function

- Celiac disease
- Dermatitis herpetiformis
- Ulcerative colitis
- Rheumatoid arthritis
- Glomerulonephritis
- Systemic lupus erythematosus
- Vasculitis
- Thrombocytopenia

Removal of the spleen is associated with an increased risk for infection. This increased risk of infection makes children and adults particularly susceptible to pneumococcal pneumonia. About 2.5% of patients who have their spleen removed die of pneumococcal pneumonia within 5 years of splenectomy. It is often recommended that a child who has undergone a splenectomy receive a pneumococcal vaccine and receive long-term antibiotic treatment. Use of spleen extracts, especially those rich in tuftsin, may be a natural alternative.

Spleen extracts should probably be viewed as a necessary medicine for people who have had their spleen removed. If the thyroid, adrenals, or ovaries are removed, most patients would be prescribed the corresponding hormone. It only makes sense that if the spleen is removed, the body should be supplied with necessary spleen substances like tuftsin and splenopentin.

The increased risk of infection is attributed primarily to a deficiency of tuftsin.[41,42] Tuftsin is produced only in the spleen; without the spleen, there simply is no tuftsin in the circulation. Without tuftsin, the body is without one of its key stimulators of the immune system. Individuals without spleens need an outside source of tuftsin, like spleen extracts.

Dosage

Clinically, hydrolyzed (predigested) products concentrated for tuftsin and splenopentin content are preferable to crude preparations. The daily dose should provide 50 mg tuftsin and splenopentin or roughly 1.5 g of total spleen peptides.

No side effects or adverse effects have been reported with the use of oral spleen preparations.

Polyerga

Before the development of manufacturing techniques for human insulin to be used in the treatment of diabetes, the source was insulin isolated from pig pancreas. In Germany, after World War II, there was a shortage of pigs and subsequently a shortage of insulin. A German researcher, Walter Kuhlmey, MD, PhD, subsequently sought to produce insulin from other animal organs, most notably the spleen. In the process, this led to the serendipitous discovery of Polyerga. Kuhlmey found that the pig spleen extract not only had some insulin-like activity but that it also increased the general sense of well-being and gave people more energy. He named his new product Polyerga (in Latin, *poly* means "multiple," and *erga* means "power").

Initially, Polyerga had a general use. In 1951 an event changed Polyerga's clinical use. Julia Meir was a patient of oncologist Heinrich Pophanken, MD. She had an advanced cancer of the pancreas. She was considered incurable, and her death was expected shortly. In an effort to ease her pain, lift her fatigue, and stimulate a sense of well-being in Julia, Pophanken gave her Polyerga (via injection). Surprisingly, the

dying patient began to recover. Pophanken gave Julia three to six intramuscular injections of Polyerga per week during the first 2 months and then just two injections a week thereafter. In 1954 Julia died of causes unrelated to her cancer. When the autopsy was conducted, the egg-sized tumor in her pancreas had disappeared entirely. This single case history led to the focus of research on Polyerga as a cancer therapy.

Cancer Therapy

Polyerga has been evaluated in several clinical studies in cancer patients. In one of the largest trials, 158 breast cancer patients were divided into two groups. The women in the Polyerga group received injections of Polyerga three times per week, whereas the women in the control group received a placebo injection. In the Polyerga group, the percentage of white blood cells, various parameters of immune function, body weight, and general sense of well-being all improved significantly compared with the control group.[43]

In a double-blind, placebo-controlled study in patients with head and neck cancers, Polyerga was shown to support patients who received the chemotherapy drugs 5-FU and cisplatin.[44] Polyerga was shown to stabilize the levels of lymphocytes. Typically, patients receiving 5-FU, cisplatin, and other chemotherapy drugs experienced a reduction in lymphocytes. This effect was noted in the placebo group but not in the patients receiving Polyerga. In addition, the Polyerga group reported less fatigue and higher energy levels than the placebo group, and there was no weight loss. Prevention of weight loss is a major goal in support of the cancer patient because significant weight loss reduces the tolerance to anticancer drugs, reduces the functioning of the immune system, and is considered to be a major cause of death in the cancer patient.

In another study of 248 cancer patients, giving them Polyerga orally for 4 months improved appetite, reduced pain, increased energy and activity levels, and improved their general sense of well-being.[45] Furthermore, a reduction of the extent of the illness, along with a clear improvement of health, was recorded by observing physicians. The best results were obtained in breast cancer patients and patients experiencing colon and other carcinomas, whereas lung cancer patients and patients with metastases did not seem to respond as well to Polyerga.

Other studies have shown Polyerga to produce similar benefits, as well as enhance survival time and reduce metastasis (spreading) in patients with cancers of the colon, stomach, and lungs.[46] From the totality of existing clinical studies, animal studies, and test tube (in vitro) studies, it can be concluded that Polyerga does the following:

- Exerts significant immune-enhancing effects
- Prevents some side effects of chemotherapy, especially the detrimental effects on the immune system
- Enhances the effectiveness of conventional chemotherapy and radiation treatment
- Prevents metastasis
- Enhances the general sense of well-being, improves energy levels, and prevents detrimental weight loss in cancer patients
- Enhances both the quality of life and survival time in cancer patients

The Mechanism of Action

Many effects of Polyerga may be the result of boosting the output of γ-interferon.[47] This important chemical acts as the communication link between the macrophages and lymphocytes. Reduction in the level of γ-interferon results in significantly impaired immune function. Low γ-interferon levels are common in cancer patients. By increasing γ-interferon levels, Polyerga creates a cascading of effects that lead to enhanced immune function in cancer patients. Polyerga increases the activation of natural killer cells.[48–51]

Other Uses

Polyerga may be helpful any time immune support is required, such as in chronic viral infections, including hepatitis C, human immunodeficiency virus (HIV), and Epstein–Barr syndrome. In a study of 10 patients with chronic hepatitis B, Polyerga administration (intramuscularly twice weekly and orally three tablets daily for 24 weeks) led to complete resolution in 3 of the 10 patients and lowering of liver enzymes in individuals with lower viral loads.[52] Polyerga may also be quite helpful to people who have had their spleens removed.

Dosage

Most studies with Polyerga used injectable preparations. Based on dose-effect studies in animals, as well as human clinical data, an effective oral dosage was determined. Each Polyerga tablet contains 100 mg of polypeptides. The optimum dosage recommendation is one to two tablets three times per day. For patients up to 140 lb body weight, the dosage is one tablet three times per day. For each additional 40 lb body weight, add a tablet (e.g., a 220-lb person would take five tablets daily in divided dosages). There is no toxicity with Polyerga, so there is no concern about overdosage.[53] However, taking more than the recommended dose does not necessarily produce better results. For best results, Polyerga should be ingested on an empty stomach before meals.

Thymus Extracts

A substantial amount of clinical research supports the effectiveness of orally administered thymus extracts. Specifically, numerous clinical trials have shown that oral administration of predigested calf thymus extract, rich in thymus-derived polypeptides, is effective in doing the following:

- Preventing recurrent respiratory infections in children
- Correcting the T-cell defects in HIV infections (acquired immunodeficiency syndrome [AIDS])
- Treating acute hepatitis B infections
- Restoring the number of peripheral leukocytes in cancer patients with chemotherapy-induced depression of white blood cell counts
- Treating asthma, hay fever, and food allergies in children[54,55]

The effectiveness of the thymus extract in these conditions is reflective of broad-spectrum immune system enhancement presumably mediated by improved thymus gland activity. This effect fits in nicely with one of the basic concepts of glandular therapy (i.e., that the oral ingestion of glandular material of a certain animal gland strengthens the corresponding human gland). The result is a broad general effect indicative of improved glandular function. Interestingly, thymus extracts have been shown to normalize the ratio of T-helper cells to suppressor cells, whether the ratio is low, as in AIDS, chronic infections, and cancer, or high, as in allergies, migraine headaches, and autoimmune diseases like rheumatoid arthritis.

Chronic Viral Infections

Recurrent or chronic infections, including chronic fatigue syndrome and chronic postviral syndrome, are characterized by a depressed immune system. This is a difficult condition to treat because of the repetitive cycle of a compromised immune system leading to infection, which leads to damage to the immune system, further weakening resistance to viral infection. Thymus extracts may provide the answer to chronic infections by restoring healthy immune function.

The ability of thymus extracts to treat and then reduce the number of recurrent infections has been studied in groups of children with a history of recurrent respiratory tract infections. Controlled clinical studies revealed not only that orally administered thymus extracts were able to effectively eliminate infection, but also that treatment

over the course of a year significantly reduced the number of respiratory infections and significantly improved numerous immune parameters.[56]

One of the most difficult viral infections for the body to eliminate is type B viral hepatitis. Thymus extracts have been shown to be effective in several clinical studies in both acute and chronic cases. In these studies, a therapeutic effect was noted by accelerated decreases of liver enzymes (transaminases), elimination of the virus, and a higher rate of seroconversion to anti-HBe, signifying clinical remission.[57,58]

The most extreme example of a chronic viral infection is AIDS. Although thymus extracts have not been shown to reverse this difficult disease, studies have shown an ability to improve several immune parameters, including an ability to increase the T-helper cells, a critical goal in AIDS treatment.[59]

Cancer

The primary application of thymus extracts in cancer has been to counteract the immune-suppressing effects of radiation and chemotherapy. The net effect of thymus extract administration is to prevent the tremendous depression of white blood cell levels and activity that result from chemotherapy or radiation.[55,60]

Allergies

In patients with allergies, levels of the allergic immunoglobulin-E antibody and eosinophils are typically elevated, whereas levels of suppressor T cells are typically depressed. These abnormalities are clear indications of altered immune function.

The oral administration of thymus extracts has been shown in double-blind clinical studies to improve the symptoms and course of hay fever, allergic rhinitis, asthma, eczema, and food allergies.[55,61–63] Presumably, this clinical improvement is the result of the restoration of proper immune function because levels of immunoglobulin-E and eosinophils have been shown to be reduced, whereas the ratio of helper to suppressor T cells is improved.

Interestingly, in several clinical studies, children receiving thymus extracts during food allergy elimination diets were often able to tolerate foods that had previously been allergenic and symptom producing.[62,63]

Autoimmune Disorders

Autoimmune disorders, such as rheumatoid arthritis, are characterized by autoimmunity. Central to this immune dysfunction is a high ratio of T-helper to suppressor cells. A high ratio of T-helper to suppressor cells results in increased antibody formation. The higher the ratio, the higher the number of antibodies being produced to damage body structures. In one clinical study, rheumatoid arthritis patients with a ratio of T-helper to suppressor cells of 3.3 achieved normal ratios (1.02–2.46) after 3 months of therapy with a thymus extract.[55]

Although the use of a thymus extract may not result in substantial clinical improvement, it appears to be useful in restoring proper immune function in autoimmune diseases, including rheumatoid arthritis, lupus, and scleroderma.

Dosage

From a practical view, products concentrated and standardized for polypeptide content are preferable to crude preparations. The daily dose should be equivalent to 120 mg pure polypeptides with molecular weights less than 10,000, or roughly 750 mg of the crude polypeptide fraction.

No side effects or adverse effects have been reported with the use of thymus preparations.

Thyroid Extracts

Desiccated natural thyroid is available by prescription according to USP guidelines. Preparations are derived from porcine thyroid glands. Many naturopathic physicians prefer natural thyroid to isolated synthetic T_4 because it contains both thyroxine (T_4) and tri-iodothyronine (T_3). Typical levels of thyroid hormone contained per grain in USP thyroid are 38 mcg of T_4 and 9 mcg of T_3.

The thyroid extracts sold as "nutritional supplements" are required by the FDA to be thyroxine-free. However, it is nearly impossible to remove all the hormone from the gland. These nutritional thyroid preparations can be considered milder forms of desiccated natural thyroid.

The primary use of thyroid preparations is in the medical treatment of hypothyroidism. In all but its mildest forms, treatment involves the use of desiccated thyroid or synthetic thyroid hormone. For more discussion, see Chapter 209.

Dosage

Dosage is determined by clinical evaluation, including blood measurements of thyroid hormones (see Chapter 209 for directions).

SUMMARY

From the scientific data that currently exist, there is enough evidence to support the use of orally administered glandular extracts. For the best results, physicians should choose glandular products made by reputable companies that employ established methods of manufacture to produce extracts of known concentration.

Homeopathy

Andrew Lange, ND,* and *Susan Ann Gaylord, PhD*

OUTLINE

INTRODUCTION

Homeopathy is a highly systematized method of medical therapeutics and clinical evaluation. The term *homeopathy* is derived from the Greek words *homeos*, meaning "similar," and *pathos*, meaning "suffering." The medicines used in this system of therapeutics are chosen according to the Law of Similars (the concept of like curing like), a fundamental homeopathic principle based on the observed relationship between a medicine's ability to produce a specific constellation of signs and symptoms in a healthy individual and the same medicine's ability to cure a sick patient with similar signs and symptoms. This principle was first recognized by Hippocrates, who noticed that herbs given in low doses tended to cure the same symptoms they produced when given in toxic doses.

Homeopathic medicines are derived from a wide variety of plant, mineral, and chemical substances. They are prepared according to standards of the *U.S. Homeopathic Pharmacopoeia*, a revised version of which has been approved by the U.S. Food and Drug Administration and U.S. Congress.

HISTORY

The homeopathic school of medicine was founded by a German physician, Samuel Hahnemann. He had already gained a reputation in chemistry and medicine, having formulated a soluble form of mercury and developed a safer method for its use and having written a number of works on pharmacology, hygiene and public health, industrial toxicology, and psychiatry. His treatise on arsenic poisoning (1786) is still considered authoritative. A prolific writer, Hahnemann collected, compiled, revised, and edited the existing pharmacological knowledge. The work was well received by the medical profession of the time. Hahnemann was one of the most learned men of his generation in medicine, chemistry, and pharmacology, making his later criticisms of medicine all the more significant.[1]

Disillusioned with the theories and practice of 18th-century medicine, Hahnemann retired from practice in 1782 and spent the next 14 years earning a meager living doing chemical research; writing; and translating English, French, Italian, and Latin works. He wrote of his time of practice:

> *It was painful for me to grope in the dark, guided only by books in the treatment of the sick. To prescribe according to this or that (fanciful) view of the nature of diseases, substances that only owed to mere opinion their place in the materia medica; I had conscientious scruples about treating unknown morbid states in my suffering fellow creatures with these unknown medicines which, being powerful substances, may, if they were not exactly suitable (and how could the physician know whether they were suitable or not, seeing that their peculiar special actions were not yet elucidated) easily change life into death, or produce new affections and chronic ailments, which are often more difficult to remove than the original disease.*

In his struggle to determine a reliable basis for therapeutics, he was distressed by his inability to provide medical care for the acute illnesses of even his own growing family. In 1790 during his translation of William Cullen's (a Scottish physician) *Materia Medica,* he added a footnote disagreeing with Cullen's conclusions that the basis of cinchona bark's effectiveness was its bitter and astringent qualities. *Cinchona officinalis* (Peruvian bark), from which the drug quinine is derived, was known to be clinically effective in malaria and intermittent fevers (then called ague). He argued that there were several drugs in common usage that, in smaller doses, had greater bitter and

*Previous edition contributor

astringent qualities yet had no specific action on fevers. As an experiment, Hahnemann took four drachms of cinchona twice daily and soon developed the paroxysmal symptoms characteristic of intermittent fevers.

This duplication of symptoms was a revelation to him and ultimately resulted in his formulation of the concept of determining the properties of a medicine by studying its effects on healthy humans.

Although homeopathy offers a profoundly deep and unified evaluation in the treatment of chronic diseases (see the section "Follow-Up and Case Evaluation"), it gained most of its early reputation in the treatment of acute and epidemic diseases. An uproar was caused in Cincinnati in 1849 when two immigrant German homeopaths, treating cholera with camphor and other homeopathically prescribed remedies, published statistics in newspapers indicating that only 35 of their 1116 treated cases had died. During the 19th century, 33% to 50% of patients with cholera who were given standard medical care died. In the 1879 epidemic of yellow fever, New Orleans homeopaths treated 1945 cases with a mortality rate of 5.6%, whereas standard medical doctors were losing 16% of patients. These and similar statistics had a profound effect on Congress and public opinion.[2]

Over time, homeopaths established their own network of treatment facilities. By 1892, in the United States, they controlled 110 hospitals, 145 dispensaries, 62 orphan asylums and retirement homes, more than 30 nursing homes and sanatoria, and 16 insane asylums.

Constantine Hering established the first homeopathic medical school in the United States in 1835. It later moved from its original site in Allentown, Pennsylvania, to Philadelphia, where it remains today as an orthodox medical school: the Hahnemann Medical College and Hospital. Hering's promotion of homeopathy and development of the materia medica were equaled only by Hahnemann himself. Hering's 10-volume work, *The Guiding Symptoms of Our Materia Medica,* remains a definitive work on the clinical verifications of the homeopathic approach. Unfortunately, of the many medicines introduced by Hering, only nitroglycerine remains in orthodox medical practice as a tribute to his medical genius.

Throughout the world, homeopathy has maintained a consistent tradition. Frederick Harvey Foster Quinn introduced it to England in the 1840s. It has since become a postgraduate medical specialty, recognized by the Department of Health by virtue of an Act of Parliament. Homeopathic hospitals and outpatient clinics are part of England's national health system. Homeopaths have been engaged as personal physicians to the royal family for the past four generations.

Homeopathy is widely practiced in Europe, India, Argentina, and Mexico and is experiencing a renaissance in the United States.

PHILOSOPHY

Provings

Hahnemann defined his method of testing medicines on healthy people as "provings." He expanded his investigations to include a wide range of substances, using his family, friends, and associates as experimental subjects.

Historically, Hahnemann was not the first to use this methodology. In 1760 Anton Stoerck reported testing stramonium *(Datura)* by rubbing it on the skin, inhaling the vapors of the freshly crushed leaves, and finally, ingesting the fresh extract. He theorized that if stramonium disturbs the senses and produces mental derangements in healthy people, it might be administered to maniacs for the purpose of restoring the senses by effecting a change of ideas.

The medical literature contains examples of inadvertent provings: in 1983 a study in the *New England Journal of Medicine* reported that pyridoxine (vitamin B_6), which is used in the treatment of some types of peripheral neuropathy, was also capable of producing neuropathies when given in large doses.[3] In 1796 Hahnemann published, in *Hufeland's Journal,* the fruit of his investigations in the article "Essay on a New Principle for Ascertaining the Curative Power of Drugs, with a Few Glances at Those Hitherto Employed."

Like Treating Like

Hahnemann also recognized the tendency of a natural disease to have a "homeopathic effect" (i.e., a preventive or therapeutic effect) on other diseases with similar symptomatology. Although he ascribed this to the stimulation of the organism to eradicate the disease, he felt the deliberate induction of a disease to be difficult, uncertain, and dangerous.[4] This concept has many parallels in modern medical science. Descriptions of viral interference under natural conditions were described in 1937 by G. Findlely and F. MacCallum, who found that monkeys infected with the Rift Valley fever virus were protected from the more fatal yellow fever virus. They adopted the term "virus interference" and believed that when one virus infects a group of cells, a second virus is somehow excluded.[5] This eventually led to the discovery of interferon in 1957 by Alick Isaacs and Jean Lindenmann. These methods of inducing self-regulation are critical in enhancing the body's ability to recognize and resolve illness.

In 1799 Hahnemann gained increased professional acceptance of his ideas by the successful application of *Atropa belladonna* (deadly nightshade) in the prevention and treatment of scarlet fever (which had at that time reached epidemic proportions). In 1860 it was recommended as the treatment of choice in the National Dispensatory, which stated: "As long as persons are under the influence of belladonna the liability to contract scarlatina is very much diminished."[6]

The *Organon of Medicine*

In 1810 Hahnemann published his *Organon of Medicine,* a book that, through six editions, formed the foundation and definition of the homeopathic practice of medicine. It contains the philosophy, observations, and clinical applications of homeopathy, as well as citations from the historical and current literature of the time. Hahnemann challenged the reductionistic and mechanistic practices of his time, stating that the nature of disease is dynamic and cannot be defined by isolating processes, grasping for an explanation. He further asserted that the cause of disease could not be known and that the categorization of disease states and attempts to manipulate physiology were insufficient because they did not address the integrity and complexity of the organization of the organism as a whole.

He described this organization as dynamic, meaning "in accordance with the animating principle of life," which is the underlying energetic pattern to which matter conforms.

Disease is therefore addressed descriptively in the context of the whole patient, with the patient's unique symptoms being indicative of that individual's vital response to the condition. For any given disease there may be a long list of remedies that have been clinically effective, but it is the individualization and differentiation among medicines, based on the patient's unique indications, that leads to a successful homeopathic prescription.

Vitalism

Disease, in the homeopathic model, is thought to arise from inherent or developed weaknesses in the patient's defense mechanisms, creating a susceptibility to "morbific influences" (e.g., toxic factors in the environment, bacteria, psychological stresses). This viewpoint is considered "vitalistic" (see Chapter 2, Hierarchy of Healing, and Chapter 5, Philosophy of Naturopathic Medicine, for further discussion), and although it does not deny a corporeal reality, it considers pathology to be but a singular focus in a complex net of interactions.

William Boyd, in *A Textbook of Pathology,* discussed the limitations of the causal approach to disease currently in vogue in medicine when he stated[7]:

> *We must admit, however unwillingly, that we seldom or never really know the cause of anything. Many a beautiful idea has been slain by ugly fact. We merely note a constant association with one thing always following another. We say that the tubercle bacillus is the cause of tuberculosis. That is merely another way of saying that the bacillus is associated with a constant type of lesion; it is no explanation of how the lesions are produced by the bacillus. Nor does it explain why some persons and animals are susceptible to the infection while others are immune.*

Vitalism can be better understood in the context of Hahnemann's time, when theories of the causation of disease and its treatment abounded, such as Galen's doctrine that the secondary quality of a medicine (i.e., its action on the disease) could be determined from its primary qualities, such as its taste or smell; the evaluation of medicines by the study of their interactions when mixed with human blood in a jar; iatrochemistry, which had been reduced from the Paracelsian application of spagyric tinctures or oils of metals to dangerous toxic doses; the classification of drugs according to the Dioscoridian approach, which was based on the physiological action (e.g., diuresis, diaphoresis) and chemical composition; and the "doctrine of signatures," which held that the outer form and color of a plant revealed its inner archetypal action.[8,9]

Although some studies of the effects of medicinal agents were done with animals, Hahnemann observed that they had different effects on humans; pigs could safely eat *Nux vomica* in quantities that would immediately kill humans. Dogs could eat *Aconitum napellus,* a deadly poison to humans, without injury. He also rejected the method of testing drugs by studying their effects on the sick as haphazard and unreliable, particularly because the results being sought were often only symptomatic relief rather than eradication of the disease state.

Hahnemann defined the application of medicines whose purpose was to alter physiology or act as an antagonist to disease as the practice of "allopathy" (*allo,* meaning "contrary" in Greek). The current dominant medical system is heavily influenced by the causal and allopathic paradigms. This results in the diagnosis being the focal point of practice, without which appropriate therapy cannot be instituted. The pharmacological approach is usually limited to the end results of disease rather than the origins of pathogenesis. Subsequent problems are classified as unwanted side effects because only the primary action of the pharmaceutical agent is used for treating a specific disease state. By focusing on only the primary effects of a drug, a diverse remaining range of physiological, as well as psychological effects, is ignored.

In the homeopathic model, the side effects are an important part of the agent's action and the body's response to it; by ignoring them, a drug's range of usefulness is greatly limited, whereas its toxicity is increased. Hahnemann's empiric investigations not only led to new applications of medicines but also provided a method for integrating the physical, mental, and emotional effects of a drug. This allowed the treatment of the totality of a patient's symptoms as a dynamic pattern of interaction.

Vitalists stress the teleological behavior of organisms (i.e., the goal directedness and design in biological phenomena). Disease is therefore regarded as a positive expression of the organism's self-regulatory process in response to environmental or other stresses. Disease is not accidental but is rather the effort of the organism to ward off deeper or more internal disorganization. It is the natural wisdom of the body, the *vis medicatrix naturae,* or, using current scientific terminology, the tendency of the body to maintain homeostasis. Medical intervention often acts in conflict with these vital intracellular and extracellular regulatory functions.

Karl Menninger, in 1948, commented on this medical dilemma[10]:

> *I believe that clinicians have come to think more and more in terms of a disturbance in the total economics of the personality, a temporary overwhelming of the efforts of the organism to maintain a continuous internal and external adaptation to continuously changing relationships, threats, pressures, instinctive needs and reality demands … It is the imbalance, the organismic disequilibrium, which is the real pathology, and when that imbalance reaches a degree or duration that threatens the comfort or survival of the individual, it may correctly be denoted disease.*

Homeopathy is a method of specific induction of nonspecific resistance that stimulates the body's inherent defense and self-regulatory mechanisms, rather than taking over a function of the body, initiating dependency on the medicine itself.

THE CLINICAL APPLICATION OF HOMEOPATHIC PRINCIPLES

The homeopathic clinical and therapeutic process consists of three interrelated processes: case taking, evaluation, and prescribing. The process is comprehensive and engages the observations of the patient as well as those of the doctor. Hahnemann described the process in paragraphs 84 to 103 of the *Organon* and stressed the importance of distinguishing between chronic and acute, or self-limiting, disease.

The Homeopathic Interview

The initial history of complaints is elicited from the patient with as little interruption as possible (as long as the patient does not digress unduly) so that the patient's train of thought is not disrupted or directed along lines imposed by the physician's biases. According to Hahnemann:

> *The physician elicits further particulars about each of the patient's statements without ever putting words in his mouth, or asking a question that can be answered only by yes or no, which induces the patient to affirm something untrue or half true or else deny something really there to avoid discomfort or out of desire to please, thereby giving a wrong picture of the disease, which would lead to the wrong treatment.*

An entire review of symptoms is recorded in descriptive detail, taking into consideration all modalities that affect a symptom. Hahnemann emphasized the general symptoms (i.e., those affecting the entire organism) as the leading indications for the remedy. These key symptoms include mental and emotional effects, the metabolism and its reactions to environmental stimuli, sleep positions, food cravings and aversions, thirst, body type, and all manifestations of unconscious and autonomic regulation.

Unique characteristic symptoms, particularly those regarded as "strange, rare, and peculiar," are important considerations in the selection of the remedy. These might be the expression of a paradoxical or unusual relationship, such as pain ameliorated by pressure or the sensation of the legs being made of wood or glass. The association of the start of a disease or symptom complex with an environmental or emotional event can be key and emphasizes the importance of an accurate and extensive interview.

Hahnemann emphasized the importance of taking a comprehensive case, particularly in chronic disease[11]:

> *In chronic diseases in women one should pay particular attention to such things as pregnancy, infertility, sexual desire, confinement, miscarriages, nursing, vaginal discharges, and the condition of the*

monthly flow, especially noting whether it recurs at intervals that are too short or too long, how many days it lasts, whether or not it is interrupted, the quantity, how dark with color, any leukorrhea before or after the flow. If there is leukorrhea, what it is like, what symptoms accompany it, what is its quantity, under what conditions does it appear, what brings it on?

Because the patient's symptoms are the expressions of the body's attempts to heal itself, symptomatic treatment (i.e., many allopathic therapies) can impair the physician's ability to obtain vital information and complicate the taking of the case. This problem has also been recognized by some medical authors, such as Boyd, who stated: "We recognize that the pattern of disease has changed out of recognition during the past 30 to 40 years owing to modern drugs, particularly the antibiotics."[7]

Follow-Up and Case Evaluation

Considering the vitalistic and holistic perspective of the homeopathic approach, a clear definition of cure is necessary to establish the treatment goal. Mere palliation or suppression of symptoms at the cost of the overall vitality and function of the individual is considered negligent by the homeopathic practitioner. For example, if a patient's skin disease is treated and appears to resolve but is followed by asthma, fatigue, and confusion, the treatment is evaluated as having been suppressive. If, upon proper treatment, the more serious lung and systemic disruptions are alleviated and the previous skin lesions return, the patient is considered as progressing toward a cure. When further appropriate therapy results in final alleviation of the skin disease, without any undue stress to the patient, it is then considered a true cure.

This evaluative procedure is part of Hering's Law of Cure, an observation of the principles of curative responses that can be applied to any healing process, regardless of the school of thought. In true healing, according to this set of observations, symptoms follow these patterns:

- From above, down the body to the extremities
- From within to without (often in the form of discharges and other eliminative processes)
- From the most important organs (e.g., the central nervous system) to the least important organs (typically, the skin)
- In reverse order of their appearance (i.e., the chronologically most recent being replaced by those of the earlier stages of the disease and, in some instances, earlier in the patient's life)

Homeopathy holds that the disease first affects the vital force and is manifested initially by a change in the patient's well-being, long before any objective changes can be observed. Illness is usually first recognized when the patient becomes aware of the early manifestations of the disease.

Disease and cure must also be considered in the context of the belief system and culture of the patient. Much of what we call disease arises from the individual's inability to find meaning and purpose. Many forms of healing are capable of enabling the person to integrate into the fabric of daily life and of providing ways to help the person address personal needs for fulfillment.

In his study of disease, Hahnemann noted that there were inherited predispositions to disease, which he related to the improper treatment, and therefore suppression, of skin eruptions and venereal disease. He called these predispositions *miasmas* and, in 1828, published his findings in *Chronic Diseases: Their Nature and Homeopathic Cure.* He observed that many people, despite apparently healthy lifestyles, develop degenerative diseases. These often become established in childhood and continue to plague the person throughout life, despite medical treatment. He described three miasmas: psora, which represents a fundamental flaw in the human ability to eradicate disease related to the suppression of skin disease; syphilis; and sycosis, which is caused by the suppression of the fig wart, or what is now known as human papillomavirus. Hahnemann described the chronic effects of bacterial and viral diseases in his explanation of miasmas. In his discussion of viral diseases such as smallpox and other epidemic diseases, Hahnemann's descriptions of the nature of viruses and their treatment predate their discovery by 50 years. He was a contemporary of Edward Jenner and supported Jenner's use of smallpox vaccination.

More recently, George Vithoulkas, a contemporary homeopathic author and teacher, defined health on three levels: mental, emotional, and physical. The mind should be capable of functioning with clarity, rationality, coherence, and logical sequence. It should be capable of engaging in creative service for the good of others, as well as for the good of oneself, demonstrating freedom from selfishness and possessiveness. On the emotional level, there should be a state of serenity free from excessive passion, a state that should not be confused with a lack of emotional response generated as protection against emotional vulnerability. Finally, on the physical level, there should be freedom from pain. The healing person should experience a subjective sense of well-being and a progressive increase in vitality.[12]

Prescription

Because homeopathy is oriented toward the administration of a single medicine at a time, careful prescribing is important. It is through the application of single medicines that homeopathic physicians have been able to record clinical verification of the provings and amass an impressive body of literature.

Combination homeopathic medicines have been introduced as specific remedies for diseases and therefore have not represented homeopathic methods, although many studies support their efficacy.

The process of selecting the correct remedy involves both careful study of the patient's symptomatology and medical history and matching these with the appropriate remedy. This requires a sound understanding of the homeopathic *materia medica* (see the section "The Study of the *Materia Medica*").

The symptoms of the homeopathic *materia medica* are indexed in repertories that have evolved in both reference books and computer analysis programs.

Homeopathic Pharmacy and Potency Selection

This leads to a discussion of what has remained the greatest mystery of homeopathic medicine (and the source of considerable ridicule and misunderstanding): the use of "potentized" substances.

As Hahnemann began his research, he found that when treating patients according to the Law of Similars, there was an initial aggravation of the symptoms, the "healing crisis," when using the high dosages typical of that era. He empirically tried using progressive dilutions of the medicines, beginning with tinctures from plants and triturations with milk sugar for metals and salts. He made the dilutions serially by mixing 1 drop of the tincture with 100 drops of alcohol, which were then "succussed" (shaken by pounding against a resilient surface) vigorously. He found that, with increasing dilution, the severity of the aggravation lessened while the patient continued to improve, often with deeper and more enduring results. He called these diluted remedies "potentized." As an analytic chemist, he was aware of Avogadro's theories (they were contemporaries), but he persisted in evaluating dilutions beyond the point where chemical activity could be detected.

This challenge to the present understanding of the therapeutic mechanism has been addressed by recent workers who have suggested that the therapeutic properties of the remedy lie in the energetic impression they make on the diluting vehicle (typically alcohol and

water or lactose). Various techniques have been used to determine whether there is a physical difference between the potentized dilution and the unmodified vehicle. These studies have used ultraviolet spectroscopy, conductivity measurements, infrared spectroscopy, surface tension measurements, Raman Laser spectroscopy, nuclear magnetic resonance, and other methods. Much of this work has shown regular peaks and troughs in activity with progressive dilutions, and Heintz claimed that the peaks corresponded to the maximum effects found in the biological studies he reported (see the section "Basic Research").[13]

Mechanism of Action

To date, there is no conclusive understanding of the mechanism of action of the potentizing process. However, this has not inhibited the use of potencies, which have been diluted by a factor of 100 up to 100,000 times ($10^{100,000}$). At this time, most explanations for the mechanism of homeopathic high potencies are provisional (e.g., the postulate that the remedies act in resonance with the magnetic fields of the body, or that the physiochemical properties of water can be modified by a solute and remain so even in the absence of the solute).[14]

This has not affected clinical practice or the demonstration of efficacy in clinical trials any more than the use of aspirin did, despite the fact that the discovery of its mechanism of action through modulation of prostaglandins did not occur until the 1980s. There are many forces whose nature can only be recognized by their results (e.g., gravity). These observations of relationships, confirmations of experience, are the basis of an empiric system. Medicine remains an art in the field of science.

Interestingly, a group operating in the Hematology Department of the School of Pharmacy in Bordeaux, France, tested the effect of both common aspirin and homeopathic preparations on the vascular walls of rats. Aspirin at high concentrations (100 mg/kg) induced a decrease in platelet aggregation (amplitude and speed) as well as a decrease in the area of the thrombi (arterial and venous) and the number of emboli (arterials and venous).

Aspirin at ultralow doses (9, 15, 30 CH) induced an increase in platelet aggregation (amplitude and speed) as well as an increase in the area of thrombi (arterial and venous) and the number of emboli (arterial and venous). The antiaggregation and antithrombotic action of aspirin at high concentrations (100 mg/kg) was inhibited by the concomitant injection of aspirin 15 CH.[15]

This confirmed Hahnemann's observations of the primary and secondary effects of medicines mentioned in the *Organon.*[11] Bellavite described these effects as "biologically active compounds (which) may cause inverse or paradoxical effects on a complex homeostatic system when either the doses of the compound, or the methods of preparation and of administering, or the sensitivity of the target system are changed."[16,17]

Research into both the pharmacological effects of homeopathic preparations and the paradoxical effects of orthodox drugs that confirm the Law of Similars' underlying homeopathic prescribing is a growing body of literature. Certain pharmacological substances, when tested in high dilutions, act on the same biological systems.[18–24]

The reaction to the high dilutions can also be the opposite of that to a drug at low dilutions (e.g., proinflammatory agents can be anti-inflammatory at high dilutions).[25–28]

Paradoxical effects of medicines are the basis of the Arndt–Schultz law in pharmacology and hormesis. The Arndt–Schultz law states that weak stimuli slightly accelerate vital activity, medium-strong stimuli raise it, strong ones suppress it, and strong ones arrest it.[29]

Southam and Erlich[30] reported the stimulatory effect of an antifungal agent when used at low doses and proposed the term "hormesis." Hormesis is defined as "the stimulatory effect of subinhibitory concentrations of any toxic substance on any organism."[31] Hormesis is considered a nonspecific phenomenon that increases the resistance and growth of the treated organism. It exists in all living organisms. This "action–reaction" model shows the efficacy of the "vital activity" in fighting the poison in a nonspecific way, although specific defense molecules are also synthetized.[32–37] A modern and important pathological model showed that a single dose of an antitumoral immunosuppressive substance (cisplatin) induced increased lymphokine-activated killer activity.[38] Wagner and colleagues demonstrated that low doses of cytostatic agents stimulated human granulocyte and lymphocyte growth.[39]

The goals and methods of homeopathic pharmacy have their roots in earlier Paracelsian and spagyric medical systems. The challenge remains to define homeopathic empiric science in the context of a modern science. It may be that homeopathy presents a challenge to pharmaceutical science itself that will bring forth new models for pharmacology. The more central challenge is for homeopathy to discover how it can apply its own critical methods to develop a more effective healthcare service.

The assumption that we can find substances in nature that can alter disease underlies the history of medicine and pharmacology, yet healing remains a mystery. Further studies are necessary to confirm and develop the understanding of the mechanisms and validity of homeopathic medicines.

Determination of Potency

In terms of clinical practice, general guidelines have evolved for the determination of potency. In the sixth edition of the *Organon,* Hahnemann recommends ascending the scale of potencies gradually. In paragraph 248, he suggests that the medicinal solution be "succussed anew with use." In chronic cases, the patient is directed to take one teaspoonful daily or every other day, and in acute diseases, as frequently as needed. If the solution is used up before the problem alleviates, the next higher dilution is used (if still indicated by the symptom pattern).[40]

The higher potencies, whose use largely developed in the United States, are repeated much less frequently and are generally reserved for the experienced practitioner. The more potentized the remedy, the closer it must meet the Law of Similars (i.e., the accuracy of the prescription must be high for a curative effect). Lower potencies are often repeated daily, depending on the condition being treated.

Several ranges of potencies include the decimal scale, which uses a 1:10 dilution; the centesimal scale, which is diluted 1:100; and the LM potencies introduced in the sixth edition of the *Organon,* using daily doses of 1:50,000 dilutions.

It is important to note that the sixth edition was unavailable until 1924, 76 years after Hahnemann's death. The predominant clinical application of homeopathic potencies had developed using an ascending scale. A single dose was used until its action had ceased, when the same potency would be repeated. When that potency seemed to no longer demonstrate an enduring effect, a higher potency was used. There have been regular arguments between low- and high-potency prescribers as to the most effective method.

The Study of the *Materia Medica*

Constantine Hering once stated:

> *A mere acquaintance with the principal symptoms cannot be called studying the materia medica, although we make it the basis of our study. The study of materia medica must be regarded and dealt with in exactly the same manner as that of other natural sciences.*

To give a perspective on the way in which homeopathic physicians organize the proving symptoms into clinical pictures, we draw from an essay on *Sepia* by E. B. Nash[41]:

This is another of our wonderful remedies of which the dominant school knows nothing, except what they have learned from us. Its chief sphere of action seems to be in the abdomen and pelvis, especially in women. No remedy produces stronger symptoms here. We quote from different but equally good observers.

Sensation of bearing down in the pelvic region, with dragging pains from the sacrum; or feeling of bearing down of all pelvic organs. (Hahnemann)

Labor-like pains accompanied with the feeling as though she must cross her legs and "sit close" to keep something from coming out through the vagina. (Guernsey)

Pain in uterus, bearing down, comes from back to abdomen, causing oppression of breathing; crosses limbs to prevent protrusion of parts. (Hering)

Prolapse of the uterus, of the vagina, with pressure as if everything would protrude. (Lippe)

Experience has shown its value in cases of ulceration and congestion of the os and cervix uteri. Its use supersedes all local applications. (Dunham)

No higher authority than the united testimony of these five of our best observers could be brought to show the action of Sepia *upon the pelvic organs.*

Now when we come to examine the provings in Allen's Encyclopedia, *we find that these symptoms were mainly produced by Hahnemann and his provers, and Hahnemann advocated proving remedies in the 30th, and some of them were produced by the 200th, especially those most strongly verified by black-faced type.*

We confess that we cannot understand how so many question the value of potencies for proving or curing. Sepia, *like* Sulphur, *affects the general circulation in a very marked manner. Flashes of heat with perspiration and faintness is almost as characteristic of this remedy as of* Sulphur. *But there are, with* Sepia, *more apt to be associated with them the pelvic symptoms already given, and they are also more apt to occur in conjunction with the climacteric. Indeed, these flashes often seem with* Sepia *to start in the pelvic organs and from thence to spread over the body.*

But this irregularity of circulation extends as far as that of Sulphur. *The hands and feet are hot alternately, that is, if the feet are hot, the hands are cold, and* vice versa. *There is not so much sensation of burning with* Sepia *as with* Sulphur, *but there is actual heat, and the venous congestion, which seems to be the real state of the organs where the pressive bearing down et cetera is felt, is also accompanied with much throbbing and beating.*

This local congestion to the pelvic organs is not simply sensational. There are actual displacements in consequence of it, and the long continued congestion results in inflammations, ulcerations, leukorrheas and even malignancies or cancerous organizations. Induration with a painful **sense** *of stiffness in the uterine region is characteristic.*

This pelvic congestion also affects the rectum in a marked degree. The rectum prolapses, there is a sensation of fullness, or of a foreign substance as of a ball or weight, and oozing of moisture from the rectum. Indeed, the rectal and anal symptoms are almost as strong as the uterine and vaginal. It is impossible to enumerate all the symptoms connected with the circulatory disturbances of Sepia *in such a work as this, only a general study of the Materia Medica can do it.*

The urinary organs come in for their share of symptoms. The same pressure and fullness consequent upon the portal congestion reaches here. We will now proceed to give what we have found to be particularly valuable symptoms under the various organs in this region. "Pressure on bladder and frequent micturation with tension in lower abdomen." "Sediment in the urine like clay; as if clay burnt on the bottom of the vessel; urine very offensive (Indium), *can't endure to have it in the room, it is reddish or may be bloody." This is found mostly in women. With children there is one peculiar symptom which has often been verified. "The child always wets the bed during its first sleep."*

Upon the male organs I have found it particularly useful in chronic infection. There is not much discharge, but a few drops, perhaps, which glue up the orifice of the urethra in the morning; but it is so persistent and the usual remedies will not "dry it up." In my early practice I used to use a weak injection of Sulphate of Zinc, *but it used to annoy me that I could not use it without resorting to local measures.* Sepia *does it in the majority of cases and* Kali iodatum *will do it in the rest. I have, where there was a thick discharge of long standing and the smarting and burning on urination continued, several times finished the case with* Capsicum.

As a rule, this long continued slight, passive gleety discharge is a result of weakness of the male genitals, as is shown by a flaccidity of the organs and frequent seminal emissions. The emissions are thin and watery. Sepia *covers all of this and often sets all to rights in a short time.*

The mind symptoms of Sepia *are like* Pulsatilla, *in that she is sad and cries frequently without knowing the reason why. So if in a tearful mind with uterine disturbances* Pulsatilla *should fail you, the next remedy to be studied is Sepia. But there is another condition of mind not found under* Pulsatilla *or any other remedy in the same degree, and that is, that, notwithstanding there is no sign of dementia from actual brain lesion, the patient, contrary to her usual habit, becomes indifferent to her occupation, her house work, her family or their comfort, even to those whom she loves the best. This is a very peculiar symptom and a genuine keynote for the exhibition of* Sepia…

I once cured a very obstinate case of entero-colitis (so-called cholera infantum), after the complete failure of two eminent allopaths, with Sepia, *the leading symptom being, always worse after taking milk. Oozing of moisture from the anus finds its remedy here sometimes, but oftener in* Antimonium crudum. *The* Sepia *patient is very weak. A short walk fatigues her very much. She faints easily from extremes of cold and eat, after getting wet, from riding in a carriage, while kneeling at church, and on other trifling occasions. This fainting, or sense of sinking faintness, may be found in pregnancy, child bed, or during lactation; or, again, it may come on after hard work, such as "laundry work;" so it has come to be called the "washer woman's" remedy.*

As can be seen by this excerpt, the indications for a remedy are complex, requiring study and understanding.

RESEARCH IN HOMEOPATHY

Homeopathy arose from empiric observations and operates from empiric clinical evidence and phenomenologically descriptive fields.

Samuel Hahnemann was the first to use the methodology of provings, to gather information about the reactions of healthy subjects to the ingestion of minute amounts of substances. Both clinical trials and laboratory research, although relatively sparse and often inconclusive, do point to efficacy and activity beyond placebo. Homeopathy has faced challenges in the scientific as well as political arena because its mechanism of action is still unknown. For example, quoting from a recent review, "according to current pharmacological theory it would appear impossible that homeopathic therapy could have any effect over placebo."[42] However, as the authors go on to say, "The available hypotheses for a possible mechanism of action, however, do not claim that homeopathic remedies act through pharmacological but through biophysical pathways and all include the idea of some form of information transfer."[42] Despite adversaries who claim that research has determined that homeopathy is nothing more than placebo, homeopathy researchers, using increasingly sophisticated research designs, continue to produce intriguing evidence regarding the effects and efficacy of homeopathic substances. This evidence, which emerged from several types of research, including provings, clinical trials, and laboratory studies, may soon converge to build a promising case for homeopathy's effect.

Evidence From a Modern Proving Study

Although traditionally provings, also called *pathogenetic trials*, first involved material doses of substances, Hahnemann himself, as well as later provers, conducted proving studies using potencies beyond Avogadro's number. One recent proving study provided convincing evidence that ultramolecular doses of homeopathic substances can produce symptoms different from placebo.[43] This double-blind, placebo-controlled experimental study randomized 25 medical doctors into three groups who received 30-CH potentized doses of either *Natrum muriaticum* or *Arsenicum album* or an identical placebo. All substances were beyond Avogadro's number in terms of dilution. The main outcome parameter was the number of remedy-specific symptoms per group. The actual remedies themselves were chosen randomly from a list of 20 already-proven remedies that are frequently used in homeopathic practice; this list was not known to subjects or the study team, other than the study director and pharmacist; the two selected remedies were not known to anyone on the study team, including the study director. Participants were advised to ingest five remedy globules on day 1, then 2×5 on day 2, or until symptoms appeared, and then write their symptoms in a diary over 4 days. These symptoms were compiled and reviewed by an independent homeopathic expert, blinded to group assignment, who analyzed each symptom via a computer program for its typicality, or not, for one of the two remedies tested. The results showed that symptoms typical for the respective remedy were significantly more likely to occur in both the *Natrum muriaticum* or *Arsenicum album* groups, whereas nonspecific symptoms were more frequent in the placebo group ($P = 0.001$). Typical symptoms reported by subjects ingesting *Arsenicum album* included "strange restlessness"; "increased desire to swallow"; "lack of desire to urinate"; and "gushing diarrhea." Typical symptoms reported by subjects ingesting *Natrum muriaticum* were "difficulty concentrating"; "slight vertigo when seated"; "tearing pain in scalp"; "twitching in right eye"; and "cramping like labor in abdomen."[43] This impressive finding showed that nonmaterial doses of substances produced specific and distinctive effects—characteristic of the remedy—in subjects who were blinded to which remedy they were ingesting.

Human Clinical Trials

Although the previously described study provides evidence for an effect of ultramolecular homeopathic substances on the human organism, what is of primary interest to humans, and particularly clinicians, is whether such effects are therapeutic. In one early classic study, Gibson et al.[44] published a double-blind clinical trial of homeopathic treatment in rheumatoid arthritis. The 3-month study was elegantly designed in that the prescribing was individualized to the patient's symptoms and was controlled, on a double-blind basis, by giving half the patients the correct remedy and the rest a placebo. All patients continued to use conventional, nonsteroidal anti-inflammatory drugs, and the treated group showed significant improvement in subjective pain, articular index, stiffness, and grip strength. Other published studies have demonstrated the efficacy of homeopathic treatment for the treatment of headache, bruising, cancer-related symptoms, attention deficit hyperactivity disorder in children, asthma, upper respiratory tract infections, otitis media, arthritis, allergies, male infertility, influenza, cardiac insufficiency, herpes, osteoarthritis, acquired immunodeficiency syndrome, and chronic fatigue syndrome.[45–82]

Meta-Analyses and Systematic Reviews of Human Clinical Trials

Hundreds of human clinical trials, of varying quality, with both positive and negative results, have now been carried out. Meta-analyses and systematic reviews have been helpful in identifying promising treatments and areas where more research is needed, thus moving the field forward.

In 1991 one of the first meta-analyses of homeopathic clinical trials, by Kleijnen et al.,[83] was published in the *British Medical Journal,* with a total of 105 controlled trials. The quality of trials was described as poor for two thirds of those reviewed. Positive results for homeopathic treatment were found in 81 trials, leading the authors to state, "The evidence in this review would probably be sufficient for establishing homeopathy as a regular treatment for certain indications."

In 1997 Linde et al.[84] published another meta-analysis of 119 trials that met the inclusion criteria; 89 had adequate data for meta-analysis, and two sets of trials were used to assess reproducibility. The combined odds ratio for the 89 studies was 2.45 in favor of homeopathy, with an odds ratio of 1.78 for the 26 good-quality studies. The authors concluded, "The results of our meta-analysis are not compatible with the hypothesis that the clinical effects of homeopathy are completely due to placebo." In 2014 Mathie et al.[85] published a rigorous, focused systematic review and meta-analysis of randomized controlled trials of individualized homeopathic treatment (typically involving a long interview between the practitioner and the patient) versus placebo, finding 32 eligible randomized controlled trials (RCTs) covering 24 medical conditions, of which 22 had extractable data available for meta-analysis. Although the evidence was of uneven quality and the authors were cautious in their conclusions, their findings were that medicines prescribed in individualized homeopathy may have small, specific treatment effects. In 2017 Mathie et al.[86] published a second rigorous systematic review and meta-analysis of randomized, double-blind, placebo-controlled trials of nonindividualized homeopathic treatment and concluded that although the quality of the evidence was low, a meta-analysis of all extractable data indicated a small, statistically significant effect of nonindividualized homeopathic treatment. Their major conclusion was—as in previous systematic reviews in homeopathy—that higher-quality RCT research, with a lower risk of bias, is needed to be able to determine homeopathy's efficacy for conditions or symptoms decisively.

In some instances, accumulating evidence has made it feasible to carry out systematic reviews to evaluate homeopathy's use for the treatment of specific conditions. For example, in a review of homeopathic treatment of people with human immunodeficiency virus or acquired immune deficiency syndrome, five controlled clinical trials

were identified, with evidence for improved CD4 and CD8 counts and specific physical, immunological, neurological, metabolic, and quality-of-life benefits. The author concluded that homeopathy might play a useful role as an adjunctive therapy in this condition.[81] Pilkington et al.[82] examined the use of homeopathy for anxiety and anxiety disorders, concluding that homeopathy might be beneficial. One particularly fruitful and positive area of research, for which there are several positive trials, is in the use of homeopathy for the treatment of respiratory allergies.[74]

Human Effectiveness Studies

Effectiveness research involves the evaluation of a treatment's usefulness in more natural or real-world settings. For example, during World War II, isopathic preparations were given prophylactically, and homeopathic therapies were used in mustard gas burns. A subsequent statistical analysis found that these treatments yielded significant results compared with placebos. The remedies used were mustard gas, *Rhus toxicodendron,* and kali bichromium.[13]

More recently, Witt et al.[87] evaluated health-status changes of chronically ill patients after 8 years of homeopathic treatment. This prospective, multicenter cohort study involved 103 homeopathic primary care practices in Germany and Switzerland; in total, 3709 patients were studied, with the most frequent diagnoses being allergic rhinitis, headache in adults, and atopic dermatitis and multiple recurrent infections in children. Disease severity decreased significantly over this time, with considerable improvement in physical and mental quality of life. Another prospective multicenter observational study of 129 patients treated homeopathically by 48 physicians for low-back pain found sustained physical and quality-of-life improvements, along with decreased use of conventional healthcare services and pharmacological therapies.[88] A similar prospective multicenter observational study evaluated symptom changes in 212 adult patients with chronic migraines who were treated with individualized homeopathy by 68 physicians. Migraine severity showed marked improvement at 3 and 24 months, with improved quality of life and decreased use of conventional health services.[89]

Animal Studies: Field and Laboratory Research

In a now-classic study, *Caulophyllum* (in the 30th centesimal potency) was given to 10 sows to test its efficacy in the control of stillbirths. The results showed a statistically significant drop in the number of stillbirths and led to a larger, uncontrolled study in a whole herd. After 4 months of therapy, piglet mortality dropped from 20% to 2.6%.[90]

Cloudhury obtained dramatic results from injecting mice intraperitoneally with kali phosphoricum, calcarea phosphorica, or ferrum phosphorica (in the 30th decimal potency) 12 days after implantation of fibrosarcoma. Of the 77 treated mice, 52% were cured and survived more than 1 year, whereas all of the 77 controls died within 10 to 15 days.[91]

Scofield, in his review article, discussed numerous experiments with humans, animals, and plants using isopathic treatment for poisoning and experimental liver damage and various in vitro studies.[13]

A number of studies have been conducted to investigate the ability for homeopathic preparations to affect either the elimination or consequences of toxic substances.

There is good evidence that homeopathy may be effective in assisting in the elimination and treatment of heavy metals and other toxins. Studies of arsenic,[92,93] bismuth,[18,19,94] lead,[95] mercury,[96,97] carbon tetrachloride,[20,25] alpha-amanitine (from the mushroom *Amanita phalloides*),[26] and carcinogens such as 2-acetylaminofluorene and phenobarbital[98] have been published.

The use of homeopathic dilutions of hormones and immunomodulators has shown potential. Immunostimulatory effects of high dilutions of thymic hormones and interferons were demonstrated in mice by Bastide's group.[26,99–102] Other studies demonstrated that extremely small amounts of antigens were specific for immunomodulation.[103–107] In one study, half of a group of mice were given preparations of reticuloendothelial tissue from *Francisella tularensis*–infected mice in six different serial agitated dilutions (SADs), three of which were beyond Avogadro's number in terms of molecular content. The other half of the group of mice were given control diluents. All mice were then challenged with lethal doses of *F. tularensis* and evaluated for time to death and total number of deaths per group. The SAD preparations resulted in increased mean times to death (18.6 vs. 13.7 days) and decreased mortality (53% vs. 75%). The protective effect was not related to the level of dilution of the substance.[107]

Magnani et al. used a well-designed mouse model to examine the anxiolytic-like activity of several potencies of ultradiluted *Gelsemium sempervirens,* compared with the drug buspirone and placebo. *Gelsemium*-treated mice spent more time in a lighted compartment (a measure of reduced anxiety), similar to the effects of buspirone and significantly greater than the placebo group. The authors concluded that *Gelsemium* acted on the emotional reactivity of mice, with anxiolytic-like effects even at ultrahigh dilutions.[108]

These and other such dramatic results have tremendous implications in pharmacy, immunology, and clinical health care that demand continued research.

Basic Research

Clinical and experimental data obtained in studies about the effect of homeopathic preparations in inflammatory conditions present a considerable degree of reproducibility.[109–113]

The inability of Ovelgonne et al.[114] and Hirst et al.[115] to replicate their study published in the journal *Nature,* using the human basophil degranulation test (HBDT) to establish the ability for high dilutions to trigger the degranulation of anti–immunoglobulin-E, caused considerable distraction from other more credible research.

Brown and Ennis[116] used different methods to demonstrate the efficacy of high dilutions of histamine to inhibit the activation of basophils using HBDT. Instead of measuring degranulation provoked by ultramolecular dilutions of anti–immunoglobulin-E, as Ovelgonne et al. and Hirst et al. did, they examined the inhibition of activation of basophils by ultramolecular dilutions of histamine.

The experiments used ultramolecular dilutions of histamine (15c to 19c), prepared with vortexing (instead of succussion). The main experiment, performed by all the laboratories, was based on inhibition of basophil activation as measured by degranulation. Flow cytometry experiments at three laboratories showed compatible results, with inhibition of activation as high as 43%. Nearly all experiments showed statistically significant inhibition of basophil activation.[117–120]

Experimental study of homeopathy in allergology[121] effects have been reported in vivo[122–124] as well as in vitro.[125–129]

The physical properties of homeopathic preparations are gaining considerable understanding via research. Studies demonstrated that the physicochemical properties of extremely diluted solutions (EDSs) are different from those of pure, untreated water, notwithstanding the identical chemical composition of the two liquids.[130–132] The same conclusions were inferred by Lo.[133,134] Rey[135] showed that the structure of hydrogen bonds in pure water was different from that of an EDS obtained by an iterative procedure of successive dilutions and succussions and was not identical as expected. Recent studies on the physicochemical properties of water provided evidence that the most studied liquid by far, water, still exhibits unexpected properties.[136–142] Lobyshev et al.[143] showed that low concentrations and electromagnetic fields can produce large-scale realignments of its structure,

which can be either reversible or irreversible. One can deduce from these studies that water and aqueous solutions are complex systems, capable of auto-organization as a consequence of small perturbations of various kinds.

The question of whether water can maintain "memory" of solutes in EDS is best understood by understanding the physical characteristics of water and its ability to form stable clusters and crystals. This aspect of physics is not widely studied but is well documented.[130–133,136,141,144]

Sukal et al.[145] pointed out that ethanol molecules, via which potentized homeopathic substances are prepared and stored, are thought to promote or preserve water structures in the potentized substance. These researchers examined the Fourier transform infrared spectra of various ultradiluted homeopathic substances—*Nux vomica* 30c, *Lycopodium* 30c, *Santonin,* 30c, *Cina* 30c, *Cina* 206c, and *Cina* 1006c—as well as their diluent media, 90% ethanol and ethanol 30c. The potencies differed from each other, and from their diluent media, in the number of oxygen–hydrogen bending vibrational bands, as well as their wave number, shape, and the half-width of the bands. This study illustrated that the medicated sucrose globules used in homeopathic practice can retain specific spectral properties and can be differentiated from each other by Fourier transform infrared spectra with regard to the oxygen–hydrogen bending vibrational band.[145]

Such meticulously designed and executed studies are bringing us ever closer to understanding the mechanisms by which homeopathy may work.

SUMMARY

Homeopathy plays an important role in the context of modern naturopathic medicine. Hahnemann emphasized the importance of lifestyle in the treatment of the patient. One of his primary dictums was to first remove the obstacles to cure, as he said:

> *While taking a case of chronic disease one should examine and weigh the particular conditions of the patient's day to day activities, living habits, diet, domestic situation, and so on. One should ascertain whether there is anything in them which may cause or sustain the disease and remove it to help the cure.*

Unfortunately, homeopathy is also an extremely challenging system to master, requiring a considerable understanding of both case taking and *materia medica* as well as extensive consultation time with the patient. It has therefore often been discarded, even by those aware of its efficacy. Although attempts have been made to reduce it to simpler systems (e.g., allergy desensitizations, vaccinations, Schuessler's cell salts, and isopathic preparations from diseased tissues and heavy metals), they are not considered strictly homeopathic unless prescribed according to their effects upon healthy people or the confirmed observations of cured symptoms.

The greatest challenge to homeopathy is not how it fits into the current scientific paradigm but how it fits into health care. The same biases against homeopathy have been used against other nonpharmacological approaches to medicine, including psychology and nutritional medicine.

The wide acceptance in the homeopathic community of unaccredited educational programs has favored the spread of nonclinically trained homeopaths. Naturopathic medical schools in the United States have remained one of the few resources for clinical training in homeopathy. Homeopathic medical schools in other countries have maintained homeopathy in the context of medical and clinical training.

There have been many individualized styles of prescribing introduced into homeopathy that have created breaches between different practitioners. In addition, many new medicines are being introduced without adequate clinical verification. Unfortunately, there are few forums for critical discourse within the homeopathic community.

The divisions between different schools of homeopathic practice are attempts to parlay new ideas against an orthodox view that solely seeks to maintain the integrity of the principles developed by Hahnemann.

One basic argument by some of these schools has been that because a homeopathic prescription should not be based on a specific disease, extensive training in current medical sciences should not be primary. However, this ignores an essential part of Hahnemann's instructions. In the third paragraph of the *Organon,* he stated, "The physician should distinctly understand…what is curable in diseases in general, and in each case in particular; that is, the recognition of disease."

Correct diagnosis is primary in understanding the context and pathogenesis of a disease. Thus it would not be possible to understand the relation of much of drug proving symptoms, their clinical application, and the evaluation of efficacy or subsequent case management without understanding the nature of disease. Homeopathy is proven in the context of good health care. It is a system of therapeutics, not a replacement for common standards of diagnosis and preventive care.

Homeopathy is representative of a principle found throughout nature, and its role in bringing forth concepts of resonance, constitution, and holism are shared throughout fields of science and healing. Homeopathy represents an integrated, holistic system of natural therapeutics. Its capacity for addressing psychosomatic disease and acute pathology as a dynamic process is unique. It has remained a coherent system, with extensive clinical verification, for more than two centuries. Homeopathy is an economical and effective method that has been established as an integral part of the medical system in many countries. With the resurgence of interest in natural medicine, this discipline will undoubtedly be more widely used.

Hydrotherapy

Jamie Doughty, BSc, ND, and *Venessa Wahler, ND*

OUTLINE

A BRIEF HISTORY OF NATUROPATHIC MEDICINE INTRODUCTION

Hydrotherapy is a form of physical medicine using the therapeutic application of water in a variety of ways, both internally and externally, on the body. Topical applications of cold or hot water packs, compresses, baths, pools, steams, sweats, showers, enemas, and colonics are all forms of hydrotherapy. Profound, multisystem physiological effects result from the thermodynamic property of water and its effects on an organism's circulation and capability to remove waste and eliminate. Hydrotherapy techniques applied to a patient are a form of stress to the cells that influences their metabolic function, regulates their environment, and provides an opportunity for the body's natural healing processes to take place.

Hydrotherapy has been used by human civilizations for thousands of years and has grown to have literature demonstrating scientific evidence-based applications and uses worldwide today.

Naturopathic physicians are trained in harnessing the curative power of nature through hydrotherapy techniques to treat a myriad of chronic diseases by supporting the innate ability of the human body to heal. Naturopathic medicine follows the principle of "first do no harm," which analyzes the risks versus benefits of any therapeutic intervention. Hydrotherapy is a simple nature cure—a gentle, effective, and curative modality for modern culture. In the words of Dr. Simon Baruch (1840–1921): "No remedy in the entire *materia medica* demands as clear judgment and as much knowledge of the patient's condition as does the application of water."

In North America there are seven different accredited naturopathic educational institutions that all teach and practice the therapeutic application of water through many lecture hours and much clinical experience.[1] The working hypothesis of naturopathic hydrotherapy is that the state of being free from illness and injury is proportional to the normal flow of healthy blood, lymph, and qi.

HISTORY

Water has been associated with medicine and healing since the beginning of recorded history. As an ancient method of treatment, hydrotherapy has been used for thousands of years by people from all over the world and is documented in the writings of many civilizations. In the minds of primitive peoples, water had both supernatural and spiritual power. Religion and water were closely associated for centuries.

Ancient Hydrotherapy

Dating as far back as 10,000 BC, Native Americans used sweat lodges for healing purposes, and the waters of Bath, England, were first used by Paleolithic hunters. The waters of Baden-Baden in Germany have been used for thousands of years, and Ayurvedic steam treatments have been used in India since 5000 BC. Ruins of an ancient bath were discovered in Pakistan, dating back as far as 4500 BC. On the island of Crete, travelers and visitors had access to public baths and running water and would bathe before visiting the king at the palace of Knossos in 2000 BC. The benefits of colon hydrotherapy were recorded as early as 1500 BC, as described in an ancient Egyptian medical document, the "Ebers Papyrus."

Hippocrates, referred to as the "father of medicine," began using water extensively around 400 BC for healing purposes. He prescribed the use of baths in the treatment of both acute and chronic disease, and his writings regarding baths contain some of the earliest dictums on the therapeutic uses of water.[2] Records reveal that water was used in the treatment of rheumatism, fever, inflammation, and other illnesses. Greeks introduced water treatments to the Roman Empire, and by 50 BC, bathing became popular throughout Rome. Roman physicians Galen and Celsus wrote of preventing disease with warm and cold

baths, and by 300 AD, there were approximately 900 baths operating in the city of Rome. When the Roman Empire declined, the use of baths for hygienic, social, and medical purposes also declined.

In the Middle Ages, spanning from 500 to 1500 AD, public bathing was condemned by Christian authorities, and eventually, bathing was discouraged and considered indulgent by the Catholic Church. Although healing methods using water were no longer used in Europe, the knowledge of hydrotherapy was kept alive through monks in monasteries who dedicated themselves to replicating Greek and Roman texts by hand. Islamic countries became the main storage place of classic Western scientific thought. Sentos (public bathhouses) emerged and became popular in Japan, and saunas were invented in Finland. Around that same time, banyas were introduced in Russia. In 1242 AD, hot springs were discovered and developed in Switzerland.

Modern Hydrotherapy

In the 16th century, the Renaissance brought forth a change in medicine, and bathing once again gained popularity for health purposes. Sir John Floyer, an English physician, wrote about "curing madness by cold baths" in his *History of Cold Bathing* published in 1702. His book influenced Johann S. Hahn, who established the principles of modern hydrotherapy in Germany. More than 200 springs were operating in Europe, and private bathrooms and showers were used. During the Scientific Revolution, methods became available to analyze minerals and their effects on the body. In 1810 the first bathroom, which included a sink, toilet, and bathtub, was constructed in a private house in the United States.

The hydrotherapy movement traces its origins to two prominent hydrotherapists: Vincent Priessnitz of Austria and Father Sebastian Kneipp of Bavaria. Priessnitz had no formal training but was inspired to heal his own broken ribs using cold compresses. When he was young, he recalled a man who healed cattle by the external application of cold water. He eventually went on to open his first sanatorium in 1829 in Graefenberg, successfully treating more than 40,000 people with little loss of life. He was also persecuted by medical authorities and convicted of witchcraft because he taught people to heal themselves with the use of water, exercise, and diet.

Priessnitz published *The Cold Water Cure* in 1843, and two establishments later opened in New York City based on his principles. In 1851 Dr. T. L. Nichols and his wife, Mary Grove, opened the American Hydropathic Institute in New York. In 1853 the New York Hydropathic School was established by two medical doctors, Dr. Joel Shew and his associate Dr. Russell Trall.

Father Sebastian Kneipp, initially rejected from the priesthood because he had diabetes mellitus, went on to cure himself with water treatments and diet. After his cure, he was admitted to the priesthood and went on to write *My Water Cure,* published in 1886. In 1891 Father Kneipp treated Benedict Lust, curing him of his medical problems. Lust would later bring Kneipp's teachings to America, influencing Dr. John Harvey Kellogg, an important figure in the modern history of hydrotherapy. Lust eventually played a pivotal role in forming the foundation of naturopathic medicine.

Although the popularity of water treatments began to decline in the late 19th century, Ellen G. White, health reformer and founder of Seventh-Day Adventism, was inspired to open the Western Health Reform Institute, focusing on hydrotherapy, diet, rest, and other natural remedies. One conventional doctor, Simon Baruch, studied hydrotherapy in Europe and brought his teachings to the United States. He spent his life trying to establish hydrotherapy as a science-based treatment, as opposed to the nonscientific form, and taught at Columbia University.

In 1880 Dr. John Harvey Kellogg became the medical director of Battle Creek Sanitarium (formerly Western Health Reform Institute), which became the leading center for natural healing in North America and Europe. He wrote extensively on health, and his book *Rational Hydrotherapy* was published in 1901. In 1917 Kellogg wrote a scientific article praising the effects of colon hydrotherapy in treating the large bowel.[3]

Henry Lindlahr, a real estate tycoon in the United States, after being told he had diabetes mellitus and that no treatments were available, went to Europe to be treated by Father Kneipp. Once he was healed by Kneipp's recommendations of hydrotherapy and proper diet, Lindlahr returned to the United States, received medical training, and established a sanitarium in Chicago in 1906. He wrote *Nature Cure,*[4] the definitive guide to the philosophy and practice of nature cure medicine.

Otis G. Carroll, a modern forefather of naturopathic medicine, studied with Lindlahr and Alex Ledoux, another student of Sebastian Kneipp. Dr. Carroll developed the Constitutional Hydrotherapy treatment in 1923 in Spokane, Washington, which combines compresses with electrical stimulation. Carroll's work was continued by Harold Dick, another naturopath who entered into practice in 1955. In 1990 his work was then followed by his daughter Letitia Dick-Kronenberg, ND. The Windrose Clinic has now provided expert hydrotherapy for more than 50 years. In 2012 her book *The Ultimate Text in Constitutional Hydrotherapy: A 100 Year Tradition of Clinical Practice*[5] was published.

In 1956 Dr. John Bastyr established the National College of Naturopathic Medicine. Hydrotherapy is still taught in naturopathic medical institutions and practiced in their associated teaching clinics as a highly effective, fundamental naturopathic modality. In the late 1980s, *Lectures in Naturopathic Hydrotherapy*[6] was written by Dr. Wade Boyle, ND, and Dr. Andre Saine, ND.

PHYSIOLOGICAL EFFECTS OF WATER

> *No case of chronic disease, no matter how inveterate, unless it has reached an absolutely hopeless stage, should be abandoned as incurable without giving hydrotherapy, with the accompanying regimen of diet and exercise, active or passive, an intelligent and persevering trial.*
>
> ***—Dr. John Harvey Kellogg, 1852–1943***

Water is a universal substance. The gross composition of the human body is water, responding powerfully to its application both internally and externally. Water is the universal solvent in the body; all nutrients, wastes, gases, hormones, and toxins are carried throughout the body in this aqueous base. Water is distributed between the two major fluid compartments, intracellularly and extracellularly, which together constitute the total body water ranging from 55% to 75%, depending on age and gender. Pure water has a neutral pH of 7; it is neither acidic nor alkaline. This neutrality won't alter the pH of the body or of any substances added to the water. Water takes many shapes that can be used in a therapeutic manner to affect physiology. Examples of the various forms of water include liquid, ice, and steam vapor.[7]

Water affects human body systems in various ways depending on the method of administration and the circumstances of the individual. The physiological effects of hydrotherapy are classified as thermal, mechanical, and chemical. Thermal effects are produced by the application of water at temperatures above or below body temperature, with the magnitude of variation from body temperature predicting therapeutic outcomes. Mechanical effects are produced by the effect of water acting on the body surface in the form of sprays, douches, frictions, immersions, whirlpools, and so forth. Chemical effects are produced when water is taken orally, by nasal/sinus irrigation, through vaginal douching, or via colon irrigation.

The effects of the application of water can be generalized or local, depending on the application and administration. Water can be administered internally or externally to the human system. Water has the ability

TABLE 40.1 Definitions and Patient Perceptions of Water Temperature[58]

Water Temperature	Patient Experience
Very cold 32°F–52°F	Painfully cold
Cold 55°F–65°F	Tolerable but uncomfortable
Cool 66°F–80°F	Produces goose bumps
Tepid 81°F–92°F	Slightly below skin temperature
Warm/neutral 93°F–97°F	Comfortable
Hot 98°F–104°F	Tolerable but skin turns red
Very hot 105°F–110°F	Tolerable for short periods
Painfully hot 111°F–124°F	Intolerable
Dangerously hot 125°F	Injuries likely

to modify the physiology of a living body system through temperature effects. With variations of temperature, human body systems need to adapt. In an attempt to accommodate itself (the body) to a change in circumstance, water can change tissues to support the vital processes. The physiological effects of water will vary depending on the individual person's age, biological sex, and physiological condition. (Table 40.1)

Basic Properties of Water

Water has the ability to absorb and radiate large quantities of heat; it is this high specific heat that is the standard by which other specific heats are measured.[8]

- It takes 1 calorie to cool 1 g of water 1°C.
- It takes 80 calories to turn 1 g of water at 0°C into ice (therefore melting ice absorbs 80 times as much heat as does liquid water).
- It takes 540 calories to turn 1 g of water at 100°C into steam; condensing steam gives off 540 times as much heat as does liquid water.

The fluidity of water allows for large areas of application to a single body at one time. A topical application of water will elicit an effect through the skin, which will affect the nervous system, circulation, and finally the tissues. Water is also an excellent conductor of heat by rapidly carrying heat to and away from the body—it is faster than air by 25×.[9]

The modification of water temperature is the most commonly used mode of therapeutic application. The rate of cold or hot temperature exchange depends on the difference in temperature between the two objects, the conducting properties of the objects, the length of time the process is allowed to continue, and the area of the body through which the temperature flows (i.e., skin, fat, or muscle tissue).

Water temperature is described as varying from cold to hot.

Hydrotherapy can have a profound healing effect on the body by the support of healthy blood flow, lymph, and chi. Water can be used to increase circulation and decrease congestion of the blood and lymph, thereby affecting the quantity of these fluids. Water will also affect the quality of blood through the organs of elimination. These emunctories include the skin, liver, kidneys, bowels, and lungs. The quality of blood can be altered through water to affect the organs of digestion and elimination—the stomach, pancreas, small intestine, and colon. For example, increasing blood flow through the application of water can ensure that the body digests and assimilates more nutrients to help build up the quality of the blood.

We can manipulate the blood and body fluids through various applications of hot and cold.

Definitions of the key methods affecting blood and lymph flow are as follows:

1. Direct: local effects of hot and cold applications to a tissue depth of less than 1 cm because thermal receptors are superficial. Direct effects are effective for treating cellulitis in an extremity, mastitis, or tooth infections.
2. Revulsive: alternating hot and cold applications. The hot application magnifies the effect of the cold that follows it. When done in alternating sequences, the effects are additive. Revulsive treatments are very powerful to decongest tissues and produce analgesic effects. Examples include alternating sitz baths and alternating baths to the extremities.
3. Retrostasis: cold application for driving fluid from one area of the body to another.
4. Derivation: hot application for drawing fluid from one area of the body to another. In the presence of congestion in the circulation of an ill patient, a derivative treatment draws proportionally more blood and lymph from the congested parts, whereas in a healthy patient with normal circulation, a derivative treatment draws blood equally from all other parts.
5. Collateral circulation: the fluid dynamics of retrostasis and derivation apply to a restricted area where blood-flow modifications in a superficial artery can change the circulation of a deep artery from the same trunk. For example, a cold application to the start of a superficial branch of an artery will constrict, decreasing blood flow, while the deep branch would dilate to increase blood flow. The converse is also true; a hot application to the start of a superficial branch of an artery will dilate, increasing blood flow, while the deep branch will constrict to decrease blood flow.
6. Arterial trunk reflex: cold or hot applications exerted on an arterial trunk will influence the smaller vessels fed by that trunk. For example, a hot application to an arterial trunk will dilate the trunk and its distal arteries branching off.
7. Spinal cord reflex: symmetrically paired structures of the body are reflexively connected from their vital center to the corresponding area of skin (i.e., extremities).

Principles of Hot and Cold Temperatures

The thermal effect of water is the most commonly used principle of therapeutic hydrotherapy. In general, hot water relaxes and sedates, whereas cold water stimulates, invigorates, and tonifies. Nonetheless, very hot water can stimulate and be destructive, whereas prolonged cold water can be depressive and destructive.[10]

The duration of the application of water is the best predictor of the previously described effects of temperature on human body systems. Short applications will have a stimulating effect, whether it is hot or cold, and long applications will have a depressive effect, whether it is hot or cold. A long application will have an initial vasoconstrictive effect on circulation followed by a secondary vasodilation effect. The definition of a long application of water is one where the temperature doesn't change significantly over time, such as during a shower or bath.

The sequence of effects of hot and cold applications include initial vasoconstriction for both temperatures followed by secondary vasodilation.[11] The final sequence of a cold application ends with vasoconstriction, but with a hot application, we see venostasis. Short cold applications produce a substantial increase in oxygen absorption; carbon dioxide excretion; an increase in nitrogen absorption and excretion; an increase in tissue tone, muscle tone, and vascular tone; and an increase in peripheral white blood cell and red blood cell counts while decreasing blood glucose. Of note, short cold applications have the greatest potential for the stimulation of tissue metabolism.

Hot applications, whether short or long, will somewhat increase oxygen absorption and carbon dioxide excretion, but they will decrease tissue tone and decrease peripheral red and white blood cell counts while increasing blood glucose. Remember, the time of application and the temperature of the water determine the therapeutic and physiological effect on blood flow and can be manipulated using various time and temperature methods.

Principles of Circulation of Blood by Hot and Cold Temperatures

Hydrotherapy is based on the premise that healing is proportional to normal blood flow. When we use alternating hot and cold applications of water, it creates a pumping action in the peripheral heart. The peripheral heart includes skeletal muscle, arteriolar smooth muscle, and capillary dilation or constriction that is different from the central heart. The human body's closed circulatory system determines that it is impossible to have an effect on one part of the circulation without having effects on another part of the system. Again, the temperature of the water affects the skin, which reflexes to the nervous system, the circulatory system, and all the way down to the level of the tissues.

There are several important treatment variables when using hydrotherapy. The first is temperature; the greater the difference between the temperature of the application and the temperature of the human body, the greater the intensity of the treatment will be.

In alternative or revulsive treatments, the greater the contrast in temperature between the hot and cold, the greater the intensity of the treatment.

The duration and frequency of the timing of the application are other variables to manipulate. When the time of the application is extreme, the duration is inversely proportional to the overall intensity of the treatment. For example, short treatments of hot or cold are stimulating to the circulation, and long treatments, whether hot or cold, are depressive to the system.

If the temperature is moderate or tepid, the intensity of the treatment is going to be directly proportional to the duration of the timing of application. The more frequent the application is made, the more intense is the overall effect. Also of note is the time of the day when the application is used and whether it is ideal for a patient's vitality of constitution to enhance the therapeutic effect.

The location of the site of application is another important variable. With derivation treatments, the greater the treatment area, the greater is the intensity of the treatment. With retrostatic treatments, the smaller the treatment area, the more intense is the effect. With alternating-temperature treatments, the greater the size difference between hot and cold, the greater is the intensity of their combined effect. Of note, remember that a cold application should be smaller than a hot application when using alternating treatments.

Incorporating pressure and friction to the treatment area will increase the patient's ability to tolerate an extreme temperature because they increase the intensity of the treatment due to the greater force of water against the body. For example, friction on the skin's surface will allow a patient to tolerate cold without shivering and also draw blood to the surface, which will help increase core heat loss.

In the case of compresses and fomentations, the ability of water vapor to penetrate the material used in covering the patient is inversely proportional to the heating or cooling effects of the compress. The amount of dampness and wetness in the application is also proportionally related to the effect of the temperature on the body.

Fever and Antipyretic Treatments

Heat may be applied to the body in various ways, including hot packs, fomentations, steam, baths, and showers. All hot applications produce physiological responses that are attempts by the body to eliminate and dissipate excess heat to prevent a damaging rise in local and systemic temperatures. The effects produced by hot applications depend on the mode, temperature, duration, and the condition of the patient.

Water at 98°F or above is generally perceived as hot, and water higher than 104°F is considered very hot. At 120°F, an immersion bath becomes unendurable, although small areas of the body, such as the hand, may be conditioned to endure a temperature of 10°F to 15° higher for short periods. The mucous membranes, unlike the skin, may endure temperatures as high as 135°F, which accounts for our ability to drink very hot liquids or benefit from steam inhalation treatment. Although exposure to the high temperatures of hot tubs and saunas has become quite popular in recent years, Kneipp, Priessnitz, and Kellogg all believed that repeated and prolonged use could weaken the individual unless counteracted by frequent cold applications, such as showers or ablutions.

TABLE 40.2 Effect of Treatment Variables on Metabolism

- A short hot application of water will increase circulation and increase metabolism.
- A long hot application of water will decrease circulation and increase metabolism.
- A short cold application of water will increase circulation and increase metabolism.
- A long cold application of water will decrease circulation and decrease metabolism.

Local hot applications result in vasodilation, with a resulting increase in capillary blood flow, oxygen delivery to the tissues, local metabolic activity, and migration of lymphocytes through vessel walls and into the local tissues. Local perspiration is increased, and muscle relaxation occurs through the inhibition of muscle spindles, which decreases tone. Intense moist heat applied for a long period of time (several minutes) has a depth of penetration not exceeding about 3.4 cm. The increased blood flow through the area carries away heat conducted into the tissues from a hot application and limits the depth of penetration. (This "radiator-like" effect can be overcome by more intense applications of heat, and deep tissue destruction can occur.)

General hot applications over half of the body or greater can have dramatic effects on the cardiovascular system. The inability to dissipate heat from a large volume of tissues will result in an increase in body temperature, metabolism, and oxygen consumption. The heart rate increases 10 beats for every 1°F rise in body temperature, whereas blood pressure and cardiac output decrease. The respiratory rate increases 5 to 6 breaths per minute for every 1°F rise in body temperature, whereas the depth of respiration decreases. Hyperventilation may occur and result in respiratory alkalosis. Van't Hoff's law of temperature states that for every temperature rise of 18°F, the velocity of chemical and metabolic reactions in the body is increased 2 to 3 times. Slight increases in temperature can have a profound effect on cellular metabolism and systemic physiology, cell membrane permeability, oxidation, and metabolic rate. (Table 40.2)

Fever is defined as an increase in the regulated body temperature resulting from an elevation of the thermoregulatory set point for the body in the hypothalamus. This is often caused by infectious diseases. Fever is produced when an exogenous pyrogen is phagocytized by a macrophage, which results in the release of interleukin-1, which travels in the blood like a hormone to the hypothalamus. Prostaglandin E2 is produced in the hypothalamus to increase the body's temperature set point. At this point, the normal body temperature is perceived as being too low, so the body shifts into heat-conservation mode by initiating shivering, the vasoconstriction of surface blood vessels, and the contraction of arrector pili muscles in the skin. Interleukin-1 also induces fatigue and sleep to save energy while promoting the production of proteins in the liver that stimulate the immune system. In skeletal muscle tissue, we see liposomal activity that causes protein breakdown for the purpose of adding more amino acids to the blood for tissue repair and energy. This

will be experienced by the patient as myalgias. Gut motility is decreased with a fever above 99.5°F, causing anorexia to depress the appetite to free up energy for the healing process. It is important to fast the patient during fever because clinical experience shows that a fever will rarely go above 104°F in adults when they are fasting. Fasting during fever should be avoided with pregnant, nursing, or diabetic patients.

The purpose of fever in the body is to increase the production of white blood cells and to move those white blood cells into the circulation faster. White blood cell motility and productivity rates are increased with fever. The production of interferon is enhanced, and antibody production increases up to 20 times. During fever, blood concentrations of iron and zinc are reduced to inhibit bacterial growth.

Types of Fever

Types of fevers include the following:

1. Adaptive increases in temperature produced with exercise, by hormones (cortisol, norepinephrine/epinephrine), or in states of dehydration or heat exhaustion
2. Pyrogenic fevers (infectious) produced from bacterial toxins and foreign proteins
3. Artificially induced fever using thermo-hydrotherapy to deliberately elevate body temperature

All fevers can cause the following symptoms in patients:

- Nervous system symptoms, including insomnia, headache, or delirium
- Chilliness with goose bumps
- Shallow, rapid breathing
- Malaise or backaches
- Excessive thirst
- Shallow, rapid breathing
- Increased heart rate and cardiac output
- Anorexia, foul breath, coated tongue
- Hot, dry skin or cold, clammy skin
- Constipation or diarrhea
- Scanty, highly concentrated and colored urine

The following are measurements of normal body temperature: oral, 98.6°F; rectal, 99.6°F to 100°F; and axillary, 97.8°F. The ideal range for fever is 102°F to 103°F; this is optimal for fighting infection and is most effective. At temperatures between 104°F and 107°F, dehydration becomes a concern, and above 107°F, dangerous effects can occur, such as loss of consciousness and irreversible protein denaturation.

The degree of temperature elevation in a fever is determined by the severity of the pathogen and the vitality of the patient. We see this often when children run much higher fevers than adults or in chronically ill patients and the elderly, who can sometimes run only a slight fever if at all.

The best use of hydrotherapy in treating fever is to help the body maintain an optimal temperature between 102°F and 104°F. By using water, we can keep the patient well hydrated and can lower a dangerously high fever or raise a suboptimally low fever. When a patient is in the ideal range for fever and is sweating, the patient needs to be managed by keeping him or her well hydrated, warm, and comfortable.

Dehydration can cause the body temperature to stay elevated longer and will add to the risks for dangerous side effects from fever, such as seizures. The application or internal use of cool water is helpful for a high fever, and warm water externally or internally through teas to help promote sweating is helpful in a low fever or chilly patient. High fevers can result in fluid loss and electrolyte imbalances. Fluid-electrolyte replacement and rehydration formulas should be added to the water (e.g., vegetable broth, salt, diluted juice, or a rehydration drink). Applications of heat during fever are contraindicated in peripheral vascular disease, diabetes mellitus, brain injuries, and stroke.

Effects of Water Temperature on Fever

The effects of water temperature on fever are as follows:

- Short cold applications of temperature result in increased heat loss and increased heat production and, therefore, no net change in body temperature.
- Long cold applications of temperature result in increased heat loss and decreased heat production and, therefore, a decrease in net body temperature unless the patient is shivering.
- Tepid applications increase heat loss and cause no change in production and, therefore, result in a decrease in net body temperature.
- Short hot applications between 3 and 5 minutes greatly decrease heat loss and greatly increase heat production and, therefore, result in a great increase in net body temperature.
- Long hot applications of temperature greatly decrease heat loss and greatly increase heat production, resulting in a substantial net increase in body temperature.
- Very short hot applications of less than 3 minutes will result in a great increase in heat loss as blood is drawn to the surface to improve heat loss in the core of the body, with a slight increase in heat production, therefore resulting in a decrease in net body temperature.

In summary, the only temperature applications that offer a net loss of body temperature are the long cold, tepid, and very short hot types. Tepid and neutral baths are very effective in their ability to carry heat away from the body by conduction without increasing the body's production of heat either by the application of heat or by resulting in the patient shivering. Tepid baths range from 81°F to 92°F, and neutral baths are defined as 93°F to 96°F. Tepid and neutral water affusions involve the pouring of water onto the patient to increase the friction and effect of the treatment. A tepid sponge bath is a gentle and effective treatment for fever reduction, especially in children. The patient loses heat by conduction and evaporation, and the sponging provides gentle friction to bring more blood to the surface.

Be aware of the coasting factor, which dictates that oral body temperature readings will take some time to catch up to the core body temperature. It is recommended to stop the hydrotherapy treatment before the patient reaches the desired oral temperature by 1°F to 2°F.

GENERAL GUIDELINES FOR HYDROTHERAPY

For the Health Care Provider

1. To ensure safe and effective outcomes, it is important to take a full case history for each patient and rule out contraindications to the hydrotherapy treatment. Determine the physical, mental, and emotional status of each individual. Children, the elderly, those with major health problems, those with generally low resistance, obese individuals, and those with severe physical limitations may have a weaker response to hydrotherapy treatments and should be more closely observed.
2. Thoroughly explain each treatment before beginning. Include in your discussion the length of the session, the sequence of events, and any other pertinent details, such as the rationale for the treatment and temperatures to expect. Ensure that the patient understands the specifics of each therapy and that the patient is comfortable with all aspects of the treatment.
3. Check for and record objective findings at the onset of the therapy session. This should include taking the patient's temperature, pulse, and respiration rate.
4. Follow standard precautions that are designed to protect the patient and health care provider.

5. Stay with the client throughout the session or have an emergency signal such as a bell or alert system. Check in periodically with the client. Rerecord the patient's pulse, respiration rate, and temperature, and monitor other physiological markers such as blood sugar as needed.
6. Provide a clean treatment room equipped with all necessary supplies. Encourage hydration and provide clean drinking water. Ensure adequate temperature control in each treatment room.
7. Monitor the patient closely for side effects of the treatment. The client should not become chilled to the point of shivering. If the patient gets cold, consider initiating warming techniques such as friction rubs, offering warm drinks, or applying additional blankets or dressings while continuing with treatments. Oppositely, if the patient becomes overheated (depending on the therapy), initiate cooling techniques such as applying towels dipped in ice water and wrung out or applying ice packs where indicated. If the patient becomes dizzy or lightheaded, assess blood sugar, offer hydration, and encourage rest. Other side effects may include nervousness, heart palpitations, nausea, and aches and pains. In most cases, symptoms are self-limiting and respond to simple interventions and rest.
8. Check the temperature of both hot and cold applications before applying them to a patient's skin. Use an appropriate thermometer when using water in a treatment.
9. Record final pulse, temperature, respiratory rate, and any other pertinent physical examination findings. Adequate documentation of the therapy session will guide ongoing treatments, may prompt future research, and will continue to substantiate hydrotherapy as an effective therapeutic modality.
10. Inform your patient of any posttreatment precautions and recommendations. Some reactions may take place several hours to several days after treatment, so ensure that patients have a way to follow up with you if needed.

For the Patient or Individual

Before Treatment

1. Plan your hydrotherapy session at a time of day when you feel vital and unhurried.
2. Avoid eating 1 to 2 hours before your treatment time. Avoid alcohol and recreational drug use. Stay adequately hydrated.
3. Report all medications and supplements to your health care provider. If performing hydrotherapy at home or in a health facility such as a gym, make sure you check with your doctor first.

During Treatment

1. Report any reactions to your practitioner and stop therapy immediately if adverse effects occur.
2. Remain hydrated throughout the hydrotherapy session.
3. Take measures to warm up or cool down if you become too chilled or overheated, respectively.
4. Mindful breathing exercises may help balance the nervous system and optimize outcomes.
5. Follow safety rules and regulations of the health care facility (e.g., obey time restrictions for saunas and treatment pools).

After Treatment

1. Avoid drafts and excessive heat or cold after hydrotherapy treatments.
2. Be mindful of any side effects of your treatment, and report them to your health care provider.
3. Stay hydrated and follow dietary recommendations or restrictions specific to the hydrotherapy treatment.

General Cautions and Contraindications

Hydrotherapy is generally very safe, but, as with most medical therapies, there are cautions to consider and contraindications to be aware of. When caution is taken in hydrotherapy, it does not mean that the therapy should be avoided; it simply guides us to consider more closely the specific needs of the individual before, during, and after the therapeutic treatment. A contraindication is defined by any special symptom or circumstance that renders the use of a remedy or the carrying out of a procedure inadvisable, usually because of risk.[12]

Hydrotherapy treatments may produce unexpected or undesired effects. When this occurs, it's important to carefully to assess the individual's response to the treatment and ensure that the therapy has been properly administered. If an aggravation from treatment does occur, the therapist will need to review the intensity of the treatment and the length of treatment and reassess the appropriateness for the individual. Modifications can be made if additional treatments are indicated.

Most side effects of hydrotherapy are self-limiting, and the individual will often respond well to rest and simple interventions. Some of these effects include shivering, headache, dizziness or lightheadedness, hyperventilation, heart palpitations, skin irritation, nausea, insomnia, and minor aches and pains. Shivering will occur if the client is allowed to get too cold and therapy is not followed by appropriate warming techniques. Headaches may present secondary to dehydration; as a reaction to the water temperature, blood sugar dips, or blood pressure spikes; or as a result of a detoxification reaction. Detoxification reactions are possible within hours or may occur up to 1 or 2 days after treatment.

Dizziness or lightheadedness experienced during a hydrotherapy treatment may occur as a result of dehydration, decreased blood sugar, and/or decreased blood pressure levels. The client should be given adequate hydration and may be encouraged to lie down and get back up slowly once symptoms have subsided. Keep a source of sugar on hand in the case of hypoglycemia. Hyperventilation can develop from nervousness. A reduction in feelings of tension, as well as increased pain thresholds to hot and cold, can be achieved by having the patient perform deep- and slow-breathing techniques.[13]

Heart palpitations may accompany dizziness and result from elevated body temperature. Other factors affecting heart rate include emotions, body size and position, and medications that are shown to affect pulse rate. The heart rate is normally between 60 beats per minute (bpm) and 100 bpm, although a pulse rate as low as 40 bpm can be seen in very physically fit individuals.

Pregnancy

When used with caution and professional guidance, hydrotherapy can be supportive for women in pregnancy and during the labor process. Although warm-water therapies can promote relaxation and offer relief of minor aches and pains, prolonged exposures to heat sources such as hot tubs, hot baths, saunas, and steam rooms are contraindicated. Hot applications over the abdomen should be avoided. The American College of Nurse-Midwives (ACNM) affirms that "Warm water immersion hydrotherapy during labor provides comfort, supports relaxation, and is a safe and effective nonpharmacological pain relief strategy that promotes physiological childbirth."[14] When evidence-based clinical guidelines are followed, research demonstrates that the use of hydrotherapy for pain relief during labor does not increase risks for healthy women or newborns.[14]

The Organization of Teratology Information Services (OTIS) states that in pregnancy, a body temperature over 101°F can be of concern, especially if it lasts for a long period of time.[15] Hot baths would be a safer way to relax than would a hot tub. In a bath, the upper body remains

out of the water, and the water in the bath cools over time, reducing the risk of overheating. Although hot tubs are not recommended in pregnancy, there are steps to take to reduce risk. These include monitoring body temperature to avoid overheating, limiting time in a hot tub to 10 minutes or less, and reprogramming the hot tub to maintain a lower temperature.[16] The American College of Obstetricians and Gynecologists recommends that pregnant women never let their core body temperature rise above 102.2°F.[16] Neutral baths and Epsom salt hand and foot baths in the later stages of pregnancy have traditionally been used for symptoms of local edema.

According to the UK Teratology Information Service (UKTIS), there are limited data on most pregnancy outcomes after maternal exposure to external heat sources such as saunas, hot tubs, and hot baths, and there are no data relating specifically to steam room exposure.[17] An evidence-based assessment of the potential risks of these treatments in pregnancy is difficult due to the limitations of testing on pregnant females.

Hypertension and Cardiovascular Disease

Hydrotherapy treatments should be used with caution in individuals with cardiovascular disease, and there are several contraindications to consider. These individuals may be taking medications that modify how the body will respond to heat and cold and should be closely monitored. Heat should not be applied over artificial devices such as pacemakers or implantable defibrillators.

Elevated temperatures can cause increased demands on the circulatory system, including significant changes in local blood flow and changes in the size of blood vessels, heart rate, the volume of blood pumped from the heart, and blood pressure. High-temperature treatments such as sauna therapy, hot baths, and steam baths could be potentially dangerous in those with hypertension due to a temporary increase in blood pressure, and thus they should be avoided. Additionally, high-temperature treatments can ultimately reduce blood pressure, leading to fainting or dizziness in a person with low blood pressure.

The heart may not be strong enough for very high-temperature treatments in those with congestive heart failure (CHF), and these treatments should be avoided. In contrast, thermal vasodilation after warm-water bathing and low-temperature sauna bathing at 60°C for 15 minutes has been shown to improve cardiac function in those with CHF.[18]

Local hydrotherapy treatments are used with caution in those with varicose veins, and extreme hot and cold treatments should be avoided. Local hot and cold treatments should be avoided in those with phlebitis. When dealing with a vasoconstriction disorder, such as Raynaud's syndrome, local cold applications are contraindicated. Local hot applications are contraindicated in those with arteriosclerosis, a condition involving thickening, hardening, and loss of elasticity in the walls of the blood vessels.

In patients with coronary risk factors, there may be a risk of precipitating myocardial infarction (MI), or heart attack, when alternating heat exposure during sauna therapy is followed by rapid cooling during a cold-water bath.[19] Interestingly, animal studies have revealed that sauna therapy may serve as a noninvasive therapy for patients with MI because it attenuates cardiac remodeling after MI by improving coronary vascularity in the noninfarcted myocardium.[20]

Cancer

It is known that there are more than 100 types of cancer and that cancer can form almost anywhere in the human body. Individuals who are undergoing cancer treatment should have the approval of their physician before initiating hydrotherapy treatments. Local and whole-body hydrotherapy treatments may be useful for those diagnosed with cancer for reasons other than cancer treatment, such as for pain or relaxation purposes. However, because hydrotherapy treatments at the very least can have effects on the skin and place demands on the circulatory system, it is imperative to treat the whole person and assess where contraindications to treatment may arise.

Daily, brief cold-water stress over many months may enhance antitumor immunity and improve nonlymphoid cancer survival rate.[21] A hypothesis suggests that sudden ice-cold-water immersion can increase blood–brain barrier permeability, thereby increasing the mortality of neurovirulent infections. This could lead to immunotherapy development for some nonlymphoid cancers, including those caused by viral infections.[22]

Hyperthermic treatment of tumors can be traced back to the time of the ancient Greeks, and modern medicine has used hyperthermia as an adjunct cancer treatment in various settings. For example, research has demonstrated that hyperthermia, when added to chemotherapy and/or radiation, may positively affect treatment outcomes for patients with pancreatic cancer.[23] Research has also shown that hyperthermia can have a synergistic effect on the cell-killing effect of chemotherapy drugs and radiation.[24] Because of this, hyperthermia treatments should not be indiscriminately used in those receiving chemotherapy and/or radiation. A study on preventing alopecia caused by chemotherapy revealed that the use of a cold pillow compress could reduce hair follicle inhibition or damage caused by chemotherapeutic agents.[25]

Colon hydrotherapy is an option for colonoscopy preparation for colon cancer screening. A study showed that the quality of colon cleansing, overall tolerance, comfort, and convenience were significantly better for colon hydrotherapy compared with alternative preparations.[26] Colon hydrotherapy is contraindicated in those with cancer of the rectum or colon.

Diabetes

An estimated 30 million people of all ages—or 9.4% of the U.S. population—had diabetes in 2015, reaching a high of 25% among those aged 65 years or older.[27] Because of its prevalence, it's important to understand when hydrotherapy can safely be used for those with diabetes. Type 1 and type 2 diabetes mellitus are both associated with reduced ability to maintain core temperature during thermal stress. This has been related to impairments in the body's ability to dissipate heat, mediated via increases in skin blood flow and sweating during heat stress, as well as a reduced capacity to increase metabolic heat production and to decrease skin blood flow during cold stress.[28] Generally, warm- and neutral-temperature treatments are safer, and recommendations for hydrotherapy treatment should be approved by the patient's physician.

Acute complications of diabetes occur as a result of blood sugar levels that become either too high or too low. Chronic complications of the disease often include nerve damage and tissue damage from chronically elevated blood sugar levels. Cardiovascular disease can develop slowly in those with diabetes, particularly atherosclerosis, so high-temperature treatments such as hot saunas, hot baths, and local hot applications are contraindicated. When diabetes affects the smaller blood vessels of the legs and feet, these vessels may not dilate normally in response to heat. Heat applied to these areas leads to increased metabolism in the heated tissues, which would require more oxygen and other nutrients. When blood vessels cannot supply enough oxygen and other nutrients to the treated tissues, it can result in tissue death.

Another factor to consider is diabetic neuropathy, a nerve condition that causes, among other symptoms, a limited ability to sense pressure and temperature in the extremities. In this situation, the individual may not be able to discern if a hot application is burning the skin or if a cold application is freezing the skin. Therefore hot and cold applications are contraindicated.

Less-extreme-temperature treatments, such as alternating warm (102°F) and cold (55°F) footbaths, used under medical supervision, may help increase circulation and offer treatment for diabetic ulcers. Immersion in Dead Sea water at a temperature of only 95°F for 20 minutes was shown to produce significant reductions in blood glucose in those with type 2 diabetes.[29]

HYDROTHERAPY TECHNIQUES

The range of hydrotherapy treatments is vast, and the ways in which water is applied to the body to initiate a therapeutic response are only limited by the imagination of the therapist. Deciding on which treatment to use requires a thorough understanding of the principles of hydrotherapy, the health status of the patient, and the effects of hot and cold on the body.

Compresses

A compress is essentially the application of water at any temperature through a cloth medium or other compress material, wrung out and applied to the body. In the early 20th century, J. H. Kellogg described 12 types of compresses. They were classified according to their temperature, as (1) very cold; (2) cool or cooling; (3) warm or neutral; (4) hot; (5) very hot; (6) alternate (alternating very hot and very cold); (7) revulsive (short cold followed by prolonged very hot); (8) hot and cold (simultaneously); (9) hot and cold pack; (10) heating or stimulating (applying cold, protected by an additional material and prolonged until warmed by the body); (11) proximal compress; and (12) the irrigating compress.[30] While appreciating that each type of compress has its unique features, four basic types of compresses will be discussed: hot and cold compresses, warming compresses, and alternating hot and cold compresses.

A single compress is the use of only wet material applied to the body. A double compress, in comparison, consists of an initial wet layer covered by a water-resistant—or dry—material covering, such as wool. This double layering acts to prevent cooling by evaporation or radiation. When applied to specific areas of the body, compresses can be referred to by the area being treated (e.g., a throat compress or eye compress).

Cold Compresses and Packs

When a cloth is wrung from cold or ice water and applied to a particular area of the body, it is considered a cold compress. A cold pack, on the other hand, is made from crushed ice or produced commercially as gel packs that are cooled in a freezer. A cold pack requires almost no preparation and allows for more aggressive tissue cooling compared with a compress. Cold packs remain cold for a longer duration than a cold compress; therefore cold compresses are renewed frequently to achieve the desired cold effect. Additionally, cold packs applied for long periods have the potential to cause tissue damage, so treatment time should be limited to 15 to 20 minutes, and the skin should be occasionally monitored. Refer to Table 40.3 for a list of indications and contraindications for local cold applications.

The temperature and type of cold compress will depend on the area of the body being treated as well as the health status of the patient. Cold packs are often applied to larger, flat surfaces, such as the back, due to the limited ability to wrap them around irregularly shaped surfaces. Cold compresses are used more flexibly, can be applied over smaller or delicate surfaces such as the eyes or forehead, and are more suitable for clients who cannot tolerate very cold applications.

To elicit a more specific effect from a cold compress, a practitioner may choose to add certain chemical solutions to the compress, such as Epsom salts, essential oils, and a plethora of herbs. When herbs are used, they are steeped in water to produce a tea, and the compress material is then dipped into it, wrung out, and applied to the body. Adding essential oils to the water is much quicker than preparing herbs and requires an understanding of the effects of the oils on the skin.

TABLE 40.3 Indications and Contraindications for Local Cold Application

Indications for Local Cold Application	Contraindications for Local Cold Application
Muscle strains and joint sprains	Cold client or if the client has an aversion or sensitivity to cold
Support for an overheated individual	Impaired sensation or numbness in a given area
To reduce blood flow to an area of congestion	After eccentric exercises (resistance training)[59]
Acute and chronic low back pain	Poor circulation
To decrease local tissue metabolism via vasoconstriction	Peripheral vascular disease
To decrease muscle spasms	Open wounds
	Malignancy
	Acute asthma, sinusitis, and pleurisy
	Prolonged exposure with lymphedema
	Implanted medical device such as a cardiac pacemaker
	Uncontrolled hypertension
	Caution with children, the elderly, and those with a debilitating condition

Hot Compresses and Fomentations

A hot compress is the local application of moist heat to an area of the body to elicit a rise in local tissue temperature, improve local circulation, support muscle relaxation, and relieve musculoskeletal pain. A hot compress usually consists of a folded cloth dipped in hot water, wrung out, and applied to a surface of the body. Depending on the size of the area being treated, a washcloth, hand towel, or large towel may be used. A fomentation is a particular type of hot compress that delivers moist heat at a higher temperature for a longer period of time. It typically consists of many layers of folded towels, flannel, or other thick material that can absorb water and retain heat. A fomentation is often wrapped with a layer of wool felt to effectively hold heat and then by additional layers of towels to protect the patient's skin.

Similar to modifying a cold compress, a practitioner may choose to add certain substances to a hot compress to elicit a more specific effect. For example, a Thai herbal compress, consisting of Plai or Cassumunar ginger, turmeric, and camphor, may be used for osteoarthritis and muscle pain and can also be used as a treatment of choice to induce lactation.[31] Ground mustard plasters have long been used to warm muscle tissues and treat chronic aches and pains. Because mustard plasters are generally very hot, treatment time is often limited to 15 minutes, and the underlying skin should be checked frequently to avoid irritation or blistering. Castor oil packs can be used to increase local circulation of blood and lymph, relieve muscle and joint pain, soften scar tissue, and relax smooth muscle. Castor oil packs have been shown to effectively control symptoms of constipation.[32] Refer to Table 40.4 for a list of contraindications for local hot applications.

Warming Compresses

A warming compress consists of a cold compress covered by a layer of dry material—typically flannel or wool—that is worn for prolonged

TABLE 40.4 Indications and Contraindications for Local Hot Application

Indications for Local Hot Application	Contraindications for Local Hot Application
Poor local circulation	Sensitivity to heat or aversion to heat
To increase blood flow to an area	Impaired sensation or numbness in a given area
Menstrual cramping	Congestive heart failure
Nervous tension	Malignancy
Muscle soreness and tightness	Open wounds
Stiff and painful joints	Implanted medical device such as a cardiac pacemaker
Chilled client or chilled local area	Swelling and inflammation
To assist in reducing edema and removing waste products from an area of injury	Patients with diabetes: avoid local hot applications to legs and feet
Improve range of motion	Peripheral vascular disease
	Caution with children, the elderly, and those with a debilitating condition
	Pregnancy: avoid hot packs over the abdomen

periods until eventually warmed by the body. The top layer of dry material acts to prevent heat loss by evaporation and allows for the accumulation of heat. Also referred to as a cold double compress, a warming compress is used to improve local circulation, relax muscles, and relieve musculoskeletal pain. There is also a derivative effect that occurs when blood flow is increased as a result of warming the compress.

A popular example of a warming compress is the wet sock treatment. This treatment consists of dipping cotton socks in cold water, wringing them out completely, and applying them to previously warmed feet. Once the feet have been soaked in warm water for 5 to 10 minutes—or warmed by other means—the cold socks are applied. Cold socks can be placed in a freezer for several minutes to increase the intensity of the treatment if there are no contraindications to doing so. A pair of dry wool socks is then applied to cover the cold socks and left overnight to be warmed by the patient. The socks are often dry by morning. The wet sock treatment is commonly used for sinus congestion, upper respiratory infections, bronchitis, cough or sore throat, headaches, and ear infection.

The temperature of the initial cold application will depend on the treatment location and the health status of the individual. The same basic guidelines for cold compresses apply for warming compresses. Because a colder application can elicit a stronger secondary reaction to the cold, caution is taken with weak or debilitated individuals who are unable to generate a strong secondary response.

Alternating Hot and Cold Compresses

Alternating hot and cold compresses—or local contrast treatments—are one of the most efficient ways to improve blood flow through an area of the body. This procedure is a succession of compresses of hot and cold that combine the effects of both the hot and cold compress. The hot compress is applied for up to 3 to 5 minutes, alternating with a cold compress for 30 to 90 seconds. As a general rule, the duration of a hot application should be greater than that of a cold application and cover a slightly larger area. Additionally, the procedure should always begin with the hot compress and end with the cold compress. It is also repeated three or more times.

The heat applied initially during an alternating compress treatment causes dilation of the cutaneous vasculature. A subsequent cold application will cause vasoconstriction followed by vasodilation, allowing for marked improvements in blood flow to the treated site. This can be particularly helpful to stimulate healing and reduce swelling in a joint after injury or surgery. By increasing blood flow, contrast compresses can help relieve pain. For example, alternating compresses were shown to improve foot functionality scores in individuals with heel pain.[33]

Baths

Baths are full or partial immersions of the body into various temperatures of water to produce a wide range of therapeutic effects. With whole-body immersions, the body—except for the head—is immersed in water, which can be performed in a standard bathtub. In a partial-body immersion, only a particular part of the body is immersed in water using a variety of basic containers, such as a bowl, a bucket, or standard bathtub. Additives can be used, such as Epsom salt, sea salt, baking soda, oatmeal, mustard powder, and herbs, to elicit a more specific effect from the bath.

Hot Baths

Depending on the tolerance of the individual as well as the condition being treated, hot baths will generally range in temperature from 100°F to 106°F and are administered for 20 to 60 minutes or longer. Hot baths are used for many types of musculoskeletal pain and to stimulate the immune system, induce sweating, and cleanse the body, among other purposes. They encourage muscle relaxation, enhance circulation, and are efficient at raising core temperature. Hyperthermia treatments are useful for managing infections and can be used as adjunct cancer support. When treatments are limited to a brief period of only a few minutes, peripheral vasodilation may promote heat loss and thereby reduce fever.

The duration of a local hot immersion is typically 15 to 20 minutes and will depend on the condition being treated, as well as the tolerance of the individual. One type of local hot immersion, the hot foot bath, has been shown to relieve fatigue and insomnia in patients undergoing chemotherapy.[34] It can be used as an effective intervention for the management of sleep disturbances after traumatic brain injury.[35]

When performed at home, whole-body hot immersions should be limited to 30 minutes and kept to a temperature of 104°F. An individual should have assistance when performing hyperthermia treatments in a home setting. When performed in a clinical setting, more aggressive treatment can be administered under close supervision. The water temperature should be kept to 106°F, and the duration of treatment should be limited to 60 minutes.

Contraindications to whole-body hot immersions include seizure disorders, pregnancy, cardiovascular disorders, diabetes, loss of sensation, intolerance to heat, multiple sclerosis, and drug or alcohol ingestion. Prolonged hot immersions should be avoided in children, the elderly, weak or anemic individuals, those with severe organic disease, and those with a tendency to hemorrhage.

General precautions should be followed when performing hyperthermia treatments. Patients should wait at least an hour after eating a meal before receiving treatment to avoid symptoms such as nausea and vomiting. Likewise, if a client has gone too long without food, symptoms of hypoglycemia may arise. The individual should be adequately hydrated before, during, and after treatment. Additionally, because hot-water immersions may induce hypotension, the individual could become lightheaded and lose his or her footing. Clients should be instructed to rise slowly from the bath with assistance close by. Headaches may result from hyperthermia treatments. Applying cold compresses to the head and face early and throughout the treatment can prevent this. Hyperventilation sometimes occurs with hot-water

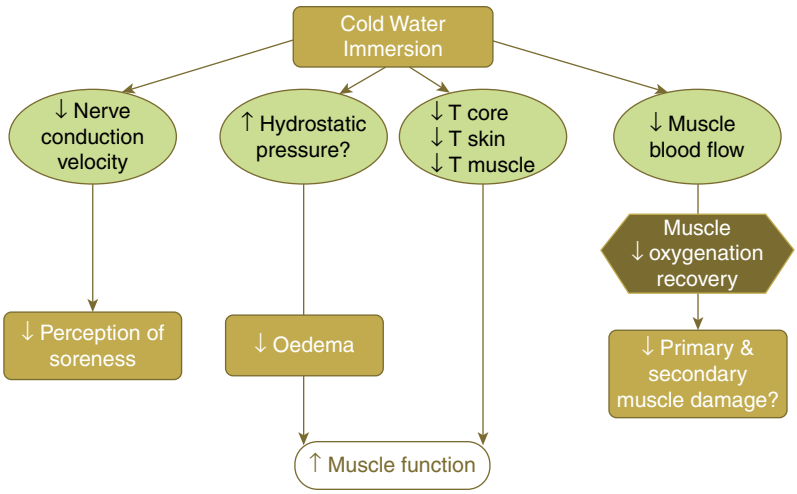

Fig. 40.1 Physiological effects of cold-water immersion. *T,* temperature. (From McGorm H, Roberts LA, Coombes JS, Peake JM. Cold water immersion. *Aspetar Sports Med J.* 2015;4[1].)

immersions and, although rare, may lead to early tetany from respiratory alkalosis. This can be prevented by monitoring the individual's respiratory rate and offering breath coaching as needed.

Neutral Baths

The neutral bath is a head-out, whole-body immersion bath given at a temperature close to that of the body and exerting as little thermal effects as possible. A minor variation in temperature by only a few degrees could result in an altered therapeutic response. Neutral baths are taken for a duration of 15 minutes to 4 hours, although warm water will need to be added after a period of about 20 minutes to maintain the appropriate temperature.

Neutral baths have been shown to lower heart rate, blood pressure, and cortisol levels while preserving metabolic rate and body temperature and increasing urine output.[36] Neutral baths have a calming effect on the nervous system and are indicated for those with insomnia, anxiety, nervousness, and pain. They may be a useful aid in detoxification treatments due to their effects on urine output, as well as an adjunct treatment for peripheral edema. Caution should be taken with those with cardiovascular disease and kidney disease, and the duration of treatment should be limited or treatment avoided in those with eczema. The air in the room should be kept warm, and care should be taken so that the individual does not become chilled after treatment.

Cold and Contrast Baths

A cold, full-body immersion bath is used at a temperature below 60°F and is often limited to a duration of only a few minutes. It generally follows a hot, full-body immersion to reverse the vasodilation of skin after a heat treatment. A meta-analysis concluded that individuals with exercise-induced hyperthermia were cooled twice as fast by cold-water immersion as by passive recovery.[37] Such an invigorating treatment should only be attempted by those in robust health. Cold baths are contraindicated in the very young and the very old; weak and debilitated patients; those who are chilled or have an aversion to cold; and those with kidney disease, cardiovascular disease, and hyperthyroidism.

A local cold immersion bath can be used therapeutically to reduce musculoskeletal pain or swelling in a particular area of the body, such as the arm, hand, or foot. Compared with the effects of using an ice pack or ice massage, a local cold-water immersion is most indicated for inducing therapeutic effects associated with the reduction of motor nerve conduction (Fig. 40.1).[38]

Contrast baths combine both hot- and cold-water immersions and are effective for stimulating blood flow to the skin and decreasing congestion in the body. Similar to other contrast therapies, treatment begins with hot and ends with cold. For local immersions, 3 to 5 minutes of hot is followed by 30 to 90 seconds of cold. Full-body immersion often requires at least 10 minutes of hot, followed by 30 to 90 seconds of cold, and is most appropriate for those in robust health. Local contrast immersions require only a few small buckets and access to hot and cold water, allowing for both home and clinical use. Full contrast immersions are typically available in a spa or clinical setting because the process necessitates two large tubs to accommodate a hot and cold immersion. Contrast water therapy can also be performed easily at home in the shower. Ending a daily hot shower with a full-body cold rinse is tonifying to the circulatory and immune systems. In a long-term prospective study, the frequency and intensity of common colds were reduced after volunteers were regularly treated with contrasting hot and cold showers over a 6-month period.[39]

Sitz Bath

A sitz bath is a partial immersion bath of the pelvic region that has long been used to treat afflictions of the abdomen, pelvis, perineum, and low back. It is carried out in a specifically designed tub—older models resemble a chair-shaped bathtub and are made of porcelain; newer models are designed to sit atop the toilet or are advanced enough to contain their own water heater. The sitz bath can be effectively taken in a standard bathtub or even a plastic tub large enough to immerse the pelvic region. A sitz bath may be taken hot, cold, neutral, or with contrasting hot and cold, and preparations such as Epsom salt, herbs, and essential oils can be added.

Hot sitz baths are analgesic and stimulate pelvic circulation. They have been used to help relieve low back pain, dysmenorrhea, spastic constipation, cramps of the uterus or ureters, ovarian or testicular pain, sciatica, and after cystoscopy or hemorrhoidectomy. After sphincterotomy for anal fissure, the sitz bath provided significant relief of anal burning and increased patient satisfaction score.[40] The hot sitz bath relieves urinary retention in patients after hemorrhoidectomy, with spontaneous micturition more likely at higher water temperatures.[41] Hot sitz baths can be used to raise core temperature as well as to create a fluid-shifting, or derivative, effect. Hot sitz baths significantly reduced urethral stricture after transurethral resection of the prostate.[42] The hot sitz bath has a duration of

3 to 10 minutes and is followed by a cool sponging or spray to the area. A hot footbath may be taken concomitantly, ending with cold water or spray to the feet. Cold compresses may be applied to the forehead or back of the neck during treatment. Hot applications to the pelvis are contraindicated during menses, in pregnancy, and in cases of acute inflammation.

A neutral sitz bath is typically taken for a longer duration of 15 minutes to 2 hours. Warm water may be added to maintain temperature as needed. It has a calming feature, appropriate for acute inflammation, and may offer relief of pruritus. A hot footbath is optional with a neutral sitz bath, and a blanket placed over the patient's upper body may be used to prevent chilling.

A cold sitz bath is used primarily for its tonifying effects—increasing the tone of the smooth muscle of the bladder, uterus, and colon. It offers support for atonic constipation, incontinence, metrorrhagia, subinvolution of the uterus, and enuresis. Cold sitz baths significantly reduce edema[43] and pain after an episiotomy,[44] and aromatherapy could offer perineal wound healing in the postpartum period.[45] The duration of a cold sitz bath is typically 30 seconds to 8 minutes. The patient should be adequately covered to avoid chilling. The cold sitz bath often follows the hot sitz bath. In this case the level of the hot water should be located at least 1 inch above the level of the cold water, which helps prevent chilling.

Contrast sitz baths are a combination of hot and cold sitz baths. The duration of the hot sitz bath is commonly 3 minutes, followed by 30 seconds in the cold sitz bath. The procedure is repeated three times and always ends with cold. Contrast sitz baths are useful for increasing pelvic circulation and smooth muscle tone in the pelvic region. They are indicated for chronic pelvic inflammatory disease, chronic prostatitis, postpartum care, atonic constipation, anal fissures, and after surgical procedures such as hemorrhoidectomy.

Cold Friction Rubs

A cold friction rub is a whole-body friction treatment performed with a cold, wet coarse bath mitt or washcloth and applied in sequential order to the body. It may be used to enhance the effects of another cold treatment, after a heating treatment to prevent the client from becoming chilled, or as a stand-alone treatment to stimulate blood flow to the skin and as a general tonic. Cold friction rubs are especially supportive for immobile or bedridden clients who are not receiving circulatory stimulation through exercise.[46]

The client lies supine, undressed to his or her level of comfort and draped, except for the area being treated. The extent of water saturation of the mitt depends on the cooling effect desired and the health status of the client. The area of the body is treated until the skin becomes reddened. Each area of the body is treated, dried, and draped to retain the heat produced by the body.

This treatment is contraindicated for those who are chilled; have a sensitivity to cold; or have infected, damaged, sunburned, or sensitive skin.

Constitutional Hydrotherapy

Developed in the early 20th century by Dr. O. G. Carroll, the constitutional hydrotherapy method incorporates the use of alternating hot and cold compresses, along with electrical stimulation via sine-wave therapy. Also acting as a warming compress, this therapy is useful for a vast array of conditions; because of its gentle nature, it has very few contraindications when used under the care of a trained naturopathic physician or qualified hydrotherapist.

The therapy begins with the application of two hot towels applied to the patient's torso, extending from the collarbone to the hips. The hot towels are then covered by a wool blanket and left in place for 5 minutes. If the patient is chilly, he or she may need more blankets. At the 5-minute mark, another fresh hot wet towel is applied quickly to the patient's torso, followed immediately by a cold wet towel. The cold towel is left in place for 10 minutes while sine-wave pads are applied to the patient's lower thoracic region and abdomen. The cold towel is checked to ensure that at least the middle portion of the towel is warmed. The patient then turns over, and the sequence is repeated again (two wet hot towels to the back, covered by wool for 5 minutes, followed by a wet cold towel, covered by wool for 10 minutes or until warmed). Dr. Letitia Dick-Kronenberg, ND, is careful to point out that a patient is not to be wrapped with a sheet before applying the wool blanket.[47] She explains that the sheet chills a patient and that the wool blankets are simply applied on top of the towels.

When the hot compress is initially applied, it acts to dilate the superficial vasculature, increasing blood flow to the surface of the body. Once the cold towel is applied, it causes vasoconstriction, shunting the blood back to vital organs. The cold compress covered by wool is warmed by the recirculation of blood back to the surface of the body. The addition of sine-wave therapy allows for a much quicker treatment than a traditional warming compress treatment. The constitutional hydrotherapy treatment takes approximately an hour and always ends with the cold compress.

Constitutional hydrotherapy is used to boost the immune system and bring balance to body functions. A pilot study completed in 2008 at Bastyr University suggests that constitutional hydrotherapy can be safely administered to HIV+ adults and revealed a statistically significant increase in energy as well as increased physical functioning and quality of life.[48] Research by Kate Wiggin, ND, at the National College of Naturopathic Medicine showed a posttreatment increase in leukocyte circulation that remained elevated for 2 hours.[49] Research conducted by Mark Carney, ND, and Bryan McConnell, ND, demonstrated a host of changes in the body after constitutional hydrotherapy treatments. These include a decrease in body fat, increased vitality, decreased pain, and decreased cholesterol levels, to name a few.[50]

Wet Sheet Pack

The wet sheet pack procedure involves wrapping the undressed patient in a cold wet sheet and then covering the patient with dry blankets to insulate, control body temperature, and regulate moisture evaporation. It is recommended to use cold water between 15°C and 20°C for soaking the sheet, and the wet sheet pack must come into close contact with all areas of skin when applied. Dry blankets must be snugly wrapped at the neck and shoulders down to the feet to prevent any airflow and eliminate patient chilling.

The physiological effects of a wet sheet pack are determined by the duration of the treatment and the number of dry covering blankets to control evaporation. There are several stages of heat generation during the wet sheet pack. The first temperature effect is the cooling stage, lasting 5 to 15 minutes as body heat is removed by evaporation. The cooling evaporation stage is helpful for reducing fevers. In the cooling stage, the patient's body is attempting to warm the sheet back to body temperature; it is complete when the patient no longer perceives the wet sheet as cold. The degree of wetness in the sheet can be tailored for individual patient needs; weak and frail patients will require a well-wrung-out sheet, whereas vital patients can benefit from the toning effect of added sheet wetness.

The second neutral stage begins when the sheet reaches or slightly exceeds the temperature of the skin. Here, the property of derivation is acting upon cerebral blood flow by lessening the amount of blood in the brain, which induces a sedative-like stage and tends to induce sleep. The neutral stage can last from 15 minutes to an hour, depending on the vitality of the patient and how many dry covering blankets are used in the wrap. The more dry coverings, the sooner the completion of this stage.

The third stage is the heating and sweating stage. Here, the sheet pack has been warmed, and the rise in skin temperature causes superficial blood vessels to dilate and draw blood away from congested organs. The heating stage can last from 15 minutes to an hour.

Finally, as the patient's body temperature increases, the patient begins to perspire and eliminate toxins through various detoxification processes. Toxins such as those from alcohol, tobacco, coffee, and processed and refined foods can be removed via the diaphoretic process. Febrile patients will reach the elimination phase much sooner than the weak or frail, and all patients will require plenty of fluids (water, electrolytes, teas, etc.) to maintain adequate hydration. The detoxification phase can last up to an hour and should be promptly discontinued if the patient gets chilled or uncomfortable. Upon completion of the wet sheet pack, the patient's skin should be frictioned quickly with a dry towel before the patient redresses.

The wet sheet wrapping sequence and dry blanket applications are illustrated in detail in *Lectures in Naturopathic Hydrotherapy* by Boyle and Saine.[5]

Indications for the wet sheet pack include the following: fevers, insomnia, mania, delirium, restlessness, nervous exhaustion, hypopepsia, detoxification from substances, gout, bronchitis, common colds, influenza, jaundice, measles, scarlet fever, constipation, hepatic congestion, and splenic congestion. There are very few contraindications, but caution should be taken in patients with diabetes, poor circulation, or skin eruptions and in very weak or ill patients.

Colon Hydrotherapy

Colonic hydrotherapy is a healing tradition that has been used by nearly every culture across the earth. The ancient healing tradition of using water to cleanse the colon has been used in India for more than 5000 years in the Ayurvedic medicine methods. Worldwide, many prescriptions for enemas were found on Babylonian and Assyrian tablets. The earliest record of using an appliance to administer an enema is from in the late 14th century. These early methods used tubes or cannulas made of bone, reed, or metal attached to a bladder or sleeve made from silk cloths, animal skin, or an ox bladder. Enemas are documented to have been used by Chinese, Hindu, Greek, Roman, Sumerian, and African cultures.

Modern colonic equipment was introduced into the United States by Kellogg, Dierker, and Vattenborg in the early 1900s. These early machines used large amounts of water to flush the colon. Current equipment uses a disposable plastic speculum and tubing to avoid and omit any danger for cross-contamination between patients. Water pressure, flow, and temperature can be manipulated to maximize therapeutic goals and patient comfort.

Effects of Colonic Hydrotherapy

The effects of colonic hydrotherapy include the following:

1. Removal of solid fecal matter from the colon. Solid fecal material can cause distension of the colon and contribute to prolapse. Hardened fecal material interferes with motility and results in constipation. Decreased physical stress by removal of such material will allow the colon to maintain optimal anatomical position, function, and tone. Pathogenic bacteria and parasites can be removed, thereby relieving the imbalance of putrefactive organisms that contribute to dysbiosis. Also, undigested foodstuffs in the colon will result in overactive fermentation, putrefaction, and rancidification of macronutrients, which encourages the growth of pathogenic bacteria and decreases the growth of healthy bacteria.[51]
2. The removal and dilution of toxins during colonic hydrotherapy allows for a decrease in the overall toxic load on the body through the enterohepatic recirculation. Elimination of toxic metabolites serves to prevent colon cancer and helps increase the growth of beneficial health-promoting bacteria. The removal of toxic compounds produced by colonic bacteria decreases the risk of colon cancer formation due to the dilution and removal of such compounds.
3. Cellular detoxification is augmented with colonic irrigation. Cells will readily release their waste products in a hypotonic solution of water. Cells also become oxygenated through the colon wall by dissolved O_2. Several forms of oxygen can be added to the water, such as ozone or H_2O_2.
4. The water temperature will affect the muscular function of the colon. Warm water between 98°F and 102°F will relax the muscles and decrease spasm. Cool water between 90°F and 95°F will stimulate the muscles to contract to improve tone. This is very helpful with atonic constipation. Retraining the muscles of the colon will address constipation and produce normal daily formed bowel movements.

Indications for Colon Hydrotherapy

Many systemic diseases can be relieved by the removal of toxic material from the colon. Headaches, premenstrual syndrome (PMS), arthritis, dermatitis/eczema, and neurocirculatory disorders are all aggravated by bowel toxemia.[51] The symptoms of PMS are associated with high levels of unconjugated estrogen, which are hepatotoxic. Colon irrigation detoxifies the liver and allows for normal liver function through lavage of toxins via the enterohepatic circulation. Detoxifying the colon takes the burden of detoxifying the entire system off the liver. A liver overburdened by diseases such as cirrhosis, hepatitis, or fatty infiltration; chronic exposure to toxins from alcohol, drugs, solvents, and heavy metals; or chronic exposure to endotoxin is unable to handle the full load, and toxins therefore spill over into the systemic circulation. When toxins enter the bloodstream, they travel to other organ systems, causing tissue damage and destruction usually in the weakest organ system first. This theory to explain disease was coined "autotoxemia" by Dr. John Henry Tilden (1851–1940) in the book *Toxemia Explained,* first published in 1926.

When the liver is overburdened from exogenous or endogenously produced toxins, we see the skin become burdened to eliminate the toxins, and conditions such as acne, eczema, and psoriasis result.

Many autoimmune conditions, such as rheumatoid arthritis (RA), multiple sclerosis (MS), and ankylosing spondylitis (AS), have an overgrowth of pathogenic bacteria in susceptible individuals. Gut bacteria cross-react with genetic markers on the cells of patients with RA, MS, or AS, which can trigger the onset of symptoms. Hashimoto's thyroiditis, Reiter's syndrome, and iritis have also been linked to cross-reactivity with pathogenic gut bacteria.[52]

Colon hydrotherapy eliminates bile from the enterohepatic circulation. Bile removes toxins; therefore overall detoxification is supported. Bile is also acidic in nature, and its removal promotes alkalinity in the tissues, which is health promoting. Colon hydrotherapy can also increase the rate of bile synthesis and secretion by 20%.

Bowel tonification through colon hydrotherapy will address chronic constipation, atonic colon, spastic colon, irritable bowel syndrome (IBS), and neurogenic colon from plegic traumas.

Colon irrigation is effective during fasting protocols, during drug and alcohol detoxification, and in preparation for a colonoscopy procedure.

Contraindications for Colon Hydrotherapy

Contraindications include acute ulcerative colitis, acute Crohn's disease, acute abdomen/appendicitis, colorectal cancer, congenital megacolon (Hirschsprung's disease), acute diverticulitis, and neurogenic

constipation from diabetes. Due to the increasing levels of fluids during colon irrigation, other contraindications include hypokalemia, congestive heart failure (CHF), kidney disease/renal failure, active hemorrhage in the gastrointestinal (GI) tract, and uncontrolled hypertension (HTN). The use of colonic irrigation is avoided in acute stroke; during pregnancy or nursing; and in patients with an aneurysm, bowel perforation, severe anemia, acute abdominal hernia, or recent colorectal surgery.

It is advised to take precautions when using colon hydrotherapy in the deficient, fragile, elderly, or very young patient. Patients with diverticulosis, fecal impaction, long-term steroid use, symptomatic painful fissures or hemorrhoids, hepatitis, and AIDS can be directed to use enemas at home for the treatment of these conditions as a safeguard against aggravation of the condition.

Additives for Implantation

Herbal solutions are common additives for rectal use during colon hydrotherapy. Chlorophyll or wheatgrass will provide nutritive, anti-inflammatory, antioxidant, and soothing effects to help heal the cells of the colon. Chlorophyll provides an alkaline environment and provides electrolytes. Solutions with sodium, potassium, and magnesium will support electrolyte balance, healthy hydration, and smooth muscle contraction (peristalsis).

Retaining coffee implants for 10 to 15 minutes during colon hydrotherapy promotes bile elimination via gallbladder emptying. Organic coffee with higher amounts of caffeine and palmitic acid are used in the Gerson and the Kelley programs to address cancer and chronic disease. In addition, theophylline and theobromine (two other chemicals in coffee) dilate blood vessels and counter inflammation of the gut. Palmitates enhance the enzyme system responsible for the removal of toxic free radicals from the serum, and the fluid of the colonic then stimulates the visceral nervous system to promote peristalsis and the transit of diluted toxic bile from the duodenum and out the rectum.

All the blood in the body passes through the liver every 3 minutes; therefore "colon irrigation represents a form of dialysis of blood across the gut wall."[53]

It has been clinically proven that the compound berberine from goldenseal and Oregon grape provides full-spectrum antibiotic benefits in the treatment of infections of the mucous membranes and parasites while also helping decrease inflammation of the gallbladder and liver. A tinctured berberine implant will have direct action on *Staphylococcus* spp., *Streptomyces* spp., *Chlamydia* spp., *Pseudomonas* spp., *Escherichia coli, Giardia lamblia,* and *Candida albicans*.

Garlic has also been proven to provide broad-spectrum antimicrobial effects against many bacteria, viruses, parasites, and fungi. Garlic is also effective against roundworms and hookworms.

Inflammatory conditions of the colon can benefit from demulcent herbal implants, such as slippery elm, marshmallow root, licorice root, comfrey, and plantain, to help heal and soothe the mucous membranes.

Astringent herbal implants will help dry, tone, and constrict mucous membranes through various phytochemicals, of note for their rich tannin content. Goldenseal, yarrow, bayberry, burdock, myrrh, and yellow dock are used to alleviate various digestive disorders.

Antispasmodic herbs are useful to support normal, rhythmic colon peristalsis; chamomile, catnip, and peppermint will benefit spastic constipation.

Rectal oil infusions of sesame, flax, or olive oil will aid in the removal of hard, retained stool or impacted feces, as well as support dry mucous membranes resulting from many pharmaceutical medications.

Practical Procedural Techniques

Before colon irrigation, it is important to have the patient fully empty the bladder. Then the patient is directed to lie in the lateral decubitus position, facing away from the colon irrigation equipment for speculum insertion. Single-use sterile specula and flexible tubing come in various sizes (adult and small child) and shapes (one or two pieces); most adult patients will require a single-piece speculum. Patients with hemorrhoids or degrees of uterine or bladder prolapse will require a two-piece speculum for comfort of insertion and to minimize tissue prolapse interference during releases. The insertion of the speculum should not hurt if it is properly lubricated with organic coconut oil or sterile lubricating jelly. A slow, steady insertion with deep, full, open-mouth breathing will help relax the internal and external anal sphincters. Once the speculum has been inserted, most patients will benefit from assistance turning on their back for the remainder of the therapy. A supported supine position will allow the therapist to assess the placement of abdominal organs/viscera and the level of congestion, bloating, or tightness of the tissues. A pillow should be behind the head to prevent any neck strain, and a bolster should be placed under the knees to relax the abdominal muscles and hip flexors. Always assess the patient's abdomen with palpation to establish a baseline and identify any areas of tenderness, gas, hardness, or fascial restrictions before beginning the water flow.

The average time for a colon hydrotherapy session is 45 minutes to 1 hour from start to finish. There are several options for water flow into the patient; gravity fills are very gentle and easily tolerable because they derive pressure from the force of gravity. Water is flowing from a height above the level of the patient to allow for 1 psi of natural water pressure.

Pressurized fills have an upper limit for the colon of 2 psi; this safeguard is built into current technology and equipment. Pressured fills can benefit patients who require a more vigorous treatment or when gas or stool clogs the speculum. Most patients release best with gravity fill cycles and pressurized release cycles. The goal is to maximize the efficacy of the water to enter the colon without overwhelming the patient. Most fills will take about 1 to 3 minutes or around 3 to 4 quarts of water to stimulate releases. The client could experience abdominal pressure or resistance as the water is pushing past gas, fecal material, or flexures of the colon; deep breathing and tension relaxation will help should that occur. When the release valve is opened, abdominal massage release techniques and nervous system support will optimize the expulsion of fecal and waste water.

Some patients may benefit from side-lying during the entire colon hydrotherapy session. Side-lying will assist the release of trapped gas and is also helpful in obese patients with tissue requiring more support to allow for the speculum to stay inserted and the tubing to be unobstructed.

If a patient is experiencing water leaking during the fill and release cycles, this is usually due to poor rectal tone or a degree of sigmoid prolapse; side lying and Kegels with cooler water fills will help support the seal between the speculum and rectum.

Treatment Analysis and Expectations

Possible patient reactions during colon hydrotherapy include nausea, abdominal cramping, dizziness, and hot flashes or chills. These reactions are all considered normal and can be moderated by coached breathing, frequent verbal check-ins, pelvic tilting adjustment, and diaphragm or chakra releases. Autonomic system discharges can occur and present with flushing of the skin, sweating, clamminess, muscle fasciculation, or emotional releases. The use of essential oils on the soles of the feet, over the liver, on the chest, or for inhalation will assist in mitigating nervousness and supporting emotional balancing.

The equipment observation tube allows the physician to interpret the fecal material released. Fresh, well-formed stool is normally yellow to light brown in color. Darker brown or black stool indicates prolonged retention or excessive bile secretion. Small, round, hard balls of stool are seen in all cases of constipation. Black, tarry stool can indicate the presence of blood from the upper bowel or ingestion of iron supplements or bismuth. A greenish color can be seen during gallbladder flushes when the bile is flowing and being released quickly; gallstones are often seen. Pale gray stool indicates impaired bile excretion, often found with liver or gallbladder disease. Bright red blood is observed with acute hemorrhoid or colon cancer, whereas pinkish-red waste and water is seen after the consumption of beets. Mucus-coated stool indicates inflammatory conditions such as inflammatory bowel disease (IBD), parasitical infections or dysbiosis, stress, or food sensitivities. Greasy stools and tubing indicate improper fat digestion, whereas foam in the tube indicates excessive fermentation, such as what is seen with bacterial imbalances or overgrowth.

Sauna

A Finnish proverb reads: "The sauna is Finland's medication and a poor [person's] apothecary."[54] The word *sauna* often indicates a bathhouse or spa in many parts of the world. Saunas have been an integral part of Finnish tradition for 2000 years, spreading throughout all of Europe and North America. Early saunas were made from natural materials such as wood, stone, clay, skins, and cloth. The heat source of these saunas was rocks that had been placed in a fire or water that was heated by fire.

With the advent of modern technology came new ways of constructing heat therapy besides a wood-burning fire. Other types of saunas include those heated by gas-burning stoves, electric light bulbs, electric heaters, smoke, steam heat, and infrared energy.

Conventional saunas can be divided into two types: dry heat or steam applied to the entire body inside a wood-paneled cabinet, room, or chamber. Dry-heat saunas and steam rooms will raise the core body temperature, induce sweating, and increase the heart rate. Their effects on the respiratory tract differ; breathing steam room air provides a 100% humidity level, which soothes the mucous membranes of the upper nasal passages, throat, and sinuses and lower respiratory tree, whereas dry-heat saunas are between 10% and 20% humidity.

Saunas will increase epithelial circulation from 5% to 10%, becoming 50% to 70% of the cardiac output, whereas blood flow to internal organs decreases.[55] The increase in skin circulation promotes the healing of wounds, minimizes scar tissue, and aids the recovery of muscle tissue from trauma or exercise. The increased circulatory effect, along with the opening of epithelial cells, will provide a way for toxins to be removed from the body system. Toxins removed by saunas include solvents, pesticides, insecticides, heavy metals, phenols, formaldehyde, bisphenol A (BPA), polychlorinated biphenyls (PCB), and volatile organic compounds (VOCs). Naturopathic physicians should incorporate the use of saunas into any detoxification or weight-loss program.

Saunas can decrease rheumatic pains and increase joint mobility in patients with arthritis, and they can provide relief in chronic pain syndromes such as fibromyalgia. Saunas will also relax spastic or stiff muscles.

The hemodynamic effect of sauna bathing has been documented to support the lowering of systolic and diastolic blood pressure, improved cardiac ejection in congestive heart failure, and enhanced pulmonary function to alleviate asthmatic conditions. Cardiac output increases by 60% to 70% in relation to the increase in heart rate, whereas cardiac stroke volume does not change.[56] Contraindications to sauna therapy include unstable angina pectoris, recent myocardial infarction (MI), and severe aortic stenosis.[57]

A modern technology called infrared sauna was invented in Japan in the mid-1960s. Infrared saunas raise the body temperature directly via radiant heat rather than heating an entire room. The use of far-infrared rays invigorates cells, promoting cellular metabolism and renewal. Far-infrared radiation saunas transmit a specific bandwidth of between 5 to 15 microns to human body cells via a process called cellular resonance. This absorption supports the release of waste products and fat-soluble toxins from the body's tissues (Fig. 40.2).

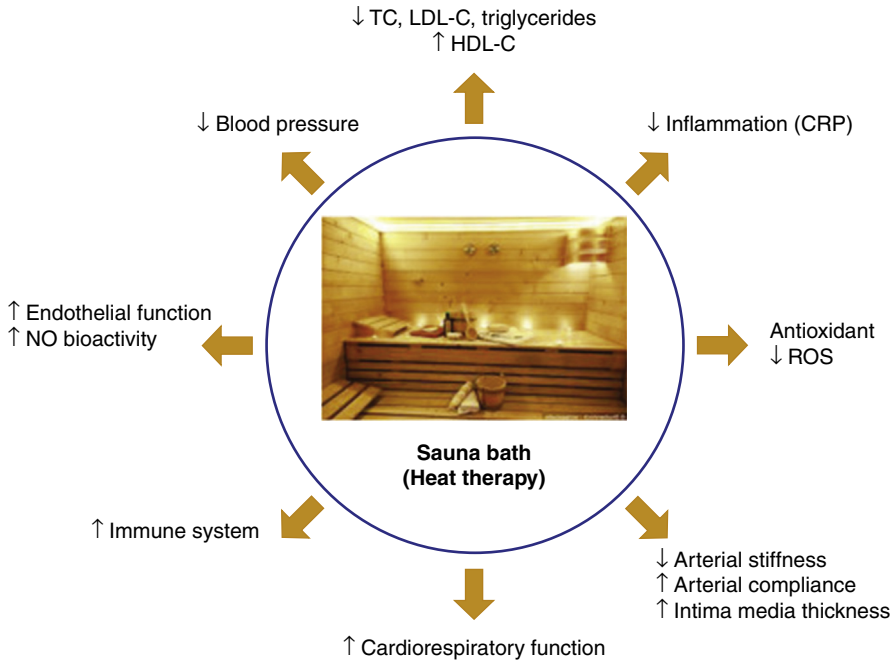

Fig. 40.2 Pleiotropic effects (proposed mechanistic pathways) of Finnish sauna baths. *CRP,* C-reactive protein; *HDL-C,* high-density lipoprotein cholesterol; *LDL-C,* low-density lipoprotein cholesterol; *NO,* nitric oxide; *ROS,* reactive oxygen species; *TC,* total cholesterol. (From Laukkanen JA, Laukkanen T, Kunutsor SK. Cardiovascular and other health benefits of sauna bathing: a review of the evidence. *Mayo Clin Proc.* 2018;93[8]:1111–1121.)

Local Steam Inhalation

When water is heated and converted to steam, the vapor consists of minute water droplets in the air that can be inhaled to warm and relax the respiratory tract. Steam inhalation will liquefy mucus secretions, making them easier to expectorate from the sinuses and lung passages. Spasmodic cough, bronchitis, and asthma can be relieved through the relaxation of the bronchial tree and increased circulation. Steam inhalation is contraindicated with CHF or any severe compromise to the cardiovascular system due to the potential for breathing difficulty with steam.

SUMMARY

This chapter provides an overview of the history of hydrotherapy and its foundational role in naturopathic medicine today. The information provided here serves to alert and inform both the physician and patient of the benefits provided by hydrotherapy, any cautions or contraindications, and the supplies and equipment needed to apply it in a safe manner. Understanding the physiological effects of water and following the general guidelines for hydrotherapy techniques allow for the stimulation of the body's vital force and immune system to facilitate the natural healing process. Literature demonstrating scientific, evidence-based applications of water continues to shed light on this long-standing, versatile, and powerful healing modality.

Manipulation

Terry M. Elder, DC, and *Robert M. Martinez*, DC, ND*

OUTLINE

THERAPEUTIC KEYS

Manipulation is a passive manual maneuver that introduces movement beyond the passive range of motion (ROM) through the elastic barrier but does not exceed the anatomical barrier.[1] Mobilizations are passive stretches with or without oscillations over which the patient can exert control.[2] Naturopathic, chiropractic, and osteopathic professions use adjusting techniques that range in force from a nearly imperceptible force to high-velocity thrusts causing joint cavitation (popping noise). It should be known that the terms *adjustment* and *manipulation* are synonymous.

As a prudent starting point, the initial evaluation should determine whether manipulation of the patient is appropriate, seeking out "red flags" that contraindicate manipulation, such as fracture, infection, neoplasm, progressive neurological deficit, cord pressure, or cauda equina syndrome.[3,4]

For an extensive list of contraindications and precautions concerning manipulation, see Table 4.1, page 93, in *Chiropractic Technique, Principles & Procedures,* 3rd edition, by Bergman and Peterson.

- A correct differential diagnosis is crucial to the selection of patients, and the functional assessment is crucial to the selection of appropriate manual medicine techniques.[5]
- If gross signs of inflammation are present in a joint (heat, swelling, redness, and pain), and repeated movement to end range (ER) worsens the signs, manipulation in that direction would most likely aggravate the condition.
- When bringing the joint complex to tension, if the pain peripheralizes, it is a relative contraindication to manipulation.
- The practitioner should be alerted that an adverse outcome is likely from manipulation when repetitive motion with progressive force in the direction of the manipulation peripheralizes pain and reduces function.
- Relaxation techniques (heat, muscle work, and calming environment) are helpful to patients complaining of anxiety, muscle tension, stiffness, and aching before manipulation.[6]
- "The goal of manipulation is to restore maximal pain-free movement of the musculoskeletal system and postural balance."[7]
- Do not treat muscle spasm as a primary condition. Muscle spasm is almost always a response of the body to a noxious stimulus. Find the cause and treat it.[8]
- Trigger points are myofascial irritations that are frequently caused by underlying joint fixations. Manipulation performed improperly at hypermobile segments can irritate a trigger point and can precipitate a muscle spasm later that day.[9]

HISTORY

Manipulations are depicted in prehistoric cave drawings and Chinese statues, circa 2700 BC,[10] but Hippocrates is credited with the earliest recorded written physician's prescription of manipulative treatment methods, which changed little until the 6th century. He advocated the key principles of judicious use of force, direction of thrust, and proper levering of joints.[11]

During the Dark Ages, priests provided medical treatment at their monasteries. Kessler stated: "Friar Moultan, of the order of St. Augustine, wrote *The Complete Bonesetter*. The text, which was revised by John Turner in 1656, suggests that manipulation was practiced in medical settings throughout the Middle Ages and Renaissance."[12]

Three main concepts developed during the 1700s still have a major influence on manipulation today. The first held that "vertebral luxation" (bone out of place) was responsible for spinal deformity. The second, the mainstream medical opinion, maintained that "caries of the spine" caused spinal deformity, which was treated with bloodletting and rest, while condemning extension and manipulation as both useless and dangerous and citing concerns about the potentially

*Previous edition contributor

disastrous effects of manipulating tuberculous, neoplastic, rheumatic, or fractured joints. The third held that muscles were the main cause of problems, and treatment should be complete rest or active exercise, as the case warranted.[11]

More recently, questions of vertebral disc herniation, precipitation of cerebral vascular accidents, controversial issues of the cost-effectiveness and efficacy of manipulative treatment, and the lack of a differential diagnosis by many nonallopathic manipulators have become the cause célèbre.

It is interesting to note the following:

- Hippocrates railed against the abuse of manipulative therapy by physicians and others of his time.
- Physicians of the late 1700s assailed one another's methods of treatment (e.g., in *The Lancet,* December 16, 1826, the banner on page 347 appropriately read, "THE YELLOW JOURNAL").
- Surgeons held "bonesetters" in great contempt "when they condescend[ed] to speak at all of bonesetters and their works."[10]
- Bonesetters held their secrets and passed them from father to son.
- Financial competition was noted early in the literature: "It is known to most practitioners of surgery, and has been made known to many to their great cost and loss, that a large portion of the cases of impaired mobility or usefulness of limbs after injury fall into the hands of a class of men called 'bonesetters.'"[13]
- Although there has been a great deal of animosity, and claims of superiority made by the various practitioners of manipulative treatment even to this day, "specific conclusions cannot be derived from the scientific literature for or against either the efficacy of spinal manipulative therapy or the pathophysiologic foundations from which it is derived."[14]

SCHOOLS OF THOUGHT IN MANIPULATION

Bonesetters of England

The bonesetters of England generally held that a bone was out of place and had a "feel" for what was wrong. Hutton described the information gained from a bonesetter as "bring[ing] some spoils out of the camp of the Philistines."[13]

Chiropractic

D.D. Palmer, the "founder" of chiropractic, rediscovered the principle of "lost nerve tone" in a revelation from a deceased friend, Dr. Atkinson, and reestablished this method of healing. D.D. Palmer and his son B.J. Palmer, the "developer" of chiropractic, added one of the most colorful pages to the history of manipulative treatment.

D.D. performed the first chiropractic manipulation on a deaf janitor whose hearing had been lost when he stooped over and felt something give in his back. D.D. reasoned that if the deafness occurred from something slipping out, restoring the vertebra to its correct position should cure the condition: "With this new objective in view, a half-hour's talk persuaded Mr. Lillard to allow me to replace it and his hearing was restored."[15]

Although there are multiple schools of thought in chiropractic, each with its own strengths and weaknesses, the literature supports the need to combine therapeutic exercise with manipulation. *Rehabilitation of the Spine, A Practitioner's Manual,* 2nd ed., edited by Craig Liebenson,[4] is considered a landmark publication by many in the field and addresses this topic at length.

Naturopathic

Almost all naturopathic techniques result from the blending of thoughts of the other schools of medicine. This is appropriate when one realizes there is little new in manipulation, only refining and relabeling. It is also appropriate that naturopathy does not lay claim to originating a school of thought on manipulation but uses this method of treatment when indicated, not exclusively but as part of a therapeutic regimen.

Several naturopathic schools in the past were associated with the chiropractic and eclectic schools of medicine. The genesis of the naturopathic profession is well documented in Chapters 3 and 4, History of Naturopathic Medicine.

Osteopathic

Andrew Still left the practice of allopathic medicine and started a school of osteopathy in Kirksville, Missouri. It is highly probable that the first chiropractor, D.D. Palmer, went to this school and learned some of the techniques, but it is not well documented. The famed "equal but separate" movement of the osteopaths led to a 1921 resolution, submitted at the American Osteopathic Association convention, that allowed the entrance of chiropractors with advanced standing into their schools. Andrew Still, before his death, saw the defection of his osteopathic profession into the ranks of medical orthodoxy.[16–18] Interestingly, manipulation is now only an elective segment in some American osteopathic schools, whereas in England, where osteopathy is not part of the medical establishment, manipulation is still the mainstay of osteopathic practice.

The resurgence of interest in manual medicine has been brought to the forefront by the Osteopathic College at Michigan State University. This school teaches manual medicine to physical therapists, doctors of medicine, and doctors of osteopathy. Greenman's[1] *Principles of Manual Medicine* adds a useful text to the field of manual medicine.

Allopathic

James Cyriax, James Mennell, and John Mennell were brilliant physicians who worked to reintegrate manipulation into medical practice. They wrote valuable texts on manipulative therapy, although they did not totally agree on the effects they achieved with manipulation. Both James and John Mennell held to the correction of lost joint play and denied the effect on the intervertebral disc,[19] whereas Cyriax claimed reduction of a protruding disc.[8]

"Controversy and contention" best describe the higher levels of the respective schools of medical thought. The impression one gets in reading through the literature is intolerance of others' ideas expressed in ad hominem attacks. The mistake "lay" manipulators and "nonphysicians" make is not ineffectiveness but their willingness to seek training outside the fraternal order of the "medical" brotherhood; to address the public directly rather than communicating exclusively within the order; and, worst of all, to openly compete, economically and politically, against the fraternal order.[11,13]

Donald B. Tower, in the chairman's summary at the National Institute of Neurological and Communicative Diseases and Stroke conference in 1975,[20] noted a physician who received little credit for his early contribution to the field: J. Evans Riadore, a London physician who wrote a treatise on the irritation of spinal nerves in 1843. He attributed many diseases to this condition, stating: "If any organ is deficiently supplied with nervous energy of blood, its functions immediately, and sooner or later its structure, become deranged." This was a viewpoint subsequently echoed by osteopaths and chiropractors.[20]

The fifth edition of *Spinal Manipulation* by Bourdillion et al.,[21] the first authors of which were medical manipulators, has been largely reworked from previous editions and heavily influenced by osteopathic methods.

Awareness of manual medicine has been fostered by Calliet, McNabb, Maigne, Maitland, Kaltenborn, Williams, Jirout, Lewit, Janda, Bogduk, McKenzie, and many others.

Physical Therapy

James Cryiax influenced Robin McKenzie, a New Zealand physical therapist who subsequently developed a systematic approach called mechanical diagnosis and treatment (MDT) of musculoskeletal conditions. It is a process of evaluation and treatment of musculoskeletal disorders based on a mechanical history and the patient's symptomatic and mechanical response to movement, positions, and loading.[4] McKenzie's approach is often prejudicially dismissed as "extension exercises for the low back." He proposed a new tack in the approach to back pain that was found to be highly effective in populations with acute and chronic back pain, as well as low in cost.[22] MDT includes McKenzie's observations that most conditions are self-resolving and that focus should be on prevention and recovery of function by teaching patients proper posture and self-management. After years of studying, performing, and researching manipulation, he felt that only 20% of patients needed manipulative therapy, and 80% could self-treat using ER loading strategies learned from books or practitioners.[23]

IS MANUAL MEDICINE THE RIGHT TREATMENT?

Patients with somatic pain caused by psychosocial factors often seek a physical cause and treatment for their pain. If the presenting complaints do not seem to follow a mechanical pattern and the pain diagram is nonanatomic, consider the possibility of psychosocial factors. Psychosocial workplace factors associated with risk of spinal injury include job dissatisfaction, stressful working conditions as perceived by the employee, employer practices reported as being unfair, poor coping skills, lack of recognition at work, low supervisor support, a high frequency of job problems, and negative beliefs of or attitudes toward the consequences of having "low back trouble."[24,25] A major factor in identifying the incidence of future pain is the patient's perception of being disabled.[26] If the patient's history and records include previous evaluations by multiple providers with conflicting and confusing reports from the patient, caution is advised in approaching the management of the patient. If in doubt, seek a consultation with an astute colleague, physiatrist, or appropriate specialist.

Is It Safe to Move?

A clinician must answer the question, "Is it safe to 'move the patient' using conservative therapies, exercise, mobilizations, and manipulations?" Red flags have been shown to have many false positives, resulting in unnecessary additional diagnostic testing. Recent studies showed less than 1% of patients presenting to general practitioners with conditions that warranted further diagnostic evaluation. Red flags are a source of unnecessary medical interventions. When the medical history and examination indicate a serious disease, neurological compromise, or progressive neurological deficit, further evaluation or consultation is warranted. Although the question of safety is usually answered by the provider's clinical training, a general outline of triage is presented as a starting point to help determine whether further evaluation is indicated before initiating or continuing care.[27]

Signs of Neoplasm

The combination of age over 50 years, a history of cancer, unexplained weight loss of more than 10 kg (22 pounds) within 6 months, failure to improve after 1 month of conservative care, and an elevated erythrocyte sedimentation rate (ESR) have a sensitivity of 100% in identifying patients with a neoplasm. Night pain, especially pain that prevents the patient from getting sleep or "drives them from the bed" also generates a high degree of suspicion.[28,29]

Signs of Infection/Inflammation/Illness

Heat, swelling, pain, redness, and loss of function are the cardinal signs of inflammation. Acute inflammation lasts from 1 to 3 days, and chronic inflammation usually is considered from 7 days to 7 weeks but may last up to 12 months. The stages between acute and chronic inflammation overlap, and a continuum exists.[30] The clinical picture may be confused by chronic pain.

Laboratory tests may show signs such as an elevated C-reactive protein, ESR, or other tests for inflammatory arthritides. Signs of infection may be as simple as a low-grade fever, chills, a shift to the left in the white blood cell count, signs of a worsening chronic illness, or frank presentation of an acute illness.[31] Clinical signs are pain that is constant 24 hours a day, described as aching, throbbing, or burning and aggravated by movement, with no position that gives relief.

Manipulation is contraindicated over an area of acute inflammation, but acute pain may be the result of mechanical pain. This confusion can usually be resolved during the palpatory process. During palpation, an acutely inflamed joint will exhibit deep pain upon pressure and movement. This deep pain will persist long after palpation is concluded. Palpation of a manipulable joint restriction will also cause pain, but only as long as the palpation pressure is applied. Treatment of the tissues should be guided by the level of inflammation and the response of the tissue to mechanical testing, according to MDT methodology, to determine whether the patient should rest or pursue specific therapeutic movements. Observe the posttreatment results to see if signs of inflammation worsen, indicating incorrect application or inappropriate therapy.

Signs of Neurological Disorder or Progressive Neurological Deficit

A loss of sensation, decreased or absent deep tendon reflex, loss of muscle strength, and positive nerve root tension are signs of nerve root involvement. If only these neurological findings are present and do not become progressively worse, appropriate conservative care may be effective.[32] Dizziness, drop attacks, diplopia, dysarthria, dysphagia, numbness, nystagmus, and nausea are more concerning signs of central nervous system involvement. Loss of bladder or bowel control or saddle anesthesia requires urgent evaluation with magnetic resonance imaging of the lumbar spine. If progressive neurological deficit of weakness, loss of sensation, and loss of function, or the previously mentioned signs and symptoms, are present, a consultation with a competent colleague, physiatrist, or neurosurgeon is indicated.

Signs of Fracture

A fracture typically has an obvious traumatic cause when the patient is young or middle-aged. It should be noted that even in the young and middle-aged, something as simple as chronic bronchitis with severe cough can result in rib fracture; therefore diagnostic caution is always warranted. In older patients, pathological fractures are a concern, especially if there is a history of prolonged or repeated steroid use. Be wary of occult fracture after motor vehicle accidents or athletic injuries and nontraumatic fractures in the elderly. The red flags suggesting vertebral fracture are age more than 50 years, female sex, major trauma, pain and tenderness, and a distracting painful injury. In particular, look above and below the site of injury, because the force of trauma may be transmitted and cause a fracture some distance from the site of impact.[33] In a pelvic fracture, there is always a fracture in two places in the ring.[34]

Is the Best Treatment Movement or Rest?

Pain can be confusing and lead one to conclude that inflammation is present. If pain is constant aching, throbbing, or burning, it suggests

that the pain has a chemical cause, and it is inflammation. When the pain goes away, even for 30 minutes in a day, it suggests that the pain is due to mechanical pressure on tissue. To illustrate this point, bend your finger backward until you feel strain and hold it. At first you may only feel discomfort, but after an extended period of time, it will become painful. Next, try bending the finger backward beyond strain until it hurts. The pain you feel is due to abnormal stresses on a normal tissue; there is nothing wrong with your finger! You do not need drugs, modalities, or manual therapy. Simply stop overstraining the soft tissues. Robin McKenzie used this seemingly simple example to teach the consequences of sustained ER loading as a common cause of pain—mechanical pain rather than pain from inflammation.[23]

If the pain is caused by inflammation, it is best to rest until the inflammation has been reduced. If the pain is mechanical, it is often best to move, but how far should one move, and in which direction?

Which Direction to Move?

Common approaches to determine which direction to move the patient are orthopedic tests, selective tissue tension tests, and McKenzie's MDT. Each can inform the practitioner of which tissues are involved and help formulate an appropriate treatment program.

Orthopedic Tests

Orthopedic tests are designed to stress the damaged tissue and reproduce the pain of the primary complaint. The examiner is not looking merely for pain to be reported as a result of the maneuver but, rather, pain that is specific for the test and reproduces the pain of the primary complaint. Therefore the following should be remembered:

- The examiner can make the patient worse by forcing tests or performing them incorrectly.
- The least stressful tests should be done first. If the first test causes severe pain, most of the other motions will be painful afterward and confuse the findings.
- The test by definition has a positive response, which correlates to a specific condition that must be produced when the test is performed for the test to be positive (e.g., Lindner's test and Soto Hall's test are performed in the same way, but the findings to report a positive test are different).
- The test must reproduce the pain of the primary complaint and be positive by the test's definition.
- Tests are centered in allopathic medicine to diagnose pathology, fracture, moderate to severe sprain/strain, and dislocation. Although the patient feels pain from the movements of these tests, these are not true positive tests just because the patient reports that the movement hurts.

When multiple orthopedic tests are indiscriminately performed on one visit, without an understanding of the mechanism of action of the stress these maneuvers put on the tissues, the unwitting examiner merely subjects the patient to the trauma of a series of painful maneuvers that only serve to confuse the practitioner and aggravate the patient's condition. Detailed texts that cover this area include those by Magee[35] or Evans[36]; such texts are helpful and should be referred to for additional information. It is even more helpful to attend programs in which experienced practitioners teach skills and knowledge to inexperienced practitioners.

Selective Tissue Tension Tests

This section provides an introduction to the differential diagnosis of soft tissue injuries by means of active and passive movements using the selective tissue tension tests of James Cryiax[8]; this topic is covered in depth by Kessler[12] and Magee.[35]

Active movements. First, active ROMs are performed to determine voluntary ROM and patient status. Measuring active ROMs cannot differentiate whether the loss of function is due to pain, weakness, stiffness, and/or lesion, but it is helpful to determine patient tolerance to motion and how guarded the patient is when moving.

Resisted isometric tests. Next, isometric muscle tests are performed to test the contractile tissue (muscle and tendons) with the joint in neutral to avoid involving the noncontractile tissues. The following results may be noted:

- Normal—painless and full strength
- Minor tear—pain with full strength
- Moderate tear—pain with little strength
- Neurological deficit—no pain and little strength

Passive movements. When the joint is put through passive motion, it reaches an end point, which has an "end-feel" that helps determine the status of the soft tissue around the joint. The end-feel of a joint may be one of the following:

- Normal—the amount of motion and feel of the tissues are appropriate for age.
- Abnormal—normal end-feels that are not normal for the joints and ROMs that are being tested (e.g., the feeling of bone on bone is the normal end-feel at the elbow when extended but is abnormal when it occurs at the ER of knee extension).
- Pathological—these end-feels are present only in joints that have undergone pathological changes.

Normal end-feels

Capsular end-feel. This is a firm, "leathery" feeling, felt, for example, when the normal shoulder is at full external rotation. When felt in conjunction with a capsular pattern of restriction, and in the absence of significant inflammation or effusion, it indicates capsular fibrosis.

Bony end-feel. This feels abrupt, as when moving the normal elbow into full extension. When accompanying a restriction of movement, it may suggest hypertrophic bony changes, such as those that occur with degenerative joint disease, or possible malunion of bony segments after healing of a fracture.

Soft tissue approximation end-feel. This is a soft end-feel, as when fully flexing the normal elbow or knee. It may accompany joint restriction in the presence of significant muscular hypertrophy.

Muscular end-feel. This more rubbery feel resembles what is felt at the extremes of straight-leg raising (SLR) from tension on the hamstrings. It is less abrupt than a capsular end-feel.

Abnormal end-feels. The tissue involved is determined by the response to the passive ROMs and by moving the joint to ER and into closed pack position.

Muscle or tendon. Active and passive movements are limited or painful, or both. Pain is caused by active contraction or passive stretching of the inflamed or torn muscle–tendon unit.

Ligaments. Both active and passive movements are limited or painful, or both, in the same direction due to stretching of the inflamed or torn ligament.

Capsular pattern. Only joints that are controlled by muscles have a capsular pattern. Pain is caused by both active and passive motions, and the limitation of motion is in a specific proportion that is listed in tables in Kessler's text.[12]

Pathological joint end-feels. Pathological joint end-feels indicate a disease process; they are limited and are never normal:

- Empty—bursitis, space-occupying lesion, neoplasm
- Boggy—joint effusion
- Spasm—guarding from inflammation
- Internal derangement—loose body/torn meniscus

McKenzie's Mechanical Diagnosis and Therapy

MDT is an invaluable system for practitioners who perform manual therapy. Rather than a technique, it is a method of diagnosis determined by response to repeated movement and pressure to joints and soft tissue that, once mastered, allows rapid assessment and selection of patients for treatment. It also identifies those not likely to respond to manual therapy so that the provider's treatment program can be altered, or the patient can quickly receive an appropriate referral. Resources available are classes from the McKenzie Institute on MDT, McKenzie's textbooks,[37,38] and a chapter in Liebenson's text.[4] Only a few of the many helpful concepts from the McKenzie method are covered in the following discussion. Keep in mind that McKenzie asserted that only 20% of patients needed manipulative therapy, and prevention is key to success in his model.

Centralization and Peripheralization

A cervical spine problem can refer pain to the shoulder blade, arm, forearm, and hand. A low back problem can refer pain to the sacroiliac joint (SIJ), buttock, thigh, leg, and foot. When the referred pain from the spine is brought closer to the midline in response to movements, position, or load, and remains reduced, it is called "centralization."[22] When the pain moves out from the spine in response to movements, position, or load, it is called "peripheralization." When a movement produces centralization, it is a motion to pursue for treatment. When a movement causes peripheralization, it is a motion to avoid because it will likely worsen the condition. If no movement or position centralizes the pain, it is a poorer prognosis for the response to the treatment method being used. Although this phenomenon is typically associated with vertebral disc problems, it can be observed in many musculoskeletal problems.

End-Range Pain and Pain During Motion

End-range pain (ERP) is felt only when the joint is moved to ER. It is a sign of deranged or adaptively shortened soft tissues around the joint complex. The importance is that this is an indication that stretching and mobilizing techniques should be used before manipulation. If the joint is not mobilized to ER repeatedly, the manipulation may cause aggravation of the complaint. When the joint is fully stretched, after a progression of forces described in the "Performing Manipulation" section, the practitioner can determine whether and in which direction the mobilization or manipulation is indicated.

Pain during motion (PDM) is pain that is felt during joint movement, as well as at the ER. The joint ROM may be restricted as well. PDM is a sign of soft tissue derangement, often thought of as a vertebral disc problem. Movements or positions that increase the PDM and cause increased restriction of movement after the movement is performed should be avoided. When a mobilization or manipulation increases PDM or restriction, it is important to find a motion or position that will reduce the PDM and restore the motion as soon as possible to reduce the irritation of the tissues. Application of ice, analgesic, and/or anti-inflammatory medications may be indicated as well.

PRETREATMENT ASSESSMENT

Functional Assessment

Often the focus is on injury, pathology, and disease, but the majority of musculoskeletal pain is from pathomechanics due to postural and repetitive strain, disuse, deconditioning, fatigue, and nutritional factors that must be addressed if treatment is to be successful. Once the portion of the patient's condition that is a musculoskeletal problem has been established, the mechanical fault should be determined. Manipulative treatment without correction of the mechanical fault results in prolonged treatment and recurrence. Detecting this is sometimes easy, whereas at other times it is a mystery that takes careful investigation, as discussed by McKenzie,[39] Greenman,[1] Lewit,[5] and Liebenson.[4]

Observe the posture of the patient. If he or she is tilted and antalgic to the side and/or forward, due to an episode of neck or back pain, it indicates a large space-occupying mass, which is most often the disc, but it could be other soft tissue or pathology. Proceed slowly and carefully, avoiding any movements that cause peripheralization, increase PDM, or increase the obstruction of motion.

Establish the baseline of the location of the complaint and its response to motion, and then repeat motions to ER. In the cervical spine, test flexion, extension, rotation, and lateral bending. In the lumbar spine, test flexion, extension, and lateral translation. The testing procedures are described in detail, with photos, in Liebenson's text.[4]

Note the ROM. If there are complaints at or below the shoulder blade or buttock, it is important to test reflexes, muscle strength, sensation, and nerve root tension signs to assess if the nerve root is affected. Additional tests can be added as indicated.

Cervical Spine

The cervical spine presents a diagnostic challenge (Fig. 41.1). Although the mechanism of the tests in the lumbar spine is similar, the area is much more delicate and thus requires more careful application.

There is considerable discussion of the topic of vertebrobasilar stroke (VBS) after manipulation of the cervical spine. Tests done in the office have not proved effective, but the history should alert the practitioner to the possibility of VBS insult, and manipulation is

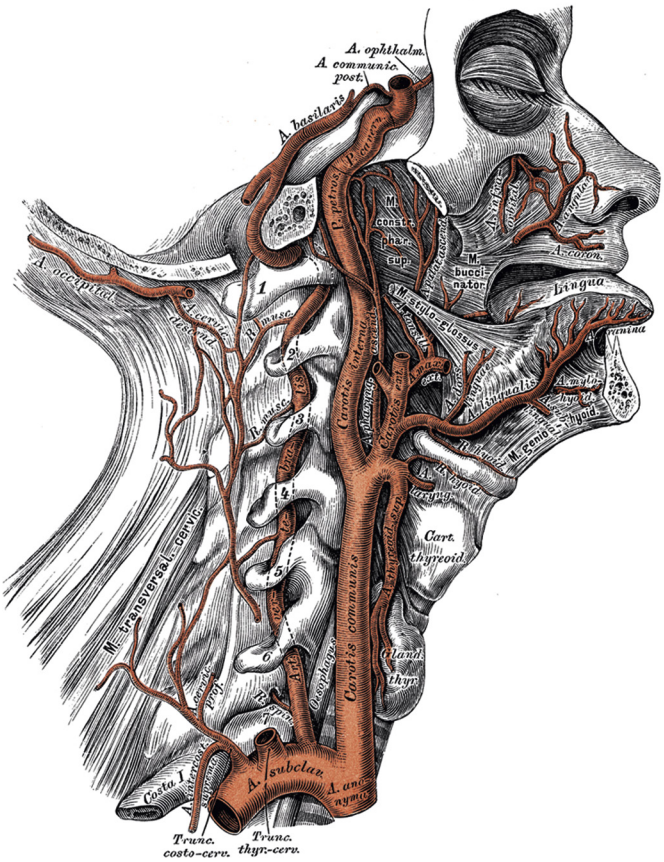

Fig. 41.1 Cervical spine. (From ilbusca/iStock.com.)

contraindicated. The presence of the signs listed in the section on Signs of Neurological Disorder is an important indicator that mobilization or manipulation should not be used. The most important risk factors identified by Terrett[40] are dizziness, unsteadiness, giddiness, vertigo, and sudden severe pain in the side of the head or neck, which is different from any pain the patient has had before. If the practitioner elects to follow the pattern of the progression of force, the occurrence of these symptoms in the early mobilizations contraindicates progressing the force and manipulation. However, VBS has occurred during an examination simply by having the patient turning his or her head. The incidence is small, but missing this clinical presentation is devastating, although not clearly caused by the evaluation or manipulative treatment.[41]

If there is compression of the nerve root or cervical instability, the patient may present holding the head, lifting it cephalically to decompress the spine and root, which is a clear indication to stabilize and transport immediately. Any such presentation is best handled by emergency department staff because even passive ROM assessment may cause permanent injury.

If there is irritation of the brachial plexus or a nerve root, the patient may support the arm in abduction and flexion, often resting the hand on the top of his or her head. This is a sign to proceed cautiously. Any movements that cause peripheralization must be avoided, and movements that produce centralization should be pursued. In cases where there are no deficits and all signs and symptoms are relieved by elevation of the arm, this may be the only treatment needed. If overt signs of nerve root compression are present, mobilization and manipulation must be performed with caution.

Cervical Distraction

If distraction of the head from the shoulders causes aggravation of the patient's complaints at 12 lb of traction (the average weight of the head), stabilization and relaxation techniques are indicated. If distraction of the head from the shoulders causes relief of the radiating pain at 12 lb of traction, slowly increase the traction to 25 lb. If this relieves the complaint of neck pain, it is an indication that mobilization and traction are indicated therapies. If it aggravates the complaint, it is an indication of inflammation or instability and suggests caution in using mobilization or traction.

Cervical compression that causes radiating pain to the arms is a sign that indicates nerve root irritation from the disc and is treated by symptom response that centralizes the arm complaint.

Maximum Cervical Rotation, Lateral Bending, and Compression

If maximum cervical rotation, lateral bending, and compression cause radiating arm pain, it is a sign of nerve root compression, and only a skilled practitioner should attempt manipulation in that direction.

Spurling's Maneuver

When combined cervical rotation, lateral bending, and extension with overpressure (Spurling's maneuver) aggravates or reproduces the complaint or causes radiating pain to the midback or arm, this indicates nerve root irritation, and manipulation in that direction places the patient at risk for aggravation of this condition. If the pain is local, it is a sign of facet irritation that often responds well to manipulation. The practitioner can test the response with repeat mobilization to the ER; if only ERP is produced, then increased force can judiciously be used.

After determining that the lesion is not a "hard" orthopedic or neurological lesion, differential tissue tension tests are used to determine the involved tissue. Appropriate repeated movements to ER and skilled mobilization and/or manipulations are identified by centralization of the symptoms and improved function.

Signs of Upper Limb Tension

Butler[42] described, in detail, the identification of signs of cervical root tension using upper limb tension tests developed by Elvy in 1979. The tests are useful to help guide treatment.

Lumbar Spine and Sacroiliac Joint

During supine SLR, the lumbar nerve roots begin to develop tension at about 35 degrees. If SLR causes leg pain below 30 degrees, it is likely due to stretching of the lumbar nerve root in the presence of a space-occupying lesion or significant hip pathology. SLR above 35 degrees causes increasing ipsilateral nerve root tension and ipsilateral hamstring tightness, and it may expose lumbar dysfunction or derangement as the straight leg moves toward ER. Once the painful ER is found, one lowers the limb to the pain-free range and then performs internal rotation and dorsiflexion of the foot and great toe (Fig. 41.2). If this maneuver causes a return of the leg pain, there is likely tension on the lumbar nerve roots. Because the SLR maneuver stresses multiple tissues, the test can be misleading, and it can be somewhat difficult to determine what a positive finding is until the practitioner's skills develop, but the positive result should be described to help clarify the findings.

Assessing Radiating Leg Symptoms

Following the principle of "Do no harm," one should test reflexes and sensation first, then proceed to active tests such as the Valsalva maneuver to test for increased intrathecal pressure. If radiating pain results from the Valsalva maneuver, it is a sign of a space-occupying lesion. Next, the practitioner should do SLR, adding dorsiflexion of the foot with extension of the great toe to determine whether the root tension reproduces or aggravates the radiating leg symptoms. Assessment with MDT protocols is recommended and is superior to standard orthopedic protocols for functional assessment. Commonly used tests are compression tests (Milgram's bilateral leg raising and Lindner's test [forcefully flexing the trunk while the patient is supine]); these force the disc posteriorly (if herniated) and cause increased intraabdominal pressure, resulting in increased intrathecal pressure (Valsalva effect).

Some additional ideas for finding the area of a lesion in the lumbar spine are as follows:

- Support Adams (the belt test)—With the patient standing, the doctor has him or her bend forward and notes the level of pain. The doctor then secures the patient's pelvis by hugging the anterior

Fig. 41.2 Supine straight-leg raise (Lasegue) test. Jan-Otto/iStock.com.)

superior iliac spines with the arms, pressing the patient's sacrum into the doctor's hip. If the patient's pain is decreased, it indicates the lesion is in the pelvis (probably the SIJ or hip); if pain increases, it is in the lumbar spine.

- Patrick's test—Flexion, abduction, and external rotation of the hip are blocked; this causes pain over the inguinal fossa and into the thigh when a hip lesion is present.

This is only an introduction to one common problem that may present with many variations. A careful study of the mechanism of action of the tests used can confirm, rather than confuse, a diagnostic impression.

Assessing the Sacroiliac Joint

The SIJ is the "dumping ground" for pain from the lumbar spine, just as the shoulder blade is the "dumping ground" for pain from the cervical spine. The key to determining whether the problem is in the SIJ is to rule out all lumbar problems first. Second, Laslett[43] determined that when two or more of the following SIJ tests produce concordant pain, it is highly likely that the SIJ is the pain generator:

1. Gapping test—The patient is supine. The examiner crosses his or her arms, placing the heels of the hands on the anterior superior iliac spine, forcefully pressing laterally and down into the table to "gap" the SIJ, attempting to stretch the anterior SIJ ligaments.
2. Compression test—The patient is lying on his or her side with the painful SIJ up. The pressure is directed to the opposite iliac crest, attempting to compress the anterior SIJ and stretch the posterior SIJ ligaments.
3. Posterior shear or "thigh thrust"—The patient is supine. The practitioner's hand, a small block, or sandbag is placed under the patient's sacrum. The hip is flexed to 90 degrees (perpendicular to the floor), the knee is maximally flexed, and a thrust is applied down the shaft of the femur. One should avoid adduction of the hip, as this will cause pain in normal patients.
4. Pelvic torsion (Gaenslen's test)—The patient is supine at the edge of the table with one thigh extended over the edge of the table. On the other side, the hip and knee are flexed to the chest. Overpressure is applied to the extended thigh to accentuate the posterior rotation of the opposite side. This should be performed on both sides.
5. Sacral thrust—With the patient lying prone, the examiner thrusts down on the sacrum.
6. Cranial shear—With the patient prone, cranial pressure is applied to the apex of the sacrum with the examiner's hands, whereas the painful side ankle is placed between the examiner's knees and is tractioned caudally.

Techniques for correction of these fixations are described by Maigne,[44] Bourdillion,[21] and Maitland.[2]

TREATMENT CONCEPTS

Notes on the Art of Manipulation

Manipulation is an art. Assuming a proper differential diagnosis, one acquires a "feel" that allows recognition of the differences among the types of joint fixations and knowledge of when to manipulate.

When a movement causes pain, it should not be performed unless the diagnosis of the patient's condition is sure and the motion will cause no harm.[44]

Joint Motion

Joint motion descriptions can become elaborate, or one may simply say that there are six degrees of freedom of motion (plus long-axis extension): flexion, extension, left and right rotation, and left and right lateral bending. Not all joints have all six degrees of motion. The normal degrees and ROMs of joints are listed in anatomy and kinesiology texts (Fig. 41.3). If a degree of motion is lost or blocked, the type of fixation and which form of manual medicine is indicated should be determined.

Barrier Concepts

Joint motion is described from neutral to an ER that is ultimately limited by the anatomical barrier, which, if exceeded, causes tissue trauma. The extent of the active ROM can be increased by passive motion to a point at which all of the tissues around the joint have been brought to tension, called the elastic barrier.[1] Beyond the elastic barrier is a small ROM referred to as the paraphysiological space.[45] It is within the paraphysiological space that joint cavitation, the "popping" sound, occurs. When joints and soft tissues are dysfunctional, alterations of ROM may occur both within the ROM and at the end of it. If one focuses only on working in the paraphysiological space, one severely limits the effects that can be made on dysfunction.

Before using manipulation, think about the joint end-feel (the way the joint feels at the end of its ROM) and determine which pattern is present:

- Edematous and boggy end-feel—indicates joint effusion and possibly inflammation. Muscle spasms should not be treated as a primary condition because they are almost always the body's response to a noxious stimulus or pathophysiological fault. The best treatment for muscle spasm generally is to find the origin of the noxious stimulus or pathophysiological fault, which can be joint dysfunction at a distal site, nutritional deficiency of magnesium orP-5-P, and so forth (see Chapter 47, Soft Tissue Manipulation).
- Springy and taut end-feel—ligamentous fixations (as felt in the normal knee in lateral bending stress tests and drawer tests). Manipulation works well on these types of fixations. Surging

Joint		Normal Range of Motion (Degrees)
Shoulder	Flexion	0-180
	Extension	0-60
	Abduction	0-180
	Internal rotation	0-70
	External rotation	0-90
Elbow	Flexion	0-150
Forearm	Pronation	0-80
	Supination	0-80
Wrist	Flexion	0-80
	Extension	0-70
Hip	Flexion	0-120
	Extension	0-30
	Abduction	0-45
	Adduction	0-30
	Internal rotation	0-45
	External rotation	0-45
Knee	Flexion	0-135
Ankle	Dorsiflexion	0-20
	Plantar flexion	0-50

Fig. 41.3 Ranges of motion of various joints. (From American Academy of Orthopedic Surgeons (AAOS) as reported in Appendix B of Reese NB, Bandy WD. *Joint Range of Motion and Muscle Length Testing.* 2nd ed. St. Louis: Saunders; 2010.)

sinusoidal and interferential current, ultrasound, and moist hot packs facilitate the treatment. One can follow with cryotherapy in the subacute stages.

- Bone-on-bone end-feel—usually indicative of degenerative joint disease (as felt in the normal elbow in extension). If there is fine crepitus, mild degenerative joint disease (DJD) may be present; coarse crepitus indicates moderate DJD, and joint creaking may be advanced DJD. Diathermy, contrast baths, and other naturopathic therapies indicated in osteoarthritis are helpful.

Preparation for the Manipulation

The room should be at a comfortable ambient temperature, and the physician should wear no watches or jewelry that might catch the patient's hair or skin.

Performing Manipulation

Manipulation of a joint is performed to correct joint fixation. Once the area to be manipulated has been appropriately assessed:

1. Test the direction of manipulative thrust with repeat mobilization to ER to ascertain that the pain does not peripheralize, the movement does not increase PDM, and the movement does not result in increased obstruction to motion from mobilization, using a progression of force to determine the effect of the direction and force applied.

This is a logical stepwise progression of the force generated first by the patient, then by the practitioner. The advantages are increased patient comfort, ability to "test the waters," and decreased risk of harm from the procedure. The steps are as follows:

Patient-generated force—the patient does all the motion actively.

Patient-generated overpressure—the patient uses a strap, fulcrum, or other device to increase the movement to ER.

Practitioner-generated force—the practitioner mobilizes the joint to ER repeatedly.

Practitioner uses manipulative thrust if positive responses occur that include centralization, reduction of antalgic postures, increased ROM, and decreased PDM. It is a relative contraindication to continuing to step 4 if there is no positive response in steps 1 to 3.

2. Stabilize the area to be manipulated: A point of stabilization is created by one hand and the physician's body weight while the other hand performs the manipulation. Minor corrections of the position of the stabilized part or hand, or both, are frequently interpreted by an observer as twisting or wrenching motions. Twisting and wrenching are difficult to control and may injure the patient.
3. Bring the joint to tension, removing the periarticular tissue slack. Mobilization with tissue slack not taken up is safe, but manipulation when tissue slack is present invites injury.
4. Thrust only when the patient is relaxed and the fixation is felt.

The manipulative thrust can be described according to the following:

- Direction of line of thrust—through the joint space, parallel to joint surfaces, or tangential to the point of fixation.
- Velocity—slow for mobilizations. High velocity can correct joint fixations, and the speed must be faster than the patient's reaction time, or a strain injury will result if the patient's muscular resistance occurs at the time of the manipulative thrust.
- Amplitude—governed by the quality of the health of the tissue, the quality of the fixation, and the location of the condition on the spectrum of the inflammation response.

After the elastic barrier has been stretched, repeated manipulation in the same direction is complicated because the end-feel tension normally felt before a manipulation is reduced or absent for at least 20 minutes. The same phenomenon occurs when one "pops" knuckles. The risk of injury is much greater, and changing to mobilization or active muscular relaxation techniques is recommended rather than repeated manipulation.

Reassess

The condition of the joint fixation should be reassessed after each treatment to determine whether the therapy has been successful.

A single manipulation rarely corrects a problem completely. The use of a joint-scanning technique shows where the problems are that need further evaluation. The goal is to alleviate acute conditions or, if unsuccessful, to turn them into subacute conditions and resolve subacute and chronic conditions before they cause a chronic fatigue response, joint fixation, degeneration, or chronic myositis.

Troubleshooting Technique

Common problems blocking successful manipulation can be overcome by the following:

- Learning joint play analysis on the peripheral joints and practicing manipulations of those joints before attempting to manipulate the spinal joints.
- Practicing the manipulative procedure with repeated light oscillatory movements while modifying the direction to feel the changes in joint tension, thus gaining experience, confidence, and knowledge without inflicting injury.
- Being confident of the procedure; otherwise, the patient may sense the physician's hesitation and guard, preventing the manipulation and increasing the risk of a poor outcome.
- Feeling the fixation of the joint as it is brought to tension; otherwise, the manipulation traumatizes the tissues unnecessarily or does not gain the desired result.
- Learning the arthrology of the joint to be manipulated so as not to put the joint in a "locked" or jammed position that will cause the force of the manipulation to be dispersed to the surrounding tissues and joints.

Personal instruction is invaluable, but unless the rationales of joint mechanics, pathomechanics, and pathophysiology are the basis of the teacher's approach, it can be confusing and lead to erroneous conclusions. The Further Reading list includes texts by Bourdillion, Greenman, Liebenson, and Maitland; these are good sources for learning the basics of the art.

FURTHER READING

Books

Bourdillion JF, Day EA, Bookhout MR. *Spinal Manipulation*. Boston: Butterworth-Heinemann; 1992.

A good text that covers the basics. It is exceeded in many areas by Greenman's text.

Dagenais S, Haldeman S. *Evidence-Based Management of Low Back Pain*. St. Louis: Elsevier Mosby; 2007.

The North American Spine Society's up-to-date, clinically oriented, evidence-based medicine text. It details and references the description, theory, efficacy and harms of various treatment interventions for low back pain that are readily transferable to many musculoskeletal conditions.

Greenman P. *Principles of Manual Medicine*. Baltimore: Williams & Wilkins; 1996.

A great text that covers the material in a clear, understandable, and usable format.

Haldeman S. *Principles and Practice of Chiropractic*. 2nd ed. New York: Appleton-Century-Crofts; 1992.

The second edition has major changes and new contributors and is an excellent source of information on history, research, diagnosis, and treatment of all phases of manipulation, with special attention to the spine.

Liebenson C. *Rehabilitation of the Spine: A Practitioner's Manual*. 2nd ed. Baltimore: Lippincott Williams & Wilkins; 2007.

Liebenson brought together many fine contributors who address the cutting-edge methods of manual medicine. It covers much of what is needed in clinical practice. Very useful and readable. The second edition is a major update and a gold mine of information.

Maitland GD. *Vertebral Manipulation*. 4th ed. London: Butterworth-Heinemann; 1977.

A physical therapist's approach, with emphasis on patient selection, pretreatment assessment, assessment during treatment, assessment after treatment, and therapeutic approach for each area of the spine.

Maitland GD. *Peripheral Manipulation*. 3rd ed. London: Butterworth-Heinemann; 1991.

The same approach as the previous book, but for the extremities. The author suggests learning the extremities before attempting to learn spinal manipulation. After all, a joint is a joint.

Journals

Nonpharmacological Control of Pain

Richard J. Kitaeff, MA, ND, Dip Ac, LAc

OUTLINE

INTRODUCTION

Pain in its myriad forms is one of the most common symptoms for which patients seek relief. Acute pain is an unpleasant experience primarily associated with tissue injury, and the protective response patients have to pain provides the clinician with valuable diagnostic information.

The reaction to pain is highly subjective and, as a function of higher centers, is extremely variable. It is influenced by many factors, depending on the individual patient and his or her situation. When pain becomes chronic, the multifactorial influences (e.g., anxiety, depression, social, cultural, and economic factors, secondary gain) play an even larger role.

When treating a patient for pain, the clinician must first determine the primary cause, the pathogenesis, and the secondary or contributing factors. The relief of pain may then be achieved by removal of the primary cause (e.g., cure of an infection), neutralization of the effect of the stimulus (e.g., emollients for an ulcer), relief of discomfort (e.g., biofeedback), suppression of the disease process (e.g., antiinflammatory agents), and dulling or obliteration of the sense of pain (e.g., analgesics or acupuncture).[1]

Although the medical profession has chosen to emphasize the pharmacological methods of pain control, many nonpharmacological options are available. Their applicability and efficacy are documented here. (Although this chapter liberally utilizes pain control in childbirth, the examples and concepts can be generalized to any situation involving acute and/or chronic pain.)

THE EXPERIENCE OF PAIN

A Psychological Model

Pain is generally acknowledged to be a complex physiological/psychological phenomenon. It involves motivational and emotional components and conceptual interpretation, which may or may not have their basis in actual nociception. Verbal reports of pain and associated behavioral responses are controlled, at least in part, by psychological, cultural, and situational factors.

For acute pain, such as that of childbirth, in which the painful experience can be directly related to nociceptive input, a multiprocess feedback model can be considered. However, one must keep in mind the complexity of the psychological processes intervening between the sensory event and the observable response, ranging from the physiological to the social aspects of personality. These include elements of the following:

- Information processing
- Performance ability
- Attention
- Memory
- Expectancy
- Attitudes and beliefs
- Secondary gain
- Self-concept
- Designated sick roles

In the psychological model, the brain infers information from bodily signs and integrates it with existing personal and situational variables to direct behavior. When consideration must also be given to the interactions with interested observers, such as physicians, family members, and birth attendants, who influence the interpretation with their own experiences and attitudes about pain, the complexity becomes even greater.

According to this model, which does not differ in essence from a general model of stress, a primary appraisal of the personal danger or threat posed by the painful stressor is followed by a secondary appraisal of one's ability to cope, based on emotional feedback, and contributions of situational and sociocultural response factors. On this basis, a woman in labor could choose to regard pain as "positive," "functional," or "creative"; "pain with a purpose"; or alternatively, "part of a process involving injury."[2] In the course of a pain management program carried out with 84 patients with low back pain, those who more strongly endorsed "organic" concepts about the nature and treatment of pain reported higher levels of disability, whereas reductions in reported "organic" pain beliefs improved

reported disability, and endorsement of "psychological" concepts about the nature and treatment of pain was not associated with disability.[3] Several studies indicate that "catastrophizing" predicts pain or is associated with lower pain tolerance.[4,5] This conceptualization of painful stress suggests that intervention could be successful at several levels: cognitive patterning, physiological arousal associated with emotional stress, and control of environmental stimuli. Examples of appropriate strategies are cognitive coping skills such as restructuring and utilization of preparatory information and attention shifts; muscular relaxation, physical or electrical stimulation, and biofeedback techniques; and structuring of the environment in a way conducive to effective coping (such as by making it nonthreatening and comfortable).[6]

Neuropsychological Mechanisms of Pain

According to research on the mechanisms of pain, pain can be treated not only by anesthetic blocks, surgical intervention, and the like but also by influencing the motivational-affective and cognitive factors.[7] The traditional specificity theory of pain, first enunciated by Descartes in the 17th century, holds that pain messages are conducted from specific pain receptors at the periphery through discrete pathways to pain centers in the brain. However, there are individual differences in pain responses, pain is not consistently stopped by cutting or blocking of the "pain pathway," and it is now known that nonpainful types of stimulation activate the A-delta and C fibers (see next paragraph) that are associated with pain. Therefore later modifications of pain theory took into account the patterning of nerve impulses over time to reflect differences in the degree and intensity of stimuli and the summation of signals from an extended area.[8]

One model of pain is the gate-control theory, which Melzack and Wall[9] formulated in 1965. Based on neurological data and a categorization of the words used to describe pain, this theory conceptualizes the pain experience as having sensory-discriminative, motivational-affective, and cognitive-evaluative components or modalities, corresponding to different patterns of nerve impulses. Neurologically, a specialized cluster of nerve cells in the substantia gelatinosa of the spinal column is thought to operate like a valve or gate, controlling nerve signals before they evoke the perception of, and response to, pain. Besides this monitoring of sensory data in the central nervous system, gating is also influenced by the relative amount of activity in large-diameter (A-beta) and small-diameter (A-delta and C) nerve fibers. The large fibers tend to inhibit transmission, or close the gate, preventing pain, and the small fibers tend to facilitate transmission, or open the gate, resulting in pain. The fact that large fibers are activated by pressure, touch, massage, and vibration suggests a mechanism for such pain control techniques as acupressure, acupuncture, and transcutaneous electrical nerve stimulation (TENS). Such stimulation apparently closes the spinal gate via the large-fiber system. Melzack and Casey[7] expanded this theory by proposing the possibility of a higher-level gate, in the reticular or limbic structures of the brain, that probably mediates the drive to escape from unpleasant stimuli. At central nervous system (CNS) levels, the biochemical mechanisms of gate control may involve the endorphins, natural morphinelike substances that have been implicated in the pain-controlling effects produced by acupuncture.[10]

Although the pain circuit generally is considered to include the thalamus, the somatosensory cortex, the anterior cingulate cortex (ACC), the amygdala, the hippocampus, and the prefrontal cortex, recent imaging studies have focused on supraspinal CNS areas associated with the experience of pain: the prefrontal cortex, anterior cingulate cortex, sensory cortex, and insula. The prefrontal cortex (often considered the "executive brain") is thought to encode cognitive aspects of acute and chronic pain, including coping ability and a general inhibitory effect on the severity of pain. The anterior cingulate cortex, part of the limbic system, relates to the affective/emotional or fear and suffering component of pain. The insula can be considered the sensory component of the limbic system. Imaging studies have recently found that different chronic pain conditions appear to involve pain condition–specific patterns of cortical activity. For example, postherpetic neuralgia and osteoarthritis of the knee appear to be represented primarily in the insula, whereas back pain appears to be associated with activity in the prefrontal cortex. Peripheral structures of the nervous system play a role mostly in long-term effects or in chronic pain. Nociceptive input from the periphery can sensitize cortical areas involved in processing, for example, in conditions such as fibromyalgia or chronic low back pain. In such chronic conditions, decreased gray matter in the prefrontal cortex may be associated with a decreased ability to inhibit the experience of pain.[11]

Neuroimaging studies have also shown the right ACC to be activated with unilateral pain. Pain memory, a learned pattern of brain activity, is involved in the central sensitization model of chronic pain, known as "kindling": repeated exposure to painful stimuli leads to increased sensitivity to later noxious stimuli.[12]

The implication of these observations of the brain areas and processes involved in the perception and processing of pain is that a "top-down" psychological process of cognition operated by the neocortex can inhibit lower brain functions (such as emotions) of the subcortical limbic system, as in cognitive learning strategies and techniques such as eye movement desensitization and reprocessing (EMDR).[12]

Toxins that Increase Pain Sensitivity

Contemporary Western diets contain acid precursors more than base precursors, yielding a daily systemic net acid load of varying amounts. For example, when salt (NaCl) is added to the diet, it becomes a condiment, not a requirement, and when consumed acutely in large quantities, NaCl can be noxious. High protein intake and phosphate-rich soft drinks also contribute to an increased load of dietary acid. A blood pH constantly at the lower end of the normal range has been termed *latent acidosis*. It has been suggested that latent chronic acidosis might contribute to an increase in pain symptoms resulting from swelling of connective tissue because eof changed acid–base homeostasis.[13]

Inorganic arsenic exposure exacerbates the degree of inflammatory pain (i.e., enhances pain perception) and could worsen the pathological state of painful inflammatory diseases.[14] Lipopolysaccharides (LPSs), also known as endotoxins, from the cell walls of gram-negative bacteria have been shown to increase sensitivity to visceral and somatic pain and increase musculoskeletal pain sensitivity correlating with both changes in IL-6 and negative mood.[15]

Pain in Childbirth

A psychological/social learning approach to pain emphasizes control of motivation, expectation, focus of attention, and stress and feelings of anxiety, depression, and helplessness. Factors specifically operative in labor pain involve these in addition to social support and the physiological factors of hunger, rest, and muscular tension.[16] All of these factors can contribute to the interpretation of pain being placed on the nociceptive message provided by uterine contractions. The influence of motivation on labor pain was effectively demonstrated in a prospective study of maternal attitudes toward pregnancy in 8000 American women. One of the factors found to be strongly related to maternal attitude toward having a baby was the need for analgesics in labor.[17]

Cultural conditioning may also be fundamental to the labeling of childbirth as painful. Throughout most of the world, analgesics are not required for labor; in fact, a Japanese anesthesiologist suggests that the idea of "painless delivery" is a strange one to his culture.[18] American women, on the other hand, "live through a largely self-fulfilling prophecy of birth as a painful, terrifying ordeal, and/or as a medical, drugged process over which they have no control."[16] This idea relates to body fantasies of injury, brought about in a hospital environment where distress is an expected response to the expulsive reflex.[2]

PAIN CONTROL

Moderating Variables and Psychological Techniques

Psychological Strategies

The psychological strategies recommended for control of labor pain, many of them part of prepared childbirth programs, generally aim to provide control, communication, relaxation, attention focus, and support in addition to physical counterstimuli. Considerable psychological research supports the use of these strategies in the development of pain tolerance.

The significance of various characteristics of an individual's psychological profile has been studied by evaluating the effects on pain perception of such parameters as the following:

- Introversion–extroversion[19–21]
- Augmenters–reducers[22]
- Field dependence[23,24]
- Repression–sensitization[25–27]

For example, on the repression–sensitization axis, repressors may be characterized as people who avoid having to cope with pain. Sensitizers, however, have an obsessive need to cope; they like to be informed in advance about the situation and to have control over it. The superior initial tolerance exhibited by repressors in response to heat and pressure stimuli disappears in repeated trials, showing that the sensitizers' predilection for challenge enables them to endure long-term pain better.

The importance of individual difference variables is also illustrated by the observation that one third of patients undergoing surgical operations do not request pain-killing medication.[28] This common ability to suppress pain indicates that not all surgical patients consider themselves passive victims. In fact, during the postoperative period, pain persists longer for those who accept medication.

Cognitive Strategies

The impetus for devising cognitive strategies to promote tolerance of pain has been particularly supported by investigations showing that pain tolerance increases with greater predictability and perception of control.[29–33] Similarly, preparatory communications and information received before the onset of experimental or surgical pain consistently decrease the subjects' perception of pain.[34–36] Animal studies have demonstrated higher rates of instrumental responses when painful shocks are signaled than when they are unsignaled.[37] Kanfer and Seidner[38] found that subjects who could advance slides of travel pictures at their own rate tolerated iced-water immersion of the hand longer than yoked subjects whose slides were changed by the experimenter.

When surgical patients were given a sense of control by being provided with preparatory information about postoperative discomforts and operative care, in combination with training in rehearsal of realistic, positive aspects of the surgical experience, they showed a significant reduction in postoperative anxiety (as indicated by nurses' observations), requests for sedatives, and length of hospital stay.[39] Furthermore, preparation for second periodontal procedures by auditory and visual messages classified as "control enhancement" was associated with a reduction of pain after a second operation.[40] Subjects who could cognitively redefine a threat of electric shocks as interesting new physiological sensations also reduced stress to a greater extent than subjects not provided with this coping strategy.[41]

A typical cognitive behavioral procedure utilizes "stress inoculation," beginning with an educational phase (in which the client is given a conceptual framework for understanding the nature of his or her stressful reactions), followed by rehearsal of behavioral and cognitive coping skills, based on a set of coping self-statements generated by the client in collaboration with the therapist. Such cognitive-behavioral techniques, sometimes in combination with electromyography (EMG) biofeedback control, have been found successful in the treatment of chronic low back pain.[42–44] Also, cognitive-behavioral strategies have been effective in alleviating the pain of irritable bowel syndrome,[45] temporomandibular joint syndrome,[46,47] cancer,[48] migraine headaches,[49] rheumatic conditions,[50–52] fibromyalgia,[53] and complex regional pain syndrome.[54] Low back pain has been effectively controlled utilizing cognitive-behavioral or social learning strategies addressing fear-avoidance beliefs[55] or catastrophizing,[56b] whereas voxel-based morphometry (VBM) has revealed structural changes in regions of the brain with higher levels of pain intensity and negative cognitions in cases of low back pain.[57] Older adults given pain-coping skills training (PCST) were able to control the pain of osteoarthritis of the knee.[58]

This emphasis on conceptualization, preparatory information, and cognitive transformation seems to have been incorporated into the Read method of natural childbirth, which replaces fear with knowledge about birth.[17] Sheila Kitzinger,[2] in her method of prepared childbirth, similarly emphasizes the necessity of "acquiring knowledge and understanding of what labor involves, the terminology used by obstetricians and midwives, and information about what happens in hospitals."

A study by Stevens and Heide[59] conducted at the University of Wisconsin used iced water to test perception and endurance of pain in subjects who had been taught methods used in childbirth education classes. The control subjects for this training and an additional control group were offered only distraction during the tests. Those who had been taught the techniques reported only about half the pain of that reported by control subjects and endured it 2.5 times longer. The prepared childbirth strategies improved with practice, were effective for pain lasting longer than most contractions in labor, and were more effective than distraction techniques.[59] However, this last finding introduces some confusion because some prepared childbirth methods include either distraction techniques or some other deliberate disposition of one's attention.

Attention Focusing

Distraction or focused attention, mostly utilizing the rhythms of the breath, is essential to the Lamaze method, the most popular prepared childbirth program in America, and is important in the Bradley and other methods. Sheila Kitzinger[2] describes the controlled attention focusing as:

> *concentration on what is happening, one's response to it as a task, and visualization of what is being achieved by the work of the uterus during contractions. The focus may be on the fantasy of the contractions as a shape provided by actual objects (furniture, architectural details, flowers, a painting) in the room, or a combination of these factors.*

Stevens and Heide[59] found that attention focusing functions effectively as analgesia for labor pain. Such strategies are strongly supported by much psychological research. Hospitalized children with chronic

illnesses who were taught distraction techniques were able to reduce measures of distress before and during medical procedures such as intramuscular and intravenous injections.[60] In a study of patients with burn pain, sensory focusing techniques were more successful than distraction techniques in controlling pain, and both were more successful than standard care.[61] The focus may be on a competing response, as in a study by Kanfer and Goldfoot[62] showing that when attention was directed to self-presented external slides, individuals were able to increase their tolerance of the pain of cold water. Focus on a competing response is also shown in the use of hypnosis as an analgesic and in the meditative states of Raj yogis, who pinpoint attention on the tip of the nose or a point on the back of the skull and then do not react physiologically to cold water, bright lights, or sudden sounds.[63,64] Other adepts in unusual feats of pain tolerance, such as having spikes stuck through the skin, either maintain an unfocused attitude, without evaluation, or pinpoint attention totally on the pain but without evaluation.[65] In such cases the attitude of detachment from the pain can be reflected by an undisturbed electroencephalography (EEG) pattern of alpha or beta waves throughout the performance of the feat.

Internet-Based Cognitive-Behavioral Therapy

Numerous recent studies have supported the effective use of the Internet and smartphones to implement cognitive learning strategies for pain management. Based on a meta-analytic review of 23 randomized controlled trials of guided Internet-based cognitive-behavioral therapy (ICBT), improvement was shown in general psychological outcomes, disease-related physical outcomes, and disease-related effect on daily life.[66] Specifically, chronic pain has been reduced through smartphone and Internet applications employing online journals that facilitate improved communication between patient and clinician. Feedback and coaching were provided to patients via Twitter postings and blogs, and online resources and blogs provided patient education.[67] In a randomized controlled trial, an 8-week Internet-based exercise program significantly improved pain and global health status for 81 breast cancer survivors.[68] A guided Internet-delivered self-help cognitive-behavioral therapy program was successful in treating 69 adolescents with chronic pain.[69] A smartphone-based intervention with diaries and personalized therapist feedback based on CBT principles, in addition to access to a website for self-management, reduced pain scores for 140 women with widespread chronic pain.[70] Internet-based telemonitoring of fibromyalgia patients in a 24-week multicomponent intervention influenced key health outcomes.[71]

Virtual Reality for Pain Management

A review of six studies showed that the distraction provided by the virtual reality (VR) technique reduced acute and chronic pain in adults and children in conditions such as headaches or fibromyalgia, sometimes combining VR with modalities such as biofeedback and cognitive-behavioral therapy. At the same time, VR actually seemed to produce neurophysiological changes.[72] Pain was reduced significantly for 50 medical inpatients viewing a three-dimensional (3D) VR experience using the Samsung Gear Oculus VR headset.[73] Thirty patients with various chronic pain conditions utilized a 5-minute head-mounted VR display to reduce their pain rating on a visual analog scale by 33%.[74] Twelve patients with chronic intractable phantom limb pain using machine learning, augmented reality, and VR showed statistically and clinically significant improvement in all metrics of their phantom limb pain.[75]

Relaxation Training

Relaxation training, another essential method of pain control, is found in all childbirth training programs. A considerable body of literature supports its importance in pain control because a state of lowered autonomic arousal is incompatible with anxiety. Although progressive muscular relaxation, systematic desensitization, and autogenic training are all well-established physiological approaches to muscular relaxation, meditation traditions provide quicker methods to achieve what Benson[76] has called the "relaxation response." One of the simplest meditation practices—maintaining a focal awareness of the flow of breath—is taught by Rahima Baldwin[11] in *Special Delivery* and is identical to the ancient practice of vipassana, or insight meditation.

Hypnosis

Hypnosis or autohypnosis is another method used to induce deep relaxation for pain control. It incorporates many of the therapeutic elements already referred to—focused attention, positive expectation, and a supportive or permissive attitude—in making suggestions that alleviate anxiety. Thus its success in pain management may be viewed from a cognitive-behavioral perspective.[77] In one technique, "glove anesthesia" is induced in one hand, and the "numb, heavy wooden feeling" so produced is transferred to the other hand, the face, and eventually to the abdomen to "relieve the discomfort" of uterine contractions (the word *pain* is never used because its use would be countersuggestive).[78] Pain modulation in "highly hypnotizable" subjects has been confirmed through brain measurement of somatosensory event–related potentials (SERPs) to noxious stimuli, with the highest amplitudes for these subjects recorded at frontal and temporal scalp sites.[79]

Control of Environmental Stress

Kitzinger[2] cites animal research to show how environmental stress can interfere with the physiological processes of labor and delivery. Education for childbirth therefore promotes verbal and nonverbal support from the husband, obstetrician, midwife, or anyone else who is part of the birthing environment. Touch relaxation and coaching techniques combine the essential elements of relaxation, massage counterstimulus, and the direct supportive communication of a partner.[11] Several studies agree that comfort in labor is also enhanced by a more vertical position, such as the squatting posture that is adopted in many other cultures.[80–82]

Counterstimulus Methods: Massage, Acupuncture, Transcutaneous Electrical Nerve Stimulation

The hand reflexology method of grasping combs during labor to activate points on the fingertips and balls of the hand that relate to uterine functioning is one example of counterstimulus strategy.[11] Foot reflexology, acupressure, acupuncture, and TENS might also share a common autonomic nervous mode of operation.

Transcutaneous Electrical Nerve Stimulation

The use of TENS to control pain during delivery has been evaluated by several studies. The method used in a Swedish study,[83] which was subsequently replicated in Germany and Britain, was originally developed in the United States by Shealy and Maurer[84] for the control of acute and chronic pain. In a controlled study of experimentally induced cold-pressor pain, the effect of electrical stimulation with TENS electrodes at two traditional acupoints in 20 subjects had an analgesic effect with statistical significance comparable to that of morphine, and the combined effect of TENS with morphine was stronger than TENS alone.[85] A series of controlled randomized double-blind studies on carpal tunnel syndrome pain found that the combination of low-level laser and microcurrent TENS on distant and local points significantly decreased McGill Pain Questionnaire score, sensory and motor latencies, and Phalen and Tinel signs compared with sham treatment.[86]

A British study investigating the relative hypoalgesic effects of different TENS parameters upon experimentally induced mechanical pain found that low-frequency, high-intensity, extrasegmental stimulation (i.e., over an acupuncture point rather than over a nerve distribution) produced a rapid-onset hypoalgesic effect, which increased during the stimulation period and was sustained for 30 minutes after stimulation.[87]

In TENS, the electrodes are generally placed over the painful area to stimulate the cutaneous nerves in that area. For use in labor, four electrodes are placed on either side of the midline of the spine to stimulate the posterior primary rami of the spinal segments (T11–L1 and S2–S4) receiving the painful stimuli during labor. It is interesting to note that these are the loci of acupuncture points (BL-20, BL-27, and BL-28) that are traditionally thought to reflect female reproductive function.

The selection of this area for stimulation is based on Bonica's account of the neurological mechanism of delivery pain.[88] During the first stage, pain receptors are assumed to be activated by contractions of the uterus and dilation of the cervix. The evoked impulses are mediated in afferents that run in the hypogastric nerves and reach the spinal cord via the dorsal roots T10 to L1. The pain is referred to large areas of the abdomen and back. During the second stage, pain is also caused by distention and stretching of the delivery canal, the pelvic floor, the vulva, and the perineum. The pain is localized, and the impulses reach the spinal cord mainly via the pudendal nerves and the dorsal roots S2 to S4. The pain during the first stage is characterized as an ache, considered to be mediated in small-diameter C fibers. During the second stage, the pain has the more localized intensive nature usually identified with the delta afferent fibers.[88,89]

In the typical application of this technique for control of pain during labor, low-intensity stimulation is given continuously, and a high-intensity stimulation can be initiated by the parturient herself whenever pain increases. Stimulation via the thoracic electrodes is maintained throughout the delivery at an amplitude that is maximal for a pleasant sensation, whereas sacral stimulation is added from the later part of the first stage. Table 42.1 summarizes the uniformly good results that have been reported.

Those patients who complained of backache have especially appreciated it. An Austrian study compared the analgesic effects of TENS, pethidine, and placebos on labor pain in 30 parturient women during the first stage of labor. No significant difference was found between the placebo, unspecific TENS, and control groups in the increase in pain during the test period. Patients who had received pethidine and those who had been given TENS experienced considerable relief of pain.[90] It is curious that apart from a passing reference by Shealy and Maurer[84] to its use in labor, no research on the obstetrical application of TENS appeared for many years in any of the U.S. literature. A 1996 review of 30 studies on TENS stimulation of acupuncture points in labor substantiated the conclusions of earlier research.[91]

TABLE 42.1 The Results of the Use of Transcutaneous Electrical Nerve Stimulation for Pain Control in Labor

Study	No. of patients	RESULTS (%)		
		Good	Moderate	None
Augustinsson et al.[83]	147	44	44	12
Andersson et al.[94]	27	48	37	15
Kanfer and Goldfoot[62]	35	20	62	18
Stewart[93]	67	31	56	13
Kubista et al.[138]	102	55	24	21
Bundsen et al.[139]	347	47	42	11

In view of the relatively good results and lack of complications, the consensus of all the preceding studies is that the TENS method is recommended as a primary pain-relieving measure, to which conventional methods can be added as needed. Robson[92] comments that TENS is noninvasive and is believed to be safe for both mother and baby. It is easy to apply and can be operated throughout labor by the doctor, midwife, father, or mother. Augustinsson et al.[83] were most impressed by the lack of complications because the conventional methods, including analgesic and sedative drugs, nitrous oxide inhalation, epidural anesthesia, and local blockades, all possess a varying level of potential risk.[83] Another advantage is that TENS, because it does not give complete analgesia, does not eliminate pain as a diagnostic tool; it can be interrupted whenever needed for clinical evaluation. More important, perhaps, from the point of view of the woman in labor is the fact that her consciousness is not altered to the point of excluding her own active participation in, and experience of, the delivery.

Both Stewart[93] and Augustinsson et al.[83] reported TENS alone to be inadequate for analgesia in the second stage of labor. The second group of researchers regards this difference as possible support for the assumption that C fiber–mediated pain is more amenable to blocking by electrical stimulation than A fiber–mediated pain. Stewart[93] mentions simply that many women did not wish to use the stimulator at that stage because it proved a distraction from their efforts to bear down. In this connection, it is interesting to note that "those who were well prepared and keen on natural childbirth were not always the most enthusiastic and, in fact, two of the early failures were patients who had been to relaxation classes."[93] Robson[92] explains that TENS could distract some patients from their breathing or other focus of attention learned in childbirth preparation classes.

A related issue in the TENS literature is introduced by the comment of Andersson et al.[94] that there was a correlation between the level of hypnotizability and that of pain relief in their subjects. Such a correlation may, of course, imply only susceptibility to any type of therapeutic effect. Neumark et al.[90] tested this effect by including a placebo group that was given no current through the electrodes; these researchers found that the result for the placebo group was not different from that of TENS applied nonspecifically (i.e., incorrectly) but was significantly different from the effect of TENS placed over the relevant nerve distribution and from that of pethidine. Robson,[92] although making no attempt to assess a patient's level of susceptibility to hypnosis, switched off the TENS machine for at least two contractions. All patients asked for it to be switched on again, indicating that the technique was providing pain relief. Augustinsson et al.[83] consider the suggestive effect, if it occurs, to be of minor significance because several investigators have found the pain-reducing effect of TENS to be achieved through demonstrable neurophysiologic mechanisms. Stewart[93] points out that the greater personal contact between patient and attendant essential to the use of this method may introduce an element of suggestibility or distraction that affects the pain experience.

Acupuncture

Thousands of studies have investigated the efficacy and mechanisms of acupuncture analgesia for acute and chronic pain, in surgical operations, and in childbirth. In a review article of 24 studies, Lewith and Machin[95] found that the typical clinical trial showed a 70% efficacy of acupuncture compared with placebo treatment. Reichmanis and Becker[96] found similar results in a review of 17 studies of acupuncture analgesia in experimentally induced pain. A systematic review and meta-analysis concluded that acupuncture relieved pain within 30 minutes of treatment, compared with sham acupuncture and

analgesic injection.[97] In a randomized controlled trial, electroacupuncture administered together with general anesthesia for 64 patients receiving surgical operations in a Malaysian hospital significantly reduced pain ratings and total morphine requirements.[98] On the basis of a thorough review of the clinical and experimental research on acupuncture pain control, Stux and Pomerantz[99] concluded that acupuncture analgesia helps from 55% to 85% of patients with chronic pain, comparing favorably with the effects of potent pain medication (such as morphine, which is 70% effective), and clearly distinct from the placebo effect, which helps 30% to 35%.[99] At the same time, somatosensory EEG–evoked potential studies have provided objective evidence of the analgesic effect of acupuncture.[100–102]

Recent randomized and double-blinded controlled studies have demonstrated the clinical effectiveness of acupuncture in treating chronic lateral epcondylitis[103] and chronic neck pain.[104] In the neck pain study, stimulation at distant points of the neck-related meridians were more effective than sham acupuncture points and "dry-needle" injections of local myofascial trigger points, reducing motion-related pain by one third after a single treatment. A single-blind randomized controlled trial showed that electroacupuncture (EA) is superior to manual acupuncture in treating patients with tennis elbow.[105] A review article on the treatment of fibromyalgia pain for patients at a hospital in Brazil showed improvement with traditional acupuncture, measured on subjective scales and number of tender points.[106] Preoperative EA has led to a reduction in the intraoperative and postoperative requirement for analgesic medications (alfentanil and morphine) in patients receiving gynecological lower abdomen surgery.[107] In fact, surgery that requires general anesthesia in Western countries is routinely performed in Chinese hospitals with the combination of acupuncture and local anesthesia for pain control, providing a considerable decrease in risk for surgical patients. When acupuncture was combined with Western (pharmacological) medicine in the treatment of chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS), the combined treatment approach was more effective on measures of pain and other symptoms than either acupuncture or Western medicine alone.[108] A randomized trial treating 50 cases of osteoarthritis of the knee, using warm-needling moxibustion, another traditional method of stimulating acupuncture points, was found to significantly relieve pain, improve function and muscle balance, and strengthen extensor and flexor muscle power.[109]

Hyodo and Gega[18] of the Osaka Medical College have reviewed the literature (summarized in Table 42.2) on acupuncture anesthesia and analgesia in normal delivery and found mixed results. For example, Wallis et al.[110] reported that although 19 of their 21 volunteer parturients considered acupuncture unsuccessful in providing analgesia for labor, one third indicated that they would choose acupuncture analgesia in labor again. Some researchers criticize the technique as being inconsistent, unpredictable, incomplete, and time-consuming and interfering with movement and electronic monitoring.

In their own study, Hyodo and Gega[18] tested 32 patients, equally divided between primiparas and multiparas. Low-frequency electrical current was introduced through needles at LI-4, ST-36, and SP-6, a standard therapeutic repertory for sedation of the reproductive organs. The results were assessed in terms of relief noted by the patient (subjective scale) and through the obstetrician's observation (objective scale); among the primiparas, 62.5% found good or excellent effect on the subjective scale, and 62.6% found good or excellent effect on the objective scale; among the multiparas, 93.8% had subjective relief, and 93.7% had objective relief. Overall, 90% of the patients experienced relief of pain within 20 minutes of initiation of acupuncture anesthesia. These researchers noted the considerable disparity in reports of the effectiveness of acupuncture from Japan and the United States, explaining it as a novelty effect. It is natural that in Japan, where no analgesic methods are normally used, the scoring in favor of acupuncture would be high compared with that in the United States.

TABLE 42.2 Results of Acupuncture Analgesia in the Control of Labor Pain

Study	No. of Patients	RESULTS (%) Good	Poor or None
Hyodo and Gega[18]			
Primiparas	16	62.5	37.5
Multiparas	16	93.7	7.3
Ito[140]	80	85	15
Wallis et al.[110]		9–33	67–91
Abouleish and Depp[112]		80.5	19.5

Hyodo and Gega[18] concluded that acupuncture analgesia is useful for delivery, especially because of its safety, even though its results are more erratic and less potent than those of conventional anesthetic techniques. More recently, a randomized controlled trial investigating acupuncture treatment as a complement or an alternative to conventional analgesia for labor in a Swedish hospital found that acupuncture significantly reduced the need for epidural analgesia, and parturients receiving acupuncture achieved a better extent of relaxation than the control group.[111]

A considerable amount of research has focused on determining a mechanism for acupuncture analgesia. A 1995 review of studies on acupuncture effects in pain and disease pointed out that, like exercise, acupuncture produces rhythmic discharges in nerve fibers and causes the release of endogenous opioids and oxytocin. Furthermore, "experimental and clinical evidence suggests that acupuncture may affect the sympathetic system via mechanisms of the hypothalamic and brain-stem levels."[112] Animal studies continue to demonstrate that acupuncture analgesia is mediated in the central and peripheral nervous systems by opioid peptides.[113–115] The cortex and hippocampus appear to participate in the modulation of chronic pain, and the analgesic action of EA seems to operate along this pathway.[114] A study carried out on dogs seems to verify the traditional theory of points of tonification and sedation, through differential production of sympathomimetic and parasympathomimetic effects on the cardiovascular system upon stimulation of different points. Carlsson,[116] a Swedish researcher, concludes that a mechanism for therapeutic acupuncture must include peripheral events that release neuropeptides; spinal mechanisms such as gate control; and supraspinal mechanisms through the descending pain inhibitory system, the sympathetic nervous system, and the hypothalamic–pituitary–adrenal (HPA) axis. He cautions that much of animal and human experimental acupuncture research shows only short-term hypoalgesia, that almost all such experimental research has been performed with EA rather than the more gentle manual style of therapeutic acupuncture, and that pain threshold elevation in human experimental research does not necessarily predict the clinical outcome.

In a study of labor induction and inhibition by EA, Tsuei et al.[117] utilized SP-6 and SP-4 points, which are located in the territory of the L4 dermatome. The spleen meridian, to which these loci belong, runs across the dermatomes of L4, L5, L2, and L1, then upward from T12 to T5. Because the sympathetic nerve controlling the uterus through the pelvic plexus receives preganglionic fibers from T5 to L4, Tsuei et al.[117] concluded that it is highly possible that stimulation of the electropermeable loci within this area may alter the physiological function of the uterus. The LI-4 points of the upper extremities, often added to the spleen meridian points in the acupunctural control of labor pain,

perhaps represent the central approach to the autonomic nervous system because these loci control pain to the head and neck. It should be noted, however, that Motoyama,[118] who has attempted to verify the traditional subtle anatomy of meridian pathways through tests of electrocutaneous resistance at meridian points, claims that these effects cannot be adequately explained in terms of the conventional sympathetic dermatomes but instead imply an alternative bioelectric transmission system.

The discovery of the Head McKenzie sensory zones has shown the possible mediation of the invisible meridians and points of traditional Eastern medicine between internal organs and corresponding skin areas. Nakatani[119] was able to detect the electropermeable line as an apparent viscerocutaneous autonomic nerve reflex when organic diseases were involved. Hyodo[120] has explained acupuncture stimulation as the transmission of impulses centrally from the reactive electropermeable loci, via a sympathetic afferent fiber, and noted that the autonomic nerve in the viscera is stimulated to response by the reverse of the McKenzie theory. An exciting recent development in acupuncture research has been the finding by functional neuroimagery of neuronal correlates of acupuncture stimulation in the human brain. In a controlled study of EA stimulation of GB-34 on the left leg, real EA elicited significantly higher activation over the hypothalamus and primary somatosensory motor cortex than mock and minimal EA, showing that the hypothalamic–limbic system was significantly modulated by EA at acupoints.[121]

Other Methods

The scope of this chapter does not permit a detailed discussion of other promising methods of pain control, but mention can be made of massage, biofeedback, and nutritional and botanical agents for the treatment of pain. A literature search led to the conclusion that massage, particularly acupressure, is effective for low back pain, especially when it is combined with exercises and education, with beneficial effects lasting at least 1 year after the end of treatment.[122] A vast literature is available on biofeedback training for pain. A meta-analysis of 21 controlled studies of biofeedback for chronic low back pain found improvements in pain intensity and other associated measures, both short term and long term.[123] BrightHearts is a biofeedback-assisted relaxation device for children, an iPad app paired with a wireless heart monitor. The application displays a digital geometrical design that responds to changes in heart rate. By slowing the heart rate, children could be taught to achieve relaxation and manage procedural pain and anxiety.[124] Another article suggesting a future direction in pain medicine describes the use of "off-the-shelf," low-cost, and low-bandwidth telemedicine equipment to deliver clinical biofeedback treatment when the patient and provider are in two different locations.[125] In a randomized double-blind trial of 30 patients with chronic maxillofacial pain, a significant reduction in pain scores and an improvement in the tolerance of experimentally induced dental pain were achieved with administration of 3 g daily of the amino acid tryptophan and a high-carbohydrate, low-fat, low-protein diet in comparison with placebo.[126] Among botanical agents for pain, corydalis rhizome or tuber (yanhusuo) is well known in the Chinese materia medica for its analgesic effect, containing combined alkaloids found to be 40% as effective as morphine. Acting probably through inhibition of the reticular activating system, corydaline was shown in one clinical study to decrease or relieve pain in 32 of 44 patients with dysmenorrhea.[127] Casperome, an extract of *Boswellia serrata,* was found effective in pain reduction in several randomized clinical studies of common inflammatory conditions, and the plasma levels of inflammatory markers were also reduced.[128] Based on an extensive literature review, specific traditional medicinal plants and isolated compounds originating from India have been reported as effective for the management of neuropathic pain.[129] Statistically significant improvement in pain resistance and suppression of edema were found in animals treated with UP 1306, a standardized blend of extracts from *Acacia catechu* and *Morus alba,* which was determined through assays to operate as a COX-2 inhibitor, comparable to a 200-mg/kg dose of ibuprofen.[130]

A current controversy revolves around the issue of whether there is objective evidence to support the widespread anecdotal testimonials for the success of cannabis products in controlling pain. An overview of systematic reviews on the efficacy of cannabis-based medicines in neuropathic pain and painful spasms in multiple sclerosis, in addition to the pain of rheumatic diseases and cancer, concluded inconsistent findings.[131] At the same time, another report found inhaled (smoked or vaporized) cannabis consistently effective in reducing noncancer pain, whereas oral cannabinoids seemed to improve the chronic pain of cancer but not acute postoperative pain, chronic abdominal pain, or rheumatoid pain.[132] Yet another study found limited evidence for the benefit of THC/CBD spray in the treatment of neuropathic pain and inadequate evidence for any benefit in the treatment of cancer or rheumatoid pain.[133]

CONCLUSION

This chapter has presented many of the current nonpharmacological strategies for the control of pain. Because the mechanism of pain perception has been shown to involve both physiological and psychological components, the optimal treatment might combine psychological factors, such as preparatory information, attention focus, relaxation, and supportive communication, with the physical stimuli of TENS or acupuncture. In fact, such a multidisciplinary approach to patients with chronic back pain was evaluated after a 4-week program that included back schooling, psychological intervention, and treatment by acupuncture, chiropractic, the Alexander technique, and a pain specialist. Significant improvement was maintained for a period of 6 months.[134]

Dental researchers of the Pediatric Pain Program of the University of California at Los Angeles School of Medicine searched several databases for reports of randomized controlled clinical trials of complementary and alternative medical modalities used to treat chronic facial pain. Three acupuncture trials, eight biofeedback trials, and three relaxation trials met the researchers' inclusion criteria, suggesting that these modalities were comparable to conventional treatment such as an intraoral appliance.[135]

Increasingly, the multidisciplinary pain management team, incorporating a variety of nonpharmacological treatment modalities, is being considered "the optimal method for delivery of comprehensive treatment to patients in pain."[136] The incorporation of "alternative" forms of pain management, including acupuncture, relaxation techniques, hypnosis, biofeedback, and guided imagery, is acknowledged by the Children's Hospital of the Medical College of Wisconsin to complement pharmacological management of children's pain.[137] The selection, balance, and application of these treatment components should be based on consideration of an individual's coping styles. Such a treatment program could be developed to provide more consistently effective analgesia than the individual components can provide separately. Relieving the pain of childbirth, for example, without diminishing or distorting the full consciousness of the experience for the mother, would be consistent with the goals of the contemporary physician of natural medicine.

Nontransfusion Significance of ABO and ABO-Associated Polymorphisms

OUTLINE

INTRODUCTION

> *"Concepts without percepts are empty; percepts without concepts are blind."*
>
> ***Immanuel Kant (1724–1804)***

Since Landsteiner first described the ABO typing system in 1900, the preeminent clinical role of this red blood cell (RBC) antigen–serum antibody system has been the prediction of reactions involving transfused blood and, to a lesser degree, transplanted organs. Despite this exceedingly important role, however, no rational individual should conclude that the proper exchange of blood or other tissues constitutes their primary biological role.

It can be argued that the overwhelming and revolutionizing influence of the ABO system on the history and practice of transfusion medicine and the general reluctance of allopathic medicine to find a workable niche for the nonreducible have had the effect of precluding interest in the nontransfusion significance of ABO polymorphism and, attendant to that, of a lack of any meaningful medical applications.

This chapter examines the biological significance of the ABO blood grouping and the ABH secretor system, with special attention to the effects of ABO expression as a "tipping point" for a variety of physiological and pathological manifestations that may be of interest to the practitioner of natural medicine.

BACKGROUND

Although a comprehensive review of the glycobiology of the ABO system is beyond the scope of this work, the brief overview given here should allow the reader to understand the basic mechanics and nomenclature of the system.

All humans can be typed for ABO blood group. There are four basic blood types: A, B, AB, and O. The system is composed of two antigens and two antibodies. The specific combination of these four components determines that individual's type. Table 43.1 shows the possible permutations of antigens and antibodies with the corresponding ABO types.

ABH ANTIGENS

The ABO blood group antigens are not primary gene products but, instead, enzymatic reaction products catalyzed by enzymes called glycosyltransferases. As depicted in Fig. 43.1, they are synthesized from an oligosaccharide intermediate, "H substance," which is produced by the monosaccharide fucose. Group A or B activity is produced by the addition of a single sugar on the nonreducing end of the H chain.

TABLE 43.1 Possible Combinations of Antibodies and Antigens in the ABO Blood Grouping System

Abo Blood Type	A Antigen	B Antigen	Anti-A Antibody	Anti-B Antibody
A	Yes	No	No	Yes (IgM)
B	No	Yes	Yes (IgM)	No
O	No	No	Yes (IgM, IgG)	Yes (IgM, IgG)
AB	Yes	Yes	No	No

Ig, Immunoglobulin.

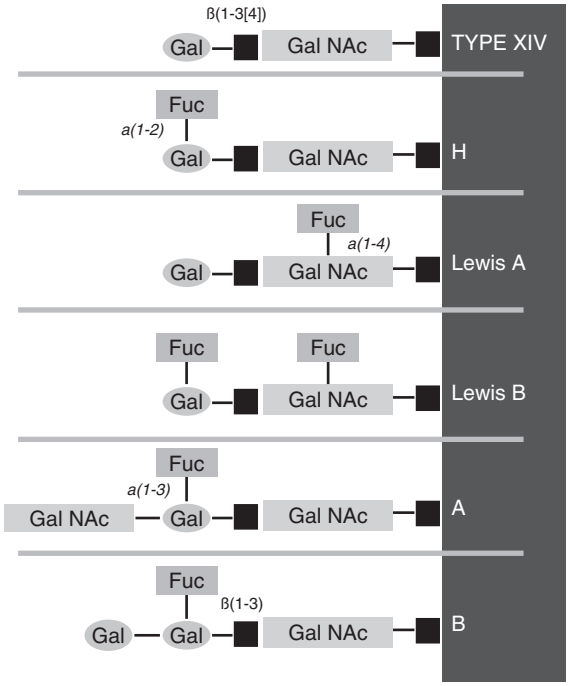

Fig. 43.1 Structures of the nonreducing end of the ABH and Lewis blood group antigen determinants.

Adding the glycoprotein *N*-acetylgalactosamine (GalNAc) to the end of the chain results in blood group A antigenicity. The terminal carbohydrate and the B group antigen is the monosaccharide galactose. There is no true O antigen: the terminal carbohydrate of O (H) antigen is the monosaccharide fucose. We identify the blood types as "ABO" but typically refer to the actual antigen system as "ABH."

ABH substances manifest quite early in life processes.[1] They are detected in the cell membranes and secretions of human embryos at about 5 weeks' gestational age in the epithelium and virtually all vascular endothelium. In fetal organs' endothelial cells, the expression of ABH antigen is ubiquitously upregulated. This is suggestive evidence that blood group antigens serve as early immunomorphological markers of the endothelial differentiation of mesenchymal cells, specifying the location of future blood vessels.[2]

All embryonic epithelia contain the ABH antigen, except those of the nervous system, adrenal glands, and liver. The antigens subsequently disappear from epithelia in an orderly and predictable manner as evidence of morphological differentiation appears. By about the end of the third intrauterine month, the adult pattern of distribution is achieved.

The embryonic expression of ABH antigens may be an important aspect in the pathogenesis of certain diseases: a scrutiny of 2557 medical records for children with type 1 diabetes and controls showed ABO blood group incompatibility in close to 90% of children with diabetes,[3] indicating that maternal–fetal ABO incompatibility may have acted to inhibit normal pancreatic islet formation in the fetus.

The expression of ABH antigens in the adult is tightly regulated, and their reappearance in adult tissue—normally devoid of them—is virtually always a sign of disease. Inappropriate ABH expression is one of the prime manifestations of the aberrant glycosylation state that is a hallmark of malignancy. Instances have been observed indicating that aberrant ABH expression may be paralleled in entirely different organ systems. A link has been demonstrated between ABH antigen expression in normal and neoplastic colonic epithelia and consequent alterations of ABH expression in the thyroid.[4]

ABH Secretors and Nonsecretors

By 1930 it had been shown that some people do and others do not secrete antigens corresponding to their ABO blood group into their saliva. Persons with these substances in saliva (secretors) have more ABH substances in their tissues than those lacking the substance in their saliva (nonsecretors). The ability to secrete behaved as a simple Mendelian function dominant to nonsecretion. Persons with blood groups A, B, and AB who are secretors secrete the antigens corresponding to their blood groups. Group H persons secrete the H substance, as do all other secretors, to a somewhat lesser extent.

ABH substances are secreted by mucous glands in many organs, including the upper respiratory tract, the gastrointestinal tract from the esophagus through the colon, and the uterine cervix. ABH secretor status is a major conditioner of the gut mucosa. ABH secretors have greater quantities of free ABH antigens in the makeup of their intestinal secretions, which has significant effects on bacterial and lectin adherence to the gut microvilli. The secretor gene regulates the synthesis of blood group substances in superficial glands of the gastric and small intestine mucosa. Large amounts of ABH material are found in all secretors,[5–8] characterized by a uniform distribution of blood type antigens in the gastric pits. ABH expression is independent of secretor status: glands situated deep in the mucosa of the pylorus and small intestine (Brunner glands) and gastric parietal glands both produce A and B substances without regard to secretor status.[9]

For a more detailed discussion of the metabolic consequences of ABH secretor status, the reader should refer to the author's article specifically on the subject.[10]

Brush-Border Hydrolases

ABO blood group determines much of the enzyme activity in the tissue (brush border) of the intestine. At least six intestinal hydrolases have ABO blood group antigenic determinants directly related to ABO blood group. The expression of ABH antigens secreted by intestinal glycoproteins is under the control of the secretor gene; therefore these antigens are not detected in the hydrolases of nonsecretor subjects.[11]

Intestinal Alkaline Phosphatase Activity

Intestinal alkaline phosphatase (IAP) is involved with both the breakdown of dietary cholesterol and the absorption of calcium. The activity of IAP and serum alkaline phosphatase (SAP) is strongly correlated with ABH secretor phenotypes. It has been estimated that the SAP activity of nonsecretors is only about 20% of the activity in the secretor groups.[11–15]

ABO polymorphism is linked to the levels and persistence of IAP.[16] Numerous studies have associated group O individuals with the highest alkaline phosphatase activity and group A with the lowest.[17] In addition, one study implied that the group A antigen itself might inactivate IAP.[18]

Bacterial Flora

The role of the ABO blood group in determining the bacteria making up a healthy gastrointestinal ecosystem is particularly strong in ABH secretors. Because ABH secretor status and ABO blood group dictate the presence and specificity of A, B, and H blood group antigens in human gut mucin glycoproteins, their status can influence the populations of bacteria capable of taking up local residence. This occurs because some of the bacteria in the digestive tract are actually capable of producing enzymes that allow them to degrade the terminal sugar of the ABH blood type antigens for a constant food supply.[19] Bacteria capable of degrading blood group B antigen can detach the terminal α-D-galactose. Group A–degrading bacteria can detach the GalNAc. These bacteria

have a competitive advantage and can thrive in the environment created by the preconditioning of ABH secretions. Although comparatively small populations of bacteria produce blood group–degrading enzymes (estimated populations are 10^8 bacteria per gram), the quantity of these bacteria are several orders of magnitude greater in different blood types, and they are much more stable residents. For example, B-degrading bacteria have a population density that is about 50,000-fold greater in blood group B secretors than in other subjects. Similar bacterial specificity and enzyme activity are found in other blood types.[20]

Evidence suggests that ABH nonsecretors have lower levels of immunoglobulin-G (Ig-G)[21,22] and secretory IgA concentrations than secretors.[23,24] ABH nonsecretors appear to have a higher prevalence of a variety of autoimmune diseases, including ankylosing spondylitis, reactive arthritis, psoriatic arthropathy, Sjögren's syndrome, multiple sclerosis, and Graves' disease.[22,25–27]

Studies to determine the patterns associated with the gut microbiome as assessed via fecal sample are still being conducted to determine ABO and ABH secretor status influence. To date, studies have shown that being an ABH secretor is associated with lower diversity index, whereas specific ABO blood groups are associated with allowing strain-specific bacterial expansion based on the bacteria's ability to degrade sugars.[28] For example, the bacteria *Lachnospiraceae* possess beta-galactosidase activity and are therefore higher in blood group B and O secretors due to the presence of D galactose residues on their antigen's terminal chain.[28] Following this thought, as we identify microbial metabolic processes, we can expect to uncover that those strains with preferential utilization of *N*-acetylgalactosamine will have better chances of colonizing the gut of a blood group A secretor.

Blood Group as Self-Declaration and Adhesion Molecules

In the larger world of glycoproteins, ABH antigens are characterized as O-linked glycans (glycosylation at serine or threonine residues by GalNAc). Many proteins in nature carry these dense and complex arrays of covalently attached sugar chains. Their biological roles are particularly important in the construction of complex multicellular organisms and organs.

Glycans are typically on the cellular outer surfaces and outside of secreted macromolecules; therefore they can mediate interactions between organisms. They are also involved in cell-to-cell and cell-to-matrix interactions that are crucial to the development and function of complex multicellular organisms.

Glycans can have a significant effect on fungal, viral, and bacterial pathogenicity.[29] ABH antigens are ubiquitous in nature, found abundantly in foodstuffs (where they are thought to play a role in the induction of opposing blood group antibodies early in life) and in a host of microorganisms.

A 1995 study showed that of 833 fungi harvested from 1977 to 1994, 422 extracts (47.8%) produced agglutination of human red blood cells (RBCs), equally distributed against type O, A, and B cells. The fungal agglutinins, in this case, are desirous of attaching and infecting seeds or other microbes that possess some "ABO blood type" activity of their own.[30]

ABH antigens appear in secretions by 8 to 9 weeks of age, first in the salivary glands and stomach, then throughout the gastrointestinal and vaginal tracts. The ABH variation of blood group antigen expression on vaginal epithelial cells and mucus has a significant role in susceptibility to urinary tract infections in women.[31]

Infertility and Spontaneous Abortion

ABO blood type incompatibility may be a critical factor in infertility. ABO-incompatible mating couples (a type A male fertilizing a type O female) are a common occurrence in miscarriages, especially very early in the gestational term. One study of 288 miscarriages showed that there was an excess of blood type A and type B in otherwise normal fetuses. The researchers concluded that the ABO incompatibility between mother and fetus was likely a cause of early miscarriages, but almost exclusively in chromosomally normal fetuses.[32–35]

In a study of 102 infertile couples, Solish[36] found that 87% were blood type incompatible. This researcher suggested that the infertility was due to the presence of antibodies in the secretions of the mother's genital tract or incompatible sperm from the father. In another study, a total of 589 compatible mating couples were compared with 432 incompatible mating couples. The mean number of living children presented a significant difference. There was a 21% deficiency of type A children in the two groups. Similarly, there was a 16% deficiency of type B children in the two groups. It appears that a 31.9% rate of miscarriage is associated with incompatible matings, compared with 17.15% in compatible matings. This finding has led some researchers to theorize that ABO incompatibility results in "cervical hostility" between the man's blood type antigens, which are present in his sperm, and the woman's opposing antibodies, present in her cervical mucus.[37]

Besides infertility, habitual abortion is also related to ABH secretor status as shown in 2010. The secretor status of 66 couples with recurrent spontaneous abortion (RSA) was obtained and compared with that of couples with successful term pregnancies. It was found that a secretor phenotype of couples with RSA, especially of the husband, could facilitate "reproductive success" and that couples in which both parents were secretors, the RSA probability was extremely diminished.[38] A previous study showed the interaction between ABO blood groups and adenosine deaminase genetic polymorphism during intrauterine life, providing results that could not be explained by strictly conventional immunologic mechanisms. The authors concluded that cell-to-cell interactions involving ABO antigens might have an important role at implantation and that adenosine deaminase, through control of local adenosine concentration, could modulate these interactions, influencing the probability of successful implantation.[39] A third and most recent study comparing secretor status compatibility between mother and child suggested an intrauterine selection against Se^- (nonsecretor) of the embryo carried by an Se^+ (secretor) mother. The selection was dependent on factors influencing the maternal environment.[40]

To measure women's fertility below age 45, follicle-stimulating hormone (FSH) levels are measured. Women with an FSH level greater than 10 are considered to have diminished ovarian reserve. In an ongoing study at Yale University and the Albert Einstein College of Medicine, it was observed that women with type A or AB blood were significantly less likely to have an FSH greater than 10 than were women with type O or B blood. They concluded that type O blood might affect fertility.[41]

Other Immune Correlates

In 1991 D'Adamo reported that individuals of group O blood reporting previous urticaria or anaphylaxis showed high residual titers of anti-A isoagglutinins. A score value was assigned to each agglutination reaction. Individuals with these disorders showed remarkably high titration scores compared with controls of the same blood group, up to three times higher. A mild increase was noted for group O subjects with severe eczema or asthma, but total scores in these subjects were only marginally greater than those of controls. A striking association was shown for group O women experiencing endometriosis.[42]

ABO and Secretor Blood Group Genetics

ABO System

In 1910 Epstein and Ottenberg suggested that the ABO blood group system could be inherited.[43] The determination of ABO status is the result of two codominant alleles and one recessive allele found on chromosome 9q band 34.

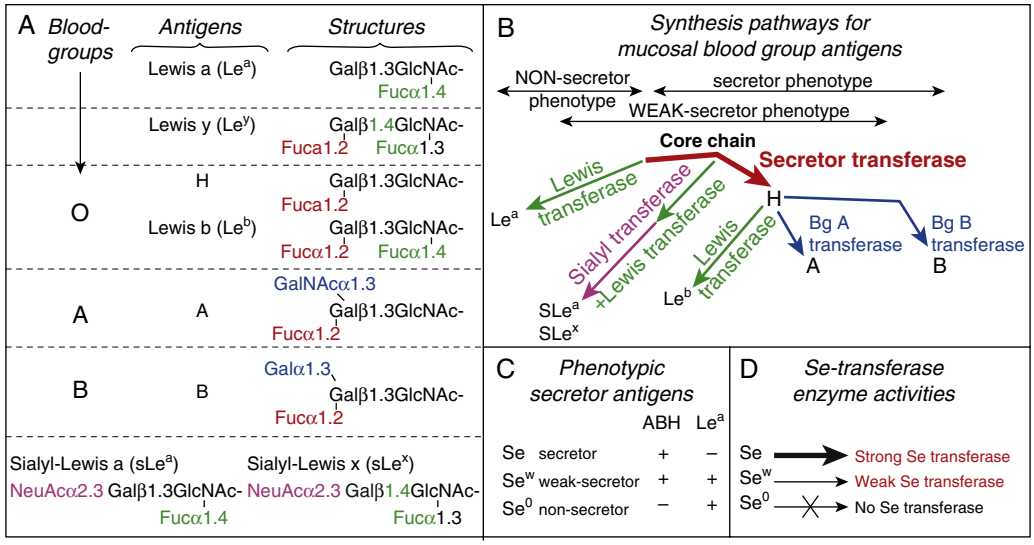

Fig. 43.2 Fucosylated and sialylated blood group (bg) antigens and associated secretor phenotypes. (A) The α1.2-fucosylated *(in red)* H and Le^b antigens define bg O. Bg A and B antigens present additional GalNAc or Gal residues *(blue),* respectively. Le^y and Le^b are both difucosylated. sLea and sLex are sialylated Lewis antigens *(in pink).* (B) Synthesis pathways for bg antigens with corresponding Se phenotypes: Le^a is found in Se^0 individuals, whereas Se^w individuals carry a mix of mucosal Le^a and Le^b. Lea is formed when the Se-transferase is inactive or weak because Le^a is a "dead end" and is not extended further. During inflammation and infection, sialyl-transferases are expressed, and carbohydrate core chains become sialylated in competition with Se-fucosyltransferase. (C) The presence of ABH and Le^a antigens in salivary, milk, and gastrointestinal tract secretions identifies individuals of Se, Se^0, or Se^w phenotype. (D) In Se^w subjects, α1.2 fucosylation is hampered by an enzymatically weak Se-transferase, whereas Se^0 individuals lack Se-transferase activity. (From Linden S, Mahdavi J, Semino-Mora C, Olsen C, Carlstedt I, Boren T, Dubois A. Role of ABO secretor status in mucosal innate immunity and *H. pylori* infection. *PLoS Pathogens.* 2008;4[1]:e2. PubMed PMID: 18179282. https://openi.nlm.nih.gov/detailedresult.php?img=PMC2174967_ppat.0040002.g001&query=ABO+blood+grouping&req=4&npos=202. Accessed October 21, 2018.)

A and B blood group genes are dominant over the O blood group, and the A and B group genes are themselves codominant. The ABH antigens are not primary and direct gene products; they are the reaction products catalyzed by glycosyltransferases type of enzymes.

ABO genes consist of at least seven exons, and the coding sequence in the seven coding exons spans more than 18 kb of the genomic DNA. The single-nucleotide deletion found in most (but not all) of the O alleles that is responsible for the loss of the activity of the enzyme is located in exon 6.[44]

ABH Secretor System

The secretor gene (*FUT2* at 19q13.3) codes for the activity of glycosyltransferases needed to assemble (secrete) free ABH antigen in body fluids like saliva, semen, vaginal fluid goblet cells, and mucous gland cells. This is accomplished in concert with the gene for group O or H *(FUT1).* Secretor status is determined by two alleles on *FUT2, Se* (dominant) and *se* (recessive), with approximately 80% of the population typing as secretors (*SeSe* or *Sese*).

Lewis Blood Groups and Their Association With the ABH Secretor System

The ABH secretor system is a major determinant of the Lewis (Le) blood grouping system (Fig. 43.2). This is due to the fact that, in addition to ABH, *FUT1* and *FUT2* provide the glycans necessary for conversion of Le antigens as well.

Two broad categories of Le blood type exist. These are the "Lewis positive" (either Le^{a+b-} or Le^{a-b+}) and "Lewis negative" (Le^{a-b-}) phenotypes. Depending on race, between 1% and 8% of the population is Lewis negative.

In Lewis-positive phenotypes, Le^a is formed initially, and in the case of nonsecretors (lacking the *Se* gene, *FUT2*), Le^a glycan is attached to the RBCs, and they type as Le^a. In the case of secretors, the *Se* gene activates the *H* gene, which causes an additional sugar to be added to Le^a, converting it to Le^b (see Fig. 43.1).

Among Le-positive individuals, ABH secretors are always Le^{a-b+} because they convert all their Le^a antigen into Le^b. Conversely, among Lewis-positive people, ABH nonsecretors are always Le^{a+b-} because they lack the *FUT2*-dependent glycosyltransferase to accomplish this conversion.

Thus it is often possible (and quite handy) to use the Lewis groups to infer ABH secretor status because Lewis typing is fairly quick to perform and easy to master compared with the traditionally used salivary inhibition test. However, the use of Lewis typing to infer ABH secretor status works only in those individuals who are Lewis-positive (about 9 of every 10 patients). Lewis-negative individuals can either be secretors or nonsecretors. Lewis-negative patients carry important metabolic consequences of their own, worthy of much attention.[10] Table 43.2 shows Lewis blood types and their relationship to ABH secretor and/or nonsecretor status.

Sialylated forms of several Lewis variations (sialyl Lewis A, sialyl Lewis X) are oligosaccharide ligands now considered crucial to the initial adhesion of white blood cells to a site of injury mediated by E-selectins. Large quantities of sialyl Lewis X have also been found on the surfaces of certain tumor and cancer cells, and one of its variants (sialyl 6-sulfo Lewis X) appears to be involved in routine homing processes involving a variety of chemokines.

Individuals of blood group O phenotype run an approximate 1.5- to 2-fold higher risk for development of peptic ulcer disease,[45]

TABLE 43.2 Lewis (Le) Blood Types and Their Relationship to ABH Secretor and/or Nonsecretor Status

Lewis Type	Category	Abh Secretor Status
Le^{a+b-} Le^a antigen but not Le^b	Lewis positive	ABH nonsecretor
Le^{a-b+} Le^b antigen but not Le^a	Lewis positive	ABH secretor
Le^{a-b-} Neither Le^a nor Le^b	Lewis negative	Lewis outcome cannot determine ABH secretor status

although there is no direct correlation between ABO blood group phenotypes and the prevalence of *Helicobacter pylori* infection. However, in addition to H type 1, the Le^b antigen is also a binding receptor for *H. pylori,* and in this capacity, it can best be described as a "virulence-promoting factor." For virulent strains, Le^b antigen binding activity targets the microbes to the epithelial cell surfaces and potentiates the effect of secretion of virulence factors, such as the vacuolating cytotoxin and/or neutrophil activating–recruiting factors.[46]

Linkage and Pleiotropism

Linked genes occur on the same chromosome and are inherited as a single unit. Gene linkage analysis shows several genes linked to the ABO locus. For example, there are strong indications that a gene regulating dopamine β-hydroxylase activity is linked to the ABO blood group locus.[47] Dopamine β-hydroxylase is a key enzyme in the conversion of dopamine to norepinephrine.

This linkage may help explain the continued significance of ABO group as a discreet and significant genetic marker for a variety of affective disorders, including type A behavior in men subsequent to myocardial infarction[48] and bipolar depression,[49,50] each of which has been associated with blood group O. The ABO locus shows putative linkage with platelet monoamine oxidase activity,[51] reduced levels of which have been noted in group O healthy men.[52]

Additional evidence implies that there is a linkage between the ABO gene and the gene that regulates the activity of the enzyme argininosuccinate synthetase, which recycles arginine from citrulline in the production of nitric oxide.[53] A letter to the editor in the journal *Lancet* reported differences between ABO groups in their responsiveness to inhaled nitric oxide therapy: types with a B antigen (B and AB) had less success with this therapy.[54]

Elevated factor VIII (FVIII) levels contribute to venous thrombotic risk. FVIII levels are determined to a large extent by levels of von Willebrand factor (vWF), a protein that protects FVIII against proteolysis.[55] ABO polymorphism is one of the best-characterized genetic modifiers of plasma FVIII; it accounts for approximately 30% of the total genetic effect.[56] Subjects with blood group non-O have higher vWF and FVIII levels than individuals with blood group O.[57]

Digit ratio, a marker of assessing the levels of prenatal exposure to androgens, has yielded mixed results[58,59] as a predictor of androgen stimulation in individuals with polycystic ovarian syndrome. However, preliminary evidence suggests that genes contributing to the expression of 2D:4D reside in the vicinity of the gene loci (chromosomal locations: 9q34.2 and 1p36.11) of the blood groups or that there may be pleiotropic effects on digit ratio as a result of the blood group genes. Associations using digit ratios may require incorporation of the ABO blood group in their interpretation.[60]

Additional Physiological Correlations

In addition to the previously described variations in IAP and brush-border hydrolase activity, several additional circumstances where ABO polymorphism exerts a significant influence on physiology have been reported.

Gastric Acidity

Because the prevalence of both pernicious anemia and gastric cancer is higher in individuals of blood group A and that of duodenal ulcer is higher in those of group O, a hypothesis relating blood group effects on acid secretion was inevitable.[61] Early work confirmed that acid output tended to be greater in group O than in group A subjects.[62,63]

Gastrin and Pepsinogen

In one study, serum pepsinogen A (pepsinogen I) levels were studied in relation to ABO blood group, age, and gender in 700 healthy blood donors. Serum pepsinogen A levels were higher in males than in females and rose with increasing age. Blood group O individuals showed higher serum pepsinogen A levels than blood group A individuals.[64] There is also evidence that the type A antigen in gastric juice binds to pepsin and possibly inactivates it.[65] A study using serum pepsinogen levels as a marker for gastric atrophy showed a high association with blood groups A and B.[66] However, possibly owing to the polygenic nature of pepsinogen activity, one study failed to find any significant difference in pepsinogen levels between ABO groups.[67]

Another study looking at ABO polymorphism and serum gastrin concentration after stimulation by a glycine drink could find no correlation with ABO blood group.[68] However, the study had a simple preprandial and postprandial methodology. In a different study, the concentrations of gastrin were measured in the blood of 121 fasting healthy Greek volunteers of both sexes and different ABO blood types, between ages 20 and 70 years. The testing took place immediately after a test meal was eaten by subjects who had fasted for 8 hours; the measurement was repeated at 10 and 40 minutes post-meal. The researchers found that gastrin levels took 40 minutes to increase after the meal in the blood type A and B subjects but that a significant increase appeared 10 minutes after the meal in the blood type O subjects.[69]

Cholesterol

Although several studies on highly select populations have yielded conflicting results,[70,71] the general consensus is that blood group A individuals have a significantly higher basal cholesterol level than those in other blood groups. The relationship between ABO blood phenotype and total serum cholesterol level was examined in a specific Japanese population. The results showed that cholesterol levels were very significantly elevated in the blood type A group compared with non-A.[72]

ABO blood group and coronary risk factor levels were measured in a nationwide sample of more than 6000 black and white adolescents aged 12 to 17 years. Blood group A was associated with significantly higher serum total cholesterol levels in white females independent of all other risk factors, in white males independent of age and weight, and in Southern black females independent of age and weight.[73] A separate study (the Bogalusa Heart Study) looked at 656 white and 371 black adolescents and found the same results with regard to total cholesterol; even higher levels of low-density lipoprotein cholesterol were found in type A adolescents than in other blood types.[74]

Stress

Several studies have identified differences between ABO group and possible chemical responses to stress. Interestingly, individuals of blood group A appeared to have a lower incidence of "type A personality."[75]

One study evaluated the influence of blood type A versus O coupled with a mirror-drawing stressor on very-low-density lipoprotein toxicity-preventing activity (TxPA). Plasma cortisol levels showed significant ABO variation. Exposure to the stressor significantly decreased TxPA and increased cortisol for the total group of 25 older men. The stress response patterns of the 15 blood type A men were different from those of the 10 type O subjects. The blood type A group had higher initial levels of TxPA and cortisol as well as quicker stress recovery rates than the type O group.[76] Another study showed that blood group A individuals responded to a stressful situation (venipuncture) with higher levels of cortisol and, possibly, of adrenaline.[77]

Rheology

For purposes of this discussion, *rheology* is used to describe the dynamics between blood clotting (moving toward a solid state) and blood thinning (moving toward a liquid state). It might be tempting to substitute the word *viscosity* for *rheology* when talking about blood types and clotting. Viscosity, however, does not cover the "dynamics" of how, when, and why blood can change texture; it only distinguishes one texture state from another.

There is evidence that the rheology of blood may play a role in a variety of chronic anxiety states. Compared with normal subjects, chronic depressive and schizoid patients had very significant differences in their blood rheology and in the ability of their RBCs to aggregate. When patients with schizoid anxiety were compared with those with depressive anxiety, their ratio of albumin to globulin was increased. When patients were divided according to their ABO blood groups, significant differences were found in their albumin:fibrinogen ratio and their blood viscosity. This was particularly true for women who had blood type A and who had depressive anxiety; their blood tended to be substantially "thicker" and to have higher amounts of serum proteins in it than women with similar depression who had blood type O.[78]

Associations between the ABO phenotype and variations in blood rheology have also been reported in high blood pressure[79]; stress[80]; diabetes[81]; heart attack, cancer, and thyroid disease[82]; kidney failure[83]; and malignant melanoma.[84]

Soluble Endothelial Cell Markers

Selectins are cell–cell adhesion molecules that are involved in leukocyte–endothelial cell adhesive interaction, which is required for extravasation at target tissue sites. Three types of selectins have been discovered: L-selectins are generally expressed on almost all leukocytes, E-selectins are inducible on vascular endothelium upon stimulation with cytokines, and P-selectins are found on activated platelets.

The role of thrombomodulin as a C-type lectin is less known. It has a domain that interferes with neutrophil adhesion to endothelial cells. Elevated levels of E-selectin ($P < 0.001$) and thrombomodulin ($P < 0.001$) are linked with blood type A individuals.[85]

PATHOLOGICAL PROCESS AND ABO BLOOD GROUPS

Mental Disease

There are several reports exploring the relationship of ABO groups, ABH and Lewis secretor type, and mental disease such as obsessional illness,[86] bipolar disorder,[87,88] depression,[89] and schizophrenia.[88] A significant part of that research was done in the 1970s and 1980s and does not seem to have been updated or explored much further. Most of the articles reviewed and not discussed here were not conclusive about blood group associations.

Cardiovascular Disease

Stroke

A European study compared 50 patients with stroke. The standard expected frequency of ABO blood types in the surrounding population showed that the frequency of the blood group A in the patients with stroke was 120% greater than would normally be expected. The percentage of blood type B was even higher (159% of expected rate of occurrence). Patients with blood type O were only 85% as likely to experience stroke.[90]

A 1979 study of 220 patients with stroke looked at the viscosity of their blood a few hours after the stroke event. About 80% of the patients had blood cells that easily aggregated. What was especially interesting was the discovery by the researchers that the clotting of blood in patients with A and B blood types was mostly due to fibrinogen, whereas in blood types O and AB, it was caused by other clotting factors.[91]

Individuals with blood types A and AB have a generalized tendency toward problems associated with blood clotting, whereas problems in those with blood types B and O appear to be linked to excessive bleeding and poor clotting. This observation was verified in several studies, the largest being performed in 1460 patients with "stroke" and reported in the *Lancet.* In 329 cases, the cause of death was certified as cerebral thrombosis (brain clot). In the thrombosis cases, there was an excess of patients of blood types A and AB and a deficiency of those with blood types O and B. In the 482 "strokes" that were due to cranial bleeding, the reverse was true: there was a significantly higher proportion of patients with blood types O and B than of those with blood types A and AB.[92]

A 2009 United Kingdom systematic review tried to assess whether the effects of non-O status on thrombosis risk were of the magnitude predicted by its effect on vWF/FVIII levels (Fig. 43.3). They confirmed the historical impression of linkage between some vascular disorders and non-O blood group status. They concluded that the odds ratios were similar to those predicted by the effect of ABO(H) on vWF levels on thrombosis. They proposed further work to understand and refine the effect of reducing O(H) antigen expression and therefore a more widespread adoption of ABO(H) typing.[93]

Peripheral Artery Disease and Venous Thromboembolism

Peripheral artery disease (PAD) occurs in approximately 12% of the adult population. The prevalence of PAD increases with age: almost 20% of people older than 70 years have the disease. E-selectin and thrombomodulin levels are always elevated in intermittent claudication, a disorder almost always found with PAD and carrying a distinct association with blood type A.[94]

In 125 patients experiencing venous thrombosis in a Brazilian population, a higher-than-expected proportion of blood group A and a lower-than-expected proportion of blood group O were observed among the patients.[95] This is consistent with the previously discussed influence of ABO on a third soluble endothelial product, vWF, and its role in thromboembolism. Another study in 2007 confirmed that non-O blood type was independently associated with risk of venous thromboembolism and added to the risk associated with FV Leiden (hypercoagulability).[96] Even in pregnancy, a nested case-control study within a cohort of 71,729 women who gave birth to 126,783 children in Denmark showed that blood groups A and AB might be associated with increased risk estimates for venous thromboembolism in pregnancy and the puerperium.[97]

Heart Disease

There is a clear-cut association with having A and AB phenotypes and an increased risk for heart disease. This association has been reported continuously in the scientific literature over the past 50 years. Individuals who have blood type A have higher rates of heart attack in all age groups, both genders, and all ethnic and national groups.

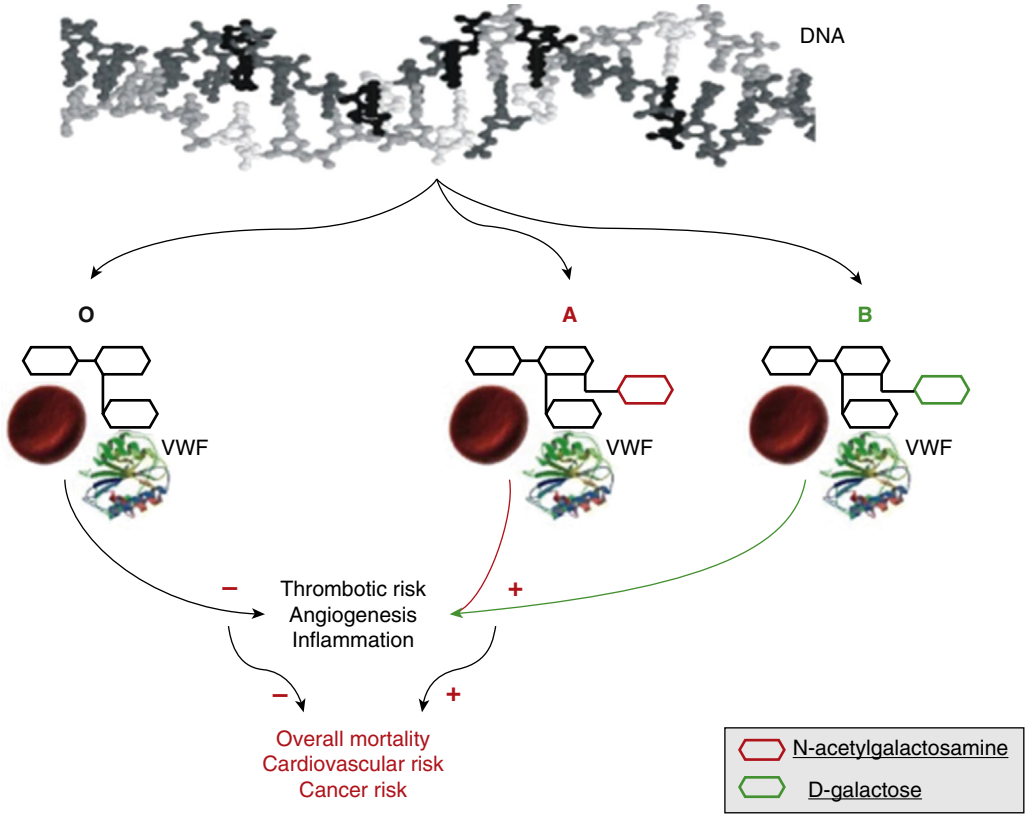

Fig. 43.3 The intriguing relationship between ABO blood group system, von Willebrand factor (vWF), and cardiovascular disease. (From Franchini M, Lippi G. The intriguing relationship between the ABO blood group, cardiovascular disease, and cancer. *BMC Med.* 2015;13:7. PubMed PMID: 25592962. https://openi.nlm.nih.gov/detailedresult.php?img=PMC4295232_12916_2014_250_Fig1_HTML&query=ABO+blood+grouping&req=4&npos=156. Accessed October 21, 2018.)

In 1962 the Framingham Heart Study typed the blood of the surviving 4125 members of the original study group of 5209 people first examined from 1948 to 1951. The most striking observance was the lower rates of nonfatal heart disease in men aged 39 to 72 years with blood type O than in those with blood type A.[98] A 1994 Polish study on patients who underwent coronary bypass surgery with highly advanced arteriosclerosis of the coronary arteries found a significantly higher number of cases with group AB and a lower number of those with group O.[99] A 1981 German study of 13,175 patients showed a prevalence of blood type A in all types of heart disease examined.[100]

In a study of 191 coronary artery bypass candidates, investigators paradoxically found an excess of type O over type A subjects. After examining the data more closely, they concluded that the tendency of type A subjects for more ready development of blood clots ("thrombotic proneness") led to a poorer prognosis. In essence, the blood type A subjects were missing from the study because they had already died in greater numbers, leaving a disproportionate number of type O subjects among the long-term survivors.[101] In a study of male survivors of heart disease, researchers found that there were fewer patients who were type A and younger than 55 years than would have been otherwise expected.[102]

A 1975 Italian study of 746 patients with high blood pressure, 3258 with congenital heart disease, and 4503 with a history of heart attack found a significant lack of patients with type O blood and a significant excess of blood type A patients in the group with myocardial infarction. The study also showed an excess of blood type A patients with high blood pressure and a lack of patients who were blood type B.[103] A 1983 study of 255 women originally investigating the effects of smoking on the rates of heart attack also found several other factors significantly associated with heart attacks in this group, including hypertension, angina pectoris, family history, diabetes mellitus, and blood type A.[104]

Platt et al.[105] examined blood type and heart attacks in two different age groups. The patients were divided into two groups: 65 years or older and younger than 65 years. The predominance of blood type A in patients with cardiac infarction was "highly significant" in both age groups ($P < 0.005$). This study was unique in that it excluded other risk factors, such as smoking, high blood pressure, diabetes, and high cholesterol levels. When the researchers looked specifically at the older group, the predominance of blood group A in those with cardiac infarction was even higher ($P < 0.001$). The researchers concluded, "Our investigation strongly suggests the existence of a genetic factor associated with blood group A and independent of the other risk factors, which is also responsible for a greater incidence of cardiac infarction."[105]

An 8-year study of 7662 British men found that blood type A was linked to the incidence of ischemic heart disease as well as higher total serum cholesterol concentrations.[106] A 2015 study confirmed this association and additionally linked any blood group that is not type O with increased mortality due to cardiovascular disease.[107]

Cancer

> *"Some cancers contain an A-like substance even when they occur in persons who are not A or AB. These observations suggest that in the tissues, both normal and neoplastic, of all persons, there are blood group A-like antigens present at a biochemical level, which are usually inaccessible to the immune system." Mourant (Blood Groups and Disease, 1977)*

Tumor development is usually associated with changes in cell-surface carbohydrates. Cell glycosylation depends on the expression and function of various glycosyltransferases and glycosidases. These enzymes modify the carbohydrate core structure or the terminal carbohydrate structures, resulting in the incomplete synthesis or modification of existing carbohydrates. Considerable research demonstrates that malignant transformation is associated with various and complex alterations in the glycosylation process.

These and other changes provide a selective advantage for tumor cells during their progression to more invasive and metastatic forms. Some of the more studied glycoprotein modifications include the following[108]:

- Increase in *N*-glycation and O-glycation and fucosylation processes
- Increase in mucins
- Alteration in galectin levels and specificities
- Increase in cell-surface sialylation
- Increase in chitinase-like proteins and proteoglycans
- Increase in glycosphingolipids

The blood group–related carbohydrate structures Le(x), sialyl-Le(x), ABH, and Le(y) are examples of terminal carbohydrate structures that are related to tumor prognosis. These structures are of increasing interest because they may function as adhesion molecules or motility factors.[109]

Thomsen-Friedenreich Antigen (Pancarcinoma-Associated Antigen)

Many malignant cells develop a tumor marker called the Thomsen-Friedenreich (T) antigen (TFA). Tn and sialyl Tn (STn) appear to result from somatic mutations in the *Cosmc (C1GALT1C1)*. Diverse neoplastic lesions, including colon cancer and melanoma-derived cell lines, express both Tn and STn antigen due to loss-of-function mutations in *Cosmc*.[110] This antigen is encrypted in normal healthy cells, much like a rock is covered over by water at high tide. T antigen becomes "unsuppressed" only as a cell moves toward malignancy, much like the example of the covered rock, which is uncovered as the tide moves out.

It has been estimated that T antigen (or its precursor, Tn antigen) is expressed in about 90% of all cancers, earning it the appellation "pancarcinoma-associated antigen."[111] As a general rule, an orderly expression of T antigens on a cancer cell usually indicates a relatively favorable outlook. However, a prevalence of Tn antigens on a cancer cell usually denotes a highly aggressive, metastatic cancer, irrespective of the form of cancer or organ involved.[112]

Tn antigen is rarely found in healthy tissue; most people produce TFA agglutinins antibodies to it, probably in response to cross-induction by the gut flora. ABO blood group appears to influence the amount and activity of these antibodies against T and Tn antigens. Although derived from the MN blood type antigen, Tn antigen shows structural homology to the A antigen because they share terminal GalNAc. Because antibodies against Tn antigen cross-react with A glycolipids, Tn antigen was concluded to be an A-like antigen in a broad sense. Blood group A patients with gastric cancer have the greatest and most uniform suppression of TFA agglutinins levels, irrespective of age, cancer stage, or tumor morphology.

Inadvertent Elaboration of Blood Group Antigens

Deletion, reduction, or inappropriate expression of blood group A or B antigen in tumors of blood type A or B individuals is clearly correlated with the level of malignancy and metastatic potential.[113] The most significant variations are summarized in Table 43.3.

A and B blood group antigens are present on carcinoma cells at the early stages of carcinogenesis and tend to disappear at later stages.

TABLE 43.3 Variation in Blood Group Antigen (BGA) Expression in Normal and Neoplastic Tissues

Tissue, Organ	Normal Expression of BGAS	Expression of BGAS in Malignancy	Reference
Colon[a]	Present	Absent	157
Bladder[b]	Absent	Present	158
Prostate	Present	Absent	159
Liver[c]	Absent	Present	160
Squamous	Present	Absent	161
Endometrium[d]	Absent	Present	162
Stomach	Present	Absent	163
Thyroid[a]	Absent	Present	164
Esophagus	Present	Absent	165

[a]Inversely correlated.
[b]BGAs better than all other tumor markers.
[c]BGAs effective at predicting hepatitis transformation to malignancy.
[d]Vast majority of BGAs secreted are H antigen.

TABLE 43.4 Correlation of CA19-9 and DU-PAN-9 Expression in Colorectal Cancer With Lewis (Le) Type

Lewis Phenotype	Ca19–9 Expression[a]	Du-Pan-9 Expression
Le^{a+b-}	Highest levels	Lower levels
Le^{a-b+}	High levels	Lower levels
Le^{a-b-}	Zero to very low levels	Highest levels

[a]Individuals having homozygous inactive Se alleles *(sese)* and homozygous active Le alleles (*LeLe*) exhibited the highest mean CA19-9 value. All of the Lewis-negative individuals (*lele* genotype) had complete absence of CA19-9, irrespective of the Se genotype.[10]

The blood group A antigen may render malignant cells resistant to apoptosis.[114]

Lewis blood groups can modulate the expression of several tumor-associated antigens, including DU-PAN9 and CA19-9. Some researchers have suggested that taking into account Lewis secretor status to establish reference ranges for the tumor antigen measurements might actually be a way to improve their clinical utility. This relationship is shown in Table 43.4.

The association of blood groups with cancer was first demonstrated by Aird et al.[115] in 1953, pointing to group A with gastric carcinoma. One hypothetical mechanism is that the carcinoma cells produce an antigen immunologically related to blood group A, which may have a protective effect, particularly in blood group O individuals, by prevention of the growth and spread of the tumor.[116] It appears that the progression of stomach cells to stomach cancer involves a necessary mutation at the ABO gene, the result of which is the production of A antigen, even if this is not the person's blood type. This "A-like" antigen may not be the true A antigen but, rather, what one researcher called "tumor-associated, A cross-reacting antigens occurring in a wide variety of human adenocarcinomas of hosts belonging to all ABO blood groups."[117] There is also a B-like antigen noted in colon or rectal carcinoma and other malignant processes.[112] More data need to be collected about different malignant processes. A 2009 study in Italy that retrieved tumor data on 15,359 patients was able to show that exocrine pancreatic malignancy

was associated with the ABO blood group, but no other probabilistically significant correlations were made, or correlations were made but discarded, about other malignancy associations.[118]

Epidermal Growth Factor

The epidermal growth factor receptor (EGF-R) bears an antigenic determinant that is closely related to the human blood group A carbohydrate structure. A higher number of high-affinity EGF binding sites was observed in donors with blood group A1 erythrocytes than in donors with blood groups O and B.[119]

That the blood group A antigen can also bind to EGF-Rs is now well documented, so it is not unlikely that free A antigen in individuals with blood groups A and AB (especially if they are secretors) can find their way onto these excess EGF-Rs and act to stimulate cell growth. As with vWF and FVIII, excessive activation of the EGF-R results in cancer cells that become more mobile and better able to develop new and additional blood supplies (angiogenesis).[120]

One reason that low stomach acid is linked to type A blood may have to do with the role of EGF discussed in the previous section on saliva, "ABH Secretors and Nonsecretors." As described, the EGF-R has a high affinity for the type A antigen, and although the major action of EGF is to stimulate repair of the digestive lining, it has also been shown to decrease acid production in the stomach.

Pancreatic Cancer

The state of the art in the field of pancreatic cancer research continues to prove the relationship of malignancy to ABO blood group. A clinical trial for pancreatic ductal adenocarcinoma that involved 3000 people from the Han population showed that higher risk, higher state of malignancy, and less survival after surgery was associated with non-O blood groups.[121] Analyzing ABO genotype alleles with a genome-wide association study (PanScan) identified significant associations at the ABO gene locus with risk of pancreatic cancer. An increase in risk was noted with the addition of each non-O allele. Compared with OO genotype, AA presented a higher risk than AO in the 3000 patients analyzed.[122]

To help identify what aspect of the O allele is involved in lowering the pancreatic cancer risk in 2009, 558,542 single-nucleotide polymorphisms (SNPs) were genotyped in 1900 cancer patients and an equal number of control patients. A link was found between a locus on 9q34 and pancreatic cancer marked by the SNP rs505922. This SNP maps to the first intron of the ABO blood group gene, corroborating the epidemiological fact that people with blood group O may have a lower risk of pancreatic cancer than those with groups A or B.[123]

The enzyme glycosyltransferase is associated with increased pancreatic cancer risk impact rather than actions of other nearby genes on chromosome 9q34. Glycosyltransferase activity is greater for the A1 versus A2 variant. In a 2010 cancer cohort study, an increased risk in participants with A1, but not A2, alleles was observed. The same study showed that the protective effect of the O allele would be equivalent for O01 and O02 variants. Secretor status was not an effect modifier.[124]

Having a non-O ABO blood group and colonization by *H. pylori* are risk factors for pancreatic cancer. In a study at the Yale School of Medicine in 2010, an association between pancreatic cancer risk and CagA-negative *H. pylori* seropositivity was found among individuals with non-O blood type but not among those with O blood type, proving that there is an association between pancreatic cancer and *H. pylori* colonization, particularly for individuals with non-O blood types.[125]

Breast and Other Gynecologic Cancers

The following articles represent a sampler of the advances in understanding relationships between ABH antigens, secretor status, and the incidence and prognosis of different gynecologic-related cancers. In 2009 a correlation between breast cancer in Greek women and ABO blood group was published. One hundred sixty-six female patients with breast cancer were examined. They revealed that blood group A is more often associated with ductal breast cancer (49.6%), in contrast to the other blood groups, and particularly to blood group AB (3.6%). The relative risk of metastasis in Rh (−) patients was 4.2 times higher than that in Rh (+) patients. Consequentially, blood group A, and particularly A (−), has the worst prognosis of all.[126]

Breast cancer researchers have given the aberrant glycosylation moiety T/Tn antigen the moniker "ligand-like complex" (LLC). By virtue of altered antigenicity, LLC allows for both metastatic egress from the regional lymph nodes and detachment from the extracellular matrix and thus is associated with cancers of poor prognosis.[127] We believe that LLC may well be the "A-like," pancarcinoma cross-reacting antigen. Observation of the GalNac-binding lectin from the Roman snail, *Helix pomatia* agglutinin, appears to identify this oligosaccharide[128]; there have been separate reports that "Springer's vaccine" (human group O RBC membrane–derived T/Tn antigen containing traces of phosphoglycolipid A hyperantigen) has had significant effect as an immune modulator in breast carcinoma of even advanced stage.[129]

A study of epithelial ovarian cancer incidence and its association to ABO blood groups and risk was performed in 2010 at Harvard and analyzed data from 49,153 women in the Nurses' Health Study. Compared with women with blood group O, women with blood group AB or B had a nonsignificant 38% increase in ovarian cancer incidence, whereas blood group A was not associated with risk. Combining blood groups AB and B, they observed a statistically significant positive association with presence versus absence of the B antigen for the serous invasive subtype and overall. In this large, prospective cohort of women, the presence of the B antigen was positively associated with ovarian cancer incidence, whereas blood group A was not associated with the same risk.[130]

Another interesting, yet not definitive, association is presented between invasive squamous cell carcinoma (SCC) of the vulva and ABO blood groups. The distribution of ABO blood group for 33 women diagnosed with invasive SCC of the vulva was determined. ABO blood group was also recorded for 100 female patients (controls) who underwent a gynecologic procedure for a nonneoplastic process during the same period. A trend was identified for women with invasive SCC of the vulva to have blood group type A, but this did not determine a definitive association between blood group type A, or any other blood group, and vulvar SCC.[131]

Other Cancers

In two large independent populations, non-O blood group was associated with a decreased risk of skin cancer. The association was statistically significant for nonmelanoma skin cancer. Additional studies are needed to confirm these associations and to define the mechanisms by which ABO blood type or closely linked genetic variants may influence skin cancer risk.[132]

In addition to original studies on gastric carcinoma, a 2016 study associated blood group A with an increased risk of cancer of the pharynx and esophageal adenocarcinoma.[133] The ABO blood group is not only associated with incidence but also prognosis. Research showed that blood group A was a negative prognostic factor in gastric carcinoma.[134] Another 2017 study showed that of gastric cancer patients with a positive postoperative CEA cancer marker, those with blood group AB were more likely to have a better survival rate.[135]

TABLE 43.5 Mechanisms of ABO Influence on Infectious Disease[10]

Class	Mechanism	Description	Example
Selectivity	Adhesion kinetics	Adhesion or lectin specificities of the infectious agent based on particular ABH glycosylation	*Candida albicans* (group O)
	Humoral dynamics	Inadequate isoagglutinin production or activity	*Neisseria gonorrheae* (group B)
	Molecular mimicry	Infectious agent is antigenically similar to host's ABO group	*Giardia lamblia* (group A)
Response variability	Host response	Variation in severity of disease through unique biological response (examples: inappropriate inflammatory response; rosette formation)	Cholera (group O) Dengue fever (group B) Malaria (group A)
	Substrain susceptibility	Different ABO groups often show variations in susceptibility between individual bacterial, fungal, or parasitic species or viral strains.	Influenza (all groups) Malaria (group O vs. group A)

In colorectal cancer, there is no specific association with blood group type, but there is a significant difference between the Rh(+) and Rh(−) groups. Further studies on blood group antigens are needed to elucidate the relationship between these antigens and colorectal cancer.[136]

Infection

To a great extent, infectious diseases, especially the worldwide epidemic diseases, have selective effects. This is demonstrated, *inter alia,* in the different "selection values" in the ABO blood group system. During the eons before antimicrobial intervention, selection variability via ABO polymorphism was a preeminent natural survival mechanism.

The previous section appears to imply a selection disadvantage for group A individuals, and it has been argued that under present-day civilized living conditions, blood type O carriers have a preservation advantage over blood group A carriers.[137] This may be the result of the deletion of the selection factor "infectious disease," which may nevertheless regain importance if environmental changes occur.[138]

Historically, some of the most catastrophic epidemic and endemic diseases are ABO selective and, in many instances, demonstrate ABO variation in morbidity, mortality, or microcharacteristics such as substrain preferentiality and level of inflammatory response. They include cholera (O), smallpox (A), malaria (A), and influenza (variable subsets depending on strain).

The influence of ABO polymorphism on infectious disease appears to stem from a multitude of unique factors. These are encapsulated in Table 43.5. A morbidity and mortality variation among the ABO and secretor groups is presented in Table 43.6. A special examination of polymorphic differences in uropathic infectious disease is presented in Table 43.7.

An interesting study done in Sudan about placental malaria showed that women of eastern Sudan are at risk for placental malaria infection irrespective of their age or parity but that women with blood group O were at higher risk of past placental malaria infection.[139] A higher seroprevalence of IgG *H. pylori*–specific antibodies was observed in gastric ulcer patients (90%) compared with the control group (60%). A significant increase of phenotypes O, A2, and Le^b in *H. pylori*–infected patients was observed. The expression of these antigens had progressive alterations in areas of ulcerous lesions and intestinal metaplasia; therefore ABH and Lewis blood group antigens appear to be a good indicator for cellular alterations in the gastric epithelium.[140]

For a more detailed examination of particular infectious scenarios, the reader is referred to the author's comprehensive survey.[141]

Periodontal Disease and Oral Malignancy

A recent study segregated populations (1220 subjects aged between 20 and 55) into three groups according to Ramfjord's periodontal disease index: healthy, gingivitis, and periodontitis. Blood types were confirmed for each of the participants. Effectively, blood group A showed a significantly higher percentage in the gingivitis group, and blood group O showed a higher percentage in the periodontitis group. The blood group AB showed the least percentage of periodontal disease. The distribution of Rh factor in all groups showed a significantly higher distribution of Rh-positive.[142]

In most human carcinomas, including oral carcinoma, a significant event is decreased expression of histo–blood-group antigens A and B. A relative down-regulation of the glycosyltransferase that is involved in the biosynthesis of A and B antigens is seen in oral carcinomas in association with tumor development. As reviewed previously, the events leading to loss of A transferase activity are related, in some instances, to the loss of heterozygosity involving chromosome 9q34, which is the locus for the ABO gene, and in other cases, to hypermethylation of the ABO gene promoter. Altered blood group antigens in malignant oral tissues may indicate increased cell migration. Some studies showed that normal migrating oral epithelial cells, like malignant cells, show lack of expression of A/B antigens and, therefore, lack of ABH antigens to key receptors controlling adhesion and motility, such as integrins, cadherins, and CD-44.[143]

BLOOD GROUPS AND DIETARY LECTINS

ABO polymorphism is one of the prime determinants of the glycosylation variability of gut mucin. As such, it affords insight into the actions of a class of carbohydrate-binding dietary proteins called lectins, which are increasingly a subject of interest for nutritional researchers.

Historical Perspective

Stillmark at the University of Dorpat in Estonia first identified lectins in 1888. While investigating the toxic effects on the blood of castor bean extract *(Ricinus communis),* he noticed that the RBCs were being agglutinated. He isolated the material responsible for the agglutination and called it ricin.

In 1945 William Boyd of the Boston University School of Medicine discovered that lectins can be blood group specific, being able to agglutinate the RBCs of one type but not those of another. He discovered that lima bean lectin would agglutinate RBCs of human blood type A but not those of O or B. The seeds of *Lotus tetragonolobus* can agglutinate group O specifically, and *Bandeiraea simplicifolia* is specific to group B. The specificity of lectins is so sharply defined that they can differentiate among blood subgroups. *Dolichos biflorens* lectin reacts more vigorously with blood group A1 than with A2.

The word *lectin* was proposed by William Boyd in 1954 to describe a class of blood type–specific agglutinins found in certain plants. The word is allegorical, to a degree, because it derives from a Latin word meaning "to choose."

Actions of Lectins

The surface epithelium of the gut is extensively glycosylated,[144] mainly because most membrane proteins, including hormone and growth

TABLE 43.6 Influence of ABO Polymorphism on Susceptibility to Various Infectious Agents[10]

Strain	Susceptible Phenotype	Comments
Amoebic dysentery	O, A	• Blood groups B and AB have a degree of resistance against developing severe or acute dysentery, especially the amoebic forms.
Candida carriage	O, NS	• *Candida* carriage was associated with blood group O ($P < 0.001$) and, independently, with nonsecretion of blood group antigens ($P < 0.01$). • *Candida albicans* extracellular polymeric material contains a mannoprotein adhesion with a lectin-like affinity for H (type 2) blood group antigen. • There was a significantly higher number of nonsecretors (48.9%) among 174 patients with either oral or vaginal *Candida* infections compared with the proportion of nonsecretors in the local population (26.6%). Nonsecretor saliva actually seemed to enhance *Candida* attachment.
Cholera	O, AB	• Blood group O individuals have a greater risk of infection with cholera and develop the most severe and life-threatening forms of this illness. This has been documented in several studies. • In contrast, type ABs appear to have the highest degree of protection from cholera infections. • Type O had more diarrhea-like stools per day than persons of other blood groups and were more likely to report vomiting and muscle cramps.
Coccidioidomycosis	B	• Blood group B individuals are more prone to disseminated disease after exposure.
Dengue fever	B	• According to researchers, blood group B was strongly associated with the severe form of dengue fever known as dengue hemorrhagic fever.
Dermatophytosis	A	• The fungus *Trichophyton rubrum,* isolated from 54.5% of the patients tested, was more frequent in individuals belonging to blood group A.
Escherichia coli	Variable subsets	• It appears that many forms of *E. coli* capable of causing diarrhea are immunologically "B-like." This results in a substantially higher number of cases of diarrhea among individuals of blood group B and AB people. • However, when it comes to the overall severity of infection with *E. coli,* types B and AB are not alone; type Os also are more likely to get a severe form of diarrhea.
Giardia	A	• Blood group A is more susceptible to giardiasis, especially the asymptomatic form, whereas blood group B is less susceptible to giardiasis.
Helicobacter pylori	O, nonsecretor	• *H. pylori* variants produce a variety of blood group antigens, including A, Lewis (a), and a variety of type 1 H like antigens (O). • Group O would be a moderate risk factor for infection by *H. pylori,* with more severe cases in men. • Group O has a more pronounced inflammatory reaction to *H. pylori.* Group O cells released significantly more IL-6 and TNF in response to *H. pylori* infection. • The Lewis^{a+b-} nonsecretor phenotype and blood group O are relevant genetic markers of peptic ulcer. • The Lewis^{a+b-} nonsecretor phenotype and blood group A were all positively associated with esophageal adenocarcinoma, with concurrent *H. pylori* infection.
Hookworm	O	• A 1972 Egyptian study correlated type O with higher incidence of hookworm and strongyloidiasis.
Influenza	Variable subsets	• Blood group A: Generate a quick and substantial antibody response against influenza type A(H1N1) and especially A(H3N2). The antibody response against influenza B is not quite as dramatic. • Blood group AB: Relatively poor ability to generate high antibody levels against any of the influenza viruses. • Blood group B: Reasonable, but not great ability to generate an antibody response against influenza A (H1N1). Slowest (3–5 months) and weakest ability to generate antibodies against influenza A (H3N2 "Hong Kong") of any blood group. Against influenza B virus, blood group B has a significant advantage and responds differently from either blood group A or O. The blood group B immune response happens much earlier and persists longer. • Blood group O: Moderate ability to generate antibody response against influenza A (H1N1) and A (H3N2) viruses. Antibody response against influenza B is not as dramatic as blood group B.
Malaria	A, AB	• The evidence suggests that blood group A individuals might have a higher predisposition to infection with the *Plasmodium vivax* species, whereas blood group B individuals tend toward higher infection rates with *P. falciparum.* • Malaria-infected RBCs sometimes bind to uninfected RBCs to form clumps, called rosettes. The rosettes can obstruct flow in small blood vessels and lead to tissue damage and severe malaria disease. The tendency for malaria to be worse among As and ABs is due primarily to a greater degree of rosette formation by RBCs with these antigens. • Von Willebrand factor, always elevated in type A, also enhances rosette formation.
Neisseria gonorrheae	B	• The relation of infection with *N. gonorrheae* to the blood groups A, B, AB, and O was examined in 584 women attending a prenatal clinic. The occurrence of gonorrhea was significantly higher in black patients with blood group B than in those with blood groups A, AB, or O. Depending on the ABO blood group, gonorrhea may affect the titers of isohemagglutinins compared with those of uninfected controls. • The isohemagglutinin titers in group O patients were significantly increased ($P < 0.001$) against erythrocytes A, B, and AB. In group A patients, only the titer against AB erythrocytes was significantly increased. • In group B patients, the titer against AB erythrocytes was significantly lower ($P < 0.001$) compared with that in sera of healthy persons.

TABLE 43.6 Influence of ABO Polymorphism on Susceptibility to Various Infectious Agents[10]—cont'd

Strain	Susceptible Phenotype	Comments
Norwalk virus (NV)	O	• It appears that group O RBCs are most easily bound by NV versus group B RBCs that are apparently little bound, if at all. Individuals with an O phenotype were more likely to be infected with NV. • The preferred binding sites are apparently the H type 2 antigen that functions as the viral receptor on human type O RBCs. • The Lewis B antigen (found in secretors) is also a binding site.
Schistosomiasis	A	• Group A tends to be more susceptible to infection, tends to get more intense symptoms after infection, and is much more likely to have damage to organs (e.g., the liver) after infection.
Shigellosis	B, AB	• A strong association between blood group B (and AB to a slightly lesser degree) and shigellosis exists.
Smallpox	A	• Group A has higher mortality from smallpox infection. • Group A individuals also have more reactions from smallpox vaccination. • The leukocytes of peripheral blood of group A individuals showed a poorer binding capacity with respect to the smallpox vaccine virus. • Blood group A also exhibited a high rate of chromosomal aberration after vaccination, resulting to some extent from increased proliferative ability of the cells.
Staphylococcus aureus	A	• Blood group A is much more likely to be a chronic carrier of *S. aureus.* This is partly due to blood group A individuals having a decreased ability to mount an aggressive antibody (or immune) response against this organism.
Streptococcus (group B)	B	• A blood group connection with neonatal group B streptococci infection exists for blood group B. Maternal blood group B is associated with about a doubling of risk for infection among their infants.
Strongyloidiasis	O	• A 1972 Egyptian study correlated type O with a higher incidence of hookworm and strongyloidiasis.
Tuberculosis	O	• Group O blood has a much higher rate of infection with tuberculosis (this is particularly true in individuals of European descent). • Tuberculosis runs a much more aggressive and detrimental course in blood group O, whereas type A is afforded the highest degree of protection. • Typically, during the first 2 years of infection with bacillary tuberculosis, there is a significant excess of infection among individuals with blood groups O and AB.

IL-6, Interleukin-6; *RBCs,* red blood cells; *TNF,* tumor necrosis factor.

TABLE 43.7 Influence of ABO Polymorphism on Susceptibility to Various Uropathic Infectious Agents[10]

Blood Group	Uropathogenic Strains
A	• *Staphylococcus saprophyticus*
B	• *Klebsiella pneumoniae* • *Proteus* spp. • *Pseudomonas* spp.
AB	• *Klebsiella pneumonia* • *Proteus* spp. • *Pseudomonas* spp. • *Staphylococcus saprophyticus*
Nonsecretor	• Uropathogenic *Escherichia coli*

As a general rule, blood group B is most plagued by chronic or recurrent urinary tract infections. Type AB is next on the susceptibility list, followed by type A. Type Os are the most protected. Nonsecretors are much more prone to repeated and severe urinary tract infections.

BOX 43.1 Factors Influencing Glycosylation in the Intestines, Hence Activity of Dietary Lectins

Animal species
Blood group specificity
Age
Particular area of the small intestine
Position along the villi
State of cell maturation
Diet
Bacterial status
Sickness or pathology

Data from Pusztai A, Bardocz S. Biological effects of plant lectins on the gastrointestinal tract: metabolic consequences and applications. *Trends Glycosci Glycotechnol.* 1996;8:149–165.

factor receptors, transport proteins, and brush-border enzymes, are glycosylated before being embedded in the brush-border membrane. Membrane lipids and gangliosides are also glycosylated, and all secreted mucins are carbohydrate-rich glycoproteins. Thus the scope of potential lectin–carbohydrate interactions is quite wide. However, not all lectins react with the epithelium, and even those that do react vary in their ability to recognize and bind to specific types of carbohydrate receptors. Because lectin reactions are quite specific, it is imperative that the correct carbohydrate structures be present on the surface of the gut mucosa. Factors that are known to influence lectin activity are summarized in Box 43.1.

Lectins can have a variety of biological effects, including induction of mitosis in lymphocytes, cellular agglutination via cross-linking of membrane sugars, preferential agglutination of malignant cells, precipitation of polysaccharides and glycoproteins, and activation of complement pathways. The variety of reported effects resulting from the ingestion of dietary lectins is summarized in Table 43.8.

Most lectins in the U.S. diet are resistant to breakdown during gut passage, so they are bound and endocytosed by epithelial cells. Endocytosed lectins act as powerful exogenous growth factors for the

TABLE 43.8 Reported Effects of Dietary Lectins

Action	Description
Induction of interleukins (ILs)	Dietary lectins are known to induce interleukins IL-4 and IL-13. Because lectins can enter the circulation after oral uptake, they might play a role in inducing the so-called early IL-4 required to switch the immune response toward a helper T-cell type 2 response and type I allergy.[166]
Induction of autoimmunity	The interaction of dietary lectins with enterocytes and lymphocytes may facilitate the translocation of both dietary and gut-derived pathogenic antigens to peripheral tissues, which in turn causes persistent peripheral antigenic stimulation. In genetically susceptible individuals, this antigenic stimulation may ultimately result in the expression of autoimmune disease.[167]
Interference with protein digestion	Aminopeptidase activity (the enzyme that breaks down polypeptides into amino acids) is inhibited by several dietary lectins.[168]
Interaction with the brush-border membrane	Lectins, which bind avidly to the brush-border membrane, are potent hyperplastic growth factors for the gut.[169] Binding of lectins to the epithelium is obligatory for growth stimulation, and their growth factor activity is determined mainly by the strength and intensity of their binding.[170]
Antinutrient effects	Rats fed a diet composed principally of raw navy bean flour were smaller and had 50% less ability to absorb glucose and utilize dietary protein than a control group that was fed navy beans in which the lectin had been inactivated.[171]
Enhancement of gut permeability	In one study, rats fed on diets containing kidney beans showed greater intestinal permeability to serum proteins that had been injected into the bloodstream. After challenge with kidney bean proteins, the protein injected into the bloodstream was detected in both the lumen (open space) and the walls of the small intestine. The researchers suggested that dietary lectins may, at least in part, be responsible for the loss of serum proteins and may contribute to other food intolerance secondary to the loss of gut integrity.[172]
Activation of gut hormones	Cholecystokinin is induced by several dietary lectins.[173]
Hormone and growth factor mimicry	Because surface membrane receptors of cells are glycosylated, lectins are good mimics of the effects of endogenous growth factors, hormones, and cytokines in all types of cells.[145] Lectins can mimic the effect of natural ligands and induce similar physiological reactions. It is also possible that bound lectin induces conformational changes in the receptor and/or physically blocks the active site of the receptor, thereby attenuating or completely abolishing the physiological effect of the natural ligand.
Mucotractive effects	Many lectins stimulate the production of mucus. This is possibly a protective function or an allergic response and was for a time thought to be an action of lectins that promised some therapeutic benefit that could be applied in patients with cystic fibrosis.[146]
Mitogenic effects	Several foodstuffs and herbal medicines are known to contain lectins that are capable of inducing T- or B-cell blastogenesis.

small intestine, and they can induce dramatic shifts in its bacterial flora and interfere with its hormone secretion. In addition, lectins that are transported across the gut wall into the systemic circulation can modulate the body's hormone balance, metabolism, and health. In contrast to dietary proteins, lectins resist degradation in the small intestine and are also resistant to breakdown by most gut bacteria. Thus most lectins survive, at least in part, the passage through the digestive tract in an immunologically and functionally intact form.[145]

Although lectin binding is most commonly studied in the small intestine, similar binding can occur throughout the entire digestive tract, from the stomach to the distal colon. However, surface glycosylation varies in the different functional parts of the gut, so lectin binding is not uniform in the digestive tract. Binding of lectins and their endocytosis by enterocytes is more extensive in the colon, where bacterial counts are high. Endocytosis in the small intestine becomes appreciable only in the presence of large numbers of commensal bacteria.[146]

How prevalent are lectins in the diet? A superficial survey done in the early 1980s implied that they are quite extensively distributed in our food supply.[147] In this study, the edible parts of 29 of 88 foods tested, including common salad ingredients, fresh fruits, roasted nuts, and processed cereals, were found to possess significant lectin-like activity as assessed with blood agglutination and bacterial agglutination assays.

Lectin content is a prime area of manipulation for the production of transgenic foods,[148] so they will probably continue to occupy the attention of nutritionally oriented physicians well into the future.

Role of ABO Blood Groups

Because ABO blood group is a prime determinant of glycosylation, it is not surprising that a substantial number of food lectins show ABO specificity. However, equally important but not typically recognized is the author's observation that ABO status appears to influence variability in secondary glycosides, which are not integral to the ABO type of the hosts. These secondary glycosides appear to provide additional conditioning of the mucin manufactured by the particular ABO type, which can explain the apparent effects of panhemagglutinins and other non-ABO specific lectins on one particular ABO type over another. These effects are listed in Table 43.9.

The benefit of using the ABO groups as a predictive device in narrowing down potential food reactions in sensitive subjects lies in its low cost to the patient and the clinician's ability to discern interactions that are not easily testable via standard food allergy isolation methods. A useful resource for clinicians seeking more information on lectins is *Lectser,* the world's most complete lectin characterization database, available at the principal website.[149]

CLINICAL APPLICATIONS OF ABO POLYMORPHISM

The "Blood Type Diet"

The advantage of a low-lectin diet can be exemplified by the best-known application of the ABO polymorphisms, the Blood Type Diet (BTD), popularized by publication in 1997 of the author's *New York Times* bestseller *Eat Right 4 Your Type.*

Eat Right 4 Your Type was the first "diet book" that looked at foods as medicine tailored to the individual rather than simply as part of a generic single-purpose mechanism (i.e., weight loss, cholesterol control). Like the very antigens that it uses for its determination, BTD is "nonreducing," meaning that the food value system is essentially stateless: a food that might cause difficulties in one ABO phenotype may well possess therapeutic value in another, a concept that harkens back to the observation of the Roman philosopher Lucretius: "What is food to one man may be fierce poison to others."

TABLE 43.9 Primary and Secondary Mucin Glycosides Known to Be Associated With ABO Polymorphism

Blood Group	Primary Glycoside	Secondary Glycoside(S)
A	*N*-Acetylgalactosamine	Mannose[174] Glycophorin A[175] Galactosyl-A glycolipids[176] "Band 3"[177]
B	Galactose	N-Neuraminic acid[178] Glycophorin B[175]
O	Fucose	*N*-Acetylglucosamine[179–181]

The BTD inventories a variety of parameters, including the physiological and pathological distinctions between the blood groups as reported in the literature, lectin and agglutinin characterizations (both from the author and from others), and variations in isoagglutinin titer and reactivity with regard to food challenge (both in vitro and in vivo). It also provides specific recommendations regarding foods that should be considered beneficial and should be emphasized and others that may be problematic and might better be avoided.

One advantage conferred by the theory is the notion that certain individuals may be better suited to Paleolithic or vegetarian diets. Despite certain locutions and circumlocutions offered by proponents of one system or the other, most clinicians have ample experience with the simple fact that certain patients make better vegetarians or carnivores than others. Conversely, the ability to identify particular individuals at risk of an adverse reaction to high-protein and/or low-carbohydrate diets can lead to actions aimed at the prevention of such consequences.

For example, high-protein diets are known to upregulate soluble endothelial adhesion factors,[150] whereas a soy-based, lipid-lowering diet is known to decrease endothelial adhesion factors, including vWF, E-selectin, and the intercellular adhesion molecule.[151–153] Because individuals with blood group A have been reported to have increased levels of all three endothelial adhesion factors and, perhaps consequently, a higher incidence of cardiovascular disease, a modified Asian and/or Mediterranean plant-based diet would appear ideal for this phenotype.

Conversely, in 1998, we examined serum cholesterol levels in a small number of group O subjects after a minimum of 1 month of the BTD recommended for that phenotype.[154] Group O individuals following the "Type O Diet" (higher protein, lower carbohydrate) showed a consistent drop in serum cholesterol ($n = 14$; average 237.3 mg/dL before diet, 200.2 mg/dL with diet); in subjects with elevated serum triglyceride values, the results were more pronounced ($n = 6$; average 387.1 mg/dL before diet, 168.8 mg/dL with diet).

In 2009 D'Adamo reported that sequential breath hydrogen levels (BHL) after lactulose administration varied significantly by ABO blood group and secretor status. Breath hydrogen excretion was significantly higher in group A subjects ($n = 35$) versus group O ($n = 31$). Secretor status appeared to influence location and temporality of bacterial overgrowth and BHL, with secretors having significantly higher levels on earlier blows (B1: $P = 0.027$) and nonsecretors having significantly elevated BHLs on later blows (B3: $P = 0.014$, B4: $P = 0.013$). Adoption of blood group–specific dietary recommendations significantly reduced mean BHLs ($n = 40$; $P = 0.007$).[155]

The BTD has produced an extensive library of works, at various levels of information density. *Eat Right 4 Your Type* has been translated into more than 60 languages, and well over 6 million individuals follow the system.[156] Self-reported outcomes collected via the Internet appear to indicate wide consumer satisfaction with the system: in more than 7000 reports, the basic ABO-based system generated an 85% level of satisfaction. Most interestingly, this percentage was essentially unchanged across the individual blood groups. In other words, 85% of the blood type A respondents reported satisfaction with a predominantly plant-based diet, whereas the same percentage of type O individuals reported satisfaction with a high-protein, Paleo-type diet. What this portends for the future of reductionist, one-size-fits-all diet systems remains to be seen.[157]

Materia Medica

ABO polymorphism and its clinical expression have led to new or rediscovered applications and contraindications for several traditional naturopathic treatment modalities. The most significant are summarized in Table 43.10.

SUMMARY

It is our hope that this abbreviated survey provides sufficient information to persuade the reader that ABO and ABO-related polymorphisms, in both genotypic and phenotypic expression, exert biological significance far beyond the surface of an erythrocyte and that this expression is worth factoring into the everyday algorithms of a nutritional practice. Perhaps the advent and acceptance of the newly emerging science of "nutrigenomics" might provide the conceptual framework needed to allow the nontransfusion significance of ABO and secretor polymorphism to parse into meaningful scientific dialogue. At that point, natural medicine could be considered to have the rational beginnings to delivering its long-awaited promise, "Treating the patient, not the disease."

TABLE 43.10 Modalities Known to Exert Effects at Least Partially Preferential to ABO Group

Agent/Species	Common Names	Actions	Notes	References
Fucus vesiculosus	Bladderwrack kelp	Antiadhesive Candicidal	Best suited for O, nonsecretors	182–184
Baptisia tinctoralis	Wild indigo	Induces anti-Tn or cross-reacting antibodies	Best suited for A, AB	185, 186
Urtica dioica rhizome	Stinging nettle root	"Superantigen" lectin T-cell mitogen (CD4+ and CD8+); Candicidal	Not useful in B or AB	87, 188
Helix pomatia agglutinin	Roman or escargot snail	Contains Tn-, LLC-, and "A-like"–specific lectins	Best suited for A, AB	27, 128
1.1.1.1.1.1 Agaricus bisporus	Domestic mushroom	Lectin stimulates insulin release by pancreatic islets. Lectin binds Tn antigen; stimulates differentiation of undifferentiated colon cancer cells; inhibits proliferation of epithelial cell lines.	Best suited for A	89, 190
Marrubium spp.	Horehound	Contains Tn-specific lectins	Best suited for A, AB	91
Salvia spp.	Sage	Contains Tn-specific lectins; attenuates soluble endothelial adhesion factors	Best suited for A, AB	91, 192
Vicia faba	Fava bean	VFA was found to stimulate an undifferentiated colon cancer cell line to differentiate into gland-like structures. The adhesion molecule epCAM is involved in this process. Dietary or therapeutic VFA may slow the progression of colon cancer.	Best suited for A; can be used by O, B	93
Griffonia (Bandeiraea simplicifolia)	African legume from which 5-HTP is extracted	*Griffonia* contains five isolectins, at least three of which are blood group agglutinating. GSA B4 is a serologically Lewis b(Le^b)–active binding lectin claimed to be blood group B specific as well. The "A"-rich lectin preferentially agglutinates blood group A, and the "B"-rich lectin preferentially agglutinates blood group B cells and is specific for alpha-galactose residues.	Not useful in A, AB, B or secretors	94–196
Artocarpus integrifolia	Jackfruit seeds	Contains T- and Tn-specific lectin (jacalin)	Best suited for A, AB; can be used by O, B	197

epCAM, Epithelial cell adhesion molecule; *GSA, Griffonia simplicifolia* agglutinin; *LLC,* ligand-like complex; *VFA, Vicia faba* agglutinin.

Nutritional Medicine

Michael T. Murray, ND

OUTLINE

Let your food be your medicine and let your medicine be your food.
Hippocrates

INTRODUCTION

Nutritional medicine, as described in this textbook, consists of the use of diet and nutritional supplementation as therapeutic modalities. The foundation of nutritional medicine is a health-promoting diet that focuses on the consumption of whole, natural foods grown organically. Nutritional supplementation—the use of vitamins, minerals, and other food factors to support good health as well as to prevent or treat illness—is an important component of nutritional medicine. However, dietary supplements are used as complementary agents, not as sole primary medicines. It is important to emphasize that diet is always primary, and supplementation secondary, within nutritional medicine.

One of the key concepts in nutritional medicine is to supply the necessary nutrients to allow the body to maintain health. The concept of "biochemical individuality" was coined by nutritional biochemist Roger Williams in the 1970s to recognize the wide range in the nutritional needs of humans. These observations also provided the basis for "orthomolecular medicine" as envisioned by two-time Nobel laureate Linus Pauling.

In addition to serving as necessary factors in normal physiology, many nutrients appear to exert pharmacological effects. The advantage of using nutrients at pharmacological dosages is that they are more recognizable and better metabolized by the body, as evidenced by a broader therapeutic index. Even so, the use of nutrients as pharmacological agents is closely akin to drug therapy. That being the case, it is imperative that they be used and monitored appropriately.

EVOLUTIONARY ASPECTS IN HUMAN NUTRITION

Although the human gastrointestinal tract is capable of digesting both animal and plant foods, several physical characteristics indicate that *Homo sapiens* evolved to digest primarily plant foods. Specifically, human teeth are composed of 20 molars, which are perfect for crushing and grinding plant foods, along with eight front incisors, which are well suited for biting into fruits and vegetables. Only the front four canine teeth are designed for meat eating. Human jaws swing both vertically to tear and laterally to crush, but carnivores' jaws swing only vertically. Additional evidence that supports the human evolutionary preference for plant foods is the long length of the human intestinal tract. Carnivores typically have a short bowel, and herbivores have a bowel length proportionally comparable to that of humans. Thus the human bowel length favors plant foods.[1]

A Look at Our Closest Wild Relatives

To answer the question, "What should humans eat?" many researchers look to other primates, such as chimpanzees, monkeys, and gorillas. Nonhuman wild primates are also omnivores or, as often described, herbivores and opportunistic carnivores. They eat mainly fruits and vegetables but may also eat small animals, lizards, and eggs if given the opportunity. Only 1% and 2%, respectively, of the total calories consumed by gorillas and orangutans are animal foods. The remainder of their diet is from plant foods. Because humans are between the weights of the gorilla and orangutan, it has been suggested that humans are designed to eat around 1.5% of their diet as animal foods.[2] Most Americans derive well over 50% of their calories from animal foods.

Although most primates eat a considerable amount of fruit, it is critical to point out that the cultivated fruit in American supermarkets is far different from the nutrient-dense wild fruits these animals rely on. Wild fruits have slightly higher protein contents and a higher content of certain essential vitamins and minerals, but cultivated fruits tend to be higher in sugars. Cultivated fruits are therefore very tasty to humans, but because they have a higher sugar composition and also lack the fibrous pulp and multiple seeds found in wild fruit that slow down the digestion and absorption of sugars, cultivated fruits raise blood sugar levels much more quickly than their wild counterparts.

TABLE 44.1 Estimated Mineral Intakes of Wild Monkeys and Humans

Mineral	Total Daily Intake of 7-Kg Adult Monkey (Mg)	Recommended Daily Allowance for 70-Kg Human (Mg)
Calcium	4571	800
Phosphorus	728	800
Potassium	6419	1600–2000
Sodium	182	500
Magnesium	1323	350
Iron	38.5	10
Manganese	18.2	2.0–5.0
Copper	2.8	1.5–3.0

Wild primates fill up not only on fruit but also on other highly nutritious plant foods. As a result, wild primates weighing one tenth as much as a typical human ingest nearly 10 times the level of vitamin C and much higher amounts of many other vitamins and minerals. Other differences in the wild primate diet are also important to point out, such as a higher ratio of α-linolenic acid, the essential omega-3 fatty acid, to linoleic acid, the essential omega-6 fatty acid[2] (Table 44.1).

Humans Versus Primates

Determining what foods are best suited for humans may not be as simple as looking at the diet of wild primates. There are some structural and physiological differences between humans and apes. A larger, more metabolically active brain is one of the key differences. It has been theorized by some evolutionists that a shift in dietary intake of fats was the likely stimulus for the brain growth in ancient humans. The shift itself was likely the result of limited food availability forcing early humans to collect shellfish and hunt grazing mammals such as antelope and gazelle in addition to gathering plant foods. Archeological data support this association—the brains of humans started to grow and become more developed at about the same time as evidence shows an increase of shellfish consumption and the presence of animal bones being butchered with stone tools at early villages. Data also show that the early humans who lived near water sources and ate seafood experienced the biggest brain change. An increased intake of the omega-3 fatty acid docosahexaenoic acid (DHA) found primarily in fish and seafood, but also in wild game, was perhaps the largest dietary contributor to brain growth.

The thought is that a higher DHA intake led to bigger brains in humans. And, with a bigger brain, early humans were able to engage in more complex social behavior, which led to improved foraging and hunting tactics, which in turn led to even higher-quality food intake, fostering additional brain evolution. In contrast, inland prehistoric humans did not have sufficient access to DHA, and the Neanderthals chose to focus on low-DHA-content meat from larger animals. As a result, both got stuck with limited brain capacity and died off.

The importance of DHA to brain function relates to its role in the composition of brain-cell membranes, and as a result, it influences the following:

- The fluidity of brain cell membranes
- Neurotransmitter synthesis
- Neurotransmitter binding
- Signal transmission
- The activity of key enzymes that break down neurotransmitters like serotonin, epinephrine, dopamine, and norepinephrine

Although improved dietary quality alone cannot fully explain why human brains grew, it appears to have played a critical role. A large part of the brain is made up of omega-3 fatty acids. In fact, 60% of the fats in the brain are omega-3 fatty acids, with DHA being the main type. A higher intake of DHA during pregnancy and early childhood was especially important to human evolution. DHA is critical for healthy brain development both in the womb and in early childhood. About 75% of brain cells are in place before birth, and the other 25% are in place by the age of 1 year—making DHA an essential nutrient for both pregnant mothers and young children. DHA is so important for early brain development that it is now automatically added to baby milk formula, and pregnant women should also strive to get sufficient levels by regularly eating fish or taking fish oil supplements.

The proper function of the brain and nerves also requires the monounsaturated fat oleic acid, the main component of olive oil as well as the chief oil in almonds, pecans, macadamias, peanuts, and avocados. Myelin, the protective sheath that covers communicating neurons, is composed of 30% protein and 70% fat, with the key fat being oleic acid. Again, the key point is that the right fat has critical effects in the human brain.

Hunter–Gatherer Diets

Data from anthropologists looking at hunter–gatherer cultures provide much insight as to what humans evolved to eat; however, it is very important to point out that these groups were not entirely free to determine their diets. Instead, their diets were molded by what was available to them. For example, the diet of the Inuit Eskimos is far different from that of the Australian aborigines. It may not be appropriate to answer the question, "What should humans eat?" simply by looking at these studies. Nonetheless, it is important to point out that regardless of whether hunter–gatherer communities relied on animal or plant foods, the rate of diseases of civilization, such as heart disease and cancer, is extremely low in such communities.[3]

It should also be pointed out that the meat that our ancestors consumed was much different from the meat found in supermarkets today. Domesticated animals have always had higher fat levels than their wild counterparts, but the desire for tender meat has led to the breeding of cattle that produce meat with a fat content of 25% to 30% or more, compared with less than 4% for free-living animals and wild game. In addition, the type of fat is considerably different. Domestic beef contains primarily saturated fats and virtually undetectable amounts of omega-3 fatty acids. In contrast, the fat of wild animals contains more than five times more polyunsaturated fat per gram and has a good amount of beneficial omega-3 fatty acids (approximately 4%).[4]

Considerable evidence indicates that a high intake of red or processed meat increases the risk of mortality. For example, in a cohort study of half a million people aged 50 to 71 years at baseline, men and women in the highest versus lowest quintile of red and processed meat intake had elevated risks for overall mortality.[5]

In another prospective cohort study, subjects were followed from 1980 (women) or 1986 (men) until 2006. Low-carbohydrate diets, either animal-based (emphasizing animal sources of fat and protein) or vegetable-based (emphasizing vegetable sources of fat and protein), were computed from several validated food-frequency questionnaires assessed during follow-up.[6] A low-carbohydrate diet based on animal sources was associated with higher all-cause mortality in both men and women, whereas a vegetable-based, low-carbohydrate diet was associated with lower all-cause and cardiovascular disease mortality rates.

The Importance of a Plant-Based Diet

The evidence supporting diet's role in chronic degenerative diseases is substantial and compelling. There are two basic facts linking the

diet–disease connection: (1) a diet rich in plant foods (i.e., whole grains, legumes, fruits, and vegetables) is protective against many diseases that are extremely common in so-called Western society, and (2) a diet providing a low intake of plant foods is a causative factor in the development of these diseases and provides conditions under which other causative factors are more active. Early naturopathic pioneers were strong proponents of plant-based diets—one of the health movements that helped define the profession was the vegetarian Grahamists. The founding leaders of the profession, Henry Lindlahr, MD, and Benedict Lust, ND, both advocated whole-foods vegetarian diets.

The Pioneering Work of Burkitt and Trowell

Much of the link between diet and chronic disease originated from the work of two medical pioneers, Denis Burkitt, MD, and Hugh Trowell, MD, authors of *Western Diseases: Their Emergence and Prevention*, first published in 1981.[7] Although now extremely well recognized, their work is actually a continuation of the landmark work of Weston A. Price, a dentist and author of *Nutrition and Physical Degeneration*. In the early 1900s, Dr. Price traveled the world, observing changes in teeth and palate (orthodontic) structure as various cultures discarded traditional dietary practices in favor of a more "civilized" diet. Price was able to follow individuals as well as cultures over 20 to 40 years and carefully documented the onset of degenerative diseases as their diets changed. On the basis of extensive studies examining the rate of diseases in various populations (epidemiological data) and his own observations of primitive cultures, Price formulated the following sequence of events:

First stage. In cultures consuming a traditional diet consisting of whole, unprocessed foods, the rate of chronic diseases like heart disease, diabetes, and cancer is quite low.

Second stage. Commencing with eating a more "Western" diet, there is a sharp rise in the number of individuals with obesity and diabetes.

Third stage. As more and more people abandon their traditional diet, conditions that were once quite rare become extremely common. Examples are constipation, hemorrhoids, varicose veins, and appendicitis.

Fourth stage. Finally, with full westernization of the diet, other chronic degenerative or potentially lethal diseases, such as heart disease, cancer, osteoarthritis, rheumatoid arthritis, and gout, become extremely common.

Since Burkitt and Trowell's pioneering research, a virtual landslide of data has continually verified the role of the Western diet as the key factor in nearly every chronic disease, especially obesity and diabetes. Box 44.1 lists diseases with convincing links to a diet low in plant foods. Many of these now-common diseases were extremely rare before the 20th century.

TRENDS IN U.S. FOOD CONSUMPTION

During the 20th century, food consumption patterns changed dramatically (Table 44.2). Total dietary fat intake rose from 32% of the calories in 1909 to 43% by the end of the century. Overall carbohydrate intake dropped from 57% to 46%, and protein intake remained stable at about 11%.

Compounding these detrimental changes are the individual food choices accounting for the changes. The biggest changes include significant rises in the consumption of meat, fats and oils, and sugars and sweeteners in conjunction with the decreased consumption of noncitrus fruits, vegetables, and whole-grain products. The greatest change in the past 100 years of human nutrition is the switch from a diet with a high level of complex carbohydrates, as found naturally occurring in grains and vegetables, to a tremendous and dramatic increase in the

BOX 44.1 Diseases Highly Associated With a Low-Fiber Diet

number of calories consumed from simple sugars. Currently, more than half of the carbohydrates being consumed are in the form of sugars (sucrose, corn syrup, etc.) being added to foods as sweetening agents. High consumption of refined sugars is linked to many chronic diseases, including obesity, diabetes, heart disease, and cancer.

THE GOVERNMENT AND NUTRITION EDUCATION

Throughout the years, various governmental organizations have published dietary guidelines, but the recommendations of the U.S. Department of Agriculture (USDA) have become the most widely known. In 1956 the USDA published *Food for Fitness—A Daily Food Guide.* This became popularly known as the Basic Four Food Groups. The Basic Four comprised the following:

1. The Milk Group: milk, cheese, ice cream, and other milk-based foods
2. The Meat Group: meat, fish, poultry, eggs, with dried legumes and nuts as alternatives
3. The Fruit and Vegetable Group
4. The Breads and Cereals Group

One of the major problems with the Basic Four Food Groups model was that it graphically suggested that the food groups were equal in health value. The result was overconsumption of animal products, dietary fat, and refined carbohydrates and insufficient consumption of fiber-rich foods like fruits, vegetables, and legumes. This in turn resulted in diets being responsible for many premature deaths, chronic diseases, and increased healthcare costs.

As the Basic Four Food Groups became outdated, various other governmental and medical organizations developed guidelines of their own, designed to reduce the risk of either a specific chronic degenerative disease, such as cancer or heart disease, or of all chronic diseases.

To create a new model in nutrition education, the USDA first published the "Eating Right Pyramid" in 1992. It received harsh criticisms from numerous experts and other organizations. One big question that should be asked is, "Is it appropriate to have the USDA making these recommendations?" After all, the USDA serves two somewhat

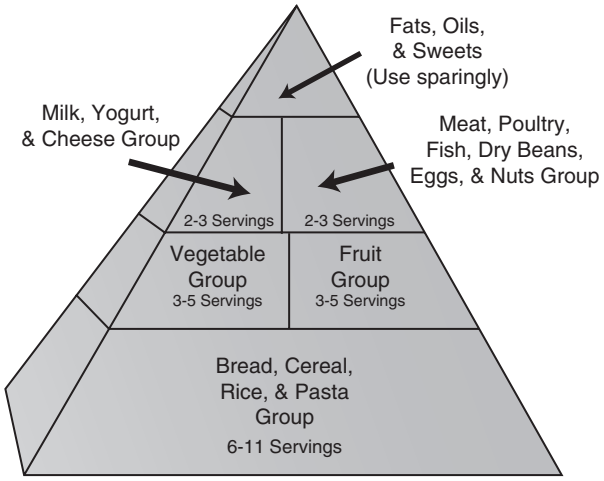

Fig. 44.1 U.S. Department of Agriculture Food Pyramid.

conflicting roles: (1) it represents the food industry, and (2) it oversees educating consumers about nutrition. Many people believe that the pyramid was weighted more toward dairy products, red meat, and grains because of influence from the dairy, beef, and grain farming and processing industries. In other words, the pyramid was designed not to improve the health of Americans but, rather, to promote the USDA agenda of supporting multinational agrifoods giants (Fig. 44.1).

One of the main criticisms of the Eating Right Pyramid is that it does not stress strongly enough the importance of quality food choices. For example, the bottom of the pyramid represents the foods that the USDA thinks should make up the bulk of a healthy diet: the Bread, Cereal, Rice, and Pasta Group. Eating 6 to 11 servings a day from this group is supposedly the path to a healthier life. In this way, the pyramid sets a person up for insulin resistance, obesity, and adult-onset diabetes if he or she consistently chooses refined rather than whole-grain products in this important category. This is one example of how the Eating Right Pyramid does not take into consideration how quickly blood glucose levels rise after eating a certain type of food—an effect referred to as the food's glycemic index (GI). The GI is a numerical scale used to indicate how fast and how high a particular food raises blood glucose (blood sugar) levels. There are two versions of the GI, one based on a standard of comparison with glucose as 100, and the other based on white bread. Foods are tested against the results of the selected standard. Foods with a lower GI create a slower rise in blood sugar, whereas foods with a higher GI create a faster rise in blood sugar.

One of the major problems with the Eating Right Pyramid is that the GIs of some of the foods that the pyramid is directing Americans to eat more of, such as breads, cereals, rice, and pasta, can greatly stress blood sugar control, especially if derived from refined grains, and are now being linked to an increased risk for obesity, diabetes, and cancer. As a result, the goal of the Eating Right Pyramid was to improve the health of Americans and, hopefully, slow down the growing trend toward obesity and diet-related disease, but because of poor individual food choices within the categories, the pyramid has only worsened the problem.

On June 2, 2011 the USDA unveiled a new food icon, MyPlate, to replace the food pyramid (see Fig. 44.2). This simplified illustration is designed to help Americans make healthier food choices. MyPlate is the first step in a multiyear effort to raise awareness and educate consumers about eating more healthfully. The initial launch came with some simple recommendations:

- Balance calories.
- Enjoy your food, but eat less.
- Avoid oversized portions.

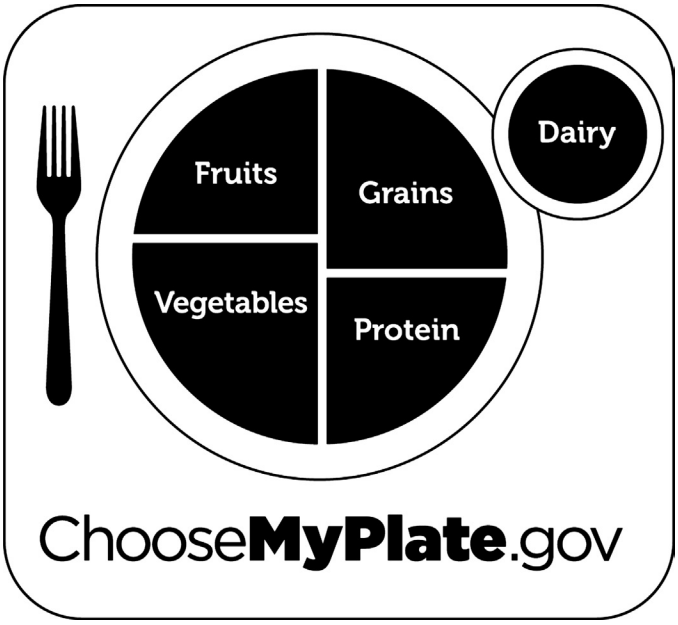

Fig. 44.2 U.S. Department of Agriculture MyPlate icon.

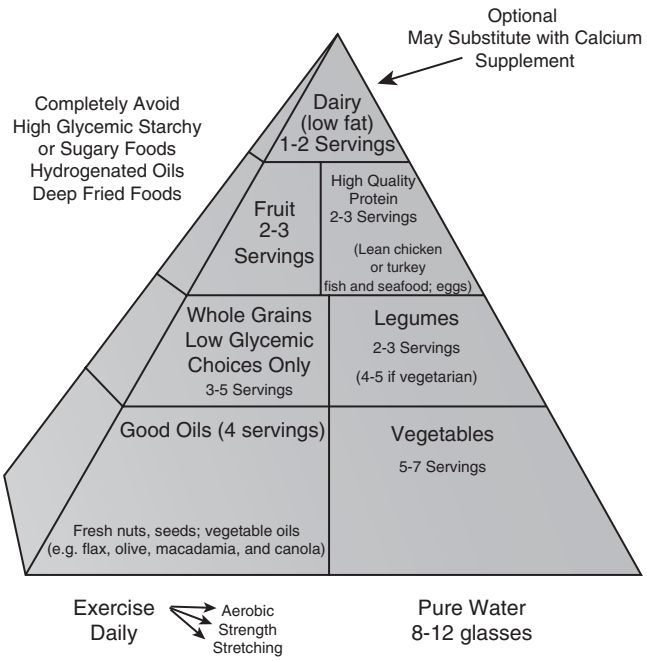

Fig. 44.3 The Optimal Health Food Pyramid.

Foods to Increase

- Make half your plate fruits and vegetables.
- Make at least half your grains whole grains.
- Switch to fat-free or low-fat (1%) milk.

Foods to Reduce

- Compare sodium in foods like soup, bread, and frozen meals and choose the foods with lower numbers.
- Drink water instead of sugary drinks.

However, this new campaign does not appear to be any more successful than prior efforts.

THE OPTIMAL HEALTH FOOD PYRAMID

Based on existing evidence, we have created the Optimal Health Food Pyramid (Fig. 44.3). The major difference from the USDA pyramid is that the Optimal Health Food Pyramid incorporates the best of two of the most healthful diets ever studied—the traditional Mediterranean diet (see later discussion) and the traditional Asian diet. In addition, the Optimal Health Food Pyramid more clearly defines what the healthy components within the categories are and stresses the importance of vegetable oils and regular fish consumption as part of a healthful diet. Appendix 9 provides a patient handout that clearly defines the components of the Optimal Health Food Pyramid.

The Optimal Health Food Diet is based on the following nine principles:

1. Eat a "rainbow" assortment of fruits and vegetables.
2. Reduce exposure to foods contaminated with pesticides and metals.
3. Eat to support blood sugar control.
4. Do not overconsume animal foods.
5. Eat the right types of fats.
6. Keep salt intake low and potassium intake high.
7. Avoid food additives.
8. Take measures to reduce foodborne illness.
9. Drink sufficient amounts of water each day.

1. Eat a "Rainbow" Assortment of Fruits and Vegetables

A diet rich in fruits and vegetables is the best bet for preventing virtually every chronic disease. That fact has been established time and again in scientific studies on large numbers of people. The evidence in support of this recommendation is so strong that it has been endorsed by U.S. government health agencies and by virtually every major medical organization, including the American Cancer Society. "Rainbow" simply means that selecting colorful foods—red, orange, yellow, green, blue, and purple—provides the body the full spectrum of pigments with powerful antioxidant effects as well as the nutrients it needs for optimal function and protection against disease (Box 44.2).

Fruits and vegetables are so important in the battle against cancer that some experts have said, and we believe, that cancer is a result of a "maladaptation" over time to a reduced level of intake of fruits and vegetables. As a study published in the medical journal *Cancer Causes and Control* put it in 1991, "Vegetables and fruit contain the anticarcinogenic cocktail to which we are adapted. We abandon it at our peril."[8] A vast number of substances found in fruits and vegetables are known to protect against cancer. Some experts refer to these as "chemopreventers," but they are better known to many as phytochemicals (Table 44.3). Phytochemicals include pigments such as carotenes, chlorophyll, and flavonoids; dietary fiber; enzymes; vitamin-like compounds; and other minor dietary constituents. Although they work in harmony with antioxidants like vitamin C, vitamin E, and selenium, phytochemicals exert considerably greater protection against cancer than these simple nutrients. Among the most important groups of phytochemicals are pigments such as chlorophyll, carotenes, and flavonoids.

2. Reduce Exposure to Pesticides, Metals, and Food Additives

In the United States more than 1.2 billion pounds of pesticides and herbicides are sprayed on or added to food crops each year. That is roughly 5 lb of pesticides for each man, woman, and child. There is a growing body of evidence demonstrating the correlation between exposure to pesticides and the development of a wide spectrum of pathologies, ranging from obesity to type 2 diabetes, low sperm counts, neurodegenerative diseases, and, of course, cancer. One of the closest links is the plight of the American farmer. The lifestyle of farmers is generally healthy: compared with city dwellers, farmers have access to

lots of fresh food; they breathe clean air, work hard, and have a lower rate of cigarette smoking and alcohol use. Yet studies show that farmers have a higher risk of lymphomas; leukemias; and cancers of the stomach, prostate, brain, and skin.[9] Exposure to pesticides is the primary reason for this occurrence.

Perhaps the most problematic pesticides are the family of halogenated hydrocarbons, such as 1,1-dichloro-2,2-bis(4-chlorophenyl) ethylene (DDE), polychlorinated biphenyl (PCB), pentachlorophenol (PCP), dieldrin, and chlordane. These chemicals persist almost indefinitely in the environment. A similar pesticide, dichlorodiphenyltrichloroethane (DDT), has been banned for nearly 30 years, yet it can still be found in soil and root vegetables such as carrots and potatoes. The human body also has a tough time detoxifying and eliminating these compounds. Instead, they end up being stored in fat cells. Moreover, inside the body, these chemicals can act like the hormone estrogen. They are thus suspected as a major cause of the growing epidemic of estrogen-related health problems, including breast cancer.[10] Some evidence also suggests that these chemicals raise the risk of lymphomas, leukemia, and pancreatic cancer as well as play a role in low sperm counts and reduced fertility in men.[11]

Avoiding pesticides is especially important in children of preschool age. Children are at greater risk for two reasons: they eat more food relative to body mass, and they consume more foods higher in pesticide residues—such as juices, fresh fruits, and vegetables. A recent University of Washington study[12] that analyzed levels of breakdown products of organophosphorus pesticides (a class of insecticides that disrupt the nervous system) in the urine of 39 urban and suburban children aged 2 to 4 years found that concentrations of pesticide metabolites were six times lower in the children who ate organic fruits and vegetables than in those who ate conventional produce.

After conducting an analysis of USDA pesticide residue data for all pesticides for 1999 and 2000, the Consumers Union[13] warned parents of small children to limit or avoid conventionally grown foods known to have high pesticide residues, such as cantaloupes, green beans (canned or frozen), pears, strawberries, tomatoes (Mexican grown), and winter squash. The University of Washington study added apples to this list.

Recommendations for Patients to Avoid Pesticides and Metals in the Diet

Patients can avoid consuming pesticides in their foods by following these recommended practices:

1. Do not overconsume foods that have a tendency to concentrate pesticides, such as animal fat, meat, eggs, cheese, and milk.
2. Buy organic produce, which is grown without the aid of synthetic pesticides and fertilizers. Although less than 3% of the total produce in the United States is grown without pesticides, organic produce is widely available.
3. Develop a good relationship with your local grocery store produce manager. Explain your desire to reduce your exposure to pesticides and waxes. Ask what measures the store takes to ensure that pesticide residues are within approved limits. Ask where the store obtains its produce; make sure the store is aware that foreign produce is much more likely to contain excessive levels of pesticides as well as pesticides that have been banned in the United States.
4. Decrease exposure to arsenic. If eating chickens, ensure they were not treated with arsenic compounds. If eating rice, be sure it was not grown with water contaminated with arsenic.
5. Try to buy local produce in season.
6. Peeling off the skin or removing the outer layer of leaves of some produce may be all you need to do to reduce pesticide levels. The downside is that many of the nutritional benefits of fruits and vegetables are concentrated in the skin and outer layers. An alternative measure is to remove surface pesticide residues, waxes, fungicides, and fertilizers by soaking the item in a mild solution of additive-free soap such as Ivory or pure castile soap. All-natural, biodegradable cleansers are also available at most health food stores. To use, spray the food with the cleanser, gently scrub, and rinse.

3. Eat to Support Blood Sugar Control

Refined sugars, white flour products, and other sources of simple sugars are quickly absorbed into the bloodstream, causing a rapid rise in blood sugar. In response, the body boosts secretion of insulin by the pancreas. High-sugar, "junk-food" diets definitely lead to poor blood sugar regulation, obesity, and ultimately, type 2 diabetes and heart disease.[14–16] The stress on the body that they cause, however, including secretion of too much insulin, can promote the growth of cancer and increase the risk of heart disease as well.

As already discussed, the GI of a food refers to how quickly blood sugar levels will rise after it is eaten. However, the GI does not tell how much of that carbohydrate is in a typical serving of a particular food,

TABLE 44.3 Examples of Anticancer Phytochemicals

Phytochemical	Action(s)	Sources
Carotenes	Antioxidants Enhance immune functions	Dark-colored vegetables, such as carrots, squash, spinach, kale, tomatoes, yams (sweet potatoes); fruits such as cantaloupe, apricots, citrus fruits
Coumarin	Antitumor properties Enhances immune functions Stimulates antioxidant mechanisms	Carrots, celery, fennel, beets, citrus fruits
Dithiolthiones, glucosinolates, and thiocyanates	Block cancer-causing compounds from damaging cells Enhance detoxification	Cabbage-family vegetables—broccoli, brussels sprouts, kale, etc.
Flavonoids	Antioxidants Direct antitumor effects Immune-enhancing properties	Fruits, particularly darker fruits, such as berries, cherries, citrus fruits; also tomatoes, peppers, greens
Isoflavonoids	Block estrogen receptors	Soy and other legumes
Lignans	Antioxidants Modulate hormone receptors	Flaxseed and flaxseed oil; whole grains, nuts, seeds
Limonoids	Enhance detoxification Block carcinogens	Citrus fruits, celery
Polyphenols	Antioxidants Block carcinogen formation Modulate hormone receptors	Green tea, chocolate, red wine
Sterols	Block production of carcinogens Modulate hormone receptors	Soy, nuts, seeds

Modified from Steinmetz KA, Potter JD. Vegetables, fruit, and cancer prevention: a review. *J Am Diet Assoc* 1996;96:1027–1039.

so another tool is needed. The glycemic load (GL) is a relatively new way to assess the effect of carbohydrate consumption that takes the GI into account but gives a fuller picture of the effect that a food has on blood sugar levels than GI alone. A GL of 20 or more is high, a GL of 11 to 19 inclusive is medium, and a GL of 10 or less is low. For example, beets have a high GI but a low GL. Although the carbohydrate in beet root has a high GI, the amount of carbohydrate is low, so a typical serving of cooked beet root has a relatively low GI (about 5). Thus, as long as one eats a reasonable portion of a low-GL food, the effect on blood sugar is acceptable, even if the food has a high GI. For example, an individual with diabetes can enjoy some watermelon (GI 72) as long as he or she keeps the serving size reasonable; the GL for 120 g watermelon is only 4.

In essence, foods that are mostly water (e.g., apple, watermelon), fiber (e.g., beet root, carrot), or air (e.g., popcorn) will not cause a steep rise in blood sugar even if their GIs are high as long as portion sizes are moderate. To help design a healthy diet, we provide a list of the GI, fiber content, and GL of common foods in Appendix 7.

4. Reduce Intake of Meat and Other Animal Foods

Study after study seems to indicate that the higher the intake of meat and other animal products, the higher is the risk of heart disease and cancer, especially the major cancers like those of the colon, breast, prostate, and lung, whereas a diet focusing on plant foods exerts the opposite effect.[17,18]

There are many reasons for this association. Meat lacks the antioxidants and phytochemicals that protect from cancer. At the same time, it contains lots of saturated fat and other potentially carcinogenic compounds—including pesticide residues, heterocyclic amines, and polycyclic aromatic hydrocarbons, which form when meat is grilled, fried, or broiled. The more well done the meat, the higher is the level of amines.

Some proponents of a diet high in meats claim that people should eat the way their "caveman" ancestors did. That argument does not really hold up. As already discussed, the meat of the wild animals that early humans consumed had a fat content of less than 4%. The demand for tender meat has led to the breeding of cattle whose meat contains 25% to 30% or more fat. Domestic beef contains primarily saturated fats and virtually no beneficial omega-3 fatty acids (discussed later), whereas the fat of wild animals contains more than five times the polyunsaturated fat per gram and has substantial amounts (about 4%) of omega-3 fatty acids.

Range-fed animals also contain 10 times as much conjugated linoleic acid (CLA) as grain-fed animals. CLA is a slightly altered form of the essential fatty acid linoleic acid. It occurs naturally in meat and dairy products. CLA was discovered in 1978, when researchers at the University of Wisconsin were looking for cancer-causing compounds that result from cooking. Instead, they found CLA, which appears to be an anticancer compound. Preliminary studies show that CLA might reduce the risk of heart disease and cancer.[19]

Particularly harmful to human health are cured or smoked meats, such as ham, hot dogs, bacon, and jerky, that contain sodium nitrate and/or sodium nitrites—compounds that keep the food from spoiling but that dramatically raise the risk of cancer. These chemicals react with amino acids in foods in the stomach to form highly carcinogenic compounds known as nitrosamines.

Research in adults makes a convincing argument to avoid these foods. Even more compelling is the evidence linking consumption of nitrates to a significantly increased risk of the major childhood cancers (leukemias, lymphomas, and brain cancers), as follows:

- Children who eat 12 hot dogs per month have nearly 10 times the risk of leukemia compared with children who do not eat hot dogs.[20]
- Children who eat hot dogs once a week double their chances of brain tumors; eating hot dogs twice a week triples the risk.[20]

- Pregnant women who eat two servings per day of any cured meat have more than double the risk of bearing children who have brain cancer.[21]
- Children who eat the most ham, bacon, and sausage have three times the risk of lymphoma.[20]
- Children who eat ground meat once a week have twice the risk of acute lymphocytic leukemia compared with those who eat none; eating two or more hamburgers weekly triples the risk.[20]

Fortunately, vegetarian alternatives to these standard components of the American diet are now widely available, and many of them taste quite good. Consumers can find soy hot dogs, soy sausage, soy bacon, and even soy pastrami at their local health food stores as well as in many mainstream grocery stores.

5. Eat the Right Type of Fats

There is no room for debate: a diet high in fat, particularly saturated fat and cholesterol, has been linked to numerous health issues, including cancer. However, just as important as the amount of fat is the type of fat consumed. The goal is to decrease total fat intake (especially intake of saturated fats, trans fatty acids, and omega-6 fats) while increasing the intake of omega-3 fatty acids and monounsaturated fatty acids.

What makes a fat "bad" or "good" has a lot to do with the function of fats in the body's cellular membranes. Membranes are made mostly of fatty acids. What determines the type of fatty acid present in the cell membrane is the type of fat consumed. A diet composed mostly of saturated fat, animal fatty acids, and trans fatty acids (from margarine, shortening, and other sources of hydrogenated vegetable oils) and high in cholesterol results in membranes that are much less fluid in nature than a diet with optimal levels of unsaturated fatty acids. Modern pathology clearly indicates that an alteration in cell membrane function is the central factor in the development of virtually every disease. As it relates to diabetes, abnormal cell membrane structure due to eating the wrong types of fats leads to impaired action of insulin.

Without a healthy membrane, cells lose their ability to hold water, vital nutrients, and electrolytes. They also lose their ability to communicate with other cells and to be controlled by regulating hormones, including insulin. Without the right type of fats in cell membranes, cells simply do not function properly. Considerable evidence indicates that cell membrane dysfunction is a critical factor in the development of many diseases.

The type of dietary fat profile that is linked to many diseases is an abundance of saturated fat and trans fatty acids (hydrogenated vegetable oils) along with a relative insufficiency of monounsaturated and omega-3 fatty acids. One of the key reasons appears to be that because dietary fat determines cell membrane composition, such a dietary pattern leads to reduced membrane fluidity, which in turn causes reduced insulin binding to receptors on cellular membranes and/or reduced insulin action. Particularly harmful to cell membrane function are margarine, vegetable oil shortening, and other foods containing trans fatty acids and partially hydrogenated oils. These "unnatural" forms of fatty acids interfere with the body's ability to use important essential fatty acids and are now linked to an increased risk for heart disease, diabetes, and cancer. Just the opposite effect has been shown for diets high in monounsaturated fats and omega-3 fatty acids.

One diet that appears to be representative of a way of eating that provides an optimal intake of the right types of fat is the traditional Mediterranean diet—a term with a specific meaning. It reflects food patterns typical of some Mediterranean regions in the early 1960s, such as Crete, parts of Greece, and southern Italy. The traditional Mediterranean diet has shown tremendous benefit in fighting heart disease and cancer as well as diabetes and rheumatoid arthritis.[22] It has the following characteristics:

- Olive oil is the principal source of fat.
- It centers on an abundance of plant food (fruit, vegetables, breads, pasta, potatoes, beans, nuts, and seeds).
- Foods are minimally processed, and there is a focus on seasonally fresh and locally grown foods.
- Fresh fruit is the typical daily dessert; sweets containing concentrated sugars or honey are consumed a few times per week at the most.
- Dairy products (principally cheese and yogurt) are consumed daily in low to moderate amounts.
- Fish is consumed on a regular basis.
- Poultry and eggs are consumed in moderate amounts (1–4 times weekly) or not at all.
- Red meat is consumed in low amounts.
- Wine is consumed in low to moderate amounts, normally with meals.

Olive oil consists not only of the monounsaturated fatty acid oleic acid; it also contains several antioxidant agents that may also account for some of its health benefits. Olive oil is particularly valued for its protection against heart disease. It lowers harmful low-density lipoprotein (LDL) cholesterol and increases the level of protective high-density lipoprotein cholesterol. It also helps circulating LDL cholesterol from becoming damaged by free radicals[23,24] and has been proven to contribute to better control of the elevated blood triglycerides that are so common in diabetes. However, it is not only olive oil that produces these benefits—frequent nut consumption is also quite beneficial to health. The Prevention With the Mediterranean Diet (PREDIMED) study is recognized worldwide as a landmark study that marked a turning point in the dietary prevention of chronic diseases because it was not an epidemiological study but a randomized trial. This study showed that when the Mediterranean diet was supplemented with the free provision of either extra virgin olive oil or mixed tree nuts, this intervention reduced the risk of having a cardiovascular event by 30% after 5 years of intervention.[25]

6. Keep Salt Intake Low and Potassium Intake High

The electrolytes—potassium, sodium, chloride, and magnesium—are mineral salts that can conduct electricity when dissolved in water. For optimal health, it is important to consume these nutrients in the proper balance. Too much sodium in the diet from salt (sodium chloride) can disrupt this balance. Many people know that a high-sodium, low-potassium diet can cause high blood pressure and that doing the opposite can lower blood pressure,[26,27] but not as many are aware that the former diet also raises the risk of cancer.[28]

In modern Western society, only 5% of sodium intake comes from the natural ingredients in food. Prepared foods contribute 45% of our sodium intake; 45% is added in cooking, and another 5% is added as a condiment.

Patients can reduce their salt intake by following these tips:

1. Take the salt shaker off the table.
2. Omit added salt from recipes and food preparation.
3. If you absolutely must have the taste of salt, try the salt substitutes such as NoSalt and Nu-Salt. These products are made with potassium chloride and taste very similar to sodium chloride.
4. Learn to enjoy the flavors of unsalted foods.
5. Try flavoring foods with herbs, spices, and lemon juice.
6. Read food labels carefully to determine the amounts of sodium. Learn to recognize ingredients that contain sodium: salt, soy sauce, salt brine, and any ingredient with "sodium" in its name (such as monosodium glutamate) or "baking soda" (sodium bicarbonate).
7. In reading labels and menus, look for words that signal high sodium content, such as smoked, barbecued, pickled, broth, soy sauce,

teriyaki, Creole sauce, marinated, cocktail sauce, tomato base, Parmesan, and mustard sauce.

8. Do not eat canned vegetables or soups, which are often extremely high in sodium.
9. Choose low-salt (reduced-sodium) products when available.

Most Americans have a potassium:sodium (K:Na) ratio of less than 1:2. In other words, they ingest twice as much sodium as potassium. However, experts believe that the optimal dietary potassium:sodium ratio is greater than 5:1—10 times higher than the average intake. However, even this may not be optimal. A natural diet rich in fruits and vegetables can easily produce much higher K:Na ratios because most fruits and vegetables have a K:Na ratio of at least 50:1. The average K:Na ratios for several common fresh fruits and vegetables are as follows:

- Carrots: 75:1
- Potatoes: 110:1
- Apples: 90:1
- Bananas: 440:1
- Oranges: 260:1

7. Avoid Food Additives

Food additives are used to prevent spoiling or to enhance flavor; they include such substances as preservatives, artificial colors, artificial flavorings, and acidifiers. Although the government has banned many synthetic food additives, it should not be assumed that all the additives currently used in the U.S. food supply are safe. Many synthetic food additives that are being linked to such diseases as depression, asthma or other allergy, hyperactivity or learning disabilities in children, and migraine headaches remain in use.[29–32]

The U.S. Food and Drug Administration has approved the use of more than 2800 different food additives. It is estimated that the per-capita daily consumption of these food additives is approximately 13 to 15 g. This amount is astounding and leads to many questions. Which food additives are safe? Which should be avoided? An extremist might argue that no food additive is safe. However, many food additives fulfill important functions in the modern food supply. Many compounds approved as additives are natural in origin and possess health-promoting properties, whereas others are synthetic compounds with known cancer-causing effects. Obviously, the most sensible approach is to focus on whole, natural foods and avoid foods that are highly processed.

An illustration of the problem with food additives is one of the most widely used synthetic food colors: Food, Drug, and Cosmetic Act yellow dye no. 5, or tartrazine. Tartrazine is added to almost every packaged food as well as to many drugs, including some antihistamines, antibiotics, steroids, and sedatives. In the United States, the average daily per-capita consumption of certified dyes is 15 mg, of which 85% is tartrazine; among children, consumption is usually much higher.

Although the overall rate of allergic reactions to tartrazine is quite low in the general population, allergic reactions to tartrazine are extremely common (20%–50%) in individuals sensitive to aspirin as well as other allergic individuals. Like aspirin, tartrazine is a known inducer of asthma, hives, and other allergic conditions, particularly in children. In addition, tartrazine, as well as benzoate and aspirin, increases the production of a compound that raises the number of mast cells in the body. Mast cells are involved in producing histamine and other allergic compounds. A person with more mast cells in the body is typically more prone to allergies. For example, an examination of patients with hives shows that more than 95% have a higher-than-normal number of mast cells.

In studies using provocation tests to determine sensitivity to tartrazine and other food additives in patients with hives, results have ranged from 5% to 46%. Diets eliminating tartrazine as well as other food additives in sensitive individuals have, in many cases, been shown to be of great benefit in patients with hives and other allergic conditions, such as asthma and eczema.

8. Take Measures to Reduce Foodborne Illness

Foodborne illness is caused by the consumption of contaminated foods or beverages. Although the food supply in the United States is one of the safest in the world, the Centers for Disease Control and Prevention estimates that 76 million people get sick, more than 300,000 are hospitalized, and 5000 Americans die each year from foodborne illness.[33] The microbe or toxin enters the body through the gastrointestinal tract and often causes the first symptoms there, so nausea, vomiting, abdominal cramps, and diarrhea are common symptoms in many foodborne diseases. Most cases of foodborne illness are mild, but serious diarrheal disease or other complications may occur.

More than 250 different organisms have been documented as being capable of causing foodborne illness.[34] Most of these cases are infections by a variety of bacteria, viruses, and parasites, but poisonings can also occur as a result of ingestion of harmful toxins or chemicals from organisms that have contaminated the food; for example, botulism occurs when the bacterium *Clostridium botulinum* grows and produces a powerful paralytic toxin in foods. The botulism toxin can produce illness even if the bacteria are no longer present.

Most of the common causes of foodborne infections are microorganisms frequently present in the intestinal tracts of healthy animals. Meat and poultry can become contaminated during slaughter by contact with small amounts of intestinal contents, and fresh fruits and vegetables can be contaminated if they are washed or irrigated with water that is contaminated with animal manure or human sewage.

The most common causes of foodborne infections are the bacteria *Campylobacter, Salmonella,* and *Escherichia coli* O157:H7 and a group of viruses called caliciviruses, also known as the Norwalk and Norwalk-like viruses. Undercooked meat and poultry, raw eggs, unpasteurized milk, and raw shellfish are the most common sources of these organisms.

The foremost measure to reduce the risk of foodborne illness is to cook meat, poultry, and eggs thoroughly. Using a thermometer to measure the internal temperature of meat is a good way to be sure that it is cooked sufficiently to kill bacteria. For example, ground beef should be cooked to an internal temperature of 160°F, poultry should reach a temperature of 185°F, and an egg should be cooked until the yolk is firm.

One must also take care to avoid contaminating foods by making sure to wash hands, utensils, and cutting boards after they have been in contact with raw meat or poultry and before they touch another food. Cooked meat should be served on a clean platter, rather than back on one that held the raw meat. To prepare produce, one should wash fresh fruits and vegetables in running tap water. A soft-bristle brush with a little mild soap can be used. Greens can be soaked in cold water as many times as needed to get them clean.

If further urging is needed, remind the patient that most of the increase in human longevity is due to public health's dramatic success in reducing foodborne infections.

9. Drink Sufficient Amounts of Water Each Day

Water is essential for life. The average amount of water in the human body is about 10 gallons. The recommendation to drink at least 48 oz of water per day to replace the water that is lost through urination, sweat, and breathing is valid. Even mild dehydration impairs physiological and performance responses.[35] Many nutrients dissolve in water so that they can be absorbed more easily in the digestive tract. Similarly, many metabolic processes need to occur in water. Water is a component of

blood and thus is important for transporting chemicals and nutrients to cells and tissues. Each cell is constantly bathed in a watery fluid. Water also carries waste materials from cells to the kidneys for filtering and elimination. Water absorbs and transports heat. For example, the heat produced by muscle cells during exercise is carried by water in the blood to the surface, helping maintain the right temperature balance. The skin cells also release water as perspiration, which helps maintain body temperature.

Several factors are thought to increase the likelihood of chronic mild dehydration: a faulty thirst "alarm" in the brain; dissatisfaction with the taste of water; regular exercise that increases the amount of water lost through sweat; living in a hot, dry climate; and consumption of the natural diuretics caffeine and alcohol.

There is currently a great concern over the U.S. water supply. It is becoming increasingly difficult to find pure water. Most of the water supply is full of chemicals, including not only chlorine and fluoride, which are routinely added, but also a wide range of toxic organic compounds and chemicals, such as PCBs, pesticide residues, and nitrates, and heavy metals such as lead, mercury, and cadmium. It is estimated that lead alone may contaminate the water of more than 40 million Americans. Patients should be encouraged to determine the safety of their tap or well water by contacting their local water companies; most cities have quality assurance programs that perform routine analyses. Patients can simply ask for the most recent analysis.

SUMMARY

The dietary guidelines and principles that are detailed in this chapter represent our answer to the hotly debated question, "What is the best diet?" After a review of several popular diet in detail as well as thousands of scientific articles on the role of diet in human health, our offering here is based on the evolutionary understanding of what constitutes the optimal diet. The bottom line for a health-promoting diet is to reduce the intake of potentially harmful substances—foods laden with empty calories, additives, and artificial sweeteners—and replace them with natural foods, preferably organically grown.

Peat Therapeutics and Balneotherapy

Mark Groven, ND,* and *Joseph E. Pizzorno, ND*

OUTLINE

INTRODUCTION

Nature has provided many gifts of healing. One of the most outstanding and exciting is peat. The use of organic peat and its constituents is ancient, yet people with pain, injury, and dermatologic, rheumatic, and other conditions are benefiting from modern peat therapy today. This pleasant and safe healing discovery has brought relief and cure for many.[1–18]

Balneology is the study of the art and science of bathing. Balneotherapy is the use of natural thermal mineral waters, additive baths, peloids, and other natural substances, as well as various atmospheric or environmental elements singly or in combination, for the prevention and treatment of disease. The aim of balneotherapy is to change regulatory and reactive functions, leading to improvement of capacity, adaptation, and self-healing.[19]

Peloid refers to the pulp of a substance that is applied to the body. It may be in pack form or bath, either local or whole body. The concentration of peloidal solutions can vary, and peloid solutions should be applied to the skin in a specific manner for a specific condition to optimize results. Common peloids are peat pulp, lake or sea muds, and plant substances.

For many conditions, balneotherapy works synergistically with peloid therapy, and the percutaneous absorption of their constituents along with the physiological and psychological effects provides an excellent therapy for people who can no longer tolerate oral or injectable pharmaceuticals and have chronic degenerative diseases. Life is stressful, and our society is aging. We would be wise to utilize the positive benefits of balneotherapy in the conventional treatment of pain and illness as well as in health maintenance and prevention of disease. The purpose of this chapter is to describe the general concept of balneotherapy, with an emphasis on the therapeutic application of peat. There certainly is a distinction between the application of peat and the application of other muds, such as lake mud or clay. The characteristics of the specific peat mud constituents being used are vitally important, as is the manner of their application.

BALNEOLOGY

History

Therapeutic bathing is an ancient art and probably the oldest of medical procedures. Hippocrates wrote about the application of therapeutic bath in 400 BC and how it soothed pain in the side, improved respiration, soothed the joints and skin, was diuretic, and removed heaviness of the head. It was suited for those who benefited, but it could be unsuitable if applied in the wrong way. It enjoyed tremendous popularity until about 75 years ago when, along with other natural

techniques, it fell out of favor as conventional medicine produced its modern successes. Since then, the large corpus of empirical wisdom has been expanded on, and much scientific evidence has contributed to the advancement of balneology as a science. Many institutions are teaching hydrotherapy and balneological techniques, and many spas have wonderful programs for people to use. It is not hard to imagine that the reason this art survived and improved is because it can better people's health.

Balneotherapy's modern-day roots lie predominantly in European spas, which have some of the longest continuously running histories of all medical institutions. Millions of patients flock to clinics throughout Europe and the world each year for treatment in hydrology departments under the supervision of physicians and their staffs. Such clinics provide a variety of balneotherapeutic techniques. *Spa therapy* is a term used for the combination of balneotherapy and other techniques usually delivered at a resort setting. The effects of spa therapy are influenced positively by the pleasure of being in a beautiful setting with the stresses of home and work removed. Medical spas are often in an area where the earth's elements are present. The pristine air, the ambient temperature, the humidity or amount of light, nourishing food, and exercise can effect a change in the spirit, mind, and body.[19]

Balneotherapy in Combination With Other Therapies

Many therapies work well together, such as phototherapy and mud therapy in the treatment of psoriasis. Mud pack therapy, peloidotherapy, massage, soft and osseous tissue manipulation, iontophoresis, phonophoresis, and exercise work together.[20] The combination of buoyancy and heat in the water makes sense, for example, in underwater traction bath and massage, which have been shown to reduce the levels of analgesic consumption in patients.[18] In my own experiences with patients, hydrotherapy, with and without mud in combination with other treatments, such as naturopathic manipulation, can work like nothing else to help people heal and stay healthy. A multitude of conditions can be treated with balneotherapeutic methods—pain, injury, and dermatologic and rheumatic conditions rank high.[2,19,21,22] Under the right conditions and with the right application, balneotherapy stimulates healing and speeds recovery.[23]

Physiological Effects

Balneotherapeutics induce direct and indirect actions on the body. The direct actions of balneotherapy take into consideration the physical actions of water on the body, such as hydrostatic pressure, buoyancy, viscosity, and frictional resistance, as well as thermal effects and the chemical and pharmacological effects of the percutaneous absorption of the substance being used.[24] Such substances are found in hot spring waters of various types, such as carbon dioxide, hydrogen sulfide, chloride, sulfate, iron, acid, and radon. Mineral waters contain cations, such as sodium, potassium, calcium, and magnesium, and anions, such as SO_4^-, Cl^-, and HCO_3^-. The concentrations of these ions are usually significantly high (1 g/L). In spring water, levels of nitrogen compounds, such as nitrate, nitrogen dioxide, and nitrogen oxide, are very low, and the water is free of or low in bacteria.[17] Peat muds, plant preparations, and mineral-containing muds are also used. In Europe, peat baths and peloids are traditional. These applications are used in combination with exercise, aquatics, steam bath, sauna therapy, climatotherapy, physical therapy, and pharmacotherapy, among others, with important consideration being given during treatment to the chronobiological and circadian-rhythm phases of the body.[1,14,20,21,25–27]

The indirect actions of balneotherapy arise from the repeated application of therapeutic stimulation, such as climatic exposure to the elements, training effects of exercises, and social and psychological effects arising from changes in the environment. These elements act as a complex stimulation in a nonspecific manner of the physiological function of the organism's central nervous system, autonomic nervous system, endocrine system, immune system, and so on. The result of these stimulations is a reactive response by the body, leading to activation and improvement of capacity, adaptation, and self-healing potential. In other words, balneotherapy has a normalizing effect on the body's systems and rhythms.

Circadian Rhythms

Biorhythms are important in the expression of many conditions.[28,29] Sunlight, mealtimes, and seasonal changes are external cues that, together with internal cues such as blood pressure and respiration, affect the hypothalamus or master clock. This part of the brain then signals hormones, enzymes, and other substances to facilitate healing, produce cells, or cause pain and symptoms. It has been shown that different times of day affect the amount of muscle torque potential, body temperature, and clock-gene messenger RNA (mRNA) expression.[30] A cold or hot foot bath can induce a rise in the temperature of the oral mucosa of up to 1°C, but the extent of the increase in the oral temperature depends on the body's reaction to this stimulus, which is influenced by the body's own internal clock.[1]

Conditions such as arthritis have pain with varying cycles.[31] It is thought that some of these cycles are in synchrony with the moon and the sun. Heart attacks, asthma, and rheumatoid arthritis joint pain are early-morning diseases, so medication and treatment can be tailored for different times of day when it is significantly more helpful and less wasteful when not needed. Serum adrenocorticotropic hormone, prolactin, luteinizing hormones, and immune parameters such as plasma levels of soluble p75 tumor necrosis factor and tumor necrosis factor-α (TNF-α) vary in 24-hour rhythms in the body.[23] These may be affected through balneotherapy, as may melatonin production and expression.[24] Melatonin affects the organization and expression of biorhythms and is easily susceptible to oxidative stress. Symptom remission in some conditions coincides with a normalization of circadian rhythms promoted by balneotherapeutic treatment.[32–33] In a European study, the combination of carbon dioxide bath and mud bath was shown to downregulate the systolic pressure in hypertension while having a balancing effect on biological clocks.[34] A study on fibromyalgia patients, in whom altered reactivity of the hypothalamic–pituitary–adrenal axis was observed, supported the theory that mud pack therapy works in synergy with antidepressant treatment to decrease pain and improve depression. Balneotherapy can promote the body's response systems, such as the stress response system, to achieve homeostasis.[35]

PEAT THERAPEUTICS

History

The ancients used peat extract baths, and the antiseptic properties of peat mud were recognized in World War I when it was applied directly to wounds to prevent infection.[36] Natives used mud externally and internally. Peat has been used as a medicinal preparation in baths and peloid packs extensively in Europe for the past 200 years. This unique substance contains many chemical constituents that can interact with organic and inorganic compounds.[37] The scientific basis for the physical, chemical, and pharmacological effects of peat baths has long been known, and such baths have been used extensively in balneotherapeutic applications in Europe and other parts of the world to treat rheumatic diseases, gynecological disorders, osteoarthritis, lumbago, sciatica, skin diseases, trauma and its sequelae, and many other ailments and afflictions. The many substances in peat offer a vast possibility of medicinal cure applications.[38–48]

It is important to consider the region and origin of the peat being used for medicinal purposes. Low moor peat has been shown to contain higher concentrations of nitrous substances, which are thought to contain a higher content of biologically active substances than the high moor peats or peats taken from a shallower depth. It is not just high nitrous content that makes a certain peat more medically useful but also the quality, type, and amount of the biologically active substances it contains that are the determining factors in its medicinal effect. In Germany, these types of peats are now a national resource.

Skin Response

The skin is a reflex, metabolic, immune, and excretory organ. It affects the autonomic, immune, and circulatory systems and participates in the biosynthesis of not only vitamin D but also acetylcholine, histamine, and serotonin.[2,4,10,15] Significantly higher concentrations of minerals and medicaments can be attained in the epidermis with baths than with systemic flooding via the vascular system. There is percutaneous uptake of many substances by the skin but not in large amounts for most natural substances. Permeation into the dermis does occur especially for humic acids, and uptake beyond the stratum corneum is exemplified by measurable urinary excretion rates.[49,50]

The primary effects of bath components take place within the skin. For instance, hydrogen sulfide acts as a trap for oxygen radicals, functioning to reduce inflammation. It is thought that the action comes from the effect of sulfur on the Langerhans cells, which play a role in immune presentation and inflammation modulation. In this way, skin responses can act as transmitter-activating helper functions. Sulfur-containing peat baths demonstrate a pain-reducing and healing effect on rheumatic and degenerative diseases. One reason may be the reduction in the activity of Langerhans cells in producing cytokines that results from the combination of the components within peat and thermal radiation.[2,7,15,19,22,50,64]

Physiological Effects

Peat has a structure containing micropores, which accounts for its sponge-like water-carrying capacity and its ability to maintain either hot or cold temperatures. When applied, peat produces a gradient rise or fall in temperature, which is especially desirable in a therapeutic bath. A peat bath formulation influences neuromuscular, endocrine, and pulmonary functions, as well as kidney hemodynamics, depending on the consistency and volume of the partial or full bath.[4,10] Peat has well-documented effects, such as tissue dilatation and increases in stroke volume, metabolism, and immunologic stimulation. A peat bath may be preferable to a water bath if one considers the gradient rise and fall of temperature, increased buoyancy, and prevention of heat loss during a bath and the possible positive chemical and pharmacological effects of the constituents of peat.[47,49–52]

Those who have experienced a therapeutic bath can appreciate the feelings of exhilaration and deep relaxation induced by a bath that contains an additive such as peat. The response is affected by the constituents in the water, the temperature of the bath, and the time of day the stimulus is given.[52]

The patient's genetics and physical capacity are also important. A peat bath enhances circulation significantly longer than a water bath.[53] Microcirculatory vasodilation in the skin has been shown to increase even without hyperthermia. The peripheral and deeper arteries, such as the intrauterine vessels, have shown prolonged increased flow after a peat bath. The effects of peat constituents can occur without heat, but heat increases the effect on the body.

The antirheumatic activity of thermal muds has a precise pharmacological character. Therapy can be prescribed according to the characteristics of the mud for specific conditions.[47,49] For example, specific muds work better with phototherapy for psoriasis and atopic dermatitis. The length of time that the peat mud has undergone humification and maturation lends unique characteristics. Maturation of peat muds increases their thermoinsulating, hydration, and, importantly, biochemical characteristics. The sulfoglycolipid content of mature mud differentiates a natural remedy from a specific application with a precise pharmacological character. These sulfoglycolipids are absorbed through the skin and stimulate an antirheumatic effect.[54] Several peat substances are able to permeate the skin.[50] Their absorption and action have been documented by the comparisons of placebo, water baths, and peat baths using Doppler ultrasound measurement. One study that measured circulation in the uterine artery after bath therapy showed that only the peat bath achieved the physiological effect of prolonged vasodilatation and circulation. This effect lasted for several hours after the treatment. It is thought that absorption of peat substances takes place through the hair follicles and apocrine glands via diffusion and partial pinocytosis.[53,55] The fractions of peat components that penetrate the skin include the humic acid fractions: fulvic, ulmic, and volvic. The excitatory effect of humic acid fractions such as fulvic acid affect the reactivity of the α2 and D2 receptors of smooth muscle cells.[51]

The functions of peat in medicinal applications are antimicrobial, antiviral, anti-inflammatory, and antineoplastic, to name a few.[52] Many biochemical effects have been demonstrated in humans and animals. The anti-inflammatory effect of peat mud has been attributed to a sulfoglycolipid associated with a decrease in serum interleukin-1 (IL-1) in patients with arthritis.[56] The effects of mud applications include elevation of protein synthesis, reduction of arachidonic acid, and inhibition of inflammatory mediators such as leukotrienes (LTB4), prostaglandins (PGE-2), and thromboxane. Biological activity is ascribed to peat ingredients, such as sulfur compounds, magnesium, manganese, iron, and humic acids.[6,7,10,11,16,19,24] Mud pack therapy decreases the proinflammation factors IL-1 and TNF-α and the radical-mediated peroxidations nitric oxide and myeloperoxidase.[57] It also increases serum levels of insulin-like growth factor 1, which is cartilage protective. Humic substances spread widely in nature, and when found mainly in highly degraded peat, they have been shown to have a proliferative effect on certain leukocytes. Water-soluble oxihumate, given orally or dermally, increases the proliferative response in mononuclear leukocytes as well as the production and expression of IL-2.[2,36,58]

Hyperthermia

The thermal properties of peat mud applications have been shown to be much greater than those of water baths because of the former's dynamic viscosity, decreased convective cooling, and protective effect on the skin with hot applications.[2] Whole-body, extracorporeal, and local infrared applications of hyperthermia have uses in cancer therapy. Hyperthermic effects include changes in heat shock proteins (HSPs) and upregulation of heart antioxidant defense proteins such as manganese superoxide dismutase.[54] Plasma B-endorphins also rise in response to hot water bathing and may be responsible for the euphoric feeling the bath may bring.[24,59] In a study of patients with cancer, hyperthermia was shown to create the same endorphin rise both after sauna bath and in whole-body infrared hyperthermia.

Whole-body hyperthermia (WBH) stimulates an increase in T cells, such as monocytes, and absolute numbers of white blood cells.[59] Heat increases granulocyte mobility, phagocytic and bactericidal properties, and enzymatic activity.[1] There is an increase in homing response to different tissues of lymphocytes, which contributes to antitumor activity. Hyperthermia may increase lymphocyte migration into inflamed tissue or lymphoid tissues such as lymph nodes and Peyer patches; this effect may help generate the cellular immune response. TNF-α and IL-6

are regulated by the stimulus of hyperthermia.[60–62] HSPs produced by hyperthermia can provide protection against the muscle damage that occurs through a pathological increase in intracellular calcium or uncoupling of the mitochondrial respiratory chain. Hyperthermia provides protection against typical damage from reperfusion after ischemia or with excessive exercise damage. Calcium homeostasis, energy loss, increased free radical–mediated reactions, and activation of apoptosis pathways are affected. I use a thermal application of the partial or full peat-additive bath for the treatment of back pain, musculoskeletal disorders, skin problems, viral illnesses, and more. The use of heat in the right amount is crucial to treatment efficacy.[54,62,63]

CLINICAL APPLICATIONS

Care must be exercised in the selection of patients for any type of thermal therapy. It is important to allow each patient time to adapt by starting with lower-temperature and shorter-duration treatments first. Patients with neurodegenerative diseases like multiple sclerosis (MS) and conditions such as diabetes are not good candidates for WBH. In MS, the excitatory effect on nerves from heat leads to muscle cramping, and in diabetes, heat may lead to an ultimate drop in blood sugar and lightheadedness or loss of consciousness. Peat has many beneficial applications, however, as described here.

Discopathy

A series of treatments using a peat bath first, followed by manual traction and then a peat pack over the affected area of the spine, has worked marvelously for many of my patients with discopathy. The first thing that is helped is the pain; then there is an improvement in structural integrity and function over time. It is necessary to perform these combination treatments three times a week for 3 to 12 weeks if there is significant discopathy.

Myopathy

Muscle pain is easily treated with a thermal peat bath or peat pack. The increase in circulation is very helpful to muscles and can be valuable in assisting with osseous manipulation once the muscles are more relaxed.

Scoliosis

A peat bath followed by traction of the spine can be very helpful in patients with scoliosis who have back pain. Applying a peat pack over the area of spinal pain can also be useful.

Arthritis

Peat treatments have shown efficacy for both osteoarthritis and rheumatoid arthritis. Matrix metalloproteinases (MMP-1 or stromelysin-1) are significantly reduced in mud bath patients with osteoarthritis.[64] One needs to be careful with acute rheumatoid arthritis because treatment may initially aggravate symptoms. Generally, in osteoarthritis, these treatments have been shown in both the literature and my experience to be very beneficial. I have observed significant decreases in swelling and pain with one treatment multiple times in osteoarthritis of the knee and other areas. Generally, a series of either combination bath and pack or single bath or packs is given. Treatments are done every day or two. Emerging research is documenting subjective and objective improvement: serum concentrations of IL-1β, TNF-α, IL-8, IL-6, and TGF-β, as well as eHsp72, were markedly decreased in 21 patients with osteoarthritis of the knee.[65]

A 2018 study of 33 patients with hand osteoarthritis found a statistically significant benefit of peloid therapy compared with a control group that used only hand exercises.[66]

Another recent study, this one of 75 patients suffering chronic lateral epicondylitis, compared peloid with lateral epicondylitis band and found a statistically significant improvement in subjective measures.[67]

A particularly interesting study followed more than 100 patients suffering bilateral knee osteoarthritis for a year after completion of a single cycle of treatment. They found statistically significant benefit for all time periods measured.[68]

Headache

Chronic headaches can respond to peat bath or to peat packs, especially on the neck or over the cervical spine. One must be careful not to overheat the medulla with the cervical pack treatment; thus mud applications are usually applied below the second cervical vertebra.

Hamstring Strain

One of the best applications of bath followed by mud pack is in a hamstring muscle strain. In my experience, athletes even of professional stature have been able to "get back into the game" faster and with more function than they would have with any other type of treatment.

Ankle Sprain

Partial peat bath immersion of the foot and leg for ankle sprain is very effective. One can see in older sprains the immediate reduction of ecchymosis after the treatment. Patients can perform home treatments in a plastic wastepaper basket on a daily basis for three to six treatments. This approach is inexpensive and wonderfully effective.

Hypertension

Ambulatory blood pressure has been shown to be affected positively by balneotherapy. After a series of treatments, blood pressure at rest and during standardized levels of ergonomic exercise tends to decrease, as does nocturnal blood pressure. The effect is sustained sometimes permanently.[34] I do not necessarily recommend this treatment for people with hypertension because people with hypertension have more cardiovascular problems that must be considered before they undergo thermal therapy. Generally, people with mild hypertension tolerate the bath better than people with mild hypotension.

Dermatologic Problems

Psoriasis and atopic dermatitis are the dermatologic conditions more commonly treated with peat bath. I, however, have had very good success in eczema and dermatitis with both peat bath and cream application. There are multiple possibilities with dermal applications.

Scleroderma

A peat bath weekly for 6 to 12 treatments is often a good method of treating scleroderma. Treatment should start with a tolerable temperature and increase slowly over the series of baths so that the patient can adapt.

Human Papillomavirus

The antiviral effects of topical peat application have been demonstrated on several viruses, including the human papillomavirus. Remission and prevention of implantation of the virus have been described. This is a measure that prevents cancer. The antiviral and antineoplastic effects are thought to be associated with the ability of peat constituents, such as humate, to bind on lectin-binding junctions, thereby blocking viral entry into cells.[39,53]

Herpes Virus

Topical treatment of herpes virus skin disease with humic and fulvic fractions of peat has been effective. I have had significant success with

zoster outbreaks. Most important, the topical application of specific peat formulation creams that include humic acids has been very helpful to some of my patients.

Infertility

A study on infertility due to immature follicle maturation syndrome demonstrated good results with peat therapy in comparison with pharmacotherapy. In the peat therapy group, the rate of pregnancy was very good, along with a practically nonexistent spontaneous abortion rate, whereas in the pharmacotherapy group, the rate of spontaneous abortions was very high.[32]

ANKYLOSING SPONDYLITIS

In the treatment of ankylosing spondylitis and spondylitis associated with inflammatory bowel disease, mud therapy showed a decrease in the level of C-reactive protein and an elevation of hemoglobin with a series of treatments. This coincided with a significant reduction in pain and an improvement in function.[35,69,70] Peat bath and pack and just the bath are options. If a patient is not a candidate for thermal bath, the packs over the spine can be very useful.

Hematoma

Organic peat, with its intense vasodilating, anti-inflammatory effects and interactions of ions and mineral properties, enhances the reduction of hematomas. Hematomas treated with thermal peat application have been reported to resolve 50% faster, with no hemosiderin residue, than those treated with only heat applications, which often leaves residues.[71] One can see bruising decrease with pack application immediately after the treatment and an enhancement in the absorption of the hematoma in significantly less time with bath and pack.

Immune Stimulation

Peat baths in combination with hyperthermia demonstrate leukocyte elevation. The immune-stimulating effects of peat baths seen clinically correspond to hematologic changes after baths.[59] Some effects on immune function are due to heat, and others are due to the constituents in peat. A favorable effect is seen on peripheral blood lymphocytes in atherosclerotic disease after hydrogen/sulfide bath, independent of heat.[63] Oxihumate has shown antiviral activity plus immunostimulatory effect on mononuclear lymphocytes while also having very low or no toxicity, showing promise for the treatment of immunocompromised patients.[36] Immune stimulation or regulation may also be due to increases or changes in immunocyte numbers and function and the balancing of chronobiological rhythms.[45,50,71,73,74,78-82] Oral oxihumate, a potassium salt of oxihumic acid, may show some activity in blocking human immunodeficiency virus type 1 infection of MT-2 cells and may be helpful in the topical treatment of herpes virus–induced skin diseases.[36]

There are also internal uses for constituents of peat. Interestingly, electrophoresis of peat mud showed benefits in patients with duodenal ulcer, secondary to hormone shifts and normalization of collagen metabolism in the duodenal mucosa.[15] The internal use of peat fractions, such as humic acid, also increased the proliferation of some T cells.[36]

Fibromyalgia

A recent uncontrolled study evaluated 30 days of daily mud bathing at 40°C for 10 min. In addition to subjective reports of clinical improvement, objective measures showed a reduced C-reactive protein level and increased telomere length in leukocytes.[72]

CLINICAL PROCEDURES

The following procedures should be applied with care and forethought as to diagnosis and the skillful administration of the treatment. These procedures are stimulations to the body, and the thermal effects should not be taken lightly. Patients must be thoroughly screened for contraindications to treatment before undergoing full-body immersion hyperthermia. The very young and very old should, in general, have very gentle hot or cold stimulation, if any at all. Generally, up to three thermal baths are given per week if they are hot. Thermal therapy can be depleting for some patients, so consideration of the patient's vitality is primary.

Hyperthermic Medicinal Peat Bath

The indications for and contraindications to hyperthermic medicinal peat bath are given in Box 45.1.

Materials

- Peat bath material—I use a commercially available peat bath formula containing peat extract, sulfur, wintergreen, and pine oil.
- Tub with water thermometer and safety features like handrails and nonslip floor mats
- Room with table for perspiration time
- Gown or loose-fitting bathing suit
- Two sheets
- Two wool blankets
- Two large towels (one for patient to dry off after treatment and one for head wrap)
- Basin with iced water and a hand towel for cooling patient's face
- Digital thermometer or otothermometer for patient monitoring (no glass mercury thermometers). A microcomputer-based data-acquisition device that records electrocardiogram (ECG) data and body and ambient temperatures during bathing can be used; this is preferred over individual readings of pulse and oral temperature during the bath because the ECG shows heart function and the clinician is freed from the task of doing the monitoring. This device can be a real-time recorder for the bath.[73]
- Exhaust fan or room air filter
- Footstool for entering and leaving tub

The design of the bath area should take into consideration getting patients in and out of the tub and then as directly as possible to a treatment table.

Procedure

1. Before a patient begins treatment, cardiovascular risk and any other conditions that do not respond to or are aggravated by thermal therapy should be ruled out. Once the patient has been classified as to risk factors for thermal therapy, the clinician should ask about previous experience with heat in sauna, steam baths, or other types of infrared heating of the tissues. Much depends on the patient's positive health perspective of the self and of the pain or disease process and the patient's expectations of the therapeutic bath or application.
2. Make sure the tub is clean and without a ring. Check log book on last treatment and cleaning. If any evidence of an unclean tank is seen, it must be cleaned and disinfected before use: wearing rubber gloves, use a soft scouring sponge to scrub the tank with disinfectant soap, followed by a rinse of hot water. Then spray the surface with 10% bleach solution, and wait 10 minutes before rinsing with very hot water. Alternatively, a nonbleach product that is antimicrobial can be used; there are many choices for practitioners to choose from on the market.

BOX 45.1 Indications and Contraindications for Hyperthermic Medicinal Peat Bath

Indications

Acne
Arthritis pain
Back pain
Benign prostatic hypertrophy
Bursitis
Carpal tunnel syndrome
Dermatitis
Eczema
Fibromyalgia
Flu
Fractures
Acute gouty toe
Chronic gout
Gynecological disorders
Headaches
Hematomas
Hives
Insomnia
Lumbalgia
Metabolic disorders
Muscle tension
Neurological disorders
Obesity
Orthopedic disorders
Osteoarthritis
Postoperative rehabilitation
Premenstrual syndrome
Prostatitis
Psoriasis
Rashes
Rheumatoid arthritis
Sciatica
Scleroderma
Skin care
Sprains/strains
Stress relief
Trauma
Viral infections

Contraindications

Acute hypertension
Breastfeeding
Cardiac deficiency
Diabetes
Multiple sclerosis
Neurodegenerative disease
Open wounds
Preexisting high fever
Pregnancy
Pulmonary deficiency
Respiratory insufficiency
Systemic lupus erythematosus

3. Fill the tub to 10 inches from the top with water at a temperature of 104°F to 113°F (40°C–45°C).
4. The starting temperature and possible duration of treatment are determined by the condition.
5. The straight water bath should not exceed 110°F. With peat additive, the temperature should not exceed 113°F.
6. Add peat to the bath.
7. Close monitoring during treatment, by means of periodic recording of the patient's pulse, oral temperature, duration of treatment, and tank temperature, is necessary. A quick spike in pulse above the initial pulse within the first minute or minutes is a contraindication to treatment. Any adverse reaction, such as tingling of the fingers and toes, nausea, headache, lightheadedness, or vertigo, should be evaluated closely and treatment terminated. Some patients may be able to tolerate only a low temperature and short duration for the first treatment. For a patient having a series of treatments, the first treatment is of shorter duration and lower temperature to see how the patient responds. The ability to tolerate treatments should improve as patients acclimate through their series of treatments.
8. The patient should enter extremely still water slowly. It will not feel as hot if the water is still.
9. Have the patient remain still as he or she becomes fully immersed, to help decrease the sensation of intense heat.
10. To treat the pelvis, use a sitz bath rather than a full bath to concentrate the effects of the treatment. A full bath after the sitz bath may be useful.
11. The water will cool as time passes, although the peat material will help maintain the temperature. If the starting temperature was 105°F, hot water may have to be added.
12. Bath duration is 8 to 20 minutes and should not exceed 20 minutes because of the additive pharmacological effects and the tendency for hyperthermia to produce increased metabolism and mobilization of chemicals within the body.
13. If the patient becomes fatigued or distressed, the patient should exit the bath to be wrapped in the waiting sheet and wool blankets; do not wait longer to have the patient leave the bath.
14. The patient must have help exiting the tub, from two people who provide lifting support from under the arms on either side. This is a time to be very careful. The clinician should assist the patient by placing an arm under the patient's arm but having the patient use his or her own ability to walk and get out of the tub. If the clinician tries to lift the patient rather than provide necessary support, the patient's tendency is to put all his or her weight on the clinician, which is not the goal. After thermal therapy, patients are usually fine to walk, but there is a chance of lightheadedness and, in rare cases, vertigo. Patients may need assistance.
15. Encourage the patient to concentrate on walking on his or her own.
16. Have the patient lie down on a fresh sheet and wrap the patient in both sheets and two or three wool blankets. Cover the head with a towel.
17. Continue to monitor pulse and oral temperature for the duration of the 20-minute perspiration time.
18. Rinse a facecloth in cold water and apply for 10 seconds or longer to the patient's face every 1 or 2 minutes during both bath and perspiration times. This is extremely important during the bath.
19. Encourage the patient to relax and help the patient focus on pleasant matters during the bath. The psychological component of the bath is huge. Having patients think and talk about whatever excites and pleases them about their lives or their future during the difficult part of the bath and the treatment will help them tolerate the heat and reframe their disease processes.
20. After the patient has been wrapped from head to foot in sheet and wool blankets (it is not necessary to have blankets under the patient because the table is a good insulator that prevents the blankets from getting wet), allow the patient to go through the hydrotherapy reaction of rise and fall in temperature, pulse, and diaphoresis three times. Then remove the patient from the sheets and allow

him or her to return to normal activities. This cyclic reaction is seen with peat baths. With water baths, the patient may or may not sweat after the bath. With peat baths, perspiration is helpful because there is increased absorption or skin effect if perspiration is allowed to continue after the bath.

21. Have the patient rest and replace electrolytes after treatment. The patient should not do a lot of exercise for 12 to 24 hours after a full bath, especially patients with back problems. The patient should promote good posture in the treated area during this time.
22. During the perspiration time, manual traction can be applied to the spine. This is done by grasping the ankles of the supine patient and pulling for 30 to 45 seconds with enough traction that the patient almost slides on the table. Indications for manual traction are disc problems, scoliosis, and impingement; it is a nice addition to any peat bath for any condition because it feels good to the patient.
23. Advise the patient not to shower with soap for up to 12 hours after the peat bath because absorption rates continue after the bath if peat additives have been used.
24. Patients should dry thoroughly and remain covered, warm, and out of drafts for 3 hours after treatment. This precaution can easily be overlooked and cause aggravation if cold stimulation is allowed to happen. More than one reminder to the patient is necessary because people naturally are ready to cool down after a thermal bath.
25. Clean the tank and room thoroughly after use. Log out times of bath and tank cleaning.

Medicinal Peat Peloid

The indications for and contraindications to this procedure are given in Box 45.2. Care should be taken to avoid burns when performing this application. It is important for the patient to have a strong feeling of warmth without a hot, burning sensation. For a typical application, this heat sensation should last for 20 to 30 minutes and may take a few minutes to start once the mud has been applied. Start timing from the point that the patient first feels warmth. The practitioner should use his or her own touch and sense of heat during the application.

Materials

- Peat poultice material—I use Healing Botanical's professional-use poultice formula containing peat pulp, peat extract, sulfur, wintergreen, and pine oil. Hot water should be added to this dry material 3 minutes before application, and the solution should be mixed so it becomes very slightly supersaturated. The point at which it just becomes shiny and has the consistency of mixed cake batter is perfect. In 1 to 3 minutes, it will be time to apply it to the area being treated. It will still be warm for application because hot water was used.
- Three large towels
- Small towel
- Facecloth
- Small blanket to cover hydrocollator
- Two small stainless-steel basins
- One small paper cup
- Hydrocollator (alternatively, hot water bottle can be used)

Procedure

This is a thermal peat pack meant to be applied for 30 minutes. The procedure is as follows:

1. Make a square layer of peat material about 0.25 inches thick, 2 inches bilaterally over the spine, and 6 to 8 inches long over the spine. If the spinal area is not being treated, the area to be treated is covered. The area of application should be as flat and level as possible.

BOX 45.2 Indications and Contraindications for Medicinal Peat Peloid

Indications

Acne
Arthritis pain
Back pain
Bursitis
Carpal tunnel syndrome
Eczema
Fibromyalgia
Fractures
Acute gouty toe
Chronic gout
Headaches
Hematomas
Hives
Lumbalgia
Molluscum contagiosum
Muscle tension
Orthopedic disorders
Osteoarthritis
Postoperative rehabilitation
Premenstrual syndrome
Prostatitis
Psoriasis
Rashes
Rheumatoid arthritis
Sciatica
Skin care
Sprains
Strains
Stress relief
Trauma

Contraindications

Open wounds
Pregnancy
Very thin, fragile skin
Heat-insensitive skin
Allergies to any of the peloid materials

2. Cover the peat directly with a single-layer warm, wet facecloth. So as to remember the borders of the peloid exactly, ridge the facecloth around the margins of the peat.
3. Border the wet facecloth–covered peloid with a rolled bath towel, making a quarter turn at the corners while folding the towel to match the margin of the peat.
4. Apply one layer of towel over the facecloth and peat material. Depending on the size and mass of the hydrocollator and its temperature, this layer may not be necessary.
5. Put a fresh hydrocollator pack directly over the towel. The hydrocollator should be heated at a gentle boil for 1 hour before use. Do not allow any exposed skin to come in contact with the hydrocollator.
6. Cover the hydrocollator pack with a towel or small blanket to insulate it and prevent heat loss.
7. Have a cup of cold water ready to pour on the wet facecloth–covered peloid if it gets too hot. In a good treatment, the peloid pack should get hot enough to require two to three dousings of water or more.

8. As soon as the patient says that the pack is getting too hot, lift up the hydrocollator pack and towel and pour the water directly over the facecloth–covered peloid until cool. Then replace the hydrocollator and coverings.
9. Never leave the patient unattended with the hydrocollator on the mud!
10. Treatment time is approximately 25 to 30 minutes.
11. To remove the peat from the skin after treatment, slide a small basin along the skin under the peat, scraping the peat into the bowl. Wipe the area with a full facecloth wetted with warm water in a gentle twisting motion back and forth to remove peat residue from the skin.
12. Cover the treated area after treatment to maintain warmth for 3 hours. The patient's clothing is fine, but a wool blanket would do a better job.

Partial-Immersion Medicinal Peat Bath

The indications for and contraindications to this procedure are given in Box 45.3.

Materials

- Deep-well basin; a tall plastic wastebasket size works well for the leg.
- Medicinal peat bath
- Water thermometer
- Small towel

Procedure

1. Fill basin to three-quarters full with 108°F to 114°F water.
2. Add peat to the bath.
3. Have the patient immerse the wrist, ankle, or elbow slowly into the water. Try to immerse the forearm and leg if treating the hand or foot.
4. Keep the body part immersed for 25 minutes.
5. After the treatment, cover the area with a wool sock or clothing and keep covered for 3 hours after treatment.
6. Peat material is often sent home with the patient to do home treatments.
7. Clean up the basin by washing with antimicrobial soap. Then disinfect with 10% bleach solution, and rinse after 10 minutes.

BOX 45.3 Indications and Contraindications of Partial-Immersion Medicinal Peat Bath

Indications
Arthritis pain
Bursitis
Carpal tunnel syndrome
Eczema
Fibromyalgia
Fractures
Acute gouty toe
Chronic gout
Hematomas
Orthopedic disorders
Osteoarthritis
Plantar fascitis
Postoperative rehabilitation
Psoriasis
Rashes
Rheumatoid arthritis
Skin care
Sprains
Strains
Tendinitis
Tenosynovitis
Trauma

Contraindications
Open wounds
Pregnancy
Heat-insensitive area

Combination Full Bath and Peat Pack

Materials

The same materials are needed as described for the two preceding applications.

Procedure

This treatment is used for many conditions. I particularly like it for treatment of vertebral disc injury or degenerative joint conditions. This procedure is also very good for injuries such as hamstring strain. It focuses the balneological effects in the area to which the peloid pack is applied. Performing the peat bath first and then applying the peat pack is the ultimate treatment for those who can tolerate the bath. After the patient steps out of the bath, he or she walks to the table and lies face-up for the regular traction sequence. After three tractions, it is appropriate to turn the patient face-down and apply the peat pack over the spine or area being treated.

ADVERSE REACTIONS

A study out of Russia evaluated peloid therapy in 128 women presenting with bacterial vaginosis and normal prolactin level and 58 women with bacterial vaginosis and concomitant hyperprolactinemia. Although peloid therapy was significantly effective in women suffering vaginosis and normal prolactin levels, the women with elevated prolactin levels clearly suffered worse clinical outcomes and an aggravation of their hormone dysfunction.[74]

SUMMARY

As a physician using balneotherapy for 15 years, I have achieved excellent results in a large percentage of patients who undergo peat therapy. This therapy often helps other therapies work better. Balneotherapy can be primary or adjunctive. The potential effect on the body should not be taken lightly.

I have observed excellent results for the following conditions:

- Arthritis
- Tenosynovitis
- Strains and sprains
- Discopathy
- Plantar fascitis
- Low back pain, including sciatica
- Scoliosis
- Fractures
- Gout
- Muscle pain
- Dermatologic conditions such as eczema

The combination of medical sophistication in diagnosis and application of various balneological methods provides an excellent tool for physicians to treat in a natural way to the great benefit of their patients.

Rotation Diet:
A Diagnostic and Therapeutic Tool

Sally J. Rockwell, PhD, CCN

OUTLINE

INTRODUCTION

Food allergy and/or intolerance is a common component of many chronic diseases (see Chapter 14). However, it is not readily recognized as problematic. Conventional laboratory diagnosis is not geared toward testing food allergies, and most allergists dismiss the concept of delayed hypersensitivity reactions to foods (see Chapter 14). A time-honored, effective approach to both the diagnosis and treatment of food sensitivities is an elimination–rotation diet. This approach has the advantage of being low cost, and the techniques must be followed assiduously to ensure clinical efficacy. Box 46.1 lists the typical indications for an elimination diet.

THE ELIMINATION DIET

The first step in the elimination diet is to remove from the diet (1) all of the most common allergenic foods—that is, wheat and other glutinous grains, dairy products, eggs, corn, soy and tofu, peanuts, citrus fruits, yeast, and refined sugars—and (2) other often problematic substances, such as highly processed foods, chemicals, additives, preservatives, artificial colorings, flavorings, caffeine (coffee, tea, cola drinks, chocolate), and alcohol.

The object is to avoid the intake of all suspect foods and substances for at least 5 days, or long enough to clear all traces of those foods from the digestive tract. The omitted foods are then reintroduced into the diet one at a time. Keeping an accurate food and symptom diary enables the offending foods to be identified and eliminated; depending on the severity of the initial test response, the foods can be carefully reintroduced into the diet within 3 to 6 months.

Although some authorities recommend eliminating only one food at a time, clinicians in this area have found that multiple allergies are the rule, not the exception. Eliminating only one allergen may not clear symptoms well enough to notice an improvement. The advantages of eliminating all major allergens in the beginning are rapid clearing, minimal adverse reactions, and accurate test results. Also, when symptoms clear rapidly, the patient becomes inspired and eager to continue with the testing.

As Dr. Doris Rapp[1] explained:

> *If there are several tacks in the bottom of a shoe, the whole foot hurts; removing only one tack will make little or no difference. But remove all the tacks, let the foot heal, then add back one tack at a time and the source of pain is isolated and easily identified. If only one tack (or food) is removed, no significant difference will be noted.*

Variations of the elimination diet range from the most stringent plan, involving elimination of all the major allergens, refined foods, and toxic substances, to a more lenient approach, which eliminates only wheat, dairy, and refined sugars. Consideration of the patient's lifestyle, age, weight, general health, food preferences, attitude, and family system determines the approach. For children and pregnant or lactating women, the amount of calories or carbohydrates should not be restricted; one should simply omit the major allergens.

Variations of the Elimination Diet

As can be seen in Table 46.1, all elimination and/or challenge diets are variations of the following four "Rs" procedure:

1. Remove suspect foods for at least 5 days.
2. Reintroduce and/or test by challenge ingestion.
3. Record reactions.
4. Rotate foods, avoiding those shown to cause adverse reactions.

Water Fasting

Water fasting should be implemented only under the close guidance of an experienced health professional. A lifetime of accumulated toxins may be released in a short time, creating unwarranted discomfort and complications that may overwhelm the patient and interfere with testing (see Chapter 37 for a complete description of fasting methodologies).

The Dilute Juice Fast

Less severe than water fasting, and more acceptable to patients, is the dilute juice fast. Diluted juices provide a modest amount of calories, stabilizes blood glucose levels, and decreases the adverse detoxification–withdrawal reactions that may occur during the elimination of all common allergens. The basic procedure is to use three parts of distilled or

BOX 46.1 Indications for the Use of the Elimination Diet

- Documented or suspected food allergies and/or intolerances
- Chronic complaints that have not subsided with treatment
- Patients who have symptoms and whose tests results are all "normal"
- Patients in whom mental health problems are suspected because of lack of significant progress
- Children and teens who are labeled as having attention deficit disorder or as being hyperactive, those who are autistic, and those who have behavior problems

TABLE 46.1 Elimination Diet Variants

Type	Protocol
Water fast	Water-only fast for 5 days; reintroduction of foods
Dilute juice fast	Diluted fruit juice fast for 5 days; reintroduction of omitted foods
Fruit, melon, and vegetable plan	Only fruits, melons, and vegetables for 5 days; reintroduction of omitted foods
Caveman (caveperson) plan	Proteins, nuts, seeds, legumes, fruits, and vegetables for 5 days; reintroduction of omitted foods Only natural, unprocessed foods are eaten

mineral water to one part of fresh, sugar-free juice. The diluted juices are sipped throughout the day. Ideally, a different juice is used each day: celery, carrot, papaya, cranberry, berry, apple, pineapple, and other fruits or vegetables that have not been consumed on a daily basis. Citrus fruits should be avoided. Low-allergen protein supplements, such as Ultra Clear, MEDIPRO Protein Powder, pure free-form amino acids, N Foods, and Vivonex, may be added after the third day. In addition, liberal amounts of pure water should be consumed throughout the day to dilute and flush out toxic substances.

Note: This approach works for most patients with *Candida* yeast infections because the juice is so dilute that it rarely creates a problem. However, commercially prepared juices (especially tomato and citrus juice) often contain molds, which can be problematic.

Fruit and/or Vegetable Plan

In the fruit and/or vegetable plan, the patient consumes unlimited amounts of clean, fresh fruit and melons and raw, steamed, or baked vegetables throughout the day. If *Candida* overgrowth is severe, or if weight loss is desired, vegetables should be emphasized and fruits limited.

The Caveman (Caveperson) Plan

The caveperson plan consists of the following basic foods that the caveperson consumed, after the major allergenic foods have been eliminated: vegetables, fruits, berries, honey, nuts, seeds, beans, peas, sprouts, roots, gourds, poultry, fish, seafood, and wild game.

Procedure

Beginning the Elimination Diet

An ideal elimination diet begins as follows:

- 2 days of diluted juices
- Fruits and vegetables for the next 2 days
- The caveperson diet for 2 days or until symptoms clear

Any one, or any combination, of the previously described elimination plans will clear the patient of allergenic substances. If after 5 days the patient's symptoms have not diminished (or disappeared), continue the diet for another 5 days. If symptoms are not clear in 10 days, begin to rotate foods because the patient may be reacting to a food or substance he or she is consuming every day. (Unsuspected environmental allergens may be contributing to the symptoms also; see "Helpful Hints and Suggestions" later in this chapter.)

Testing by Challenge Ingestion

One suspect food is introduced every other day. The object is to give the patient sufficient calories, build a reliable list of safe foods, and delay unpleasant reactions for as long as possible. The challenge should begin with rarely ingested foods that are least likely to cause adverse reactions. Foods that are known to cause severe reactions should not be tested with challenge.

Suggested testing sequence. Introduce foods back into the diet in the following order whenever possible: vegetables, fruits, melons, beans, nuts and seeds, yeasts, dairy products, and finally, grains. When dairy is added, goat products should be tested first: plain yogurt, cheeses, and then milk. Follow the same process with cow's milk. Grains are best tested in the following order (gluten-containing grains are in italics): quinoa, amaranth, buckwheat, wild rice, brown rice, millet, *barley, spelt,* kamut, teff, oats, *rye,* corn, and lastly, *wheat*. Dietary supplements should also be tested one at a time.

Food and symptom diary. The patient records, chronologically in a notebook, all foods, liquids, supplements, moods, symptoms, and reactions. The foods eaten throughout the day should be noted in either pencil or blue or black ink. Symptoms are highlighted or circled in colored ink so that those adverse reactions stand out clearly. In 2 to 3 weeks, a repetitive pattern of symptoms will be clearly visible, allowing for identification and elimination of the problematic foods or food combinations that cause symptoms.

In the beginning, a patient may not be able to describe in exact words how he or she feels, so a numbering system may be useful for noting general moods throughout the day. Numbers go from 1 (poor) to 10 (excellent); feeling sort of medium, neither poor nor excellent, would be recorded as a 5. In general, depending on the patient's health and motivation, foods causing a mild reaction should be avoided for 3 months, and those causing a severe reaction are best avoided for at least 6 months before being reintroduced.

Testing children. Play a game with children to make testing fun. Have them draw a picture of how they feel, or write their names before and after testing a substance. Note all before-and-after differences in the drawings or writings.

THE DIVERSIFIED ROTATION DIET

The basic concept of the diversified rotation diet is to achieve the following:

- Eliminate all major allergenic substances.
- Eat the remaining foods once every 4 days.
- Allow 2 to 4 days between food families.

Rotation can be simplified by using a template—the "master chart"—with foods correctly arranged according to their botanical family classifications. The spacing of the foods and food families is organized into four columns, one for each day, so the patient simply chooses foods from the appropriate column each day. A color-coding system further simplifies the process of choosing the correct foods.

See Appendix 11 for an easy-to-follow template. The chart provides 4 days between specific foods and 2 days between food families. A second chart (Master Chart II) may be needed for severely sensitive individuals. It provides 4 days between specific foods and 4 days between food families. If necessary, it can be easily adapted to a 7-day rotation.

Using the Master Charts

The clinician uses a pencil to cross out the major allergens, plus any known or suspected problem foods, in each of the four columns. The patient may eat the remaining foods from the appropriate column throughout the day. The foods that are not crossed out are allowed in the diet.

Arrows on the chart (↔) indicate a food that is essentially the only food of a family and that is not cross-reactive with other foods. Therefore it is not restricted to any one particular day and can be moved to another column if additional food choices are needed.

Patients who will be rotating foods for any length of time will welcome the benefits of using the color-coding system. A color is assigned to each day. Each column represents a day: day 1, green, is column 1; day 2, yellow, column 2; day 3, blue, column 3; and day 4, red, column 4. After day 4, the patient returns to day 1 and repeats the process. Food containers are labeled and color-coded to coordinate with the color of the day; for example, green labels, twist-ties, or rubber bands are placed on all containers of foods for day 1. The color-coding system enables the entire family to see at a glance which foods the patient is permitted to eat on each day.

Modifications for Vegans

The master charts can be used for vegans. Simply cross out all foods of animal origin. Legumes (beans and peas) are generally an important part of the vegan diet; thus all legumes should be tested, one at a time, beginning with the least allergenic, rarely eaten beans and proceeding to soy and tofu, with peanuts tested last. Depending on the allergic response to legumes, the patient may be able to tolerate legumes daily, as long as he or she eats a different legume each day. In other words, although the 4-days-between-foods rule continues to be honored, the 1-day-between-food-families rule may be ignored for less-sensitive patients.

Food Preparation

For testing purposes, fresh, organic foods should be used whenever possible. Otherwise, frozen or dehydrated foods are a better choice than canned goods. Most vegetables are best eaten raw, steamed, or baked. Fish, poultry, and meat are best poached, steamed, sautéed, baked, or simmered in a slow cooker (e.g., crock-pot). Soups and stews are fine. Use only sea salt for seasoning; all spices and flavorings must be avoided unless they are individually tested.

Blood glucose levels may need to be stabilized with small, frequent meals throughout the day. Have the patient prepare four mixtures of "trail mix"—nuts and dried fruits—one for each day (refer to the master chart for specific food choices). A supply of healthy snacks must be maintained everywhere: home, school, office, and automobile.

Helpful Hints and Suggestions

Control of Withdrawal Symptoms and Allergenic Reactions

Vitamin C buffered with calcium, potassium, and/or magnesium is suggested as the daily source of vitamin C for allergenic individuals. These substances help balance an acidic body pH and are valuable for neutralizing unpleasant allergic reactions. Stabilization of pH eases the symptoms of withdrawal from allergenic foods and the cravings that occur when the patient is breaking an addiction, whether it is to sugar, wheat, coffee, cigarettes, alcohol, or a drug.

For daily supplementation, begin with 1/8 teaspoon of buffered vitamin C powder (or one 500 mg capsule) in 1/2 cup of water three times a day (between meals and at bedtime). Gradually increase the dosage by an additional 1/8 teaspoon (1 capsule) per dose every 2 days until the patient reaches bowel tolerance—loose stool, gas, or diarrhea—at which point the dosage is reduced. As the patient improves, the vitamin C requirement will likely lessen, and the dosage can be reduced again.

Note: Buffered vitamin C should not be taken with meals because it may neutralize stomach acid, which is commonly deficient in patients with food allergy and/or intolerance (see Chapter 14).

For temporary relief of symptoms or to neutralize an adverse reaction, the patient should mix and drink 1/2 teaspoon of buffered vitamin C in 1/2 cup of water or dilute juice. Available commercial products include Klaire Labs Bicarbs (see http://www.klairelabs.com), Cardiovascular Lab's Tri-Salts (see http://www.cardiovascularlabs.com), and Alka Seltzer gold label (not the blue label, see http://www.alkaseltzer.com); if none of these products is available, 1/2 teaspoon of baking soda in 1/2 cup of water can be useful.

Environmental Allergies

If the patient does not respond to the diet in a timely fashion, and all other possibilities have been ruled out, the clinician should suspect environmental and/or chemical sensitivities. The first step in this instance is to eliminate the use of all scented toiletries, room sprays, and cleaning solutions in the home and workplace.

Ensuring Adequate Protein Intake

The most allergenic foods tend to be those highest in protein; thus care must be taken to ensure that the patient is consuming adequate amounts of protein. Patients with multiple food allergies may need to be referred to an experienced nutritionist to develop a balanced diet.

Patience

The clinician must be especially supportive and patient with individuals who have received only long-term conventional treatment. You may be the first physician to discuss the rewards of listening to their bodies and explain how symptoms are the body's way of communicating. Learning to pay attention to what they eat and drink and the possible adverse symptoms is a vital part of getting well again.

Soft Tissue Manipulation: Diagnostic and Therapeutic Potential

Terry M. Elder, DC, Leon Chaitow, ND, DO,* and *Tim Irving*, DC, MS, LMT*

OUTLINE

INTRODUCTION

The term *soft tissue* is a ubiquitous and, at times, vague term. Every profession that deals with the mobility, stability, and dynamic function of the neuromusculoskeletal system must embrace diagnostic and therapeutic soft tissue procedures. Medical and therapeutic systems such as those used by naturopaths, chiropractors, osteopaths, allopaths, physical therapists, massage therapists, and body-centered psychotherapists all have their own procedures for identifying and treating a variety of soft tissue dysfunction. Despite their differences, terms used, or the theories advocated by each profession, they all agree to some degree that soft tissue dysfunction can cause and/or indicate disease, injury, aberrant reflex activity, and aberrant movement patterns, the results of which can have minor or profound effects on the health of the individual. In addition, most professionals who diagnose and treat soft tissue dysfunction seem to refer to a common phenomenon: distinct, palpable, usually sensitive areas of soft tissue aberrations or lesions that are either directly or reflexively related to local or organ dysfunction and/or disease.[1,2]

The thoughts, ideas, and theories that are foundational to physical medicine are evolving; so, too, are the thoughts, ideas, and theories foundational to soft tissue diagnostics and therapeutics. One clinically relevant and interesting note is that many systems of health care delivery are moving to more encompassing and holistic ideas about the interrelation of many cells, tissues, organs, and systems to obtain and maintain optimal health and wellness. Functional or lifestyle medicine practitioners look at the various systems of the body in a hierarchical fashion. Treating systems "upstream" or higher up on a hierarchical list of systems allows the practitioner to optimize the health of the individual without chasing down symptoms.[3] Movement therapists and doctors who help improve and stabilize movement are looking at movement patterns instead of single or even dual-planar movement. The idea that movement only transmits from muscle origin to insertion is long gone, clinically incomplete, and inferior to the recent, more functional theories.[4–6] Soft tissue diagnostic and therapeutic procedures are currently evolving; this evolution is occurring as a result of clinical treatment and trials and other empirical methods.

Although the working definition of soft tissue has always included muscles, ligaments, tendons, fascia, and more, each individual tissue was looked at and often treated as a separate entity, not as a functional unit. There has been a recent push to look at functional groups of soft tissues. Ideas like myofascial "chains," "trains," and units are taking the soft tissue world by storm and proving to be clinically superior to some of the incomplete, older, more reductionist ideas.[7–9] Tension relationships are now ideas that permeate soft tissue diagnosis and therapies. Muscle coordination and perception are looked at as functions of these relationships rather than the work of a group of muscles and their respective myoneural units.[7–11]

Soft tissue therapy may be used to accomplish the following:

- Normalize soft tissue dysfunction in preparation for joint manipulation[12–14]
- Restore postural or functional integrity; this has been one of the primary uses of soft tissue therapies for ages, and now many are thinking about this more in terms of restoring healthy tension relationships throughout all of the integrated soft tissue structures of the body[7–9,15]
- Function as part of a comprehensive approach to health care in which tension relationships and subsequent reflex activity, manifested in soft tissues, are used diagnostically and therapeutically[16]

Of final note, professions that classically have not viewed soft tissue as the primary avenue for their treatment benefits have been evolving their paradigms. Acupuncturists specifically have been viewing soft tissue, more specifically fascia, as part of their diagnostic and treatment foundation. Various authors in the acupuncture world have noted that acupuncture points and connective tissue and soft tissue planes have a very intimate relationship and, at times, are indistinguishable.[17–19]

HEALTH IMPLICATIONS OF SOFT TISSUE MANIPULATION: THE BIG PICTURE

For every therapeutic intervention, we must first determine how best to use the technique and/or intervention. For soft tissue manipulation, there are localized responses that will be addressed later in this chapter; this section is devoted to how soft tissue manipulation affects overall health.

Immune System

Clinically, many who practice soft tissue manipulation have noted various immune responses from patients and clients. The evidence for these effects has been elucidated, mostly through studies of massage therapy. Because the immune system receives messages and is controlled by the nervous and endocrine systems, the effects of soft tissue manipulation regarding the immune system are neuroendocrine in nature.[20]

Emotional

Soft tissue manipulation has been shown to help the emotional status of individuals experiencing depression, eating disorders, excessive anger, rage, rejection, and fear. Using soft tissue manipulation as an adjunct therapy when treating individuals with emotional distress can have widespread systemic effects that may prove to be necessary.[21–26]

Endocrine

Inappropriate amounts of hormones will cause a breakdown in this important system of control. Most notable, especially with regard to soft tissue manipulation, is excess cortisol. Soft tissue manipulation has been found to decrease inappropriately elevated levels of cortisol. The effects of chronically high cortisol levels occur at the hypothalamic–pituitary–axis level and can disrupt and create aberrations in neuroendocrine function. In addition, soft tissue manipulation has also been shown to raise low levels of dopamine and serotonin; this effect has implications in treating addictions, eating disorders, depression, and more.[27–31]

What this author is referring to in this subsection is the effect that soft tissue manipulation has on our ability to maintain homeostasis or homeodynamics after the introduction of a stressful stimulus. According to Selye and proponents of the General Adaptation Syndrome line of thought, our physical, biochemical, and emotional beings can withstand a certain amount of stress.[32] Everyone has a different threshold, and soft tissue manipulation allows the practitioner the opportunity to remove layers of stress so that we can adapt and thrive.

DEFINITION: FUNCTIONAL SOFT TISSUE

As noted in the introduction, thoughts, ideas, and theories surrounding soft tissue diagnosis and manipulation are evolving. The phrase "functional soft tissue" has been used by this author and others. The idea that muscles, bones, tendons, fascia, and ligaments are separate entities is an idea that, although true in a histological sense, is not the whole truth in a functional sense. A more clinically useful idea is that all of these structures transmit tension. Some of them contract, others resist tension, others give way to tension; the bottom line is they all respond and transmit tension. What many consider the apex of the soft tissue evolution is that soft tissue pathologies exist when the transmission of this tension is altered. As a result, various authors have developed ideas that link all connective and soft tissues together functionally. Myers developed the "Anatomy Trains" idea, and Stecco developed ideas that link soft tissues together functionally through fascial motor units, centers of coordination, centers of perception, and centers of fusion. Ida Rolf was on the cutting edge of these ideas and looked at the physical body as a transmitter of tension.[7–9,15]

Taking the idea of functional soft tissues one step further, the fitness and performance professions are evolving closely with the clinical soft tissue manipulation professions to develop very integrative and useful movement therapies. These movement therapies bridge the gap between more passive soft tissue manipulative techniques and exercise. Many effective soft tissue manipulative techniques include active movement and mobilization on the patient's and/or client's part. These therapeutic procedures, combined with more passive soft tissue interventions, are proving to be more effective than passive techniques alone.[33]

SOFT TISSUE PATHOLOGIES

Many of the focal soft tissue lesions and dysfunctions listed can be classified as myofascial points; some are more descriptive, whereas others are the terminology used when describing a diagnosis. This author feels it necessary to note that this is not a comprehensive list of potential soft tissue points and/or lesions, but that most, if not all, soft tissue lesions will fall into these categories:

- Tender points
- Trigger points
- Fascial densifications
- Strains/sprains
- Fibrosis
- Adhesions
- Chapman's reflex points

Researchers and clinicians have used different terminology to describe similar phenomena, resulting in confusion of what is essentially an uncomplicated pattern. In the musculature and connective tissues of the body, often in the regions of the origins and insertions of the muscles, soft tissue points are often commonly found at motor points and in the muscle belly. The commonality, despite differing opinions on diagnostic criteria and the manner in which they are assessed, is palpable, sensitive areas of altered structure resulting from injury, anoxia, irritation, stress, aberrant reflex activity, and/or aberrant movement patterns. Another commonality to these points is their size, which ranges from 0.5 to 1.0 cm across, and their feel, which is described either as harder or firmer than surrounding normal tissue or as having an "edematous," "boggy," "fibrous," or "stringy" feel.[34]

It is often noted that these localized areas of altered structure and function occur in bands of stressed fibers, both fascial and muscular. In all cases, such localized areas are, to a greater or lesser degree, sensitive or tender out of proportion to the amount of pressure exerted.[35] All these points are potential "trigger points," but only those that, upon pressure, are noted to refer pain or other symptoms to a distant (target) area and that are recognizable as "familiar" to the individual are classified as such points.[36,37]

Methods of Identification

Despite all of the advances in imaging, the most widely used clinical procedure to identify soft tissue pathology is a combination of movement, special (orthopedic) tests, and skilled palpation. The diagnostic use of movement patterns will be discussed in the next section; they, too, can be used to locate focal soft tissue lesions and points.[16,38–40]

The definitions of the previously mentioned soft tissue pathologies can be and are debated. Often, clinicians name a focal soft tissue lesion a "trigger point" when many more of us would call it a "tender point." Likewise, fascial densifications can be tender points, trigger-point adhesions, and/or fibrosis. Then there are reflex points that can elucidate functional and pathological problems in and around the viscera; Chapman's points are examples of such points.

There are a variety of methods by which soft tissue changes may be located through palpation. They include the following:

- Traditional massage methods—mainly palpatory awareness during various massage strokes like effleurage, petrissage, tapotement, and vibration.
- Specific palpation techniques—such as those developed by massage, naturopathic, chiropractic, physical therapy, and osteopathic schools. The common thread is the development of fine motor skills and palpatory awareness, the foundation of which is a solid knowledge of structural and functional anatomy.
- Neuromuscular technique—a method of combined assessment and therapy developed in the 1930s by Stanley Lief, an American-trained naturopathic and chiropractic physician working in Europe.
- Skin distraction, pinching, and gliding techniques

All of these, as well as other methods of palpation, may be used to identify areas of local soft tissue dysfunction that may be either sources or results of reflex activity or other local adaptive responses. All of these techniques are used to assess and notice areas of tone, texture, and temperature abnormalities as well as developmental and structural asymmetry.

The analysis of the available information present in localized areas of the soft tissues requires consideration of a variety of classifications and systems. It is necessary to examine some of the systems that have described the same tissue changes in different ways, to compare the similarities and differences in the descriptions of points (discrete, usually sensitive areas of altered structure and function in the soft tissue) and the diagnostic and therapeutic significance ascribed to them.

Aberrant Movement Patterns

As noted in the introduction, soft tissue diagnostics and therapeutics are evolving into a more functional paradigm; with this evolution comes a journey into the idea that movement patterns will help clinicians elucidate soft tissue dysfunction and focal lesions.[4–9,11,36]

Methods of Identification

The simplest description of detecting and diagnosing movement patterns is that they are performed through observation and patient movements (active and passive). All of the techniques for this type of assessment have this in common; which movements and how they should be performed are debatable.

Simple, single planar movement patterns have been assessed by many.[6,11] These are often easier to assess, but their relevance has been questioned over the past 10 years. Multiplanar movement patterns have been purportedly better, more accurate, and more clinically relevant in the assessment of soft tissue and other neuromusculoskeletal structures.[4–9,36] There is no definitive proof as to which strategy and which motions are the most clinically relevant. Clinicians have begun to use patterns described as "primitive" by Gray Cook and Kyle Kiesel.[4,5] The aforementioned clinicians and authors designed a succinct and concise assessment of seven movements. These movements range from deep squats to toe touches, lunges, push-ups, and active straight leg raises. The assessment of these motions has been given a point system: 0 means there is pain with the movement pattern; 1 is difficulty performing it even after some compensatory correction; 2 is difficulty performing it without said compensation but having the ability to perform it with said compensation; and 3 is full ability and stability while performing each pattern. The relevance of each pattern is speculative and debatable. Gray[36] designed a complex assessment of movement patterns through triplanar movements. Although the theory behind his assessments is similar to Cook's and others, his procedures are unique. This is not a concise and neatly packaged technique, but many clinicians are seeing great results with their patients using Gray's theories and applications.

TABLE 47.1 General Soft Tissue Manipulative Technique

Technique	Description
Articulation	Repetitive passive movements employing leverage through variable ranges of the arc
Effleurage	Superficial drainage technique derived from massage therapy
Inhibition/ischemic compression	Describes an objective rather than a method; consists of pressure applied for lengthy periods, slowly applied and slowly released, using thumb contact as a rule
Kneading	Deep or superficial rhythmical pressure, usually applied by thenar or hypothenar eminence
Positional release methods	Approaches that, instead of acting directly on restricted or shortened structures, aim to position them in a state of "ease" by moving away from restriction barriers, allowing a spontaneous normalization to occur, involving neural (muscle spindle) resetting and circulatory enhancement These methods include what is known as strain/counterstrain as well as much craniosacral work
Rhythmic traction	Repetitive attempts to separate articulations to stretch interarticular and periarticular structures
Springing	Repetitive, usually slowly applied, pressure of a gradual nature, often used diagnostically
Stretching	Short and long amplitude attempts at separation of muscular attachments and stretching of ligaments, fascia, and membranes
Vibration	Rapid oscillatory pressure or movement

Soft Tissue Manipulation Techniques

Therapeutic efforts and techniques may be directed toward the diagnosis and treatment of the mechanical aspects of dysfunction (trauma, strain, aberrant movement patterns, etc.) and toward the use of the available information from such reflex areas in a more wide-ranging, holistic approach to the health of the patient.[37]

General, rhythmic techniques are often employed on the soft tissues to relieve local dysfunction and/or to prepare for subsequent adjustment of osseous structure. There are common threads to each technique; many use rocking and other rhythmic movements, compression and ischemic compression, and a variety of contacts (hands, digital pressure, elbows, and various devices). In all of the available soft tissue techniques, the objectives are the improvement of circulation and drainage; release of contracture, fibrosis, and/or adhesion; greater range of movement; decreased pain and improved movement; and stability. Most soft tissue methods can be applied in a stimulatory as well as a relaxing or inhibitory manner, but care should be taken to prevent stimulation from becoming an irritation. Table 47.1 presents a survey of various soft tissue techniques and a brief description of each.

The Potential of Soft Tissue Manipulation

The professions that use manual medicine are experiencing a resurgence in the tradition of "hands-on" assessment, treatments, and therapies. The musculoskeletal system is both the greatest energy consumer and the largest organ of sensory input in the body. This primary machinery of life has long been unappreciated in

therapeutic terms. The development of methods such as strain/counterstrain, muscle energy technique, fascial manipulation, trigger-point therapy, and neuromuscular technique and research, as well as other reflex systems, ensures that the diagnostic and therapeutic potential of the soft tissues is increasingly being recognized and used.

Korr, the premier osteopathic researcher of the second half of the 20th century, summarized another vital implication of soft tissue dysfunction—interference with axonal transport mechanisms—as follows:

> *Any factor that causes derangement of transport mechanism in the axon or that chronically alters the quality or quantity of the axonally transported substances could cause the trophic influences to become detrimental. This alteration in turn would produce aberrations of structure, function and metabolism, thereby contributing to dysfunction and disease. Almost certainly to be included among these harmful factors are the deformation of nerves and roots, such as compression, stretching, angulation and torsion that are known to occur all too commonly in the human being and that are likely to disturb the interaxonal transport mechanisms, intraneural microcirculation and the blood-nerve barrier. Neural structures are especially vulnerable in their passage over highly mobile joints, through bony canals, intervertebral foramina, fascial layers and tonically contracted muscles. Many of these biomechanically induced deformations are of course subject to manipulative amelioration and correction.*[41]

SUMMARY

This survey touched on some of the many ways in which soft tissue dysfunction may impinge upon the economy of the body as a whole. Soft tissue manipulation is an important diagnostic and treatment modality and should be considered an integral part of the practice of any physician or practitioner whose intent is to care for the whole person. Although a great variety of assessment, diagnostic, and treatment procedures exist, there are common threads that transcend their differences.

Spirituality, Religion, and Healing

Wayne Jonas, MD, and *Maeba Jonas, MDiv*

OUTLINE

INTRODUCTION—WHY SPIRITUALITY, RELIGION, AND HEALTH?

Spirituality plays a key role in the creation of healing, health, and well-being. This chapter describes what spirituality is; how the research on spirituality and health is evolving; how to appropriately address spirituality and provide information on resources; and processes that can help the provider attend to the spiritual dimension of patients' care and, in doing so, provide whole-person care.

When faced with serious or chronic illness, most people ask the question, "Why?" Physicians and healthcare providers are trained to answer this question in physical terms and will usually launch into explanations involving chemistry, molecules, genetic predispositions, environmental exposures, and so forth. However, for many seeking the full answer to healing, this is not enough. Although patients may be grateful for these explanations, there is another meaning of the question that they may also seek to answer. That question may be expressed like this: "Why did this happen to me? What does this mean for my life? What will happen to me if I die?" These are not medical questions. They are spiritual questions. When asked, 70% to 80% of patients with a serious or chronic disease or those in the hospital will say they would like to discuss spiritual issues, to pray with their provider, or to see a professional chaplain.[1,2] There is a desire by patients to address spiritual dimensions of their lives in health care.

Fortunately, many hospitals respond to this by providing professional spiritual assistance in the form of chaplains and spiritual counselors. Unfortunately, most medical providers in the hospital (and in the clinic) never ask their patients if they need or want spiritual services. Holistic, person-centered care requires this gap be filled. To care for the whole person means that we attend to the mental and spiritual dimension of the individual's being. The roots of the very word *healing* attest to this fact. Derived from the ancient German *hael,* we also get the words *whole* and *holy,* illustrating the unity of these concepts.[3] But this is not just a linguistic or conceptual unity; it is an actual unity with practical implications for health care. Fig. 48.1 illustrates what a whole-person model looks like. The one that I (WJ) use has four dimensions, constructed for simplicity and utility in clinical practice: (1) the external dimension of the body, (2) the behavioral dimension of lifestyle, (3) the social and emotional dimension of the psyche, and (4) the mental and spiritual dimension of the soul. Healthcare professionals are usually trained to attend to one or the other of these dimensions; however, regardless of one's training or focus in health care, care for the whole person requires that we acknowledge the existence and unity of these dimensions and help provide spiritual assistance, whatever our discipline or specialty.

DEFINITIONS—RELIGION, SPIRITUALITY, HEALTH, HEALING

The words *spirit, spiritual,* and *spirituality* have several but mostly consistent meanings:

Spirituality: The quality or condition of being spiritual.

Spiritual: Of, pertaining to, or affecting the spirit or soul, especially from a religious aspect.

Spirit: (1) The animating principle in humans and animals. (2) The immaterial part of a corporeal being.[4]

Many have heard the phrase "spiritual but not religious," but what is the difference between the two? In a general sense, religion refers to a system of beliefs, practices, and traditions agreed upon by a community or institution, often having to do with a connection to a higher power or a higher self. Spirituality is a set of beliefs, ethics, moral convictions, or sense of connectedness practiced by an individual. In other words, religion refers

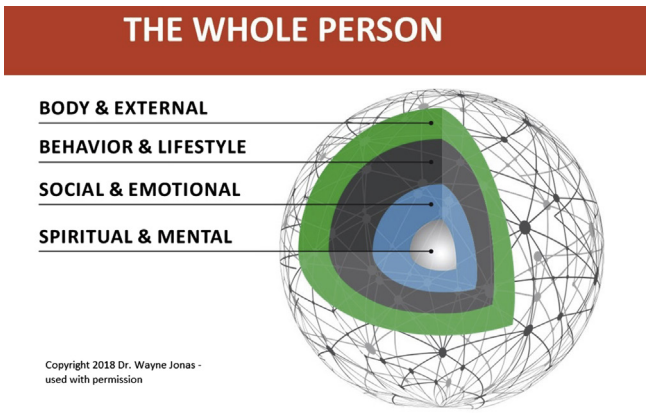

Fig. 48.1 Schematic of a whole person in four dimensions—external, behavior, social/emotional, mental/spiritual.

to spiritual traditions (e.g., Christianity, Judaism, Islam, Buddhism, etc.) and the practices that arise from the cultures and communities surrounding these traditions. In contrast, spirituality is a much more amorphous term that has been used increasingly in many societies by people who may be uncomfortable with the "institutions" of organized religions but still seek a sense of wholeness, connection, or simply peace in their lives.

Spirituality, then, depends on a variety of beliefs concerning the soul, theology, ritual, culture, and so forth. Within specific traditions, there are differing definitions. This might include "being saved" (Evangelical Christian), "submission" (Islam), or "nonattachment" (Buddhism). To favor the idea that one of these concepts is the "truth" is to endorse certain spiritual viewpoints while dismissing others. Given the world's spiritual diversity, each view must be interpreted within the context of its a particular tradition. These traditions share the fundamental goal of giving meaning to the experience and concept of spirit, but each has unique perspectives and values. This creates challenges for the study of spirituality and health, especially in multicultural societies. In the West, the default response has been to either follow Christian theology or to make definitions that are often secular and less specific to any one religious tradition. These definitions are more "transcendental" in scope and seek to make all humans and human behavior spiritual rather than allowing for specificity in religious expression based on the individual patient. These definitions tend to make the meaning of spirituality "fuzzy" or even "vague and contradictory."[5,6]

This also conflates spiritual, religious, and psychological factors, reducing the validity of the terms—such as when a psychological factor like optimism is used as a "spiritual" metric. This can confound results and become tautological. If, however, the meaning of research terms varies from common use, the results may lack ecological validity. These challenges can be seen in the common complaint that very spiritual people are somehow "better" than others or that one must be spiritual to be ethical or compassionate. Broad definitions that universalize spirituality can be especially damaging in pluralistic settings, such as in science and multicultural contexts. To remedy this, we recommend distinguishing between religion and spirituality.[7] For some, all spiritual beliefs and practices are completely within the framework of their religion. For 20% to 30% of Americans, spirituality is largely outside religion.[8,9] A Pew survey found that 24% of Americans say they go to the religious services of at least one faith other than their own. Spiritual and religious pluralism is the norm for many places in the world, especially the United States.[10,11] Although Christianly still dominates the American scene, there are other growing and powerful influences shaping American religious heterodoxy, such as the spiritual traditions of Asia, principally Buddhism and Hinduism (especially meditation and yoga), Islam, and nonreligious spiritual-like experiences.

WHY RELIGION AND SPIRITUALITY ARE IMPORTANT IN HEALTH CARE

It is likely that among our Neolithic ancestors there was little distinction between spirituality and physical healing. Most tribal societies involve shamans in healing, even of the physical body. Most major healing traditions also postulate and have a close connection between the spiritual and physical bodies in their treatment models.[12] The separation between spirituality and health care is largely a modern, Western phenomenon.

Although the advent of the scientific method has created breakthroughs in evidence-based health care, the consequence for conventional medicine is a lack of emphasis on context in any given treatment. The research on "complementary and integrative medicine" and "optimal healing environments" has demonstrated the need for better attention to whole-person health care that has only recently started to return to the healthcare system.[13,14]

In contrast, systems of Eastern medicine, such as Ayurveda or the chakra system in India, acupuncture or tai chi in China, and meditation or singing bowls in Tibet (to name a few), regularly incorporate priests, shamans, or spiritual healers together with prescribed treatments and rituals to address not only the symptoms but also the root of the disease itself.[15] Just as a psychologist might ask probing questions to understand the cause of one's mental distress, in many parts of the world, disease may not only be a physical problem but a result of spiritual misalignment or dis-ease.

Within a Christo-centric framework, science in the West has sought to distance itself from such a model, for fear that assigning spiritual values to a physical problem may result in the outdated and even dangerous conflation of placing responsibility for illness on the patient or the patient's "sins." This, of course, can lead to ostracization or even maltreatment from a medical perspective, which we indeed must try to avoid. However, what if one's religious or spiritual beliefs do not include the concept of sin? In a Buddhist or Hindu context, one's disease might have much more to do with *karma,* a concept that assigns no more responsibility to an individual than the act of being born! Of course, once one has a disease (much like karma), it is possible to do something to treat it, which must occur by addressing not just the symptoms of the illness but also the whole person, and that is where spirituality and ritual become important.

More and more, the defining "spiritual" experiences of people in the West stem from adopting the religious practices of other traditions, such as yoga from Hinduism or meditation or mindfulness, which largely came to the United States from the Buddhist tradition. Because Buddhism is a nontheistic religion (that is, it does necessitate a belief in God), spiritual Westerners find it particularly appealing, and mindfulness has found large applications as a primarily nonreligious spiritual practice. It is important to remember, however, that these now secularized practices have spiritual and even religious roots.[16] Therefore what "spiritual" means to any one patient can vary widely and has great implications for health care. For example, one might identify as Jewish or Christian but may not be able to readily assume the rituals, practices, or even belief system based on these identities alone.

Patients want greater attention to spirituality when they are in the hospital. A 2003 survey of more than 1,700,000 patients, involving 33% of all US hospitals, showed that patient satisfaction with the emotional and spiritual aspects of care had some of the lowest ratings and was an area in great need of improvement.[17] The Joint Commission on Hospital Accreditation requires all hospitals to have a process and place to assess the "spiritual health" of all patients. This is usually done by taking some sort of "spiritual history"[18,19] (discussed later in the chapter).

Prayer is a common practice in the United States and is often directed toward health concerns. A national survey in 2004 revealed that 35% of respondents used prayer for health concerns; 75% of these prayed for wellness, and 22% prayed for the healing of specific medical conditions. Of those praying for specific medical conditions, 69% found prayer very helpful. Factors independently associated with the increased use of prayer included age 33 to 53 years (odds ratio [OR], 1.6), age more than or equal to 54 years (OR, 1.5), female sex (OR, 1.4), and education beyond high school (OR, 1.5). Patients with depression, chronic headaches, back and/or neck pain, digestive problems, and allergies were also associated with more frequent prayer. Only 11% of respondents described using or discussing prayer with their physicians.

Most people in the United States believe that spirituality can powerfully affect human health and want physicians to include faith as part of a comprehensive doctor–patient interview[20]:

- A Gallup poll published in 1990 found that 94% of patients admitted to hospitals stated they believed that spiritual health is as important as physical health, 77% believed that physicians should consider their spiritual needs as part of their medical care, and 37% wanted their physician to discuss their religious beliefs more.[21]

- A telephone survey conducted in 2002 found that 80% of respondents believed God acts through physicians to cure illness; 40% believed God's will was the most important factor in recovery; and 69% said they would want to speak to someone about spiritual concerns if seriously ill, although only 3% would initiate a conversation about spiritual factors with a physician.[22]

Even outside of a faith tradition, nonreligious spirituality is used in finding meaning, whole-person healing, and the cultivation of caring patient–provider relationships.

It seems clear, then, that spirituality, in its various manifestations, such as religion, prayer, rituals, meditation, meaning and purpose, exceptional experiences, and behavior, is a core component of holistic health care. An individual is not only a body but also a spiritual being. Caring for the whole person, then, requires that we ask about and work with the spiritual dimension of health care. But what does this mean in daily practice? How do we address spirituality in routine health care? When is it most needed, and who should provide such care?

RESEARCH ON RELIGIOUS AND SPIRITUAL PRACTICES AND HEALTH

The scientific research on religion, spirituality, and health is a growing field. There are measures for spiritual belief, practice, and experience, as well as research linking spirituality and health.[23,24] However, the subjective nature of spirituality and the inability to randomize patients to most spiritual practices require correlative and mixed-methods approaches for their evaluation, including systematic qualitative research. The following is a brief summary of research on spirituality, religion, prayer, and the effects of intention and selected "biofield" practices common in spiritual practices.

The Health Effect of Religious and Spiritual Practices

There is considerable research showing that participation in religious and spiritual activities, including churchgoing, Bible study, prayer groups, rituals (both community and private), or other behavior oriented to a "higher being" or "God," correlates with health outcomes. Summaries of these studies have been done by a number of scholars, such as Harold Koenig, Larry Dossey, Daniel Benor, Stephan Schwartz, Marilyn Schlitz, Wayne Jonas, and others. My colleagues and I examined this research extensively and published a critical appraisal in the book *Healing, Intention and Energy Medicine: Science, Methodology and Clinical Implications,* from which a summary is provided for this chapter.[25] Nearly 200 studies examining the health effects of religious and spiritual behaviors on various conditions and outcomes have been published. Most of this research shows that religious practices are associated with beneficial effects on health. This includes reduced mortality, improved physical health and quality of life, and reduced mental illness and drug abuse. More than 75% of these studies report statically significant effects on those associations. Few studies report (or even measure) the adverse effects associated with religious practices. The vast majority of this research is epidemiological. This blunts the certainty of these associations because multiple confounding factors besides religious behavior, such as changes in diet, lifestyle and behavior, social connections, and risk and resilience factors, are hard to control. These confounding factors cannot be randomly distributed, but they can be approximated with control comparisons and analyzed.

Intercessory and Healing Prayer

There are a few studies of prayer—defined as healing intention or appeals toward a "higher being or force." Most of these studies examine if health outcomes changed compared with no or less prayer. A review was conducted by John Astin, who focused on randomized studies of distant healing and prayer for clinical conditions. Astin's review included a total of 13 randomized studies on prayer involving 2328 patients. Of these, six (46%) reported statistically significant effects of prayer on at least one outcome and a mean effect size across trials of 0.30, which is considered small in most clinical research. The research had an average quality score of 45% of the maximum using a standard quality score for controlled studies.[26] No effects at this level of evidence were reported for the healing of warts or for alcoholic relapse in a small trial.[27] Four more randomized, controlled trials were published after this review. One was positive, and three reported no significant effects from distant prayer.

"Bioenergy" Healing Research

What is often called "energy healing" involves the intentional direction of spiritual "energy" or a hypothesized "biofield" toward a patient, with the goal of improved health. A review of clinical studies of energy healing was conducted by Sara Warber, MD; Gaia Kile, MSN, NP; and Brenda Gillespie, PhD, of the University of Michigan. The review focused on randomized controlled trials of clinical conditions treated with these energy methods. Nineteen randomized controlled trials involving 1122 patients were included. All but one were on Therapeutic Touch—a semiformalized process used by nurses and others in which a practitioner holds his or her hand over the patient. Eleven (58%) of the studies reported statistically significant effects, with a mean effect size of 0.60—a moderate effect. Positive effects were found for the alleviation of pain in burn patients and reduced anxiety in institutionalized elderly patients. There have been more than 50 studies published on laboratory models of energy research involving mainly cellular and animal models. Although much of the findings are reported as positive, an overview shows no studies that were independently replicated at this time.

Qigong

Qigong is an ancient energy healing method developed in China that claims to accumulate and direct this energy, which is called "qi." Although a vast amount of Chinese literature exists, it is difficult to evaluate because it is mostly in Chinese. We examined both clinical and laboratory studies of "external qi" (qi projected from a practitioner). The evaluation of clinical studies also captures qigong practice, or "internal qi" (qi cultivated by meditation and exercises). In the latter, we focused on blood pressure because this area has the largest amount of evaluable literature. A review was conducted by Michael Mayer, PhD, OMD. Thirty-three controlled studies (out of 72 reports) on the effects of qigong on hypertension were reviewed. All studies reported positive effects, but only five of the studies were randomized. However, the quality of the research was poor (quality score of 13% of maximum). No high-quality replications were done. One study reported adverse effects.

A review of the laboratory (cell and animal) studies of qigong was done by Juliann Kiang, PhD, and Ping Y. Lu. Kiang and Lu sorted through studies from multiple databases (including those in Chinese). Fifty-eight studies (out of 130 reports) had enough detail to review. Studies reported positive effects on a variety of outcomes, including cancer growth and cellular and enzyme changes and immune modulation, in both animals and cell culture. However, the quality of the research was poor (quality score of 20% of maximum), and there were no independent, high-quality replications. Significant publication bias is likely in both the clinical and laboratory studies because positive studies are published much more often than studies showing no effects.[28,29]

Direct Effects of Intention

There are many studies, including high-quality, independent replications, examining the effects of intention on biological and physical parameters. One set of studies examines if a person can affect the conductivity of the skin of another person using mental intention. Another body of research involves examining whether people can alter chance events (e.g., the throw of a die or an electronic random event generator [REG]) by intention. In both these sets of research, there is a clear and highly statistically significant effect of intention on the outcome. Intention clearly has direct effects on a number of parameters. However, these effects are small (often less than 5% difference from controls). Although these studies have proven that intention does have effects, how these studies relate to prayer and other spiritual practices is unclear.

The Effect of Healing in a Clinical Setting

What is the effect of having a spiritual healer as part of medical practice? Two studies have been described by Tim Harlow, MBchB, DCH, and one study was described by Harald Walach, PhD. Initial observations indicated benefits from introducing healers into a clinic where controlled assessments of healing effect were performed. A healer was brought into the conventional practice without compromising conventional medical care or altering the healer's methods. The healer resulted in an improvement in the symptoms and well-being of some (but not all) of the chronically ill patients and changed the perceptions and behavior of doctors, other providers, and patients about spiritual healing. Physicians took more time to listen, and patients communicated more often about the complementary therapies they were using. In a study by Harald Walach, PhD, 12 chronically ill patients offered distant healing had improved quality of life compared with those not treated by healers. This effect was significant, both statistically and clinically. When including these additional quality criteria, the evidence level is B because no high-quality meta-analysis or independent replication has been done.

Advancing Research on Spirituality and Health

There is clearly a need for further research on the relationship between religion, spirituality, and health. But advancing the field is complex. Not only do concepts and definitions in spirituality and healing vary widely, but the models of research used for more tangible constructs often do not provide a good fit with the subtle aspects of spirituality, such as meaning, transcendence, the sacred, prayer, holiness, and so forth. Although measures of spiritual experiences and religious practice have been developed, these may not capture the meaning of faith for many people. Dr. Chris Feudtner, a palliative care pediatrician at the Children's Hospital of Philadelphia, has designed a thoughtful model of research allowing fluid "mediation between domains," both the concrete and fluid concepts in spirituality in health.[30]

In summary, there is evidence to suggest that mind and matter interact in a way that is consistent with the assumptions of distant healing. Mental intention has effects on nonliving random systems (e.g., random number generators) and may have effects on living systems. Although conclusive evidence that these mental interactions result in the healing of specific illnesses is lacking, further quality research should be pursued. For further information, there are a number of references providing details on any part of this analysis.[31]

WHO PROVIDES SPIRITUAL CARE?

With the separation of the spiritual and physical in modern medicine and the decline of formal religions in the West, the role of spiritual care has been distributed across a wide variety of groups. Although spiritual healing, prayer groups, meditation, and other faith-based practices continue to be widespread, modern professional spiritual care has been largely consolidated in clinical pastoral care providers. Before 1906 and what was called the Emmanuel Movement, psychotherapy was part of the domain of both ministers and physicians. However, after the emergence of psychotherapy as a formal discipline, the practice of psychotherapy was formalized under the medical domain, and chaplains wanting to do psychological counseling were required to get special training and certification in that skill.[32] During this time, formal hospital chaplaincy and clinical pastoral education (CPE) emerged as the professional certification for ministers. Those with CPE training are now hired by hospitals specifically to provide spiritual care services. They largely deal with providing spiritual support and care in areas such as depression and pain, dealing with anxiety and anger, coping with the effects of treatments, and dealing with loss and death.[33]

Although ministers have denominational training, CPE provides skills for dealing with multidenominational, multifaith, and even nonreligious beliefs and contexts. Care of hospital staff to assist in coping with stress, burnout, and traumatic experiences is also a frequent role of hospital chaplains.

Chaplains also have a role in assisting with ethical decisions in health care. Challenging treatment decisions and withdrawal of treatment in seriously ill patients and differences in opinions between family members or between medical professionals and family members all may require spiritual discernment and assistance from chaplains. However, medical personnel often do not know how or when to use chaplains in these decisions. Whereas 88% of healthcare providers say that chaplains should be on hospital ethical committees, for example, only 22% to 32% of those committees actually appoint chaplains.[34] Recently, organized educational courses have emerged to help healthcare professionals learn how to better deal with religious and spiritual issues and how to work more closely with chaplains in health care.

Those wanting to learn how to work more closely on these issues would be wise to take such training. One of the most fully developed is the yearly course conducted by Dr. Christina Puchalski, founder of the George Washington Institute of Spirituality and Health (GWish), which provides a comprehensive introduction to team-based spiritual and healthcare integration.[35]

Faith communities have often been integral to the provision of healthcare, from Catholic and Jewish hospital systems to community-based multidenominational groups seeking to address poverty, housing, food insecurity, safety, and other social determinants of health. Recently, the National Academy of Medicine convened a workshop to explore novel faith–health community collaborations addressing population health delivery. The workshop (1) provided an overview of faith-based assets in communities and their relationship to population health and the work of health improvement, (2) highlighted areas where faith-based health assets are using evidence to inform their work and demonstrating effectiveness in improving health outcomes, (3) provided examples of effective partnerships involving faith-based health assets, and (4) shared lessons learned from working with faith-based assets that could contribute toward principles for engagement of healthcare organizations and public health agencies. Here, a prominent body is giving space, time, and thought on how the gap between medical care and faith care could be better filled.[36] Those wanting to affect public health and the "upstream" determinants of health and disease could do so by getting more involved in these community–healthcare collaborations.

TOOLS FOR CARING FOR THE WHOLE PERSON IN DAILY PRACTICE

How can providers and others who deliver their services address the spiritual aspects of patient care without some of the infrastructure

TABLE 48.1[a] Questions for an Integrative Health Visit Using the HOPE Note

Dimension	Questions	Description
Spiritual and mental	***Why do you want to be healthy?*** ***What is most important for you in your life?***	This addresses a person's **inner life:** • Desires, beliefs, and needs • Why they get up in the morning • Their purpose in life **"What matters"** rather than "what's the matter"
Behavioral and lifestyle	***How is your diet?*** *—Listen to the global assessment; count the F&V.* ***How is your sleep?*** *—Listen to the global assessment; determine pattern—rested?* ***How is your activity level?*** *—Assess level and intensity of movement.* ***How is your stress?*** *—What do you do for stress management?*	• Lifestyle and behavior can affect up to 60%–70% of chronic illnesses and are key to reversing chronic disease and improving function. • Behavior change must be connected to what is meaningful for the person, or it cannot be sustained. ***Does the client believe that what he or she does is helping?***
Social and emotional	***How is your social support?*** *—Inquire about family, friends, frequency, fullness.* ***How was your childhood?*** *—Explain that ACE can influence healing*	• Loneliness is epidemic; is a risk factor for disease and death; and influences recovery, resilience, and readmission. • So often, the reason and process for healing have to do with relationships. • Men—spouse; women—friends, family; church; community; work colleagues • The depth (quality) of the relationships is more important than the number (quantity).
External environment	***What is your home like?*** *—Do you have a place and time for yourself?* ***How is your work environment?*** *—Gauge the level of stress, control, and privacy.* ***Do you get out in nature?*** *—Most people underestimate its importance.*	Community, worksite, school, and home environments shape the following: • What a person is able to do • What happens to a person • How safe or stressed a person feels • How well a person flourishes and functions • How long a person lives

ACE, adverse childhood experiences; *F&V*, fruits and vegetables.

and teams described previously? How can they bring in the mental and spiritual aspects of a patient's life without going beyond their professional domain of providing medical care? One approach is to conduct an "integrative health" visit. Integrative health (IH) is the coordinated intersection of conventional care, complementary medicine, and self-care. The goal of IH is to move from the former to the latter by providing the dialogue and support to help a patient to become engaged in self-care in a rational and evidence-based way. The IH visit starts by asking the patient to describe "what matters" to him or her in life and reflect on what he or she most lives for. What gives the patient meaning, purpose, and joy in life? It is by connecting "what matters" to "what's the matter" that patients both begin and sustain their healing journey. I do this with two tools that get at this very "existential" (shall we say "spiritual") dimension of a person.

The first tool is the Personal Health Inventory (PHI). The PHI is a simple two-page questionnaire given to patients before a visit. It asks them to state what is most important to them in their lives and then to rate (on a scale of 1 to 5) where they are and where they are ready to change in three other domains that determine health: behavioral, social, and emotional and environmental. The PHI sets the stage for a dialogue during the integrative visit to discuss all the domains of healing of a person. Fig. 48.1 shows the elements of the PHI.

The second tool is used during the visit. It is called the HOPE Note. HOPE stands for Healing-Oriented Practices and Environments, and the tool is designed to elicit more details of the patient's personal determinants of health and start a Personal Health Plan (PHP). HOPE asks questions about lifestyle (diet, activity, sleep, stress management); the social and emotional dimension (social support, loneliness); the mental and spiritual dimension (mental attitude; goals and joys in life); and the external environment (exposure to beauty, art, and nature). The discussion seeks to link the mental and spiritual dimension to the other healing pathways of a person. Table 48.1 shows the questions of the HOPE Note.[37]

This approach allows a holistic assessment of the individual in an everyday office visit. From this, the patient's needs and wants can be taken into account and merged into the patient's own personal health plan. From that point, support in the patient's healing journey is provided to actualize the plan. This provides truly patient-centered care. Such care requires a team that includes expertise in medicine, social determinants, lifestyle and behavior change, and spiritual care. It also includes the patient and family members as part of the team.

CONCLUSIONS

The mental and spiritual dimension is a core part of all human beings. As such, any healthcare system or provider that seeks to care for the whole person needs to address this dimension. We know that patients need and want to address spiritual issues when they are ill. We know that there is evidence for the reality and effectiveness of spiritual practices on health outcomes. There are professionals and groups trained and prepared to assist in helping patients with religious and spiritual needs. Tools and training are available to bring the mental and spiritual dimension into the practitioner's daily encounters with patients. Thus it is important for all physicians and other healthcare providers to address the core dimension of spirituality in their practice.

Unani Medicine

Yaser Abdelhamid, ND, LAc, MS, BS, BA

OUTLINE

INTRODUCTION

Unani Medicine: Greco-Arabic Healing and the Islamic Genius

The Arabic term *unānī* derives from the word *Ionian,* which is a general adjective signifying "things-Greek." The linguistic translations and transliterations of this word took place between the Greek, Arab, and Persian civilizations. The particular usage of this term, however, has more often been a descriptive allusion to the composite system of medicine born of the Arab world's inheritance—within the larger framework of Islamic civilization—of the medical tradition of ancient Greece.

The literary sources of Unani medicine (al-tibb al-yunānī, or sometimes referred to simply as "Tibb," or "Hikmat" in Pakistan and Afghanistan) were Arabic translations of ancient Greek, Roman, Egyptian, Arabic, Persian, Indian, and Chinese medical texts. However, there is no question that the initial, primary, and most honored textual sources were of Greek origin. The Arabs immersed themselves in the medical knowledge and wisdom contained in the writings of Hippocrates (Buqarāt) and Galen (Jālinūs),[1] as well as Plato (Aflātūn), Aristotle (Aristatīl), Dioscorides (Dīsqūrīdis), and Empedocles (Abrāqlīdis).

It is well recognized by contemporary historians that the ancient Greek—and to some extent Roman—intellectual heritage of the West would have been almost totally lost were it not for the integrating and synthesizing Arab genius within the Islamic world.[2] In this regard, one must marvel at the Arabs' level of care and precision in "first collecting, then translating, then augmenting, and finally codifying the classical Greco-Roman heritage that Europe had lost."[3] However, "so many people in the West wrongly believe that Islam acted simply as a bridge over which ideas of Antiquity passed to medieval Europe. Nothing could be further from the truth, for no idea, theory, or doctrine entered the citadel of Islamic thought unless it became first Muslimized and integrated into the total world-view of Islam."[4]

Unani Medicine: Comparisons and Contrasts With Other Health Care Systems

Apart from Unani medicine's introduction onto the stage of world history as a legitimate synthesis—in time and space—of primarily Greek and Islamic civilizational influences, there is yet another dimension to Unani medicine that is often overlooked and of great significance. Along with the medical traditions of other civilizations of the past, like the Ayurveda of Hindu India or traditional Chinese medicine, Unani medicine continues to be preserved and persevere—especially in the face of modern cultural trends in many nations that have moved toward changing the old guard of ancient medicine for the shiny hopes and promises of a new system of powerful drugs, "healing steel," and high-tech diagnostic tools and machinery. Unani medicine is still practiced today as an organic, living, breathing, whole system of health care helping millions of people around the world (especially in the Indian subcontinent, Pakistan, Afghanistan, Persia [Iran], China, Indonesia, Malaysia, Bangladesh, Sri Lanka, South Africa, and certain sectors of the Middle East [such as Saudi Arabia, Kuwait, and Dubai]).

Furthermore, Unani medicine historically had the opportunity, capacity, and satisfaction of embracing the numerous folk medicines that existed within the borderlands of the Islamic world, from the traditional use of herbal remedies in ancient Palestine to the folkloric ore-based therapeutics of the people living on the high plateaus of the Himalayan Hindu-Kush mountains.

Unani medicine also shares medical theories, philosophies, cultural identities, and spiritual insights regarding human health and disease with ancient systems of medicine, such as Hindu India's Ayurveda and traditional Chinese medicine, because its knowledge and wisdom hail from the traditional Eastern "Orient" while contrasting tremendously with the single system of contemporary medicine that one could say belongs to the world of the modern Western "Occident."[5] This is what led Hakim Chishti (an American researcher and practitioner of the science and art

of Unani medicine) to present a very thoughtfully indexed comparison between all of these healing systems (as found on http://www.unani.com), whose general points are outlined in Table 49.1.

HISTORY

Contributions and Influences From Antiquity

There were a variety of strands of medicine that came together at the crossroads of Islamic history that proved to be of tremendous significance for the birth of Islamic medicine in general and for Unani medicine in particular.[6]

First, there was the synthesis of the ancient sciences (including medicine) of the Egyptian and Mesopotamian civilizations in Greek life and thought, centered in Alexandria. Only in the light of recent archeological and anthropological discoveries have we discovered the high level of scientific sophistication that was present in these two kingdoms. The medical knowledge attributed to these earlier civilizations became forged in the fire of the Greek intellect into an even more systematic model of diagnostics and therapeutics.

Second, the main centers of Greco-Hellenistic learning were pushed farther East as a result of a decline of intellectual energies due to shifting political and economic realities constantly confronting and fracturing Western Christendom. This encouraged two other civilizations to take up the reins of the transmission of essential elements of Greek knowledge: Persian and Harrānian (i.e., Sabaean). The Sabaeans were independent heirs to the Babylonian and Greek scientific estates through their reliance on the wisdom contained in Hermeticism and neo-Pythagoreanism. Also, it was in the city of Jundishapur that the Persians vivified the sciences coming out of India and China.

In summary, the "scientific knowledge that originated in India, China, and the Hellenistic world was sought out by Arab and Muslim scholars and then translated, refined, synthesized, and augmented at different centers of learning, starting at Jundishapur in Persia around the 6th century—even before the coming of Islam—and then moving

TABLE 49.1 Comparing the Three Great Traditional Healing Systems With Modern Western Medicine[8]

	Unani	Ayurveda	Chinese	Modern Western
Origins	Persia; circa 980 AD	India; circa 2000 BC	China; circa 2700 BC	Europe; United States; late 19th century
Primary dynamic elements	Rūh (spirit force)	Prana (life breath)	Chi (life energy)	Brain and heart
Disease correlates	Humors	Tridoshas	Yin–yang; chi	Named pathology
Disease causes	Imbalance of humoral temperament	Ama is the "harbinger of misery"; the cause of disease	Systemic imbalances; no overriding emphasis on one	Bacteria; virus; fungus; parasite; metabolic disturbances; trauma
Basis of diagnosis	Humors: blood, phlegm, yellow bile, black bile	Tridosha: Vata, Pitta, Kapha	Four diagnoses of TCM	Based on patient's history, physical examination, laboratory testing
Diagnostic models	Restore balance to humors and organ systems	Concept of Shiva-Shakti; balance in the tridosha or three humors system	Achieve balance of yin (passive) and yang (active) physiological functions	Specifically named pathology
Chief diagnostic modality	Differential; mizāj or temperament assessed for each of four humors	Differential; states of consciousness aligned with each of the three humors	Differential, questioning, observation, palpation, and listening; Zang Fu organ syndromes	Differential; named disease
Diagnostic tests	Observation, lifestyle, pulse, urine, stool, and palpation	Tongue, pulse, urine, and palpation	Tongue, pulse, and palpation	Urinalysis, x-rays, and standard blood tests; sampling organ tissues; diagnostic x-rays; angiography (Note: in the United States, as a whole, about 8.5 billion laboratory diagnostic tests were done in 1996.)
Pulse diagnosis	Reveals humoral imbalance in organ system. Taken with three fingers at radial pulse of wrist; more than 1,000 potential factors evaluated in seconds	Correlates pulse to the tridosha or three humors Taken by the index finger of the physician; qualities of pulse are described in terms of several animals	Direct manifestation of the circulatory energy of the body; classical five phase pulse correspondences Taken on the wrist; about 40% reliable as a sole diagnostic method by most TCM practitioners	Speed: fast pulse to slow pulse
Elements of nature	Four: fire, air, water, and earth	Five: fire, earth, water, air, and ether	Five: fire, earth, metal, water, and wood	22 basic elements of chemistry
Main dietary influences	Nonalcoholic; regular fasting; nonporcine	Vegetarian	Rice and vegetables	High refined sugars; alcohol; fats; drugs
Patient participation and will	Empower patient to make changes in diet and lifestyle	High objectivity	Personal determination	Not significant

TABLE 49.1 Comparing the Three Great Traditional Healing Systems With Modern Western Medicine[a]—cont'd

	Unani	Ayurveda	Chinese	Modern Western
Deity of system	Abrahamic monotheism; primarily God (Allah) of Islam	Polytheistic; Panentheistic; Nondualistic Advaita Vedanta (Brahma Siguna, Brahma Nirguna); God of Hinduism	Nontheistic; Confucianism; Taoism (Tao); Buddhism (Amida Buddha, Avalokiteshvara)	Secular atheism; agnosticism; modern evolutionary nihilism
Primary treatment modalities	Diet; herbs; fasting; cupping; purgation; baths; attars (essential oils or medicinal scented perfumes)	Pancha Karma (detoxification);[b] herbs; diet; emetic therapies	Acupuncture, herbs; cupping; moxibustion; diet	Chemotherapy; radiation therapy; pharmaceutical drugs; surgery; rehabilitative physical therapy
Primary treatment objective	Mizān: restore to balance; provoke "the healing crisis"	Clear the entire GI tract; regulate the bowels; improve digestion	Tonification of energy	Symptom suppression; kill germs and bacteria; palliative end-of-life management
Some instruments used	Glass cups	Glass cups	Glass cups; acupuncture needles	Ophthalmoscope, laryngoscope, and x-ray; sphygmomanometer; electrocardiogram; chemical tests of body fluids and tissues
Side effects	Overdose of herbal substances; very rare	Overdose of herbal substances; very rare	Potential for acute symptoms from improper needle techniques; overdose of herbal substances; all very rare	106,000 die annually from improper medications; severe and frequent drug reactions;[c] very common
Cancer rates (WHO rates out of 93 countries)	6th lowest	6th lowest	30th lowest	93rd lowest (worst of all)
Annual per capita health care expenses	$9.45 Source: World Bank	$9.45 Source: World Bank	$3.96 Source: World Bank	$1,301.00 Source: World Bank
Common medicines used	Senna pods, black seed, cumin, ginger	Amla; guggul; Bibhitaki; Triphala	Ginseng, codonopsis, dang quai, astragalus	Antibiotics, antidepressants, corticosteroids, analgesics
Chief complaints	Nonregulation of practitioners; lack of clinics	Nonregulation of practitioners; lack of clinics	Obtuse language	Adverse reactions; patient dissatisfaction; skyrocketing medical costs
Direction of development	Training practitioners in powers of observation; building schools; sources for formulations	Training practitioners; building schools; develop formulations	Integration with Western hospital medicine	Higher costs; more complex diagnostics; genetic medicine; shaped by new healthcare reform laws
Typical U.S. $ cost of treatment	$15–$200	$150–$200	$45–$300	$200–$4,000

GI, gastrointestinal; *TCM,* traditional Chinese medicine; *WHO,* World Health Organization.

[b]From Vasant Lad. An Introduction to Panchakarma. http://www.ayurveda.com/pdf/pk_intro.pdf.

[c]"A 1998 report estimated that 106,000 Americans die each year as a result of adverse reactions to prescription medications. This figure represents three times the number of people killed by automobiles and is the fourth leading cause of death in the United States. Only heart disease, cancer, and stroke kill more Americans than adverse reactions to drugs. This staggering figure does not include drugs administered in error or those taken as a suicide gesture. If medication errors were included in this statistic, the death toll would probably be as high as 140,000 deaths per year. As a result of 39 separate studies nationwide, it was found that 3.2 out of every 1000 hospitalized patients die each year as the result of adverse reactions to prescription drugs in each and every hospital in this country. Of the 106,000 people killed each year by an adverse reaction to a prescription drug, 43,000, or 41%, were initially admitted to the hospital because of the adverse drug reaction. The other 59%, or 63,000 patients, were hospitalized for some other cause but developed a fatal reaction to a prescription drug received while hospitalized." (Montague P, National Writers Union, UAW Local 1981/AFL-CIO. Another kind of drug problem. *Rachel's Environment & Health Weekly* 1999;632. http://www.drsuzy.com/summaryInterest.html.)

to Baghdad,[7,8] Cairo, and finally Toledo and Cordoba, from whence this knowledge spread to Western Europe."[3]

The Torchbearers of Islamic Medicine

With the advent of the Islamic spiritual tradition, one must mention the intellectual power and genius found in the physicians of Islam. For if history did not give birth to these giants in the field of medicine, one could not really speak in the present tense at all of contemporary Unani medicine, let alone its subtle historical influences on the character of modern conventional medicine.

Ibn Ishāq (Johannitus Onan), 809–873 AD

Hunayn ibn Ishāq al-ʿIbādi was "the greatest of all translators of this period … [and] an outstanding physician of his day. [He] often translated texts from Greek into Syriac. At other times he would translate directly from Greek into Arabic."[6] He was "reputed to have been paid

for his manuscripts by an equal weight of gold. He and his team of translators rendered the entire body of Greek medical texts, including all the works of Galen, Oribasius, Paul of Aegin, Hippocrates, and the *Materia Medica* of Dioscorides, into Arabic by the end of the ninth century. These translations established the foundations of a uniquely Arab medicine."[3]

Al-Tabari, 810–855 AD

Ali ibn Rabbān al-Tabari was the teacher of the great Rhazes. He was the "author of the first major work of Islamic medicine … entitled *Kitāb Firdaws al-Hikma* ("The Book of the Paradise of Wisdom"). In 360 chapters, he summarized the various branches of medicine, devoting the last discourse, which consisted of 36 chapters alone, to a study of Indian medicine (Ayurveda). The work, the first large compendium of its kind in Islam, is of particular value in the fields of pathology, pharmacology, and diet, and clearly displays the synthetic nature of this new school of medicine, now coming into being."[6]

Al-Rāzi (Rhazes), 841–926 AD

Abu Bakr Muhammad ibn Zakariyya al-Rāzi was born in the town of Rayy in Persia, near what is present-day Tehran. He was reputed to be Islamic medicine's greatest clinician. His works include *al-Kitāb al-Mansūri* (*The Book of Mansūr* or the Latin *Liber Almansoris,* in which Rhazes delineated principles of medical theory, diet, pharmacology, dermatology, oral hygiene, epidemiology, toxicology, and even climatology and its effects on the human body), *al-Judari wa al-Hasbah* (*Smallpox and Measles,* which was the first treatise ever written on the subject), and his magnum opus *al-Kitāb al-Hāwī* (*The Comprehensive Work* or the *Liber Continens* of later Latin translators; this monumental collection of 25 volumes contained all the medical knowledge of the age, including the master's own observation and experience; Fig. 49.1).[3]

Fig. 49.1 This memorialized stained-glass window of Al-Razi (Rhazes), the great Persian physician, is found in Princeton University Chapel. (The Revd Dr A. K. M. Adam, https://www.flickr.com/photos/akma/2150287950/)

Ibn Sīna (Avicenna), 980–1037 AD

Abu 'Ali al-Husayn ibn 'abd Allāh ibn Sīna was born in the city of Bukhāra in what is today Uzbekistan. He was the preeminent physician of his time, earning the epithet of "Prince of Physicians." He began studying medicine at the precocious age of 13, became a physician at 16 years of age, attended to kings and princes at 18 years of age, and was appointed as court physician to the ruler of a Persian province at 20 years of age. His literary corpus includes *Kitāb as-Shifā'* (*The Book of Healing,* which was primarily a text of encyclopedic proportions on medicine and philosophy) and *al-Qanūn fi 'l-Tibb* (*The Canon of Medicine,* a one-million-word text summarizing the entire Hippocratic and Galenic traditions and describing the Syro-Arab and Indo-Persian medical practices of his time). *The Canon* quickly was, for several hundreds of years, the standard medical textbook of the Islamic, medieval Christian, and later Indo-Pakistani worlds. Avicenna's *Canon of Medicine* was "a five-volume compendium of Greek and Islamic healing that became one of the principal textbooks in European universities centuries later."[9]

It is from this remarkable polymath that Unani medicine draws its breath of life. Avicenna is perceived by some to be the "father of Unani medicine," and his *Canon* its gospel (Fig. 49.2).[3]

Post-Avicennan Medicine

Egypt and Syria: Ibn Nafīs

Ibn Nafīs was born in Damascus and died in Cairo in the 12th century AD. Ibn Nafīs has only recently gained fame as the rightful discoverer of pulmonary circulation, which was mistakenly thought to have been identified in the 16th century by Michael Servetus. There have been several studies in recent years that incontestably demonstrated that Ibn Nafīs discovered the lesser circulation of the blood before Servetus. See A. O. Soubani's "The Discovery of the Pulmonary Circulation Revisited," in which this medical doctor and researcher

Fig. 49.2 A portrait of Avicenna. It is from this remarkable polymath that Unani medicine draws its breath of life. Thus some historians perceive Avicenna to be the "father of Unani medicine" and his *Canon* its gospel.[4] (Chouchou2017 [CC BY-SA (https:///creativecommons.org/licenses/by-sa/4.0)].)

pooled together and summarized a host of earlier literature regarding this hallmark of medical subjects.[6,10]

Spain and Morocco: Al-Zahrāwī (Albucasis) and Ibn Rushd (Averroes)

Abu al-Qāsim al-Zahrāwī (976–1013 AD) is considered to be the greatest surgical figure in Islamic medicine. He was also original in this medical arena in inventing and manufacturing the requisite surgical instrumentation that did not exist, or existed previously in very crude form only, to conduct operations as painlessly and effectively as possible. Some of these instruments of surgery have not changed significantly in design for more than 1000 years. A more comprehensive sketch of the significance of Albucasis in the field of surgery can be found in Kasule.[11]

Abu al-Walīd Muhammad ibn Ahmad ibn Muhammad ibn Rushd[12] (1126–1198 AD) was born in Cordoba, where he trained in law and philosophy, although he made his living as a physician. He wrote his *Kitāb al-Kulliyyāt* (the Latin translator's Colliget, *The Book of General Principles*) in which he covered the whole field of medicine in abridged form (Fig. 49.3).

The Eastern Lands of Islam, Persia, and India: Al-Jurjāni, Nurbakhski, and Dara Shukūh

Isma'īl Sharaf al-Dīn al-Jurjāni followed Avicenna by one generation, producing the most important medical encyclopedia in the Persian language, the *Zakhira-i Khwarizmshahi (Treasury Dedicated to the King of Khwarazm)*. The size, as well as the style of the work, places it between Avicenna's *Canon* and Rhazes's *Continens*.

Muhammad Husayni Nurbakhski was a physician of 15th-century Safavid, Persia, who wrote a large medical work entitled *The Quintessence of Experience*. He was the first person to identify and treat several common diseases, including whooping cough.

The 16th and 17th centuries were the major centuries in which Islamic medicine spread into India and came to be known as al-Tibb al-Yunānī (Unani medicine). One of the major patrons of the medical arts in India during this time was Dara Shukūh, a Mogul prince who was also a Sufi and a student of the Vedanta. ʿAyn al-Mulk al-Shirāzī was responsible, at least in large part, for composing *The Medicine of Dara Shukūh,* which is the last great medical encyclopedia written in the world of Islam.

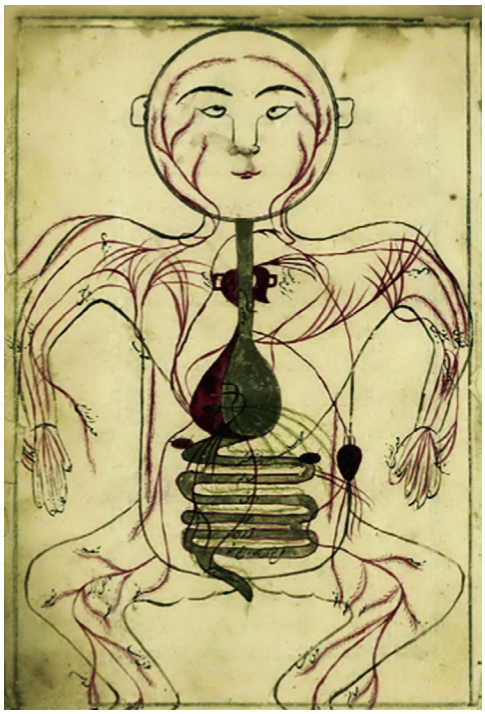

Fig. 49.3 Ibn Naffīs made his discovery of the structure of pulmonary circulation (the "lesser circulation") three centuries before its rediscovery in Europe by Michael Servetus (d. 1553) and Realdo Colombo (d. 1559), both of whom historians mistakenly thought for centuries to have been the original discoverers. (Reproduced with kind permission of Tabriz Central Library.)

METAPHYSICAL AND PHILOSOPHICAL FOUNDATIONS

Unani medicine's philosophical underpinnings are tied to the Islamic spiritual tradition. The true and original meaning of the word *philosophy* as *philo-sophia* ("love of wisdom") has only accidental affinities to what is termed philosophy in the modern lexicon today. Traditional philosophy as *philo-sophia* was, and still is, tied to a spiritual vision of humanity and the cosmos.

Epistemology and Ontology

Epistemology and ontology deal directly with the nature of knowledge—what something "is," how it is obtained, and its methods of use—and the study of existence or "being," respectively. Because Unani medicine is rooted in the Islamic tradition, it is from this spiritual source where one must search for the answers to the questions regarding its theories on knowledge and existence.

Within the Islamic world, as well as other traditional religious worlds, knowledge has a definite hierarchical structure.[13-15] This hierarchy maintains the essential links that exist between Heaven and Earth, between God and humans. First, there exists an acknowledgment of a presiding Divine Knowledge (i.e., God as wise and all-knowing). Following this is the knowledge found in Revelation (i.e., a perfect dispensation from Heaven that enlightens the human intellect).[16] As this revelatory knowledge sparks the heart's depths, it necessarily begins to involve the mind–intellect in its quest for knowledge of this earthly domain (ʻilm al-dunya), this physical world.

Ontologically, the "being-ness" of humanity is intimately connected with the Being of God. God is seen as the Supreme Being Alone, without whom nothing can rightfully claim existence for itself. Thus God's Being is termed Wājib al-Wujūd ("Necessary Being"). In this light, humanity—and everything else in the world of forms—is seen as "borrowing" its existence from the indispensable nature of Divine Being.

Cosmology and the Human Microcosm

The basic cosmologic premise in Islam, as well as in other traditions such as Hinduism, Christianity, and Judaism, is that the Absolute Truth of Divinity (al-Haqq) manifests Itself in the world of forms and within the human heart in a process called the "arc of descent."[17] There is in response to this arc of descent of the Divine a reciprocal "arc of ascent" of the human spirit.[18] These adwār ("arcs" or "cycles") of descent and ascent relate directly to the interdependence of all things on all levels of existence. Everything in creation is perceived as acknowledging, in one form or another, the all-pervading Divine Presence. From the traditional view, the human being is seen as the most concentrated theophany (i.e., a locus of Divine Presence in the world of forms), especially as it concerns the qualities of an active intellect and free will. According to the Hermetic dictum, "As above, so too below," the human being acts as a mirror to the Divine. Furthermore, the Sufis (the mystics of Islam) have a popular saying that addresses this reality on the cosmic scale: al-insān qawn saghīr wa 'l-qawn insān kabīr ("The human is a small universe, and the universe is a large human").

The guiding principle of the dynamic interplay between the Divine Order and the rest of creation is called Tawhīd ("the principle of Divine Unity"). All of the traditional sciences in Islam agree that there exists a dependence of creation on the Divine, an interdependence between all forms in the cosmos, and an intradependence of all elements within each specific form. There is an obvious analogy to the profound knowledge found in that sacred oriental symbol of the Tao's tai chi ("Supreme Principle of Unity") with the complementing and harmonizing forces of yin and yang. This is also known in Islamic cosmologic language as al-wahdah fi 'l-kathrah wa 'l-kathrah fi 'l-wahdah ("the one in the many and the many in the one").

Unani medicine bases its medical theories of diagnosis and treatment on this specific understanding of the intradependent relationships that exist between the four humors as it concerns the subtle (latīf) aspects of human physiology and spiritual psychology (Fig. 49.4).[19]

Teleology and Spiritual Correspondences

The teleological component of Unani medicine's philosophy entails extracting "meaning" and "purpose" in relation to the realities of creation and the human experience. To what end is human life? What is the goal of all of creation? Is there a plan or purpose that governs the created order and all of its particular elements?

The Qur'ān explicitly states that inna li 'Llāhi wa inna ilayhi rāji'ūn ("Verily we belong to God, and to Him is our return"). The human race hurls itself forward, in time and space, toward an inevitable reunion with its Creator. It is this understanding of the nature of things that permits traditional hakīms (the "doctors" of the Unani medical tradition) to find solace in the fact that every patient is ultimately a patient at the doorsteps of the Divine Doctor.

The notion of forcing "heroic" measures upon the sacred human frame is problematic to the philosophical principles upon which Unani medicine is based. This is not to say that surgery and trauma care are perceived in a negative light in Unani medicine. Rather, the question is really one of proportions. The traditional Tabīb ("man of medicine," or physician) always has an eye to the Divine within the human temple. This is really a cultivated virtue that the hakīms practice as part of their art to remain true to the doctrine that "God is everywhere present"; that in keeping with the wisdom of Plato, it is the "eye of the soul" that witnesses "tō Agathōn" ("the Supreme Good"). Therefore any decision made by a hakīm must include an analysis of the risk-to-benefit ratio within the larger ethical framework of the Divine's presence in human life. As a prayerful supplication of ʿAli, the son-in-law of the Prophet Muhammad and the spiritual pole of Shiite Islam, says: Yā man Ismuka dawā', wa dhikruka shifā' ("Oh Ye whose Name is a sacred medicine, and in whom remembrance of Thee [dhikruka] is a healing balm …").

(Nada Pop-Jordanova, Olivera Sarakinova, Silvana Markovska-Simoska, Sofija Loleska, Anxiety and Personality Characteristics In Children Undergoing Dental Interventions, Contributions. Sec. Med. Sci., XXXIV 3, 2013. UDC: 616.89-008.441.1-02:616.31-053.2.)

UNANI MEDICAL THEORY IN PRINCIPLE

Vis Medicatrix Naturae

It is only with the "eye of the heart" (ayn al-qalb) that the doctors of Unani medicine are able to gain proper intuition of vision concerning the state of the jism al-latīf (the "subtle body") of the patient in whom is found the flowing, dynamic streams of the humors. It is at the level of the subtle body that the hakīm desires to enliven the self-healing power, the vital force, or the *vis medicatrix naturae* to affect a change in the patient's being in the direction of health and wellness. It is this particular "organizing principle" (al-quwwa al-mudabbirah), as a component of the hidden physiology of the subtle body, that affects a harmonizing reaction in the face of "disease" or illness. One may perceive the vis as being the thread that holds the fabric of the human body, mind, and soul together in close conjunction with the spirit. This is the general medical theory of the "healing power of nature" that Unani medicine posits as a guiding principle, on which is built more complex specific understandings of human health and disease.

A Personal Thought on the Invisible Vis or Quwwa

We encounter many opportunities in life that allow us to witness obvious demonstrations of the *vis medicatrix naturae*. An everyday example of the obvious workings of the vis is a paper cut. Many of us have had this experience and have considered it a very irritating situation. However, if we look carefully at what is actually happening, we cannot but assume that the "natural healing instinct" in the human body, when undergoing injury or trauma, is to mobilize mechanisms that will allow for self-preservation and homeostasis, which would be disorder and chaos. Why should the body even mobilize these mechanisms to begin with? We know to a great degree the science behind these mechanisms, but what we do not know is why these mechanisms should initiate such a nonentropic response. This is still a mystery.

As simple as a paper cut is, it is usually followed by a natural biochemical and physiological inclination toward wound healing (homeostatic repair). We usually never see a paper cut to a finger progressively develop into an open wound, fester with pus and infection, turn gangrenous or necrotic, and die, necessitating amputation of the finger; this is simply not the natural, instinctual response of the human body. In actuality, what we do see happen is the influence of this organizing principle—call it what you may: qi, prana, vis, quwwa, ki, and so forth—leading the organism's biochemistry toward a healing homeostasis, not a death-inducing "diseased" disturbance.

There is yet another common example that relies heavily on the signaling of this "power" or "quwwa" for healing, and that is surgery. How many times have we heard what surgeons say after surgery? It usually goes something like "Well, it's now up to the patient to heal"

or "I've done all I can; the rest is up to the patient" or "I look forward to seeing you for your follow-up to see how you're healing." What do statements like this really mean? I believe that what is actually being invoked is a subconscious acknowledgment of and reliance upon the vis. However, because the language of modern conventional medicine does not give this ever-present healing power a name, it is vicariously mentioned under ambiguous terms, phrases, and allusions. All other traditional systems of medicine in the world have a name for this "elephant in the room" as a distinct reality.

The Doctrine of the Seven Naturals

There are hosts of medical systems around the world with their own understanding of what constitutes the primary and basic functional components that cause health to reign or disease to take root, progress, and finally manifest in constellations of signs and symptoms of illness. In Chinese medicine, we have physiological concepts such as qi, blood, yin, and yang. In conventional medicine, physiology is dominated by the key concepts of organic issues relating to organ tissue morphology (anatomy) and fluid dynamics (medical biochemistry; Fig. 49.5).

In Unani medicine, these concepts fall under the strict heading of umūr al-tabīʿiyyah ("principles of natural physiology"), comprising the "Seven Naturals" that are the pillars and determinants of health. These are as follows (Fig. 49.6):

Elements (arkān)
Temperaments (mizāj)
Humors (akhlāt)
Organs (aʿdā')
Forces, drives, faculties, or powers (quwwāt)
Actions or functions (afʿāl)
Pneuma or spirit substance (rūh)

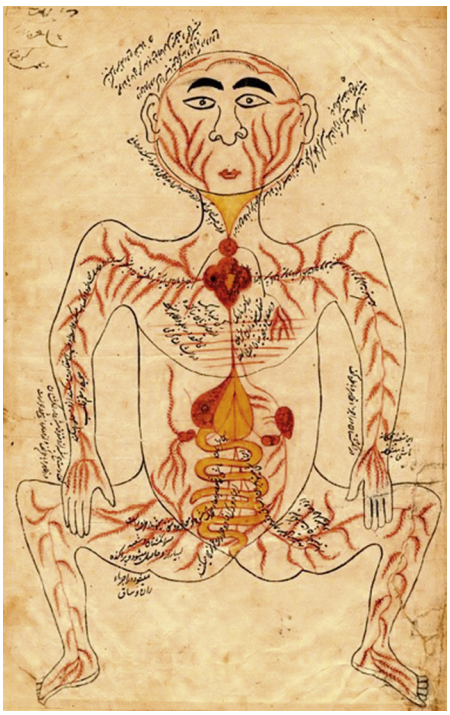

Fig. 49.5 Mansūr ibn Ilyās's 14th-century work on anatomy contained illustrated chapters on five systems of the body: bones, nerves, muscles, veins, and arteries. The page shown depicts the arteries with the internal organs shown in watercolors.

Elements, Qualities, Properties, and States

The elements are the simple building blocks of matter in nature, including the human body. They are nondivisible, but they do have qualities that are both active and passive that determine the states of matter. They are as follows:

Fire (nār), which is hot and dry (hār and yābis): determines the energetic state.
Air (hawā'), which is hot and wet (hār and ratab): determines the gaseous state.
Water (mā'), which is cold and wet (bārid and ratab): determines the liquid state.
Earth (ardh), which is cold and dry (bārid and yābis): determines the solid state.

These elements do not mean literally clods of dirt, buckets of water, and so forth. "Likewise, the burning fire that we see is not the element fire, which is really the potentiality of fire within the substance."[20]

Temperaments

The interplay between the qualities of the elements leads ultimately to a uniform configuration of a temperament. "Each [Temperament] is named after a certain Humor, and is characterized by the predominance of that Humor and its associated basic qualities."[21] The classical temperaments correlate well to today's psychological constitutional types: choleric, melancholic, phlegmatic, and sanguine. Imbalances of temperaments cause disharmony, especially on the mental and emotional fronts. The following is a concise, but thorough medical depiction of the temperaments (Table 49.2).

Humors

There is no doubt that the principle of the humors (Akhlāt) originated with the "father of medicine," Hippocrates, describing it in his book entitled *Tabīʿat al-Insān.*[22] He observed upon examination of blood

Fig. 49.6 A metaphysical vision of the Islamic cosmos: metacosm, macrocosm, microcosm. This depiction shows the seven planetary spheres dominated by seven prophetic presences (in time and space), surrounded by the lunar and zodiacal influences and encompassed by the angelic sphere signifying the Divine as the Immanent Sacred Presence and the Transcendent Beyond Being. (From Celestial map, signs of the Zodiac and lunar mansions in the Zubdat-al Tawarikh, dedicated to the Ottoman Sultan Murad III in 1583.)

TABLE 49.2 The Four Different Temperaments

SANGUINE TEMPERAMENT

Humor	Blood
Basic qualities	Hot and wet
Face	Oval or acorn-shaped face and head. Delicate, well-formed mouth and lips. Beautiful almond-shaped eyes, often brown. An elegant, swanlike neck.
Physique	In youth, balanced, neither too fat nor too thin. Moderate frame and build. Elegant, statuesque form, with ample, luxuriant flesh. Joints well-formed; bones, tendons, veins not prominent. Can put on weight past 40 years, mostly around hips, thighs, buttocks.
Hair	Thick, luxuriant, wavy. Abundant facial and body hair in men.
Skin	Pink, rosy, blushing complexion. Soft, creamy smooth, luxurious feel. Pleasantly warm to the touch.
Appetite	Quite hearty, often greater than digestive capacity. A predilection for rich gourmet foods.
Digestion	Good to moderate; balanced. Can be overwhelmed by excessive food.
Metabolism	Moderate, balanced. Bowel tone can be a bit lax.
Predispositions	Metabolic excesses of the blood. Uremia, gout, diabetes, high cholesterol. Intestinal sluggishness, putrefaction. Congested, sluggish liver and pancreas. Congested blood, bleeding disorders. Respiratory catarrh, congestion, asthma. Urinary conditions, genitourinary disorders. Excessive menstruation in women. Skin conditions, hypersensitivity, capillary congestion.
Urine	Tends to be rich or bright yellow and thick.
Stool	Well-formed, neither too hard nor too soft.
Sweat	Balanced, moderate.
Sleep	Moderate, balanced, sound. Can be some snoring.
Dreams	Usually pleasant, of a charming, amusing, romantic nature. Travel, enjoyment, games, distractions.
Mind	Faculty of judgment well developed. A synthetic intellect that likes to see the whole picture. An optimistic, positive mental outlook. Rather conventional and conformist; good social skills.
Personality	Exuberant, enthusiastic, outgoing. Optimistic, confident, poised, graceful. Expansive, generous. Romantically inclined; loves beauty, esthetics, arts. Sensual, indulgent nature. Sociable, gregarious, light-hearted, cheerful.

CHOLERIC TEMPERAMENT

Humor	Yellow Bile
Basic qualities	Hot and dry
Face	Broad jaw. Sharp nose, high cheekbones. Sharp, angular facial features. Reddish face common. Sharp, fiery, brilliant, penetrating eyes and head.
Physique	Compact, lean, wiry. Good muscle tone and definition. Prominent veins and tendons. Broad chest common. An active, sportive type. Weight gain usually in chest, arms, belly, upper body.
Hair	Often curly. Can also be thin, fine. Balding common in men. Blonde or reddish hair common.
Skin	Ruddy or reddish color if heat predominates; sallow or bright yellow if bile predominates. Rough and dry, quite warm.
Appetite	Sharp and quick. Soon overcome by ravenous hunger. Fond of meat, fried foods, salty or spicy foods, alcohol, intense or stimulating taste sensations.
Digestion	Sharp and quick. Tendency toward gastritis, hyperacidity, acid reflux. When balanced and healthy, can have a "cast iron stomach," able to digest anything.
Metabolism	Strong, fast, active; catabolic dominant. Strong innate heat of metabolism. Liver and bile metabolism can be problematic. Digestive secretions strong, bowel transit time short. Adrenals, sympathetic nervous system dominant. Strong inflammatory reactions.
Predispositions	Fevers, infections, inflammation. Hives, rashes, urticaria. Fatty liver, bilious conditions. Hyperacidity, acid reflux, inflammatory and ulcerative conditions of middle GI tract. Headaches, migraines, irritability. Eyestrain, red sore eyes. Purulent conditions. High cholesterol, cardiovascular disorders. Gingivitis. Bleeding disorders from excess heat, choler in the blood. Hypertension, stress.
Urine	Tends to be scanty, dark, thin. Can be hot or burning.
Stool	Tends toward diarrhea, loose stools. Can have a yellowish color, foul odor.
Sweat	Profuse, especially in summer, or with vigorous physical activity. Strong body odor. Sensitive to hot weather, suffers greatly in summer.
Sleep	Often fitful, restless, disturbed, especially with stress, indigestion. Often tends to wake up early or in the middle of the night.
Dreams	Often of a military or violent nature. Dreams of fire, red things common. Fight or flight, confrontation.
Mind	Bold, daring, original, imaginative, visionary. Ideation faculty well-developed. Brilliant intellect; sharp, penetrating insight. The idea man who prefers to leave the details to others.
Personality	Prone to anger, impatience, irritability; short temper. Bold, courageous, audacious, confrontational, contentious. Dramatic, bombastic manner; high powered personality. The rugged individualist and pioneer; thrives on challenge. The fearless leader. Seeks exhilaration, intense experiences. Driven, "Type A" personality. Prone to extremism, fanaticism.

TABLE 49.2 The Four Different Temperaments—cont'd

MELANCHOLIC TEMPERAMENT

Humor	Black Bile
Basic qualities	Cold and dry
Face	Square or rectangular head and face. Prominent cheekbones, sunken hollow cheeks common. Small, beady eyes. Teeth can be prominent, crooked, or loose. Thin lips.
Physique	Tends to be thin, lean. Knobby, prominent bones and joints common. Prominent veins, sinews, tendons. Muscle tone good, but tends to be stiff, tight. Rib cage long and narrow, with ribs often prominent. Can gain weight in later years, mainly around midriff.
Hair	Color dark, brunette. Thick and straight. Facial and body hair in men tends to be sparse.
Skin	A dull yellow or darkish, swarthy complexion. Feels coarse, dry, leathery, cool. Calluses common.
Appetite	Variable to poor. Varies, fluctuates according to mental or emotional state.
Digestion	Variable to poor; irregular. Digestion also varies according to mental or emotional state. Colic, gas, distension, bloating common.
Metabolism	Often slow. Can also be variable, erratic. Prone to dehydration. Nervous system consumes many nutrients, minerals. GI function variable, erratic; digestive secretions tend to be deficient. Blood tends to be thick. Nutritional deficiencies can cause a craving for sweets, starches. Thyroid tends to be challenged, stressed.
Predispositions	Anorexia, poor appetite. Nervous, colicky digestive disorders. Constipation. Spleen disorders. Nutritional and mineral deficiencies, anemia. Blood sugar problems, hypoglycemia. Wasting, emaciation, dehydration. Poor circulation and immunity. Arthritis, rheumatism, neuromuscular disorders. Nervous and spasmodic afflictions. Dizziness, vertigo, ringing in ears. Nervousness, depression, anxiety, mood swings.
Urine	Tends to be clear and thin.
Stool	Can either be hard, dry, compact; or irregular, porous, club-shaped. Constipation, irritable bowel common.
Sweat	Generally scanty. Can be subtle, thin, furtive, indicating poor immunity. Nervous stress can increase sweating.
Sleep	Difficulty falling asleep, insomnia. Stress, overwork, staying up late aggravates insomnia. Generally a light sleeper.
Dreams	Generally dark, moody, somber, disturbing. Themes of grief or loss common.
Mind	An analytical intellect; detail oriented. Efficient, realistic, pragmatic. Reflective, studious, philosophical. Retentive faculty of memory well-developed. Thinking can be too rigid, dogmatic. A prudent, cautious, pessimistic mental outlook.
Personality	Practical, pragmatic, realistic. Efficient, reliable, dependable. A reflective, stoic, philosophical bent. Can be nervous, high strung. Frugal, austere; can be too attached to material possessions. Serious, averse to gambling and risk taking. Can be moody, depressed, withdrawn. Can easily get stuck in a rut. Excessive attachment to status quo.

PHLEGMATIC TEMPERAMENT

Humor	Phlegm
Basic qualities	Cold and wet
Face	Round face; full cheeks, often dimpled. Soft, rounded features. Double chin, pug nose common. Large, moist eyes. Thick eyelids and eyelashes.
Physique	Heavy frame, stout, with flesh ample and well-developed. Often pudgy, plump, or overweight; obesity common. Joints dimpled, not prominent. Veins not prominent, but can be bluish and visible. Lax muscle tone common. Feet and ankles often puffy, swollen. Women tend to have large breasts. Weight gain especially in lower body.
Hair	Light-colored, blondish hair common. Light facial and body hair in men.
Skin	Pale, pallid complexion; very fair. Soft, delicate, cool, moist skin. Cool, clammy perspiration common, especially in hands and feet.
Appetite	Slow but steady. Craves sweets, dairy products, starchy glutinous foods.
Digestion	Slow but steady to sluggish. Gastric or digestive atony common. Sleepiness, drowsiness after meals common.
Metabolism	Cold, wet, and slow. Conserves energy, favors anabolic metabolism. Congestion, poor circulation, especially in veins and lymphatics. Kidneys slow, hypofunctioning, inefficient. Adrenals and thyroid tend toward hypofunction; basal metabolism low. Metabolic water drowning out metabolic fire.
Predispositions	Phlegm congestion. Water retention, edema. Lymphatic congestion, obstruction. Poor venous circulation. Gastric atony, slow digestion. Hypothyroid, myxedema. Adrenal hypofunction. Weight gain, obesity. Frequent colds and flu. Chronic respiratory conditions, congestion. Swollen legs, ankles, feet. Cellulite. Poor tone of skin, muscles, and fascia.
Urine	Tends to be clear or pale and thick. Tends to be scanty in volume, with excess fluid accumulation in the body.
Stool	Well-formed, but tends to be slightly loose, soft. Bowels tend to be sluggish.
Sweat	Cool, clammy sweat common, especially on hands and feet. Sweating can be easy and profuse, especially with kidney hypofunction. Sensitive to cold weather; suffers greatly in winter.
Sleep	Very deep and sound. Tends toward excessive sleep, somnolence. Snoring common; can be loud or excessive.
Dreams	Generally very languid, placid. Water and aquatic themes common.
Mind	Tends to be dull, foggy, slow. Slow to learn, but once learned, excellent and long retention. Patient, devoted, faithful. Faculty of empathy well-developed. Sentimental, subjective thinking. A calm, good-natured, benevolent mental outlook.
Personality	Good natured, benevolent, kind. Nurturing, compassionate, sympathetic, charitable. Great faith, patience, devotion; tends to be religious, spiritual. Sensitive, sentimental, emotional, empathetic. Passive, slow, sluggish; averse to exertion or exercise. Calm, relaxed, takes life easy. Excessive sluggishness can lead to depression.

GI, gastrointestinal.

From Osborn D. The four temperaments. http://www.greekmedicine.net/. Accessed April 23, 2012. Used with permission.

that the red portion of fresh blood is the blood humor (Dam; corresponding to the sanguinous temperament), the white material mixed with blood is the phlegm humor (Balgham; related to the phlegmatic temperament), the yellow-colored froth on top is the yellow bile humor (Safra; corresponding to the choleric temperament), and the heavy part that sediments down is the black bile humor (Sauda; related to the melancholic temperament).[20]

It is important to realize that the humor associated with the blood and called "sanguine" is not identical with the blood drawn by phlebotomy. Nor is the phlegm the same physical phlegm produced by the lungs. Cameron Gruner, MD, called them "quasi-material," or what some have termed "semi-gaseous vapors."[20]

Similarly, qi is beyond physical or corporeal form. Qi and the Seven Naturals are really and truly best understood as a "formless substance," often referred to in the language of philosophy as a Platonic "form" or "idea."[23] Ultimately, it is understood that true "health is a harmony of [these] humors."[20]

Organs

The organ component in the doctrine of the Seven Naturals is actually very straightforward. There are four primary organs that the rest of the organs support and whose work they may enlist. These are as follows:
Heart: the seat of vital power and heat
Brain: the seat of sensations and movements
Liver: the seat of all vegetative, nutritive, and eliminative powers
Gonads: the seat of generative capacity for reproduction of the species

The medical traditions of antiquity all agree that when considering an approach that is centered on health, wellness, and prevention, the two most important organs to focus emphasis on are the liver and the colon. Modern medicine focuses its emphasis on the heart and the brain, for good reason. "Miracles" occur every day in emergency rooms, operating rooms, trauma care facilities, burn units, first-line responder ambulance services, life flight transportation services, etc. "In fact, emergency medicine is one of the most legitimate and impressive achievements of [modern] orthodox medicine."[20]

Forces, Energies, Faculties, Drives, or Powers

The groundwork energies that animate the Seven Naturals are termed forces or faculties (quwwāt). These forces are the legitimate activating principles for the functioning of the humors. Without the quwwāt, there would be no accomplishment of organ function or of anything else. There are primarily three faculties that give rise to a variety of functions. These faculties are:

Natural (as in "from the world of nature") or vegetative faculty (quwwah tabīʿiyyah): governs the nutritive power of the liver and reproductive powers of the generative organs.

Vital or animal faculty (quwwah haywāniyyah): responsible for preserving the integrity of the vital force.

Psychic or soul faculty (quwwah nafsāniyyah): controls the brain and the rational faculty. "It is of significance to note that in Arabic as in many other languages the words for breath (nafas) and soul (nafs) are related. Therein lies a profound cosmological principle which is also related to the invocation of the Name of God (dhikr) as the central technique of Sufism for spiritual realization."[4]

Actions or Functions

Functions or actions (afʿāl) are the manifesting activities of the previously mentioned humoral and organ powers. The functions ultimately are the by-products of the will or power of the humors and organs. For example, the heart's function is to beat; the stomach's function is to receive food and drink and prepare them for further digestive processing; the brain's function is to allow for reception of stimuli, with higher functioning allowing for the expression of reason and thought.

Pneumata or Spirits

The spirit (Rūh) is the otherworldly vehicle for the transmission of that divine spark of life force, a heavenly command that "descends upon this mixture of the humors and which is the subtle body standing intermediate between the physical body comprised of the humors and the force of life which comes from the world above. It is worth drawing attention to the similarity between the words rūh (spirit) and rīh (the wind or air) in Arabic."[4]

> *The spirit or rūh in its medical sense is, according to Muslim physiologists, and following Galen, of three kinds:*
> *Vital Spirit: hot and dry; has its center in the left ventricle of the heart; preserves life; causes the body to grow, move, and reproduce; and travels within the arteries.*
> *Psychic Spirit: cold and wet, has its center in the brain, causes sensation and movement, and moves within the nerves.*
> *Natural Spirit: hot and wet; has its center in the liver; is concerned with the reception of food, growth, and reproduction; and travels within the veins.*[4]

Thus there is an association between physical health and spirituality. "According to some of Avicenna's writings, and in keeping with the Hermetic Tradition, Avicenna sees these natural laws as embodying a component of Divine creative perfection, which to him explains the tendency inherent in natural systems to direct themselves toward a point of … equilibrium."[24]

Another aim toward understanding the physiology and pathology of the doctrine of the Seven Naturals involves answering the question "to what end?" The answer to this has to do with achieving a healthy constitution for every patient by meeting the goals of the six essential causes (of health; al-asbāb al-sittah al-dharūriyyah)[22]:

- Air
- Food and drink
- Body movement and repose
- Mental movement and repose
- Sleeping habits
- Retention and evacuation

It is these basic causal pillars that ultimately guide the hakīm toward satisfying the criteria for health as set forth by Avicenna himself in his *Canon of Medicine,* which are as follows[25]:

- The complexion of an individual is pleasing, with shades and color that are normal to the individual's respective biological environment.
- Body build is medium, neither too lean nor too heavy.
- Hair is not too profuse nor scanty.
- The feel of the body is balanced in respect to heat, cold, moisture, and dryness.
- Sleep and wakefulness are moderate.
- Movements are free and easy.
- Intellectual functions and memory are good.
- Habits and behavior are balanced between timidity and assertiveness, anger and calm, leniency, humor, pride, and humility.
- Growth and repair are rapid, whereas deterioration is slow.
- Dreams are interesting and pleasing.
- Food is enjoyable.
- Food is digested and assimilated normally.
- Excretory functions are regular.

Techniques of Inquiry and Assessment

Pulse

Unani medicine pulse diagnosis as a science takes tremendous practice and requires sensitivity to the characteristics of 10 physical criteria of the radial pulse[20]:
Quality of expansion (length, width, depth)

Quality of impact (strong, weak, moderate)
Duration of cycle (fast, slow, moderate)
Duration of pause (successive, different, moderate)
Between beats (full, empty, moderate)
Compressibility (hard, soft, moderate)
Pulse perspiration (full, empty, moderate)
Regularity
Order and disorder (ordered, irregular, irregularly disordered)
Rhythm (similar, different, out of rhythm)

Avicenna's pulse diagnosis was so profound that he even "recognized 'physiological psychology' in treating illnesses involving emotions. From the clinical perspective Ibn Sina developed a system for associating changes in the pulse rate with inner feelings which has been viewed as predating the word association test of Carl Jung. He is said to have treated a seriously ill patient by feeling the patient's pulse and reciting aloud to him the names of provinces, districts, towns, streets, and people. By noticing how the patient's pulse quickened when names were mentioned, Ibn Sina deduced that the patient was in love with a girl whose home Ibn Sina was able to locate by the digital [pulse] examination. The man took Ibn Sina's advice, married the girl, and recovered from his illness" (Fig. 49.7).[26]

Uroscopy, the "Urine Wheel," and the "Alvine Discharge" (Fig. 49.8)

Unani medicine demonstrates sophistication in realizing that there is much legitimate insight and wisdom to be gained through the macroscopic study of urine (often termed *uroscopy*) and stool. These tissues of the body reveal indices of the body's internal metabolic terrain and activity. For example, "urine wheels" were used by hakīms to forward assumptions about diagnosis or prognosis, treating urine essentially as a "liquid window through which physicians felt they could view the body's inner workings."[27]

"Laboratory medicine began 6000 years ago with the analysis of human urine, which was called uroscopy until the 17th century and today is termed urinalysis. From ancient times until the Victorian era, urine was used as the primary diagnostic tool. Physicians spoke of urine as a 'divine fluid', or a window into the body. Babylonian and Egyptian physicians began the art of uroscopy. Uroscopy, from the word 'uroscopia,' means 'scientific examination of urine.' The word is derived from the Greek 'ouron' meaning 'urine' and 'skopeo', meaning to 'behold, contemplate, examine, inspect.'"[27]

Building on the uroscopy and medicine of Galen, "Theophilus Protospatharius, a seventh century physician, wrote De Urinis. This manuscript from Byzantium was the first publication exclusively on the subject of urine."[27] It was later used in the system of Unani medicine and translated for use down through the European Middle Ages.

In Avicenna's system of urine inspection, "important points to be considered in using urine in diagnosis are color, density, turbidity,

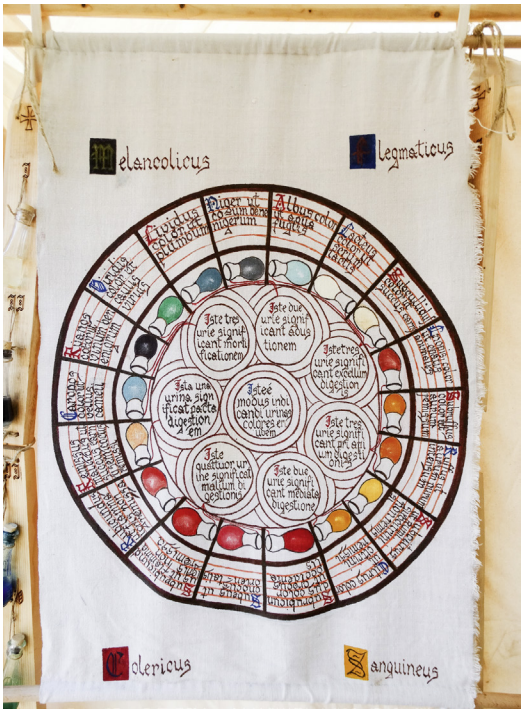

Fig. 49.8 Medieval urine wheel. Labeled in Latin, this 15th-century diagram shows some of the possible colors of urine (outer edge of circle) to help doctors diagnose urine-related disease. Artwork from *Fasciculus Medicinae,* a collection of medieval medical manuscripts published in Europe that date from 1491. (shoricelu/iStock.com.)

Fig. 49.7 Avicenna (Ibn Sīna) Commemorative Medal. UNESCO issued a commemorative medal in 1980 to mark the 1000th anniversary of Ibn Sīna's birth. One face of the medal depicts a scene showing Avicenna surrounded by his disciples (inspired by a miniature in a 17th-century Turkish manuscript), and on the reverse is a phrase by Avicenna in Arabic and Latin: "Cooperate for the well-being of the body and the survival of the human species." (Jaeger, S. (2020). Iran Art Medals - (Artmedals.net) [online] Artmedals.net. Available at: http://www.artmedals.net/iranmedals.html. [Accessed 27 Feb. 2020].)

sediment, quantity, froth, and odor."[25] Of course, one can quickly see allusions in these criteria to even modern macroscopic urinalysis. However, even collection techniques were considered. "Ismail of Jurjani, an 11th century physician, recommended collecting the full amount (of urine) over 24 hours in a large clean vessel and keeping it out of the sun or heat, which could alter color. Ismail also recognized that food and aging altered urine, and required a good night's sleep and empty stomach before collection. He wrote about this in what became the most comprehensive instructional book on urine collection and examination"[27] of his time.

Stool analysis and the patient's history of bowel movements were also tools used by hakīms that allowed for the responsible investigation into the possible causes of illness. Stool has "certain characteristics vis-à-vis color, odor, volume, and consistency," [22] whereas bowel movement history includes "time, duration, and frequency of defecation."[22]

Just to give a brief example, differing stool colors approximate differing illnesses and imbalances of humors. Hakim Moinuddin Chishti summarized this category of investigation by what stool color signifies from an Unani medicine point of view in his book's section called "The Alvine Discharge"[20]:

- White stool: an obstruction of the passages carrying bile; is seen with jaundice.
- Red stool: reveals the crisis point of a disease.
- Black stool: means high oxidation; maturing of a disease caused by imbalance of the black bile humor; bad sign; presence of blood in small or great quantities, which is a sign of diseases of the liver, intestinal ulcer, or rupture of internal vessels.
- Green stool: indicates diminished internal heat.
- Yellow stool: sign of the imbalance of the yellow bile humor (at the onset of illness); is a sign that the body is eliminating harmful substances (at the resolution of an illness).
- Multicolored, pus-filled, sticky stool: very grave sign of the degeneration of internal organs.[20]

UNANI MEDICAL THEORY IN PRACTICE

The Practice Framework

Because of the obvious difficulties that confronted personalized physician-to-patient travel and care, Avicenna drew up plans on the centralizing and standardizing of medical operations for the masses in hospitals. "These hospitals kept records of all their patients and their medical care, something done for the first time in medical history."[26]

"From the tremendous impetus of advancement of medicine supplied by Avicenna, the Arabs took the huddled masses of sick and established them in sleek and elegant hospitals. Their hospitals were immense structures with courtyards and had features such as lecture halls, libraries,[26,28] mosques and chapels (they treated people of all religious beliefs), charity wards, kitchens, and dispensaries. All patients were attended by qualified male and female nurses. The mood at the magnificent Mansūr Hospital of Cairo is reflected in the following account of the amenities arranged for the benefit of all patients:

'Day and night, fifty reciters intoned the Qur'ān aloud. At nightfall, musicians played soft melodies to induce drowsiness in the patients. Professional storytellers entertained the sick with their tales. When the patients left the hospital, they were given enough money so that they would not have to resume work immediately.'"[20]

Furthermore, even before Avicenna's lifetime and progressive influence, "there was a separate hospital in Damascus for lepers, while, in Europe, even six centuries later, lepers were condemned and burned to death by royal decree."[26] The Bimaristans (hospital systems) and smaller "mobile hospitals," which could possibly be regarded as the first ambulances in the world, dedicated to serving under times of civil or community distress, urgency, or emergency,[26] were complex in structure and function.

Therapeutic Modalities

The bridge of therapies, in time and space, between Unani medicine and North American holistic and naturopathic medicine had much to do with the cross-pollinating of research, scholarship, practice, and politics of Europe's (especially old Germany's) "back to nature" movements, which made the trans-Atlantic shift and became rooted in the medical movements known as Eclectic Medicine,[29] Thomsonian Medicine, the American Medical School of Vitalism (which was philosophically opposed to scientific materialism[30]), and the Nature Cure,[31] wherein, like Unani medicine, "the patient is kept close to nature during illness."[22]

Examples of this North American connection with Unani medicine are found in the lives of personalities such as Nicholas Culpeper,[32] Benedict Lust, Henry Lindlahr, or William Kellogg, along with their applied therapies. "By the time of the early eighteenth century, the Tibb system was the basis of virtually all medicine in the civilized world, having been translated and formed as the basis of the work of such men as Father Sebastian Kneipp (1821–1897) and Samuel Hahnemann (1755–1843), the founder of homeopathy, who is reputed to have known Arabic and read Avicenna's works."[20] In this regard, it is important to remember that historically (Fig. 49.9):

> *The practical approaches of the Greeks and Romans were the antecedents of the 19th century nature cure pioneers. They were the only forms of medicine available, and, to this extent, naturopathic and orthodox medicine had what Saks describes as "a relatively undifferentiated past." Indeed, both schools of medicine claim Hippocrates as their progenitor. There is no doubt that Hippocrates set many of the principles we hold dear as naturopathic physicians; in particular, the concept of the healing power of nature (… vis medicatrix naturae)… Hippocrates advocated dietary adjustments,*

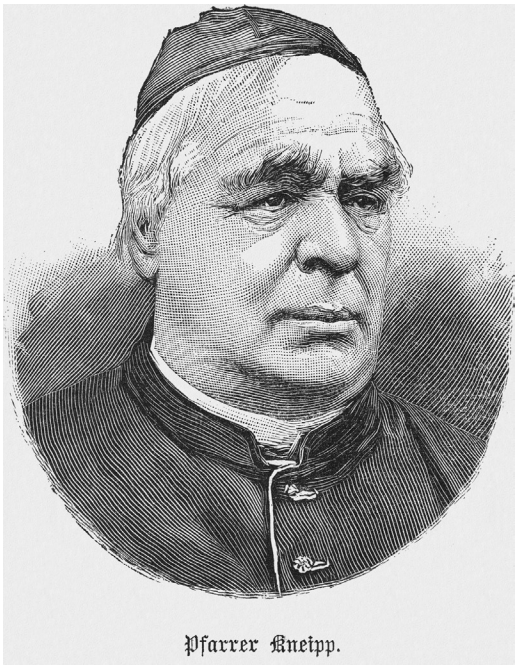

Fig. 49.9 Father Sebastian Kneipp, pioneer of modern hydrotherapy, is shown giving a bath treatment to a patient. (ZU_09/iStock.com.)

fasting, physical therapy, rest, and herbal medicines, but even he and his followers were not above using chemical drugs.[33]

For those who perceive that there is no doubt of Hippocrates's influence on setting the practical and theoretical standards for contemporary naturopathic medicine, then it must hold true that by direct historical relevance—and all that has been stated previously in this chapter regarding this—naturopathic medicine is without question an offspring of the life and thought of the "prince of physicians," Avicenna. It was Avicenna, with his singular intellect, who synthesized and expanded upon all who came before him in his *Canon* and other works and who handed down humoral medicine, along with its practical therapeutics, to generations of physicians after him.

In the late 1950s, a small group of BCNO (British College of Naturopathy, now formally recognized as the British College of Osteopathic Medicine) graduates, medical herbalists, and homeopaths formed the Research Society for Naturopathy to explore a wider range of treatment modalities. They ran seminars on such topics as humoral therapy…[33]

Fig. 49.10 This depiction of the birth of Caesar may be the first illustration of a cesarean section found in the written works of the most famous Muslim chronicler, Al-Biruni (973–1051 ad), as illustrated in the manuscript of al-Bīrūnī, Al-Athār al-Bāqiyah 'an al-Qurūn al-Khāliyah, MS 161, Edinburgh University.

Food-Based or Dietary Therapies

The objective of dietary therapy (ʿilāj bil ghida) is to properly regulate a patient's appetite, in terms of quality or quantity, to maintain the balance of the humors and strengthen the vital force. This is accomplished by prescribing patients food-based protocols, such as restriction, fasting[25,34] (which is an effective, natural process of detoxification and healing[25]), liquid diets, excess eating, semisolid diet, bland diets, and so on.[22] Attention should be paid to the seasons and the requirements of the body in relationship to the environment as to what foods to recommend, depending on the "degree of effectiveness of types of cereals, of leguminous plants, vegetables, root crops, fruits, types of meat, types of milk, of honey and sweet-meats, of water, of drinks, and [edible] aromatic herbs."[8]

Ultimately, "food is one of the most potent and yet safe instruments of establishing balance in a disturbed organism."[25] This is in line with the Hippocratic proclamation, "Let food be your medicine and medicine be your food," as well as conforming to the first principle of therapy, which stipulates "first do no harm." "It is not accidental that the Andalusian physician Abū Marwān ibn Zuhr in the 12th century wrote the first scientific work on diet ever composed, the *Kitāb al-Aghdiyah* ("The Book of Diet")."[4]

Pharmacy, *Materia Medica,* and the Black Seed

Historically, and as far as pharmacology and the *materia medica* is concerned, among the Arab inheritors of Greek knowledge and wisdom, "it is sufficient to say that Dioscorides was indisputably the greatest authority, that his work was many times translated and elaborated"[8] by scholars such as al-Biruni, Ibn-Bajjah (Avempace), and al-Idrisi (the famous geographer whose maps purportedly influenced the maritime travels and adventures of Christopher Columbus; Fig. 49.10).[35]

The predominant therapeutic modality in Unani medicine is without doubt ʿilāj bil dawā' (pharmacotherapy). Raw *materia medica* resources for this therapy came from the plant (90%), mineral (5%), or animal (5%) kingdoms. As Khan noted, "in treatment the principle that each human being is a reflection of all creation is followed by using a whole range of substances."[25]

Some examples of Unani medicine phytotherapy include the conditions and their respective remedies shown in Table 49.3.

The spiritual lore and medicine of the black seed. There is no doubt that the most well-known herb used in Unani medicine, and revered by the cultures of the Middle East and Asia, is the black seed (al-habba al-sauda, or al-habba al-barakah ["the black seed" or "the seed of grace"]). It also goes by the scientific name *Nigella sativa* (Fig. 49.11).[36]

TABLE 49.3 Examples of Unani Medicine Phytotherapy

Condition	Remedy
Fever	Lemon juice with pinch of salt
Constipation	Rose petals with milk
Diarrhea	Amla *(Emblica officinalis)*
Conjunctivitis	Aloe and opium paste
Toothache	Basil leaves paste
Baldness	*Tamarix articulata* in mustard oil
Eczema	Ghee (clarified butter)
Influenza	Long pepper *(Piper longum)*
Asthma	Turmeric powder in milk
Insomnia	Fried cumin seed powder with ripe banana pulp
Menstrual absence	Carrot and black sesame seed cold decoction
Diabetes	*Coccinia, Evolvulus, Eugenia,* and poppy seeds
Obesity	Guggul gum resin *(Commiphora mukul)* powder

Data from Jamal A, and Qadeer HA. *Unani: The science of Graeco-Arabic medicine*. New Delhi, India: Lustre, 1998:25.

The Prophet of Islam specifically mentioned the black seed as he exhorted members of his community to "Use the black seed, which is a healing for all diseases except al-Sām, and al-Sām is Death."[37] With such a pronouncement, one may infer that the prophet was the prototypic hakīm. This observation is important to note because more than 1.6 billion people in the world follow, as closely as possible, the life and thought of the prophet of Islam.

Thus the prophet's statement regarding the black seed elevates and ennobles this plant beyond its investigated scientific benefits.

However, it was posited that "advancements in the methods of analytical chemistry, physiology, pharmacology, and microbiology, etc. have led to the discovery of many active principles of the *N. sativa* [seed] such as nigellicine, nigellidine, nigellimine-N-oxide, thymoquinone, dithymoquinone, thymohydroquinone, nigellone, thymol, arvacrol, oxy-coumarin, 6-methoxycoumarin, and 7-hydroxy-coumarin, alpha-hedrin, steryl-glucoside as well as rich amounts of

Fig. 49.11 The black seed, also known as *Nigella sativa.* (Madeleine Steinbach/Shutterstock.)

Fig. 49.12 Çemberlitaş Hamami, Istanbul, Turkey. Revered Ottoman architect Mimar Sinan built Çemberlitaş Hamami in 1584. It is one of the busiest and most popular due to the separate male and female bathing sections, quality massages, and a location near the Grand Bazaar. (master2/iStock.com.)

flavonoids, tannins, essential fatty acids, essential amino acids, ascorbic acid, iron, and calcium.

"The black seed also has a number of pharmacological effects of profound therapeutic value such as analgesic, anti-inflammatory, anti-histaminic, anti-allergic, anti-oxidant, anti-cancer, immune stimulation, anti-asthmatic, anti-hypertensive, hypoglycemic, anti-bacterial, anti-fungal, anti-viral, and anti-parasitic effects."[37,38]

Environmental Regimens

There are primarily three regimental therapies[22] to take advantage of as part of Unani's movement and manual medicine approach (Fig. 49.12):

- Activity (riyādhāt), which usually means some form of voluntary movement or exercise with the purpose of achieving the following:
  - Organs that perform their functions efficiently
  - Better absorption and assimilation of food and nutrition
  - Clearing of pores in the skin
  - Removal of waste products through the lungs
  - Strengthening the physique
- Massage (tadlīk), which is physical pressure and movement given by another through gentle or aggressive touching, moving, or rubbing of muscles and soft tissues for the purpose of achieving the following:
  - Bracing the body
  - Relaxation response
  - Decreased body fat
  - Enhanced circulation
  - Good organ function
- Thermarium baths (hammāmāt), which are found around the world. These baths sometimes contain mineral constituents (e.g., sulfur) that leech out of the terrestrial basin holding these waters; the benefits of these hot baths include the following:
  - Releasing waste products and impurities through the skin
  - Reducing the viscosity of the humors
  - Reducing obesity

Of these regimental therapies, it is without a doubt the thermo-hydrotherapeutic hammām (the thermarium) that many people may be acquainted with. The hammām is probably more familiar to Western ears as the "Turkish Bath." Worldwide today, there are many medical and recreational resort facilities that incorporate traditional baths of this nature in cavernous, underground, or open-air communal systems.

What follows is an average description of a hammām experience[39]:

> *Traditionally the hammām is made up of a number of chambers with domed white roofs. The "istirāha" is the "rest salon," where visitors are received and un-robed. The inner sanctum of the hammām is usually set down from the istirāha, with further descents into the various steam rooms. The walls of the steam rooms are customarily made from hajar habash (a black stone) which holds heat for a long time. Once you have achieved a good sweat [taʿrīk], you then proceed on to another warm room where the hammāmi greets you.*
>
> *The hammāmi is the person who cleans or exfoliates your body and gives you a [vigorous] massage. One person commented, "I was pummeled, stretched, twisted like a pretzel, and scrubbed with a floor-like brush for about an hour." However, you do emerge glowing and gleaming with your metabolism raring and your fat cells pummeled and detoxified. Finally, you are returned to one of the outer chambers, wrapped up in a robe, and led to a cubicle to rest and relax and enjoy mint tea or juice.*[39]

History records that knowledge of the "medical benefits of the hammām dates back to 200 B.C. when Hippocrates stated, 'Give me the power to create a fever and I shall cure any disease.' Essentially, the steam bath induces a hyperthermia, which raises the body temperature above normal. Hyperthermia stimulates the immune system by increasing production of antibodies and interferon (an antiviral protein with cancer fighting capabilities). A good healthy sweat can help relieve pain and stiffness of joints and muscles, treat respiratory problems like sinusitis, and ward off symptoms of colds or flu. It is also excellent for detoxification, and especially in conjunction with massage it can reduce cellulite by releasing toxins from fat cells. Also, increased blood flow stimulates metabolism and rejuvenates the skin."[39]

In the West, "hydrotherapy enjoyed a great resurgence in 18th and 19th century Austria and Germany, and was a key part of Father Sebastian Kneipp's system of natural therapeutics, which went on to become the basis for Naturopathy. For example, in many European countries that have hot springs or spa resorts, [hydrotherapy] treatments are a recognized subspecialty of medicine."[40]

Surgery, Cauterization, and Bloodletting

In Manfred Ullmann's *Islamic Surveys II* and Seyyed Hossein Nasr's *Islamic Science: An Illustrated Study,* there are illustrated plates demonstrating a cesarean section[8] from an ancient Arabic manuscript; a plate[8] illustrating the diagrams for surgical instrumentation ("Numerous surgical instruments especially various types of scalpels were developed, some quite elaborate and combining as elsewhere utility and beauty, and most have survived relatively unchanged over the ages with only small local variations"[4]) developed and used by

Abu al-Qāsim al-Zahrāwī (known to the West as Albucasis), who was one of the greatest surgeons of antiquity that "took surgery [jarh] out of the hands of barbers and put it into the realm of scientific medicine"[8]; and images of surgical interventions involving hemorrhoidal correction, bone-setting, reductions of dislocations of joints, dental procedures ("Muslim physicians would even make false teeth from the bones of animals[4]), and so forth.[4] "Surgery was also used by the Arabs to correct cataracts."[41]

Many hakīms accept the fact that today, it is probably best to triage the surgical option for patients to surgeons who have been educated and trained in modern medical schools. The same would hold true for cauterization (kay; healing through heating or burning of tissue), which today is accomplished with the help of lasers, bloodletting (fasād; releasing of venous blood to purge toxic or disturbed humoral physiology), and leeching (taʿlīk; the use of leeches to evacuate "corrupt" blood).[42]

Other therapies, such as cupping (hajamāt) and cathartic colonic purgatives (ishāl), are often used hand in hand as supportive or adjunct therapies to surgery as well.

Pneumatology, Wellness, and the "Infallible Remedy"

Hakīms were often part of guilds, craft orders, or philosophical schools of thought that were supported by influential political or religious leaders of their time. Also, these guilds were mostly attached to one of the many mystical brotherhoods of Islam, known as Sufi Tarīqahs (which were spiritually or esoterically oriented "Paths" or "Initiatic Orders" leading to God, realization, and enlightenment for the aspirant).[43]

A hakīm (male doctor) or hakīma (female doctor) was usually invested in practicing more than just his or her medical science but also turning his or her mind, soul, heart, and spirit toward heaven in pursuit of the perfection of the virtues. The very word *hakīm* has as its etymological basis the linguistic root reference in Arabic to someone's attainment of spiritual *hikmah* (wisdom, sagacity, or saintliness) through the practice of the virtues. These virtues are such things as beauty of character; wisdom; respect and compassion for all of creation; charity through self-sacrifice and altruism; and most important of all, constant "remembrance" (dhikr) of God as Divine All-Possibility.

In this light, there is a natural concern and goal on the part of the hakīm for improving the lot of patients in regard to their mental and emotional well-being, not just caring and tending to the health of the physical body.

Unani medicine doctors have always known that wellness is a state of wholeness, a wholeness that cannot be learned through an academic investigation of health and disease. True wellness is a state of total satisfaction and contentment, a state of understanding that everything is as it should be (otherwise, metaphysically speaking, God would not be God, and we would not be we).

Hakīms teach that wellness can be approached through various life lessons, experiential methods, and psychospiritual disciplines. Lao Tzu explained that "at the center of your being you have the answer; you know who you are, and you know what you want."[42] The hakīm will often prescribe a variety of treatments with guidance ("huda")—when tending to the soul of a person—by precipitating in the patient a profound desire to be a more "balanced, emotionally stable, and successful individual who is able to make better decisions and realize better achievements in life."[26] This is accomplished through the practice of pneumatology (traditional psychospiritual counseling and healing), which includes some of the following subjects:

Prayers (personal, supplicatory, or intercessory)[44]

Meditation (fikr), with breath and sacred sound[45]

Contemplation or intellection (tasawwur bil ʿaql)[46]

Dhikr (remembrance through repetition of a sacred formula or Divine Name): This would be very similar to the "Jesus Prayer" or the "Ave Maria" within Orthodox and Western Christianity, as well as the tradition of Japa Yoga within Hinduism.

Recitation of holy scripture: "The Qur'an in its totality, and certain sections and verses in particular, is curative of serious conditions not amenable to other forms of treatment. The methods of using the Qur'an are many: Taʿwīdh ("seeking refuge from harm or evil" with God), Daʿwah ["supplication for help from God"], and Ruqya [reciting sacred verse to a sick person]."[25]

Solitude in nature: We should remember the contemporary resurgence of the direct healing power of nature in the movement of eco-psychology and all that it has to offer.

Visualization[47]

Music therapy: "In addition to baths, drugs, kind and benevolent treatment given to the mentally ill, music therapy and occupational therapy were also employed. These therapies were highly developed. Special choirs and live music bands played daily to entertain the patients by singing, music, and other light-hearted performances."[26]

Forgiveness for self and others[48]

Elimination of unhealthy and disturbed attitudes, thoughts, and behaviors, such as "arrogance, pride, self-deception, lack of concentration, giddiness, frivolousness, irreverence, degrading others, forgetfulness, fear of failure, hypocrisy, excessive emotionality, severe anger, and being inconsiderate."[45,49]

Philosophical counseling[50,51]

Making pilgrimages to local and international holy sites or cities such as Jerusalem, the Kaʿba, Benares, Angkor Wat, the shrine of our Lady of Guadalupe, Lourdes, Mt. Shasta, Mt. Fuji, and so forth[52]

The "Infallible Remedy"

The "Infallible Remedy" is the recitation, in the original sacred Arabic language, of the first chapter of the Noble Qur'ān 41 times for 40 days during the interval between the obligatory canonical dawn prayer and the optional prayer immediately after it. "The Prophet said: 'In Sūrat al-Fātihah there is a balm for all ailments.' He went on to provide the specific instructions for utilizing this most treasured remedy… The accumulated experience of the Sufis confirms that the reading and reciting of Sūrat al-Fātihah with true faith and sincere conviction, cures all maladies, whether spiritual or worldly, external or internal… The Companions [of the Prophet] used to read it for treatment of diseases, both physical and mental."[45] If, for whatever reason, one cannot accomplish this level of intensity or precision in the recitation of the opening chapter of the Holy Qur'ān as methodically instituted and practiced by the Prophet of Islam himself, then "simply recite 11 times: Bismi Llāh ir-Rahmān ir-Rahīm ['In the Name of God, the Most Merciful, the Most Compassionate.']."[45]

The opening chapter of the Qur'an is in Arabic, translated and transliterated. This allows those who do not read Arabic to simply pronounce the words and phrases and thus benefit from the sacred sonorous quality of the recitation as it surrounds and penetrates the human body and its immediate environment with theurgic energy and influence from Above (Fig. 49.13).

Clinical Quick Notes

This section discusses a few condition-specific protocols that are true examples of the diagnostic and therapeutic paradigms of Unani medicine. These cases and the pursuant tables illustrate the clinical mind-set and logic of a hakīm or hakīma in the traditional mode of prescriptive authority.[20,45]

Fig. 49.13 The opening chapter of the Holy Qur'an: Arabic–English translation and transliteration. **1:1 Bismillāhi r-raḥmāni r-raḥīm** In the name of Allah, the Most Gracious, the Ever Merciful. **1:2 Al ḥamdu lillāhi rabbi l-ʿālamīn** All praises to Allah, Lord/Cherisher/Sustainer of the Universe. **1:3 Ar raḥmāni r-raḥīm** The Most Gracious, the Most Merciful. **1:4 Māliki yawmi d-dīn** Sovereign of the Day of Judgment. **1:5 Iyyāka naʿbudu wa iyyāka nastaʿīn** You alone we worship, and You alone we ask for help. **1:6 Ihdinā ṣ-ṣirāṭ al-mustaqīm** Guide us to the true path; **1:7 Ṣirāṭ al-laḍhīna anʿamta ʿalayhim ġhayril maġhḍūbi ʿalayhim walāḍ ḍāllīn** The path of those upon whom You have bestowed your favor, not of those who have earned Your anger, nor of those who go astray. (volkankovancisoy/iStock.com.)

BOX 49.1 The "Opening Chapter" of the Holy Qur'an Written in Arabic

1:1
Bismillāhi r-raḥmāni r-raḥīm
In the Name of Allah, the Most Merciful, the Most Compassionate
1:2
Al ḥamdu lillāhi rabbi l-ʿālamīn
Praise Be to Allah, Lord of All Worlds
1:3
Ar raḥmāni r-raḥīm
The Most Merciful, the Most Compassionate
1:4
Māliki yawmi d-dīn
King of the Day of Judgment
1:5
Iyyāka naʿbudu wa iyyāka nastaʿīn
Thee Alone Do We Worship, and in Thee Alone Do We Trust
1:6
Ihdinā ṣ-ṣirāṭ al-mustaqīm
Guide us to the straight path;
1:7
Ṣirāṭ al-laḍīna anʿamta ʿalayhim ġayril maġḍūbi ʿalayhim walāḍ ḍāllīn
The path of those upon whom you have bestowed your favor, not of those who have earned your
anger, nor of those who go astray.

Bismi 'Llāh Al-Rahmān Al-Rahīm
Translation: "In the Name of God, the Most Merciful, the Most Compassionate." This statement, recognizing the sacred and all-embracing nature of the Divine, traditionally begins any and all literature in the Islamic world. It is an affirmation of the long-held spiritual doctrine that the Divine is everywhere and always present.

Lethargy (Chronic Fatigue)

"Its cause is the prevalence of moisture in the brain, brought on either by phlegm or by blood. Use an enema. Make the person smell vinegar and feed him only light, easily digested foods."[20]

Melancholy (Sadness, Low Mood, or Depression)

"It is caused by an imbalance of the phlegm humor. Use an enema at waking and at bedtime. Eat only soft foods. Sexual intercourse has a remarkable effect in removing melancholy."[20]

Tinnitus (Ringing in the Ears)

"Detoxification of the system should be accomplished first, along with relaxation techniques. However, it has been determined that those who suffer from a constant ringing in the ears continue to 'hear' the sound even if the auditory nerve is severed."[20]

Nosebleed

"A nosebleed can be controlled by cupping the back of the head. If blood is coming out of the right nostril only, also apply cupping to the area of the liver. Apply cupping over the spleen if there is blood coming out of the left nostril only."[20]

Asthma

"If the cause is phlegm, then the remedy is to first eliminate all foods that produce mucus, such as milk, eggs, cheese, fruits, and all sugars of any kind. Syrup of hyssop with warm water three times a day is recommended after a bout with asthma. Rub the chest with linseed oil and beeswax … If the cause of the asthma is too much internal heat affecting the lungs, then the remedy pursued should be with cold drinks and a cucumber pomade on the chest… Gargling with milk and cinnamon with honey added is also recommended."[20]

Coughing

Black Bile. A blackish or dark greenish substance comes out when coughing. Give boiled wheat bran with sugar or honey.

Cough Powder. "This remedy relieves general irritation of the throat and lungs. Use 1/8th teaspoon (in all) of each of the following; skunk cabbage, horehound, African cayenne, bayberry bark, valerian root, and gentian; mix with three ounces molasses, and take 1 teaspoon with hot tea."[20]

Unani Medicinal Herbs Used to Treat Diabetes

Plant species and preparations of Unani medicinal herbs used to treat diabetes, as well as additional uses, are listed in Table 49.4.

Unani Medicinal Herbs Used to Treat Skin Diseases

Plant species and preparations of Unani medicinal herbs used to treat skin diseases, as well as additional uses, are listed in Table 49.5.

SUMMARY

The hakīms of ancient times were persons of tremendous insight and wisdom, both in theory and in practice; inheritors of ancient Greek knowledge; and players on the stage of world history who ultimately allowed for the birth of many aspects of modern medicine. A very brief

TABLE 49.4 Unani Medicinal Herbs Used to Treat Diabetes

Plant Species	Preparation	Additional Uses
Astragalus macrocarpus DC	Leaf decoction	Heart disease
Ceratonia siliqua L.	Leaf decoction	Herpes and lip sores
Cichorium pumilum Jacq.	Foliage decoction	Bacterial infection, poisoning, and rheumatism
Cupressus sempervirens L.	Fruit decoction	Antiseptic and nervous system
Eryngium creticum Lam.	Foliage decoction	Liver diseases, poisoning, anemia, and infertility problems
Juglans regia L.	Leaf and flower decoction	Asthma and sexual weakness
Lupinus varius Gaertn	Soaked seeds	Kidney stones
Mercurialis annua L.	Leaf decoction	Cancer and skin diseases
Morus nigra L.	Leaf, stem, and fruit decoction	Teeth or gum inflammation and cholesterol
Paronychia argentea Lam.	Leaf and flower decoction	Stones in kidney and heart diseases
Pinus halepensis Mill.	Leaf and seed decoction	Sexual weakness
Prosopis farcta Sol. Ex Russell	Foliage decoction	Menstrual cramps and kidney stones
Quercus calliprinos Decne	Fruit and bark decoction	Cancer, bed wetting, and ulcer
Salvia fruticosa Mill.	Foliage infusion	Stomachache, intestinal gas, and inflammation
Sarcopoterium spinosum L.	Leaf, seed, and root decoction	Intestinal pain, kidney diseases, and ulcer
Smilax aspera L.	Fruit and root decoction	Poisoning
Teucrium polium L.	Foliage decoction	Kidney stones, liver diseases, and stomach and intestinal inflammation
Trigonella foenum-graecum L.	Seed decoction	Sexual weakness and stomach and intestinal pain

Data from Azaizeh H, Saad B, Khalil K, Said O. The state of the art of traditional Arab herbal medicine in the eastern region of the Mediterranean: a review. *Evid Based Complement Alternat Med*. 2006;3:229–235.

TABLE 49.5 Unani Medicinal Herbs Used to Treat Skin Diseases

Plant Species	Preparation	Additional Uses
Alcea setosa Boiss.	Leaf, flower, and root decoction	Stomach and intestinal pain, inflammation, and asthma
Ammi visnaga L.	Flower and seed decoction	Kidney inflammation and respiratory system (asthma)
Asphodelus microcarpus Salzm. and Viv.	Bulb and root juice	Ectoderm parasites and jaundice
Cyclamen persicum Mill.	Leaf and bulb decoction	Ear infections
Eruca sativa Miller	Seed oil	Sexual weakness and hair loss
Ficus sycomorus L.	Stem milky sap	Coughing, digestive system, and anemia
Glaucium corniculatum L.	Poultice of macerated roots	Cholesterol and acne
Inula viscosa L. Ait. Inula	Foliage macerated in oil	Muscle relaxation and infertility
Lavandula officinalis Chaix and Kitt	Leaf, flower, and seed infusion	Urinary system, asthma, and nerve system
Lycium europaeum L.	Root decoction	High blood pressure and diabetes
Malva nicaeensis All.	Whole-plant decoction	Coughing and wounds
Myrtus communis L.	Leaf infusion	Stomach or intestinal pain and inflammation
Paronychia harmala L.	Seed infusion in olive oil	Wounds and lice
Sanguisorba minor Scop.	Whole-plant decoction	Ulcer, burns, and wounds
Saponaria mesogitana Boiss.	Root decoction	Liver diseases, stones in kidneys, and joint inflammation
Scolymus maculatus L.	Stem decoction	Intestine and kidney inflammation
Solanum nigrum L.	Foliage decoction	Wounds and sunburn
Tamarix aphylla L. H. Karst.	Leaf decoction	Eye inflammation and fever
Thymelaea hirsuta L. Endl.	Foliage paste	Couching and respiratory system
Viola odorata L.	Foliage decoction	Respiratory system, stomach and intestinal inflammation

Data from Azaizeh H, Saad B, Khalil K, Said O. The state of the art of traditional Arab herbal medicine in the eastern region of the Mediterranean: a review. *Evid Based Complement Alternat Med*. 2006;3:229-235.

and pointed summary follows as an example of what is meant, in the best sense of the phrase, by the statement that "knowledge is power."

- Avicenna was the first to describe meningitis so accurately, and in such detail, that the description has scarcely been added to after 1000 years.
- Avicenna was the first to describe intubation (a surgical procedure to facilitate breathing that Western physicians began using only at the end of the 18th century).
- The use of plaster of Paris for fractures by the Arabs was standard practice; it was "rediscovered" in the West in 1852.
- Surgery was used by the Arabs to correct cataracts.
- Ibn Al Nafis discovered pulmonary circulation.
- A strict system of licensing for medical practitioners was introduced in Baghdad in 931 AD, which included taking the Hippocratic Oath and specific periods of training for doctors.

- There was a system for the inspection of drugs and pharmaceuticals—the equivalent of the U.S. Food and Drug Administration—in Baghdad 1000 years ago.
- The European system of medicine was based on the Arabic system, and even as recently as the early 19th century, students at the Sorbonne had to read the *Canon of Avicenna* as a condition for graduating.
- Unani-Tibbi hospitals were, from the beginning, free to all without discrimination on the basis of religion, sex, ethnicity, or social status.
- Unani-Tibbi hospitals allocated different wards for each classification of disease.
- Hospitals had unlimited water supplies and bathing facilities.
- Before the advent of the printing press, there were extensive handwritten libraries in Baghdad (80,000 volumes), Cordova (600,000 volumes), Cairo (2 million volumes), and Tripoli (3 million volumes).
- All Unani-Tibbi hospitals kept patient records.
- A hospital was established for lepers. As many as six centuries later in Europe, they were still burning lepers to death by royal decree.
- In 830 AD, nurses were brought from Sudan to work in the Qayrawan hospital in Tunisia.
- A system of fountain-cooled air was devised for the comfort of patients with fever.
- Avicenna described the contamination of the body by "foreign bodies" before infection, and Ibn Khatima also described how "minute bodies" entered the body and caused disease—well in advance of Pasteur's discovery of microbes.
- Al Razi was the first to describe smallpox and measles. He was accurate to such a degree that nothing has been added since then.
- Avicenna described tuberculosis as being a communicable disease.
- Avicenna devised the concept of anesthetics. The Arabs developed a "soporific sponge" (impregnated with aromatics and narcotics and held under the patient's nose), which preceded modern anesthesia.
- The Arab surgeon Al Zahrawi was the first to describe hemophilia.
- Al Zahrawi was also the first surgeon in history to use cotton, which is an Arabic word, as a surgical dressing for the control of hemorrhage.
- Avicenna accurately described the surgical treatment of cancer, saying that the excision had to be radical and remove all diseased tissue, including amputation and the removal of veins running in the direction of the tumor. He also recommended cautery of the area if needed.
- Avicenna, Al Razi, and others formed a medical association for the purpose of holding conferences so that the latest developments and advancements in the field of medicine could be debated and passed on to others.[53]

So it seems ironic that "what began as an advanced medical system that set world standards has now come to be regarded as a system of folk medicine. This decline coincided with the decline of the Islamic Empire and the dissolution of the Caliphate, as these were directly responsible for the direction and impetus of Islamic scientific scholars in all fields."[41]

The decline of this ancient system of medicine also proves, if proof be needed, that "the achievements of the Unani-Tibbi practitioners of today bear little resemblance to those of their illustrious predecessors, and some of those claiming to practice traditional medicine are woefully ill-equipped"[41] to do so. Most individuals passing themselves off as Unani practitioners today would be labeled by most knowledgeable persons as folk healers or country herbalists, but not hakīms of the Avicennan type.

Today, it is in the Indo-Pakistani subcontinent or, more generally speaking, the sub-Himalayan regions of the Orient, that Unani medicine continues to thrive as a living school of medicine, competing with three other systems of health care: Ayurveda, traditional Chinese medicine, and modern Western medicine. Although current, modern "Western antipathies to things-Arabic and Muslim"[54,55] seem to have stalled the advance of Unani medicine into the stadium of complementary and alternative therapies in the West, it is slowly and gradually gaining ground as an optional healthcare system for many patients.

In India, the government has set up a Central Council for Research in Unani Medicine, which also has a licensing system for traditional practitioners.[41] India has 18 colleges of Unani medicine, about 100 Unani hospitals, and nearly 1400 beds for inpatients. In addition, there are nearly 900 dispensaries of Unani medicines and about 30,000 registered practitioners. In India alone, the number of persons serviced by Unani medicine is estimated to be at least 23 million from more than 220 villages.[56] Unfortunately, the details of the overall medical situation in Pakistan and other countries are not as well known or are simply not available.[57]

One commentator wrote, "Since both Ayurveda and Greek Medicine are constitutionally based, it's not surprising that improving basic constitutional strength, resilience and resistance to disease should be a very important therapeutic objective in both systems. The methods and modalities employed are also quite similar: diet is first and foremost, followed by simple herbal remedies, lifestyle modification, massage and bodywork, hygienic purification treatments and exercise/gymnastics/yoga. Being humor-based, both systems consider self-poisoning, or auto-intoxication with toxic metabolic residues and superfluous morbid humors to be the primary cause of all disease and pathology, for which they prescribe various hygienic purification treatments and regimes. The Ayurvedic word for toxins, "ama" means, "crude" or "raw"—residues from faulty or incomplete pepsis that haven't been properly integrated into the body and its functioning, and therefore impede it. The word ama has its equivalent in the word 'crudities,' a common term for toxins in Greek Medicine."[58]

In the humble opinion of this author, there is no better time than the present for discovering the beauty, mystery, and power of Unani medicine. This gift from the East—along with Ayurveda and traditional Chinese medicine—will reveal itself to serious seekers as a very real healthcare option offering natural, safe, and effective approaches to healing.

16. The word *intellect* here is used in its original sense—not as a "fallen word" cut off from its true etymologic source as perceived by many of us in the modern world, but as a word signifying the knowing faculty within the human being that knows immediately and without recourse to analytic or discursive thought, a faculty that is constantly in touch with God. It is precisely this faculty of intellectual intuition that the profound mystic of the German Rhine, Meister Eckhart, described as being the "divine spark" within the human heart that is the seat of all true knowledge and wisdom.
17. There is a famous Qur'ānic verse (41:53) that addresses this claim, wherein the "signs" of God's authorship of creation are known most evidently as *fi 'l-āfāq wa fī anfusihim* ("upon the horizon [of creation] and within their [human] souls").

49. Sometimes physiologic fever is coincident with such disturbances, but according to the Prophet Muhammad (peace be upon him) this type of fever "constitutes a deep spiritual cleansing causing 'the sins to fall off like leaves being shed from a tree.' These fevers burn off impurities on the soul level."
50. "In ancient and pre-modern times, people saw the practical value of philosophy as a guide for living. . . But then, in the early 1980's, German philosopher Gerd Achenbach decided to revive the old and time-honored practice and offered his services as a philosophical counselor for those seeking to solve their problems philosophically. In 1982, Achenbach founded the Society for Philosophical Praxis to establish philosophical counseling as a profession. Praxis is a Greek word meaning the practical application of a branch of learning—in this case philosophy—to solve life's problems. In classical Greek astrology and counseling, Praxis also refers to one's career, life path, or calling. Helping clients find their career or life path is a specialty of philosophical counseling." SECTION IV

Pharmacology of Natural Medicines

Careful review of the scientific literature reveals a considerable amount of research documenting the clinical efficacy, pharmacological activity, and toxicology of numerous "natural" medicines. An important purpose of this section is the critical evaluation, from a scientific standpoint, of the historical and clinical use of natural medicines, especially botanicals. Although plants have been used as medicines since antiquity, appreciation of them as effective medicinal agents was greatly diminished until the later part of the 20th century. It is hoped that this section will further revive the appreciation for and the safe and effective use of botanical medicines.

Some plant constituents are discussed as separate entities, and for several botanicals, these constituents may be the most appropriate therapeutic substances. However, we believe that the whole herb should be used whenever possible. Many studies have demonstrated that, in many instances, the physiological and pharmacological effects of a particular plant constituent are diminished when it is given as an isolated component rather than in its naturally occurring environment. Furthermore, besides synergistic and enhancing effects, there appear to be factors in most plants that prevent many of the adverse effects of isolated plant constituents. In understanding the pharmacology, pharmacognosy, and historical use of plants, the student of natural medicine is once again inspired by the miracle of nature as well as the intuition and empiricism that ancient herbalists possessed.

We hope that this section will help better inform our readers of the impressive uses, and potential dangers, of these natural medicines. We also want to stress that botanical medicine should not be used simply as a substitute for the drugs commonly used to treat disease. The true physician of natural medicine will use them as part of the treatment of the whole person and in the context of addressing the causes of the disease and promoting health, not simply treating symptoms.

Finally, considering the unfortunate, continuing trend of forever-increasing use of prescription drugs—and in too many instances polypharmacy with unpredictable results (especially in the elderly)—the astute physician of natural medicines needs to be expert in the potential for interaction between natural and conventional medicines. These interactions can take many forms, such as enhancing or inhibiting: a drug's rate of absorption, the intended pharmaceutical effects, the rate of detoxification, and so forth. Far more research is now available on drug–herb–nutrient interactions than when the first edition came out in 1985. Almost every natural medicine covered in this textbook now has a robust drug interactions subsection.

Glossary of Some Terms Used in Section IV

Abortifacient: a substance that induces abortion.

Acrid: a pungent, biting taste that causes irritation.

Adaptogen: a substance that is safe, increases resistance to stress, and has a balancing effect on body functions.

Adjuvant: a substance that enhances the effect of the medicinal agent or increases the antigenicity of a cancer cell.

Alkaloids: naturally occurring amines arising from heterocyclic and often complex structures that display pharmacological activity. Their common names typically end in *-ine*. They are usually classified according to the chemical structure of their main structures: phenylalkylamines (e.g., ephedrine), pyridine (e.g., nicotine), tropine (e.g., atropine, cocaine), quinoline (e.g., quinine), isoquinoline (e.g., papaverine), phenanthrene (e.g., morphine), purine (e.g., caffeine), imidazole (e.g., pilocarpine), and indole (e.g., physostigmine, yohimbine).

Alterative: a substance that has a balancing effect on a particular body function.

Analgesic: a substance that reduces the sensation of pain.

Androgens: hormones that stimulate male characteristics.

Anthelminthic: a substance that causes the elimination of intestinal worms.

Anthocyanidin: a particular class of flavonoids that gives plants, fruits, and flowers colors ranging from red to blue.

Antidote: a substance that neutralizes or counteracts the effects of a poison.

Aphrodisiac: a substance that increases sexual desire.

Astringent: an agent that causes the contraction of tissue.

Balm: a soothing or healing medicine applied to the skin.

Carminative: a substance that promotes the elimination of intestinal gas.

Carotenes: fat-soluble plant pigments, some of which can be converted into vitamin A.

Cathartic: a substance that stimulates the movement of the bowels; more powerful than a laxative.

Cholagogue: a compound that stimulates the contraction of the gallbladder.

Choleretic: a compound that promotes the flow of bile.

Cholestasis: the stagnation of bile within the liver.

Cholinergic: mimic the action of acetylcholine affecting the parasympathetic portion of the autonomic nervous system and the release of acetylcholine.

Coenzyme: a necessary nonprotein component of an enzyme, usually a vitamin or mineral.

Compress: a pad of linen applied under pressure to an area of skin and held in place; may include an herbal extract.

Decoctions: aqueous extracts prepared by boiling the botanical material with water for a specified period, followed by straining or filtering.

Demulcent: a substance soothing to irritated mucous membranes.

Emulsify: to disperse large fat globules into smaller uniformly distributed particles that can remain in suspension in water.

Enteric coated: a way of coating a tablet or capsule to ensure that it does not dissolve in the stomach so it can reach the intestinal tract.

Enzyme: an organic catalyst that facilitates chemical reactions.

Essential oils: also known as volatile oils, ethereal oils, or essences. They are usually complex mixtures of a wide variety of organic compounds (e.g., alcohols, ketones, phenols, acids, ethers, esters, aldehydes, oxides) that evaporate when exposed to air. They generally represent the odoriferous principles of plants.

Extracts: concentrated forms of natural products obtained by treating crude materials containing these substances with a solvent and then removing the solvent completely or partially from the preparation. The most commonly used extracts are fluid extracts, solid extracts, powdered extracts, tinctures, and native extracts.

Flavonoid: a generic term for a group of flavone-containing compounds that are found widely in nature. They include many of the compounds that account for plant pigments (anthocyanins, anthoxanthins, apigenins, flavones, flavonols, bioflavonols, etc.). These plant pigments exert a wide variety of physiological effects in the human body.

Fluid extracts: these extracts are typically hydroalcoholic solutions with a strength of one part solvent to one part herb. The alcohol content varies with each product. They are, in essence, concentrated tinctures, constructed to represent 1 grain of the crude drug to 1 minim of fluid extract.

Glycosides: sugar-containing compounds composed of a glycone (sugar component) and an aglycone (non–sugar-containing component) that can be cleaved through hydrolysis. The glycone portion may be glucose, rhamnose, xylose, fructose, arabinose, or any other sugar. The aglycone portion can be any kind of organic compound (e.g., sterols, triterpenes, anthraquinones, hydroquinones, tannins, carotenoids, anthocyanidins).

Infusion: tea produced by steeping a botanical in hot water.

Laxative: a substance that promotes the evacuation of the bowels.

LD_{50}: the dosage that will kill 50% of the animals taking the substance.

Lipotropic: promoting the flow of lipids to and from the liver.

Menstruum: solvents used for extraction (e.g., water, alcohol, acetone).

Metalloenzyme: an enzyme that contains a metal linked to its protein structure.

Native extracts: high-potency extracts prepared via concentration under reduced pressure at low temperatures until all solvent is removed.

Oleoresins: primarily mixtures of resins and volatile oils. They either occur naturally or are made by extracting the oily and resinous materials from botanicals with organic solvents (e.g., hexane, acetone, ether, alcohol). The solvent is then removed under vacuum, leaving behind a viscous, semisolid extract that is the oleoresin. Examples of prepared oleoresins are paprika, ginger, and capsicum.

Powdered extract: a solid extract that has been dried to a powder.

Putrefaction: the process of breaking down protein compounds by decay or rotting.

Recommended dietary allowance (RDA): the estimated amount of a nutrient considered to support health.

Resins: complex oxidative products of terpenes that occur naturally as plant exudates or are prepared by alcohol extraction of botanicals that contain resinous principles.

Saponins: nonnitrogenous glycosides, typically with sterol or a triterpene as the aglycone, that possess the common property of foaming, or making suds, when strongly agitated in aqueous solution.

Solid extracts: thin to thick, viscous liquids or semisolids prepared from native extracts by adjusting the latter to the specific strength with suitable diluents. Typically, these extracts are 4:1, that is, one part extract is equivalent to, or derived from, four parts of crude herb.

Standardized extracts: an herbal extract standardized to a defined concentration of a specific compound, usually the one considered most clinically active.

Strength: the potency of an extract or the strength of a botanical extract, which is generally expressed in two ways. If they contain known active principles, their strength is commonly expressed in terms of their content of active principles. Otherwise, their strength is expressed in terms of their concentration of the crude drug. Thus a strength of 4:1 means one part of extract is equivalent to, or derived from, four parts of crude drug. A strength of 1:5 represents one part of extract comparable to 0.2 parts of the crude drug. This ratio method of expressing drug strength does not accurately measure potency because there may be wide variation between manufacturers.

Tinctures: alcoholic or hydroalcoholic solutions usually containing the active principles of botanicals in low concentrations. They are usually prepared by maceration or percolation or by dilution of their corresponding fluid or native extracts. The strengths of tinctures are typically 1:10 or 1:5. Alcohol content varies.

Tonic: a substance that exerts a gentle strengthening effect on the body.

50

Allium cepa (Onion)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

Allium cepa (family: *Amaryllidaceous* or *Liliaceous*)
Common name: onion

GENERAL DESCRIPTION

Numerous forms and varieties of onion exist because this perennial or biennial herb is cultivated worldwide. The part used is the fleshy bulb. Common varieties include white globe, yellow globe, and red globe (Fig. 50.1A and B).

Onions range in size, color, and taste depending on their variety. The two general types of large, globe-shaped onions are classified as either spring/summer or storage onions. The former class includes those grown in warm weather climates and mild or sweet in flavor. Included in this group are the Walla Walla, Vidalia, and Maui Sweet onion. Storage onions are grown in colder weather climates and, after harvesting, are dried for several months to attain dry, crisp skins. Storage onions generally have a more pungent flavor and are usually named by their color: white, yellow, or red. Spanish onions fall into this classification. In addition to these large onions, there are smaller varieties, such as the pearl onion.

CHEMICAL COMPOSITION

Onions, like garlic, contain various organic sulfur compounds:

- S-methylcysteine sulfoxide
- Trans-S-(1-propenyl) cysteine sulfoxide
- S-propylcysteine sulfoxide
- Dipropyl disulfide

Onions also contain the enzyme alliinase, which is released when the onion is cut or crushed, causing conversion of trans-S-(1-propenyl) cysteine sulfoxide to the so-called lacrimatory factor (propanethial S-oxide). Other constituents include the following:

- Flavonoids (primarily quercetin)
- Phenolic acids (e.g., caffeic, sinapic, and p-coumaric)
- Sterols
- Saponins
- Pectin
- Volatile oils

HISTORY AND FOLK USE

Although not as valued as a medicinal agent compared with garlic, onion has been used almost as widely. Like garlic *(Allium sativum),* onion has been used as an antispasmodic, carminative, diuretic, expectorant, stomachic, anthelmintic, and anti-infective agent. Externally, it has been used as a rubefacient and poultice, giving relief for skin diseases and insect bites.[1]

A. cepa originated in the central part of Asia, from Iran to Pakistan, and northward into the southern part of Russia. Onions have been revered throughout time not only for their culinary use but also for their therapeutic properties. As early as the 6th century, onions were used as medicine in India. They were popular with the ancient Greeks and Romans and were often dressed with extra seasonings because many people did not find them spicy enough. It was their pungency that made onions popular among poor people throughout the world. Onions were an indispensable vegetable in the cuisines of many European countries during the Middle Ages and later even served as a classic healthy breakfast food. Christopher Columbus brought onions to the West Indies, and their cultivation spread throughout the Western hemisphere. China, India, the United States, Russia, and Spain are among the leading producers of onions.

World onion production has increased dramatically, with current production around 44 million tons per year, making onions the second most important horticultural crop after tomatoes. Because of their storage characteristics and durability for shipping, onions have always been traded more widely than most vegetables. Onions are versatile, often used in many dishes, and accepted by almost all traditions and cultures.[2]

Fig. 50.1 (A) *Allium cepa* bulb. (B) *A. cepa* onion (Yarnell). (A, from coldsnowstorm/iStock.com.)

PHARMACOLOGY

Onions and garlic, due to their similar constituents, have many of the same pharmacological effects. However, significant differences make one more advantageous than the other in certain conditions.

One of the key nutritional qualities of onions is their high content of quercetin. To determine uptake as well as in vivo antioxidant effects of quercetin from onions, six healthy, nonobese, normocholesterolemic female volunteers participated in a randomized two-phase crossover supplementation trial to compare the antioxidant effects associated with (1) a meal of fried onions, and (2) a meal of fried onions and fresh cherry tomatoes.[3] Plasma flavonoids, lymphocyte DNA damage, plasma ascorbic acid, tocopherols and carotenoids, urinary malondialdehyde, and 8-hydroxy-2-deoxyguanosine were determined to assess flavonoid absorption and antioxidant efficacy. The results indicated that the flavonoid glucosides (quercetin-3-glucoside and isorhamnetin-4-glucoside) were significantly elevated in plasma after ingestion of the onion-only meal, and the increases were associated with increased resistance of lymphocyte DNA to DNA strand breakage. A significant decrease in the level of urinary 8-hydroxy-2-deoxyguanosine was evident 4 hours after ingestion of the onion meal. After the combined tomato and onion meal, only quercetin was detected in plasma. Endogenous base oxidation was decreased, but resistance to strand breakage was unchanged. No significant change in the excretion of urinary malondialdehyde occurred after either meal. The conclusions from the study were that both meals—onions and onions with tomatoes—led to transient decreases in biomarkers of oxidative stress, although the biomarkers affected differed. It is possible that the differences in patterns of response reflect the different uptakes of flavonoids, but the underlying mechanism is not yet understood. Onion has a combination of fructans, dietary flavonoids, and organosulphur compounds with functional benefits against diseases. Some of these benefits are a reduction of blood fibrinogen concentration, the enhancement of blood's fibrinolytic activity, antioxidant activity, lipid peroxidation inhibition, a reduction of serum cholesterol, a reduction of respiratory and skin infections, and a decreased risk of diabetes.[4]

Antimicrobial Activity

Although onions exhibit antibacterial, antifungal, and anthelmintic activity, it is not nearly as potent as that of garlic. This suggests that garlic may be better indicated in cases of infection,[5] but onion can usually be consumed in larger quantities than garlic, which may increase the concentration of antimicrobial constituents in vivo to approximate those of garlic.

Cardiovascular Effects

Like garlic, onions and onion extracts were shown to decrease blood lipid levels, increase fibrinolysis, decrease platelet aggregation, and lower blood pressure in several clinical studies.[6,7] Onion oil, compared with garlic oil, was a stronger inhibitor of the enzymes cyclooxygenase and lipoxygenase, which mediate eicosanoid metabolism (prostaglandins, thromboxanes, and leukotrienes).[8] This suggests that onions would also have a greater effect on inhibition of platelet aggregation and other events mediated by eicosanoids. In addition, extracts of onion have been shown to inhibit platelet aggregation via inhibition of diphosphate, epinephrine, arachidonic acid, adenosine, and collagen-induced platelet aggregation and inhibiting the action of platelet-activating factor.[9] Garlic and onion consumption was associated with lower levels of cholesterol and triglycerides, as well as an increase in fibrinolytic activity[10] (see Chapter 51 for details). Because the quantity of onion consumed in the study cited was so much larger than that of garlic (600 g of onion per week compared with 50 g of garlic), an argument could be made that onion consumption was the major determinant.

Onion consumption may also reduce the risk of cardiovascular disease due to its quercetin content. Epidemiological data suggest that those who consume a diet rich in quercetin-containing foods might have a reduced risk of cardiovascular disease. In a double-blind, randomized, cross-over study, subjects ingested an onion soup containing either a high or a low amount of quercetin. Plasma quercetin concentrations and platelet aggregation and signaling were assessed after soup ingestion. The high-quercetin soup contained 69 mg total quercetin compared with the low-quercetin soup containing 5 mg total quercetin. Plasma quercetin concentrations were significantly higher after

the ingestion of the high-quercetin soup than after the ingestion of the low-quercetin soup, and the high-quercetin soup also influenced some aspects of platelet aggregation and signaling.[11]

Diabetes

Onions were shown to have significant oral hypoglycemic action, comparable to that of the prescription oral hypoglycemic agents tolbutamide and phenformin.[12,13] The active hypoglycemic principle in onions is believed to be allyl propyl disulfide, although other constituents, such as quercetin and anthocyanidin, may play a significant role as well. Experimental and clinical evidence suggests that allyl propyl disulfide lowers glucose by competing with insulin (also a disulfide) for degradation sites, thereby increasing the half-life of insulin. Other mechanisms, such as increased hepatic metabolism of glucose or increased insulin secretion, have been proposed.

In one assessment of the hypoglycemic activity of onion consumption in patients with type 1 and type 2 diabetes, the ingestion of 100 g of onion caused a considerable reduction in fasting blood glucose levels by about 89 mg/dL in relation to insulin (145 mg/dL) in patients with type 1 diabetes, and it reduced fasting blood glucose levels by 40 mg/dL compared with glibenclamide (81 mg/dL) in patients with type 2 diabetes, as measured 4 hours later.[14] The same dose of onion produced a significant reduction in induced hyperglycemia (glucose tolerance test) by about 120 mg/dL compared with water (77 mg/dL) and insulin (153 mg/dL) in patients with type 1 diabetes, and it considerably reduced the glucose tolerance test by 159 mg/dL in relation to water (55 mg/dL) and glibenclamide (114 mg/dL) in patients with type 2 diabetes, as measured after 4 hours.

Antiasthmatic Action

Onions have historically been used as antiasthmatic agents. Their action in asthma, as well as in other conditions associated with increased lipoxygenase derivatives (leukotrienes), such as psoriasis and atopic dermatitis, appears to be greater than that of garlic. The net effect is similar to that of cortisol, which inhibits all eicosanoid metabolism via inhibition of phospholipase. Inhibition of leukotriene formation and onion's quercetin and isothiocyanate content are likely the primary factors responsible for onion's antiasthmatic effects. These effects have been confirmed in experimental studies.[15,16]

Antitumor Effects

Various forms of cancer are associated with an imbalance between the activities of two enzymes, histone acetyltransferase (HAT) and histone deacetylase (HDAC). Histone deacetylase inhibitors (HDACIs) regulate the activity of HDACs and are being used in cancer treatment. Onions have been reported to show potential HDAC-inhibitory activity, exhibiting antitumor effects through the activation of cell-cycle arrest, induction of apoptosis and autophagy, angiogenesis inhibition, and mitotic cell death in cancer cells.[17]

An onion extract was found to be cytotoxic to tumor cells in vitro and to arrest tumor growth when tumor cells were implanted in rats.[18] The onion extract was shown to be nontoxic, with a dose as high as 40 times that of the cytotoxic dose for the tumor cells causing no adverse effects on the host. Another species, *Allium ascalonicum* (shallots), was shown to exhibit significant antileukemic activity in mice.[19] In addition, sulfides found in onions were shown to be effective agents for controlling tumors in both in vitro and in vivo models, and the antitumor effects are likely caused by reversing the antitumor immune system.[20]

One human study evaluated onion consumption and stomach cancer in more than 120,000 men and women between 55 and 69 years of age.[21] After a 3.3-year follow-up, 139 stomach cancers were diagnosed. The researchers found a strong inverse association between onion consumption and stomach cancer incidence but no association with the use of leeks or garlic.

Hair Tonic Effects

Topical application of onions has been shown to help alopecia areata, a patchy and nonscarring hair-loss condition. Any hair-bearing surface may be involved in alopecia areata, and different modalities of treatment have been used to induce hair regrowth. One study compared the effectiveness of topical crude onion juice with tap water in the treatment of patchy alopecia areata.[22] The patients were divided into two groups. The group treated with onion juice consisted of 23 patients (16 males and 7 females) ranging in age from 5 to 42 years old (mean, 22.7 years), and the control group consisted of 15 patients (8 males and 7 females) ranging in age from 3 to 35 years old (mean, 18.3 years). The two groups were advised to apply the treatment twice daily for 2 months. Regrowth of terminal coarse hairs started after 2 weeks of treatment with crude onion juice. At 4 weeks, hair regrowth was seen in 17 patients (73.9%). At 6 weeks, hair regrowth was observed in a total of 20 patients (86.9%) and was significantly higher among males (93.7%) compared with females (71.4%). In contrast, with tap water, hair regrowth was apparent in only two patients at 8 weeks of treatment, with no sex differences. These results indicate that crude onion juice can be an effective topical therapy for patchy alopecia areata.

CLINICAL APPLICATION AND DOSAGE

This chapter highlights the medicinal value of onions, particularly in cardiovascular disease, diabetes mellitus, and inflammatory conditions. Onions can be eaten liberally as part of a nutritious diet. Therapeutic dosages in the various forms are typically equal to 50 to 150 g/day of raw onion.

TOXICOLOGY

Virtually no reports of toxicity have been documented. However, people with heartburn may note an aggravation of symptoms. One study evaluated symptoms of acid reflux in 16 normal subjects and 16 patients with heartburn.[23] Subjects were studied with an esophageal pH probe for 2 hours after eating a plain hamburger and a glass of ice water, and then on another day after an identical meal plus a slice of raw onion. In the patients without acid reflux, ingestion of onions did not increase any of the variables measured (number of reflux episodes, pH less than 4, time of pH less than 4, heartburn episodes, and belches). In contrast, subjects with heartburn experienced a significant increase in all variables. Although the authors of the study concluded that onions could be a potent and long-lasting reflexogenic agent in patients with heartburn, an alternative explanation might be that onions simply improved digestive acid secretion, making the symptoms of reflux more noticeable.

DRUG INTERACTIONS

There are no confirmed drug interactions with onion consumption. Theoretically, because onion consumption may improve blood sugar control, patients with type 2 diabetes taking oral hypoglycemic drugs need to monitor glucose levels because dosage levels of the medication might need to be adjusted.

Allium sativum (Garlic)

Michael T. Murray, ND, and John Nowicki, ND

OUTLINE

Allium sativum (family: *Amaryllidaceous* or *Liliaceous*)
Common names: garlic, allium

GENERAL DESCRIPTION

Garlic, a member of the lily family, is a perennial plant that is cultivated worldwide (Fig. 51.1). The garlic bulb is composed of individual cloves enclosed in a white skin. It is the bulb, either fresh or dehydrated, that is used as a spice or medicinal herb.

CHEMICAL COMPOSITION

Garlic contains 0.1% to 0.36% of a volatile oil composed of sulfur-containing compounds, including:

- Allicin
- Diallyl disulfide
- Diallyl trisulfide

Garlic oil is obtained by steamed distillation of the crushed fresh bulbs.[1] These volatile compounds are generally considered responsible for most of the pharmacological properties of garlic. Other constituents of garlic include the following[1,2]:

- Alliin (S-allyl-l-cysteine sulfoxide)
- S-methyl-l-cysteine sulfoxide
- Protein (16.8%, dry weight basis)
- High concentrations of trace minerals (particularly selenium)
- Vitamins
- Glucosinolates
- Enzymes (alliinase, peroxidase, and myrosinase)

Allicin is mainly responsible for garlic's pungent odor (Fig. 51.2). It is formed by the action of the enzyme alliinase on the compound alliin. The essential oil of garlic yields approximately 60% of its weight in allicin after exposure to alliinase. The enzyme is inactivated by heat, which accounts for the fact that cooked garlic produces neither as strong an odor as raw garlic nor nearly as powerful physiological effects.[1]

HISTORY AND FOLK USE

Garlic has been used throughout history for the treatment of a wide variety of conditions. Its usage predates written history. Sanskrit records document the use of garlic remedies approximately 5000 years ago, whereas the Chinese have been using it for at least 3000 years. *The Codex Ebers,* an Egyptian medical papyrus dating to about 1550 BC, mentions garlic as an effective remedy for various ailments, including hypertension, headache, bites, worms, and tumors. Hippocrates, Aristotle, and Pliny cited numerous therapeutic uses for garlic. In general, garlic has been used throughout the world to treat coughs, toothache, earache, dandruff, hypertension, atherosclerosis, hysteria, diarrhea, dysentery, diphtheria, vaginitis, and many other conditions.[1–3]

Stories, verse, and folklore (e.g., its alleged ability to ward off vampires) give historical documentation to garlic's power. Sir John Harrington, in writing *The Englishman's Doctor* in 1609, summarized garlic's virtues and faults[3]:

Garlic then have power to save from death

Bear with it though it maketh unsavory breath,

And scorn not garlic like some that think

It only maketh men wink and drink and stink.

In 1721, during a widespread plague in Marseilles, France, four condemned criminals were recruited to bury the dead. The gravediggers proved to be immune to the disease. Their secret was a concoction they drank consisting of macerated garlic in wine. This became known as vinaigre des quatre voleurs ("four thieves" vinegar), and it is still available in France today.

Garlic's antibiotic activity was noted by Pasteur in 1858. Garlic was used by Albert Schweitzer in Africa to treat amebic dysentery and as an antiseptic in the prevention of gangrene during World Wars I and II.

PHARMACOLOGY

Although garlic has a wide range of well-documented effects, its most important clinical uses are in the areas of infection, cancer prevention, and cardiovascular disease.

Antimicrobial Activity

Garlic has broad-spectrum antimicrobial activity against many genera of bacteria, viruses, worms, and fungi.[4–7] These findings support the historical use of garlic in the treatment of various infectious conditions.

Antibacterial Activity

Dating back to 1944, studies demonstrated that both garlic juice and allicin inhibit the growth of *Staphylococcus, Streptococcus, Bacillus, Brucella,* and *Vibrio* species at low concentrations.[7–9] In more recent studies, using serial dilution and filter paper disk techniques, fresh and vacuum-dried powdered garlic preparations were found to be effective antibiotic agents against many bacteria, as listed in Box 51.1.[4–7,10,11] In these studies, the antimicrobial effects of garlic were compared with commonly used antibiotics, including penicillin, streptomycin, chloramphenicol, erythromycin, and tetracyclines. Besides confirming garlic's well-known antibacterial effects, the studies demonstrated its efficacy in inhibiting the growth of bacteria that had become resistant to one or more of these antibiotics.[7]

Fig. 51.1 *Allium sativum.* (From https://www.istockphoto.com/photo/fresh-garlic-in-the-wicker-basket-gm474939904-64984191.)

Garlic administration has also been shown to significantly reduce the number of coliforms and anaerobes in the feces.[12] One clinical application of garlic's antibacterial activity may be in the treatment of *Helicobacter pylori.* A clinical investigation indicated that garlic intake for long durations (years) was associated with a significantly lower average antibody titer. This suggests an indirect inhibitory effect on the reproduction of *H. pylori* and possibly prevention of more serious peptic ulcer diseases.[13]

Antifungal Activity

Garlic demonstrated significant antifungal activity in many in vitro and in vivo studies.[4,14–19] From a clinical perspective, inhibition of *Candida albicans* has the most significance because both animal and in vitro studies showed garlic to be more potent than nystatin, gentian violet, and six other reputed antifungal agents.[4,15–17] Although allicin and the volatile oil fraction are clearly the most potent active anti-*Candida* components,[20,21] aqueous garlic extracts have been shown in vivo to be effective, even at a dilution of 1:100, against the common tinea corporis, capitis, and cruris fungal skin infections.[15]

One study compared the effects of garlic tablets (1500 mg/d × 7 days) and fluconazole (150 mg/d × 7 days) on *Candida* vaginitis in 100 married women (aged 18–44 years).[22] The results of microscopical evaluation and vaginal discharge culture showed significant differences before and after intervention in both groups, with the overall symptoms of the disease (i.e., redness of the vulva and vagina, discharge, pustulopapular lesions, and abnormal cervix) improving by about 60% in the garlic tablet group and 71.2% in the fluconazole group. In another study at a major Chinese hospital, garlic therapy alone was used effectively in the treatment of cryptococcal meningitis, one of the most serious fungal infections imaginable.[18]

Anthelmintic Effects

Garlic extracts have anthelmintic activity against common intestinal parasites, including *Ascaris lumbricoides* (roundworm) and hookworms.[12,23]

Garlic revisited: antimicrobial activity of allicin-containing garlic extracts against Burkholderia cepacian complex. *PLoS One.* 2014;9[12]:e112726.)

BOX 51.1 Clinically Relevant Microbes Inhibited by Garlic

- Bacteria
- Alpha- and β-hemolytic Streptococcus
- *Citrobacter* spp.
- *Escherichia coli*
- *Helicobacter pylori*
- *Klebsiella pneumoniae*
- Mycobacteria
- *Proteus vulgaris*
- *Salmonella enteritidis*
- *Staphylococcus aureus*
- Fungi
- *Candida albicans*
- *Cryptococcus neoformans*
- Helminths
- *Ascaris lumbricoides*
- Hookworms
- Viruses
- Herpes simplex types 1 and 2
- Human rhinovirus type 2
- Parainfluenza virus type 3
- Vaccinia virus
- Vesicular stomatitis virus

Antiviral Effects

Garlic's antiviral effects have been demonstrated by its protection of mice from infection with intranasally inoculated influenza virus and by its enhancement of neutralizing antibody production when given with influenza vaccine.[24]

The in vitro virus-killing effects of fresh garlic, allicin, and other sulfur components of garlic were determined against herpes simplex types 1 and 2, parainfluenza virus type 3, vaccinia virus, vesicular stomatitis virus, and human rhinovirus type 2. The order for virucidal activity was as follows: ajoene > allicin > allyl methyl thiosulfinate > methyl allyl thiosulfinate.

Ajoene was found in oil macerates of garlic but not in fresh garlic extracts. No antiviral activity was found for alliin, deoxyalliin, diallyl disulfide, or diallyl trisulfide. Fresh garlic extract was virucidal against all viruses tested. The virucidal activity of commercial products was found to be dependent on their preparation processes. Those producing the highest level of allicin and other thiosulfinates had the best virucidal activity.[25] The antiviral activity of an allicin-containing garlic supplement was investigated in 146 subjects randomized to receive a placebo or an allicin-containing garlic supplement, one capsule daily, over a 12-week period.[26] The garlic-treatment group had significantly fewer colds than the placebo group (24 vs. 65 patients). The placebo group, in contrast, recorded significantly more days challenged virally (366 vs. 111 patients) and a significantly longer duration of symptoms (5.01 vs. 1.52 days). This study indicates that allicin-containing garlic supplements can prevent the common cold virus.

Immune-Enhancing Effects

Extensive research has shown that garlic has many immune-potentiating properties, most of which are thought to be due to volatile factors composed of sulfur-containing compounds: allicin, diallyl disulfide, diallyl trisulfide, and others. For example, in vitro studies with allicin showed that it stimulated enhanced cell-mediated cytotoxicity in human peripheral mononuclear cells. In animal models, multiple administration of allicin elicited marked antitumor effects via immunostimulatory mechanisms.[27] Fresh garlic, commercial products containing allicin, and aged garlic preparations have all shown these immune-enhancing properties. Garlic has been shown to enhance the pathogen-attacking activity of T cells, neutrophils, and macrophages, which increase the secretion of interleukin and natural killer (NK) cell activity.[28–31] The increase in killer cell activity was a remarkable 140% in those who ate the equivalent of two bulbs a day and 156% in those who consumed 1800 mg of odorless, aged garlic.

Healthy human participants (n = 120), between 21 and 50 years of age, were recruited for a randomized, double-blind, placebo-controlled parallel-intervention study to consume 2.56 g aged garlic extract (AGE)/d or placebo supplements for 90 days during the cold and flu season.[32] After 45 days of AGE consumption, γδ-T and NK cells proliferated better and were more activated than cells from the placebo group. After 90 days, although the number of illnesses was not significantly different, the AGE group showed reduced cold and flu severity, with a reduction in the number of symptoms, the number of days participants functioned suboptimally, and the number of work/school days missed.

Anticancer Effects

The famous Greek physician Hippocrates prescribed eating garlic as a treatment for cancer. Animal research and some human studies suggest this may have been well-founded advice. It must be kept in mind that much of garlic's anticancer effect is likely an indirect effect via its effect on the immune system. Nonetheless, several garlic components have displayed significant anticancer effects, including enhancing Phase II metabolizing enzymes, antioxidant properties, inhibition of the formation of nitrosamines, direct tumor growth inhibition, and the ability to induce apoptosis.[33–51] Human studies showing garlic's anticancer effects are largely based on epidemiological studies.[33–37] These studies typically show an inverse relationship between cancer rates and garlic consumption. Human studies have also shown that garlic inhibits the formation of nitrosamines (powerful cancer-causing compounds formed during digestion).[47,48]

Cardiovascular Effects

Garlic appears to be an important protective factor against heart disease and strokes via its ability to affect the process of atherosclerosis at many steps (Fig. 51.3). Because there is substantial clinical information on garlic's beneficial effects on the cardiovascular system, the pharmacology is discussed later in the "Clinical Applications" section.

Other Effects

Anti-inflammatory Effects

Garlic extract has demonstrated significant anti-inflammatory activity in experimental models of inflammation.[2,12] This activity is probably a result of garlic's inhibition of the formation of inflammatory compounds. A randomized, double-blind, placebo-controlled,

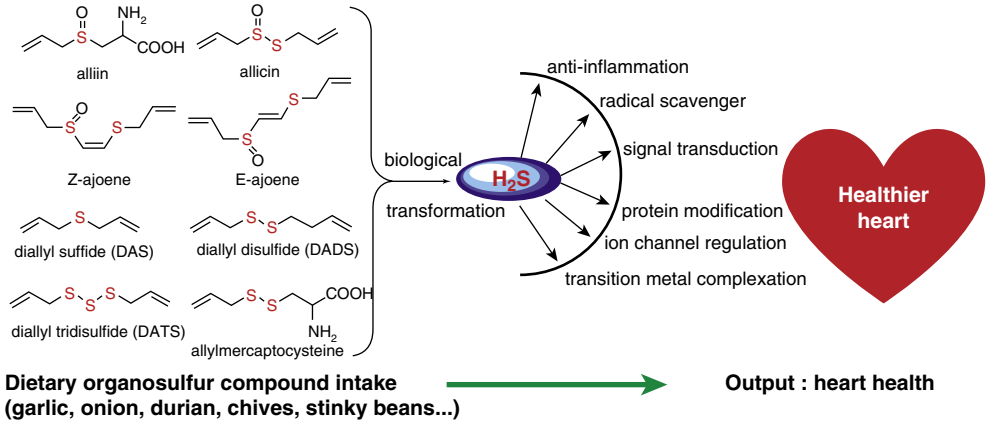

Fig. 51.3 Hydrogen sulfide as the common denominator for bioactivity of dietary organosulfur compounds. (From Tocmo R, Liang D, Lin Y, Huang D. Chemical and biochemical mechanisms underlying the cardioprotective roles of dietary organopolysulfides. *Front Nutr.* 2015;2:1.)

parallel-design trial was conducted to assess the anti-inflammatory and analgesic effects of a garlic supplement on serum resistin and tumor necrosis factor-alpha (TNF-α) concentrations and on pain severity in overweight or obese women with knee osteoarthritis (OA).[52] Eighty postmenopausal overweight or obese women (25 ≤ body mass index [BMI] ≤ 40 kg/m2, age 50–75 years) with mild to moderate knee OA were randomly divided into two groups to receive twice-daily garlic tablets (total: 1000 mg) or placebo for 12 weeks. At week 12, although serum TNF-α levels did not change significantly within or between the two groups, resistin concentrations were significantly decreased in the garlic group (6.41 ± 2.40–5.56 ± 2.16 ng/mL; $P = 0.008$). After supplementation, pain scores were also significantly lower in the garlic group compared with the placebo group (5.3 ± 2.3 vs. 6.2 ± 2.5; $P = 0.043$).

Hypoglycemic Action

Garlic and onions have often been used in the treatment of diabetes. Allicin has been shown to have significant hypoglycemic action. This effect is thought to be due to increased hepatic metabolism, increased release of insulin, and the insulin-sparing effect.[53] The latter mechanism appears to be the major factor because allicin and other sulfhydryl compounds in garlic and onions compete with insulin (also a disulfide protein) for insulin-inactivating compounds, which results in an increase in free insulin.

Interestingly, when allicin was administered to groups of rats fed a high-fructose diet, the control group that was fed a diet enriched by fructose alone continued to gain weight, whereas the groups fed allicin did not.[54] This study indicates that garlic may have some practical use in weight control.

Raw crushed garlic has been shown to have beneficial effects in individuals with metabolic syndrome and may be used as an accompanying remedy for prevention and treatment. In one study, 40 patients with metabolic syndrome underwent treatment with 100 mg/kg body weight of raw crushed garlic 2 times per day added to a standard diet for 4 weeks.[55] Results showed that raw crushed garlic significantly reduced the components of metabolic syndrome, including waist circumference, systolic and diastolic blood pressure, triglycerides, and fasting blood glucose, and significantly increased serum high-density lipoprotein cholesterol.

Miscellaneous Effects

Garlic possesses diuretic, diaphoretic, emmenagogue, and expectorant action.[1,10] A randomized, double-blind, placebo-controlled study found that fermented garlic extract improved serum of gamma-glutamyl transferase (GGT) and alanine transaminase (ALT) levels in adults with mild hepatic dysfunction.[56] It is also a carminative, antispasmodic, and digestant, making it useful in cases of flatulence, nausea, vomiting, colic, and indigestion.[12,57]

COMMERCIAL PREPARATIONS

The modern use of garlic primarily features the use of commercial preparations designed to offer the benefits of garlic without the odor. The marketplace is swamped with garlic products, and each manufacturer claims its product is the best. However, there are vital considerations when choosing a garlic product to prescribe. First, if the primary goal is to lower cholesterol or blood pressure, as well as exert immune-enhancing or antimicrobial effect, it is important to ensure that the product provides a sufficient level of allicin. Because allicin is not actually in the product at significant levels, manufacturers often refer to the allicin potential or allicin yield. These terms signify the amount of allicin produced when allinase is activated in the garlic tablet or powder.

The next issue is not so simple to tell from a label. It involves the quality and character of the enteric coating of the tablet. For the allicin to be liberated within the intestinal tract, the tablet must not only be resistant to the stomach's acid, but it must disintegrate rapidly when it reaches the small intestine. According to research conducted by the renowned garlic experts Lawson et al.,[58] when 24 brands of enteric-coated garlic were analyzed for tablet dissolution using an approved method (U.S. Pharmacopoeia dissolution method 724A), only one brand released the amount of allicin claimed on the label. The second-best brand released only 44% of its label claim, and 75% of the brands released less than 10% of their label claim. Failure to deliver an effective dosage of allicin most assuredly does not lower cholesterol or blood pressure.

Why so many garlic products fail to deliver allicin is basically due to two major problems. First, many of the garlic products contained little alliinase activity. Alliin was found to be plentiful, but because the activity of alliinase was low, the level of allicin formed was also low. Next, many tablets contained excipients (e.g., binders and fillers) that actually inhibit alliinase activity. The alliinase activity in 63% of the brands was less than 10% of the expected activity. The inability to release an effective dose of allicin would explain why so many studies on garlic supplements fail to show benefits in lowering cholesterol or blood pressure.[59] For example, studies done

on one particular garlic supplement before 1993 were mostly positive. The results from these positive studies were the main reason garlic supplements have been allowed to refer to cholesterol-lowering activity in Germany and the United States. However, most studies published since 1995 have failed to show a consistent effect in lowering cholesterol.[60–62]

Although the authors of the negative studies on garlic believe that the underlying reason for the results was a better-designed study, a more likely explanation is that they were due to a poorer-quality tablet. Specifically, research conducted by Lawson showed that tablets manufactured before 1993 were twice as resistant to disintegration in acid as tablets manufactured after 1993 and that the older tablets released three times the amount of allicin than the more recently manufactured tablets.[58] Examination of package labels shows several changes in tablet excipients between the pre-1993 and post-1993 tablets. Again, these excipients are believed to block allinase activity.

Importantly, most studies that show a positive effect of garlic and garlic preparations in reducing cholesterol and blood pressure are those that use products that deliver a sufficient dosage of allicin, other garlic components such as S-allylcysteine, and garlic extracts (e.g., AGE) that protect against atherosclerosis via additional mechanisms, including protection against low-density lipoprotein (LDL) oxidation and improvement of endothelial cell function.

Kyolic, the AGE manufactured by the Wakunaga Wakunaga Pharmaceutical Co., Ltd. (Osaka, Japan), is a highly standardized AGE produced by extraction and aging of organic fresh garlic, at room temperature, for 20 months. The process increases antioxidant levels and converts allicin to mostly stable water-soluble organosulfur compounds, such as S-allylmercaptocysteine and S-allylcysteine. These compounds have high bioavailability and considerable antioxidant effects.[63,64] AGE has minimal cholesterol-lowering and antimicrobial effects, but based on good clinical data, it does have antiatherosclerotic, antiaging, and anticancer effects.

The antioxidant effects of AGE have been shown to prevent LDL oxidation[65] and improve endothelium-dependent vasodilation via increased nitric oxide production and decreased output of inflammatory cytokines. In a double-blind, placebo-controlled, crossover study in 15 men with angiographically proven coronary artery disease, AGE supplementation for 2 weeks significantly improved brachial artery flow–mediated endothelium-dependent dilation by 44%.[66] In a double-blind study of AGE in normal, healthy individuals, dosages between 2.4 and 7.2 g/day were shown to produce a dose-dependent selective inhibition on platelet aggregation and adhesion.[67] In a 1-year study, AGE was shown to produce a modest reduction in the calcium score of 7.5, determined by electron beam tomography, whereas the placebo group demonstrated an average increase in calcium scores of 22.2.[68,69]

Epidemiological and animal studies suggest AGE and its organosulfur constituents, such as S-allylcysteine and S-allylmercaptocysteine, have anticarcinogenic effects. Several clinical studies validated an anticancer effect for AGE. In one double-blinded study in patients with colorectal polyps using high-AGE (AGE 2.4 mL/day) and low-AGE (AGE 0.16 mL/day) doses, in 37 patients chosen as efficacy evaluated subjects, 47.4% (9/19 patients) in the high-AGE and 66.7% (12/18 patients) in the low-AGE group had at least one new adenoma for the first and second interval (0–12 months after intake). The decrease rate of at least one adenoma was 50.0% (7/14 patients) in the high-AGE group for the second interval (6–12 months after intake), whereas there was no decrease in subjects in the low-AGE group.[70] The difference from baseline for total size of adenomas increased in the low-AGE group, whereas an increase in the high-AGE group was suppressed for the second interval. The difference from baseline for the total size of adenomas in subjects who had adenomas at baseline increased in the low-AGE group and decreased in the high-AGE group for the second interval. The results of this study suggest the possibility of preventive and therapeutic effects of AGE on colorectal adenomas, although it would be necessary to investigate these results in larger-scale and longer-term trials.

In a double-blind study in patients with advanced cancer, the primary end point used was a quality of life (QOL) questionnaire based on the Functional Assessment of Cancer Therapy. The sub–end points were changes in NK cell activity and salivary cortisol levels before and after administering AGE. The group consisted of 42 patients with liver cancer (84%), 7 patients with pancreatic cancer (14%), and 1 patient with colon cancer (2%). Drug compliance was relatively good in both the AGE and placebo groups. Although no difference was observed in QOL, both the number of NK cells and NK cell activity increased significantly in the AGE group.[71]

CLINICAL APPLICATIONS

Although garlic has long been used in infectious conditions, a use supported by its antimicrobial and immune-enhancing properties, the primary clinical use of garlic has focused on its role in cardiovascular disease. Specifically, garlic is recommended primarily for its ability to lower cholesterol and blood pressure in the attempt to reduce the risk of dying prematurely from a heart attack or stroke.

In addition to the use of garlic preparations, garlic consumption as a food should be encouraged in patients with high cholesterol levels, high blood pressure, and diabetes.

Cholesterol-Lowering Activity

One of the major areas of focus in garlic's ability to offer significant protection against heart disease and strokes has been the evaluation of its ability to lower blood cholesterol levels.[1,72–76] Unfortunately, the results are inconsistent. Most, but not all, of the double-blind, placebo-controlled studies in patients with initial cholesterol levels greater than 200 given a commercial garlic preparation, providing a daily dose of at least 10 mg alliin or a total allicin potential of 4000 mcg, showed an ability to lower total serum cholesterol levels by about 10% to 12%. In addition, LDL cholesterol decreased by about 15%, high-density lipoprotein (HDL) cholesterol levels usually increased by about 10%, and triglyceride levels typically dropped by 15%,[1,58,59,76–83] whereas most trials not using products that delivered this dosage of allicin failed to produce a lipid-lowering effect.[58–62] However, based on some clinical trials, even using a well-defined garlic preparation is not sufficient assurance that positive results will be seen.[84–87]

One study worth mentioning evaluated the effect of raw garlic and two commonly used garlic supplements against a placebo on cholesterol concentrations in adults with moderate hypercholesterolemia. In the trial, 192 adults with low-density lipoprotein cholesterol (LDL-C) concentrations of 130 to 190 mg/dL were randomly assigned to one of the following four treatment arms: raw garlic, powdered garlic supplement, AGE supplement, or placebo. Garlic product doses equivalent to four average-sized garlic cloves a day were given 6 days/week for 6 months. None of the forms of garlic used, including raw garlic, had statistically or clinically significant effects on LDL-C or other plasma lipid concentrations in adults with moderate hypercholesterolemia.[87]

At present, it can be concluded that the cholesterol-lowering effects of supplemental garlic preparations on cholesterol levels are extremely variable and modest at best. Nonetheless, the combination of lowering

LDL and raising HDL can greatly improve the HDL/LDL ratio, a significant goal in the prevention of heart disease and strokes. Garlic preparations exert several other beneficial effects in preventing heart disease and strokes (discussed under "Platelet Aggregation Inhibition") and have also been shown to improve blood sugar control in diabetics with hyperlipidemia.[88]

In addition to taking a garlic supplement, individuals with high cholesterol levels should eat more garlic and onions because increased dietary intake of garlic and onions can also lower cholesterol levels.[72–75,89] In a 1979 population study, researchers studied three populations of vegetarians in the Jain community in India who consumed differing amounts of garlic and onions.[90,91] Numerous favorable effects on blood lipids, as shown in Table 51.1, were observed in the group that consumed the largest amount. Blood fibrinogen (discussed in "Fibrinolytic Activity") levels were highest in the group eating no onions or garlic. The study was quite significant because the subjects had nearly identical diets, except in garlic and onion ingestion.

Hypertension

Garlic has demonstrated hypotensive action in both experimental animal models and humans with hypertension.[72–75,92–96] A meta-analysis of published and unpublished randomized controlled trials of garlic preparations was conducted to determine the effect of garlic on blood pressure relative to placebo.[92] Eight trials (seven double-blind, one single-blind) were identified as meeting analytic criteria. A total of 415 subjects were included in the analysis. All trials used a dried garlic powder standardized to contain 1.3% alliin at a dosage of 600 to 900 mg/day (corresponding to 7.8 and 11.7 mg of alliin or the equivalent of approximately 1.8–2.7 g of fresh garlic daily). The meta-analysis concluded that garlic preparations designed to yield allicin lowered systolic and diastolic blood pressures over a 1- to 3-month period. The typical drop from pooled data was 11 mm Hg in the systolic and 5 mm Hg in the diastolic. This degree of blood pressure reduction in hypertensives can be quite significant. If the blood pressure–lowering effects of garlic can be maintained, the risk of stroke may be reduced by an estimated 30% to 40% and the risk of heart attack by 20% to 25%.

Platelet Aggregation Inhibition

Excessive platelet aggregation is strongly linked to atherosclerosis, heart disease, and strokes. Garlic preparations standardized for alliin content, as well as garlic oil and AGE, have all demonstrated significant inhibition of platelet aggregation.[67,72–75,97,98] In one study, 120 patients with increased platelet aggregation were given either 900 mg/day of a dried garlic preparation containing 1.3% alliin or a placebo for 4 weeks.[97] In the garlic group, spontaneous platelet aggregation disappeared, the microcirculation of the skin increased by 47.6%, plasma viscosity decreased by 3.2%, diastolic blood pressure dropped from an average of 74 to 67 mm Hg, and fasting blood glucose concentration dropped from an average of 90 to 79 mg/dL.

TABLE 51.1 Effects of Garlic and Onion Consumption on Serum Lipids Under Carefully Matched Diets

Garlic/Onion	Cholesterol	Triglyceride
None	208 mg/dL	109 mg/dL
10/200 g/wk	172 mg/dL	75 mg/dL
50/600 g/wk	159 mg/dL	52 mg/dL

Fibrinolytic Activity

Epidemiological studies have suggested that excessive fibrinogen formation is a major primary risk factor for cardiovascular disease.[99] Garlic preparations standardized for alliin content and garlic oil as well as both fried and raw garlic have been shown to significantly increase serum fibrinolytic activity in humans.[100,101] This increase occurs within the first 6 hours after ingestion and continues for up to 12 hours.

Prevention of Low-Density Lipoprotein Oxidation and Other Vascular Effects

Growing evidence indicates that LDL oxidation plays a significant role in the development of atherosclerosis. Accordingly, substances that prevent oxidation of LDL may slow down atherosclerosis. Garlic is known to exert antioxidant activity and has recently been shown to exert significant effects on preventing LDL oxidation.[65,66,102–105] In one study, healthy human volunteers given 600 mg/day of a garlic preparation providing 7.8 mg alliin for 2 weeks had a 34% lower susceptibility to lipoprotein oxidation compared with controls.[102] These results are significant given the short amount of time in which they were produced, coupled with the importance of reducing lipoprotein oxidation.

A placebo-controlled, double-blind trial involved 23 subjects with coronary artery disease who had at least 75% blockage in one to three major coronary arteries. Two and 4 hours after the subjects ingested a single 300-mg dose of garlic powder, the atherogenicity of their sera was markedly decreased, less cholesterol had accumulated, and there were lower levels of oxidized LDL in human aortic smooth muscle cells cultured with patients' sera after treatment compared with those cultured with sera obtained before administration of garlic. After 3 weeks of therapy at 300 mg, three times daily, blood serum atherogenicity was decreased twofold compared with initial levels.[106]

Because AGE has also shown an ability to prevent LDL oxidation,[104] it is likely that S-allylcysteine and other nonallicin components of garlic play a major role in the protection against LDL oxidation.

Studies have also shown garlic or garlic components to exert positive effects on endothelial function, vascular reactivity, and peripheral blood flow.[107–109] For example, a randomized, double-blind, placebo-controlled trial demonstrated that supplementation with garlic extract favorably modifies endothelial biomarkers, such as high-sensitivity C-reactive protein (hsCRP) and total antioxidant status, associated with cardiovascular risk.[110]

DOSAGE

On the basis of extensive clinical research, a commercial garlic product should provide a daily dose equal to at least 4000 mg of fresh garlic. This dosage translates to at least 10 mg alliin or a total allicin potential of 4000 μg. Alternatively, AGE at a dosage of 2.4 to 7.2 g/day can be used.

TOXICITY

For the vast majority of individuals, garlic is nontoxic at the dosages commonly used. For some, however, it can irritate the digestive tract and cause heartburn. Others are apparently unable to effectively detoxify allicin and other sulfur-containing components. Prolonged feeding of large amounts of raw garlic to rats resulted in anemia, weight loss, and failure to grow.[111] Although the exact toxicity of garlic has yet to be definitively determined, side effects are rare at the recommended dosage. Garlic is thought to be safe during pregnancy and breastfeeding. Two studies showed that babies liked breast milk better from mothers who ate garlic.[112,113]

DRUG INTERACTIONS

Generally, garlic supplements should not be used in patients taking anticoagulant drugs (e.g., Coumadin) or in those scheduled for elective surgery because of garlic's effects on platelet aggregation. The exception to this warning is AGE because it appears safe for use in patients on warfarin therapy.[114]

Although garlic components have shown an ability to affect cytochrome P450 enzymes, they do not appear to interfere with drug metabolism.[115,116]

Aloe vera (Cape Aloe)

Michael T. Murray, ND

OUTLINE

Aloe vera (family: Liliaceous)
Common name: cape aloe

GENERAL DESCRIPTION

More than 300 species of aloe plants exist, but the most popular medicinal variety is currently *Aloe vera.* The nomenclature of *A. vera* is somewhat confusing, because the plant has been known by various names, most notably *A. barbadensis* and *A. vulgari.* The geographical origination of the plant is unclear. Historical records indicate that it may have originated from Egypt or the Middle East. Aloe has been introduced and naturalized throughout most of the tropics and warmer regions of the world, including the Caribbean, southern United States, Mexico, Latin America, the Middle East, India, and Asia.[1]

A. vera is a perennial plant with yellow flowers and tough, fleshy triangular or spear-like leaves arising in a rosette configuration. The leaves are up to 20 inches long and 5 inches across at the base, tapering to a point. There may be as many as 30 leaves per plant. The margins of the leaf are characterized by saw-like teeth. Inside, the meaty leaf is filled with gel that arises from a clear, central mucilaginous pulp. Mature aloe measures 1.5 to 4 feet long and has a base of 3 inches or greater in diameter (Fig. 52.1).

The leaf is composed of three distinct layers: an outer layer of tough tissue; a corrugated lining just beneath the outer layer; and the major portion of the leaf, the inner layer consisting of parenchymal cells containing large vacuoles of a semisolid, gelatinous, transparent gel. The bitter latex of the corrugated layer protects the plants from predators. Should an animal bite the leaf, the sap causes irritation. The dried latex (juice) derived from the corrugated layer is the source of the laxative properties of aloe. The parenchymal tissue or gel is the portion of the aloe used in other applications.

Aloe vera Terminology

- *A. vera gel*—naturally occurring, undiluted parenchymal tissue obtained from the decorticated leaves of *A. vera*
- *A. vera concentrate*—*A. vera* gel from which the water has been removed
- *A. vera juice*—an ingestible product containing a minimum of 50% *A. vera* gel
- *A. vera latex*—the bitter yellow liquid derived from the pericyclic tubules of the rind of *A. vera,* the primary constituent of which is aloin.

CHEMICAL COMPOSITION

The main feature of all aloe plant portions is a high water content. Aloe gel contains 99% water, whereas the skin and fillet fractions contain 90% and 98% water, respectively. *A. vera* contains numerous compounds possessing biological activity. Although many botanical medicines have substantial geographical variation in content, commercial aloe is quite consistent. One study found that the composition of the major compounds was remarkably invariable, with aloeresin A, aloesin, and aloin (both epimers A and B) contributing between 70% and 97% of total dry weight in a ratio of approximately 4:3:2, respectively. Minor compounds were less evenly distributed, with aloinoside

Fig. 52.1 Aloe vera habit (Yarnell).

A and aloinoside B found in higher concentrations in Western countries. The aloin content of the exudate varied, but there were no distinct geographical discontinuities.[2]

Anthraquinones

In 1851 the cathartic action of aloe was discovered to be caused by aloin, a lemon yellow powder formed from drying of the bitter latex (Fig. 52.2). From this material several anthracenes have been isolated, the major anthraquinone being barbaloin. Barbaloin and aloin are often referred to synonymously. Although aloe contains other anthraquinone derivatives, including the anthracene known as aloe-emodin, barbaloin is considered the most potent cathartic. As a whole, most of the anthraquinone compounds in aloe are water-soluble glycosides easily separated from the water-insoluble resinous material. However, rhein (4,5-dihydroxyanthraquinone-2-carboxylic acid) is a lipophilic anthraquinone in *Aloe* sp. that has been shown to exert many pharmacological effects beyond any laxative effect, including hepatoprotective, nephroprotective, anti-inflammatory, antioxidant, anticancer, and antimicrobial activities.[3]

Saccharides

Recent research on *A. vera* has focused on the glycoprotein, mucopolysaccharide, and polysaccharide constituents.[4,5] Aloe contains the polysaccharides galactose, xylose, arabinose, and acetylated mannose or acemannan. The latter has received considerable research attention and has shown significant antiviral and immunopotentiating effects, as well as osteogenic, anti-inflammatory, and antibacterial activity. Acemannan is a water-soluble, long-chain polydispersoid β(1,4)-linked mannan polymer interspersed with *O*-acetyl groups found mainly in aloe gel.[6]

Prostanoids

Several prostanoid compounds have been discovered in *A. vera* extracts.[7] The conversion of essential fatty acids to prostanoids by the enzyme cyclooxygenase in a plant such as *A. vera* is rare. The major unsaturated fatty acid in the plant is γ-linolenic acid (C18:3), which can be converted to icosatrienoic acid, the precursor to prostaglandins of the 1 series. The 1 series prostaglandins are known to exert more favorable effects on inflammation, allergy, platelet aggregation, and wound healing. The presence of γ-linoleic acid or prostaglandins, or both, in a stable medium, along with inhibitors of thromboxane synthesis, may be another important chemical characteristic of aloe responsible for its anti-inflammatory and wound-healing effects.

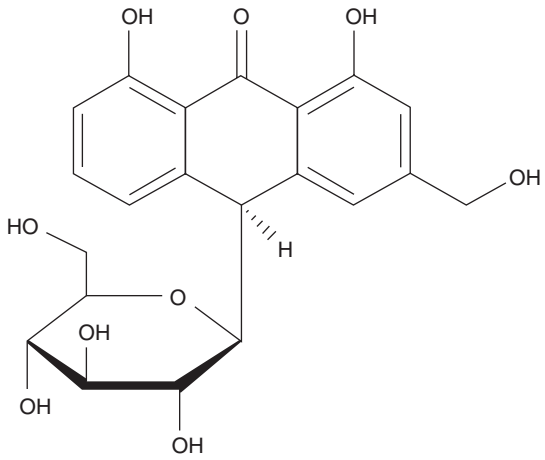

Fig. 52.2 Aloin.

BOX 52.1 Chemical Composition of Aloe Vera

Anthraquinones: Aloin, barbaloin, isobarbaloin, anthranol, aloetic acid, anthracene, ester of cinnamic acid, aloe-emodin, emodin, chrysophanic acid, ethereal oil, resistannol

Saccharides: Cellulose, glucose, mannose, L-rhamnose, aldopentose

Prostanoids: Gamma-linolenic acid

Enzymes: Oxidase, amylase, catalase, lipase, alkaline phosphatase

Amino acids: Lysine, threonine, valine, methionine, leucine, isoleucine, phenylalanine

Vitamins: Vitamins B_1, B_2, B_6, C, and E; folic acid; choline; β-carotene

Minerals: Calcium, sodium, manganese, magnesium, zinc, copper, chromium

Miscellaneous: Cholesterol, triglycerides, steroids, uric acid, lignins, β-sitosterol, gibberellin, salicylic acid

Data from Shelton RM. *Int J Dermatol* 1991;30:679-683.

Superoxide Dismutase

Extracts from the parenchymatous leaf gel and the rind of aloe (*A. barbadensis* Miller) have been shown to contain seven electrophoretically identifiable superoxide dismutases (SODs). Two of these seven are mangano SODs, whereas the other five activities are cupro-zinc SODs.[8]

Other Constituents

Other biological active compounds found in *A. vera* include the following:

- A serine carboxypeptidase
- Salicylates
- Minerals
- Vitamins
- Sterols
- Amino acids

Box 52.1 provides a partial listing of the remarkably diverse range of compounds isolated from *A. vera.*

HISTORY AND FOLK USE

A. vera has a storied history of use. Mesopotamian clay tablets dated 1750 BC indicate that *A. vera* was used for medicinal purposes. Egyptian

records from 550 BC also mentioned aloe for infections of the skin. The ancient Greeks were also aware of aloe's medicinal effects, because both Pliny (23–79 AD) and Dioscorides (first century AD) wrote of aloe's ability to treat wounds and heal infections of the skin. *A. vera* is still widely used in many traditional systems of medicine. In India, for example, in addition to external applications, aloe (whole leaves, the exudate, and the fresh gel) is used as a cathartic, stomachic, and anthelmintic. *A. vera* has been adopted into their materia medicas by many cultures of the world.[1]

In the United States the history of aloe can be traced as far back as the *United States Pharmacopoeia* of 1820, where a number of aloe preparations were described. Most of these preparations were designed to take advantage of aloe's laxative effects. By the early 1900s, more than 27 different aloe preparations were in popular use. In 1920 aloe began being cultivated for pharmaceutic use.

A major development in the modern use of aloe occurred in 1935 when a group of physicians successfully used the fresh juice to treat a patient with facial burns caused by radiographs.[9] The relief offered by aloe in the topical treatment of burns, minor irritations, skin ulcers, and other skin disorders is a major reason why companies supplying dermatological and cosmetic products have incorporated aloe into many of their formulations.

Although more and more of aloe's medicinal effects are being confirmed, it is still predominantly administered without direct medical supervision. Therefore the history and folk use of aloe are continuing to evolve.

PHARMACOLOGY

The pharmacology of aloe is surprisingly diverse. Its laxative, immune potentiation, antimicrobial, and wound-healing activities help explain its wide-ranging folk and clinical applications.

Gastrointestinal Effects

Laxative Effects

Although physicians have prescribed the whole aloe leaf as a cathartic for more than 2000 years, it was not until 1851 that the active principal aloin was discovered.[1] In small doses, aloin acts as a tonic to the digestive system, giving tone to the intestinal muscle. At higher doses, it becomes a strong purgative. Its actions are most obvious on the large intestine, where it increases colonic secretions and peristaltic contractions. In combination with strychnine and belladonna, aloin became one of the most popular laxatives for chronic constipation for many years. Because aloin often causes painful contractions, other anthraquinone laxatives like cascara and senna are now much more popular.[10,11]

A substantial amount of research activity continues in an effort to understand the laxative effects of aloe. Research using the rat large intestine showed that the increase in water content of the large intestine induced by barbaloin preceded the stimulation of peristalsis, attended by diarrhea. Therefore it was suggested that the increase in water content was a more important factor than the stimulation of peristalsis in the diarrhea induced by barbaloin.[12] Further studies by the same researchers suggested that aloe-emodin-9-anthrone (AE-anthrone) produced from barbaloin in the rat large intestine might be the actual chemical mediator of this effect. AE-anthrone not only caused an increase in the intestinal water content but also stimulated mucus secretion.[13]

Bowel Detoxification

In 1985 Bland[14] reported the effect of orally consumed *A. vera* juice on urinary indican, gastrointestinal pH, stool culture, and stool specific gravity in a semicontrolled study of 10 (5 men and 5 women) healthy human subjects.[14] Urinary indican (see Chapter 30) is used as an indicator of the degree to which either dietary protein is malabsorbed or intestinal bacteria are engaged in putrefactive processes. After a full week of drinking 6 oz. of *A. vera* juice three times daily, urinary indican levels decreased one full unit. This suggests that regular *A. vera* juice consumption can lead to improved protein digestion and assimilation or reduced bacterial putrefaction, or both.

TABLE 52.1 Antimicrobial Effects of *Aloe Vera* Extract in Cream Base Compared With Silver Sulfadiazine in Agar (AgSD) Well (6-mm) Diffusion

Organism	Aloe Vera	AgSD
Gram-negative		
Escherichia coli	16	12
Enterobacter cloacae	14	12
Klebsiella pneumoniae	14	6
Pseudomonas aeruginosa	17	12
Gram-positive		
Staphylococcus aureus	18	12
Streptococcus pyogenes	16	12
Streptococcus agalactiae	16	12
Streptococcus faecalis	6	11
Bacillus subtilis	19	14

Data from Robson MC, Heggers JP, Hagstrom WJ. J Burn Care Rehabil 1982;3:157-162. Inhibition zones measured in millimeters.

Inhibition of Gastric Acid Secretion

With Heidelberg gastric analysis, *A. vera* juice was shown to increase gastric pH by an average of 1.88 U. This supports the findings of other researchers that *A. vera* gel can inhibit the secretion of hydrochloric acid. The Heidelberg test also demonstrated that *A. vera* juice can slow down gastric emptying, possibly leading to improved digestion.

Six of the 10 subjects showed marked alterations in stool cultures after the week-long study. This implies that *A. vera* juice may exert some bacteriostatic or fungistatic activity. In the four subjects with positive cultures for yeast, there was a reduction in the number of yeast colonies.

Stool specific gravity was reduced after the week of drinking *A. vera* juice. This implies improved water retention, yet none of the subjects complained of diarrhea or loose stools.

IMMUNE-ENHANCING AND ANTIMICROBIAL ACTIVITY

Antibacterial and Antifungal Activity

Aloe demonstrated activity against many common bacteria and fungi in several studies. In a detailed review of these studies, the researchers assayed the antimicrobial properties of an *A. vera* extract and reviewed the work of others.[15-17] Both mean inhibitory and mean lethal concentrations were determined and compared with silver sulfadiazine (SSD), a potent antiseptic used in the treatment of extensive burns. As shown in Table 52.1,[18] the antimicrobial effects of *A. vera* compare quite favorably with those of SSD. A 60% *A. vera* extract was found to be bactericidal against *Pseudomonas aeruginosa, Klebsiella pneumoniae, Serratia marcescens, Citrobacter* spp., *Enterobacter cloacae, Streptococcus pyogenes,* and *S. agalactiae.* Concentrations of 70% aloe were bactericidal for *Staphylococcus aureus,* 80% for *Escherichia coli,* and 90% for *S. faecalis* and *Candida albicans.* Organisms inhibited in other studies

include *Mycobacterium tuberculosis, Trichophyton* spp., and *Bacillus subtilis.*[2,4,5] The antimicrobial activity against common skin pathogens of *A. vera* gel in a cream base was shown to be slightly better than SSD in agar well diffusion studies.[18]

Antiviral Effects

Acemannan (acetylated mannose) in injectable form has been approved for veterinary use in fibrosarcomas and feline leukemia. Its action in feline leukemia is quite impressive. Feline leukemia, like AIDS, is caused by a retrovirus (feline leukemia virus). The virus is so lethal that once cats develop clinical symptoms, they are usually euthanized. Typically more than 70% of cats die within 8 weeks of the onset of clinical signs. In a study of 44 cats with clinically confirmed feline leukemia, acemannan was injected (2 mg/kg) weekly for 6 weeks and the cats were reexamined 6 weeks after termination of treatment.[19] At the end of the 12-week study, 71% of the cats were alive and in good health.

Acemannan demonstrated significant antiviral activity against several viruses, including feline AIDS, human immunodeficiency virus type 1 (HIV-1), influenza virus, and measles virus.[20-22]

Immune Enhancement

Acemannan is a potent immunostimulant.[18,23-25] Among the effects noted for acemannan are the enhancement of macrophage release of interleukin (IL)-1-α, cytokines, tumor necrosis factor, and nitric oxide release, as well as phagocytosis and nonspecific cytotoxicity. Acemannan also enhances T-cell function and interferon production, although these actions may also be caused by enhanced macrophage function. Macrophage production of cytokines IL-6 and tumor necrosis factor-α were dependent on the dose of acemannan provided. These effects can be substantial. For example, in one study, acemannan was shown to enhance the macrophage respiratory burst (twofold increase above the media controls), phagocytosis (45% compared with 25% in controls), and killing of *C. albicans* (38% killing of *C. albicans* compared with 0%–5% killing in controls).[26]

Hematopoietic Effects

Several complex carbohydrates have been found to significantly stimulate hematopoiesis. CARN 750, a polydispersed β-(1,4)-linked acetylated mannan isolated from the *A. vera* plant, has been shown to have hemato-augmenting properties. Subcutaneous injections of 1 mg/mouse of CARN 750 optimally increased hematopoietic progenitors, measured as IL-3, supported colony-forming units, culture (CFU-C) and high proliferative potential colony-forming cell (HPP-CFC) assays in the spleen. Providing 2 mg/animal of CARN 750 optimally increased bone marrow cellularity, frequency, and absolute number of HPP-CFCs and CFU-Cs. The hematopoietic activity of CARN 750 increased with the frequency of administration. The greatest increase in activity occurred in mice myelosuppressed with radiation.[27]

Anti-inflammatory Activity

A. vera has been shown to exert a number of anti-inflammatory actions, including blocking of the generation of inflammatory mediators like thromboxanes and bradykinin, reducing neutrophil infiltration during inflammation, and reducing edema. Several compounds in aloe are responsible for these actions. The most important are glycoproteins, which inhibit and actually break down bradykinin, a major mediator of pain and inflammation; various anthraquinones; and salicylates. These anti-inflammatory substances may be of significance in both topical and oral applications.

One comprehensive study evaluated the effects of aqueous, chloroform, and ethanol extracts of *A. vera* gel on carrageenan-induced edema in the rat paw and neutrophil migration into the peritoneal cavity stimulated by carrageenan. The capacity of the aqueous extract to inhibit cyclo-oxygenase activity was also evaluated. The aqueous and chloroform extracts decreased the edema induced in the hind paw and the number of neutrophils migrating into the peritoneal cavity, whereas the ethanol extract only decreased the number of neutrophils. The aqueous extract was also found to inhibit prostaglandin E_2 production from arachidonic acid, demonstrating an inhibitory action on cyclooxygenase. The aqueous extract contained anthraglycosides, reductor sugars, and cardiotonic glycosides, whereas the ethanol extract contained saponins, carbohydrates, naphthoquinone, sterols, triterpenoids, and anthraquinones. The chloroform extract contained sterols and anthraquinones.[28]

Another useful aspect of aloe is its ability to inhibit lipid peroxidation and scavenge free radicals. One study measured the activity of seven anthraquinones and four anthrones against nonenzymatic and enzymatic lipid peroxidation in vitro and their ability to scavenge free radicals. Using rat hepatocytes exposed to strong oxidizing agents, dithranol and anthrone provided the strongest inhibition of nonenzymatic peroxidation. Rhein anthrone and aloe-emodin showed the highest inhibitory activity against peroxidation of linoleic acid catalyzed by lipoxygenase. Anthrone, dithranol, and rhein anthrone were the most effective free radical scavengers.[29]

Alcohol Detoxification

Oral administration of aloin (300 mg/kg) given 12 hours before administration of alcohol (3 g/kg) significantly decreases the blood alcohol area under the curve by a remarkable 40%. This suggests an increase in the rate of blood alcohol elimination from the body of 45% to 50%. Analysis of hepatic triglyceride levels revealed that both ethanol and aloin given alone significantly increased the triglyceride levels in a comparable manner. However, the level obtained by the combined treatment of aloin and ethanol was not statistically different from that produced by either treatment alone. The levels of serum L-aspartate:2-oxoglutarate aminotransferase and L-alanine:2-oxoglutarate aminotransferase activities were not increased by acute alcohol intoxication, aloin alone, or the combined treatment of alcohol and aloin.[30]

Wound Healing

The topical effects of *A. vera* appear to be caused by a combination of enhancement of wound healing along with anti-inflammatory, moisturizing, emollient, and antimicrobial actions.[31] *A. vera* contains a number of compounds necessary for wound healing, including vitamin C, vitamin E, and zinc. Unlike many other anti-inflammatory substances, *A. vera* has been shown to stimulate fibroblast and connective tissue formation, thereby promoting wound repair. Finally, aloe appears to stimulate the epidermal growth and repair process, including increasing the manufacture of supportive glycosaminoglycans, presumably as a result of its polysaccharides.[32] Mannose-6-phosphate, the major sugar in the *A. vera* gel, may be its most active growth substance.[33]

Another interesting effect of aloe in wound healing is its ability to counteract the wound-healing suppression effects of cortisone. In one study, *A. vera* at doses of 100 and 300 mg/kg daily for 4 days blocked the wound-healing suppression of hydrocortisone acetate up to 100% using the wound tensile strength assay. The authors suggested this response was because of the growth factors present in *A. vera* masking the wound-healing inhibitors.[34]

CLINICAL APPLICATIONS

Skin Health, Wound Healing, Burns, Frostbite, etc.

Despite growing consumer awareness of *A. vera*'s soothing effects on burns and wound healing during the past 50 years, few human studies

have been conducted.[35] Virtually all of the studies support the topical use of *A. vera* gel, especially in minor burns or skin inflammation. There is also some support for use in more severe tissue damage.

Although limited, the human research has been promising. For example, one study found *A. vera* gel quite successful in three patients with chronic leg ulcers of 5, 7, and 15 years' duration.[36] The gel was applied to the ulcers on gauze bandages. Rapid reduction in ulcer size was noted in all three subjects, and complete resolution occurred in two. Encouraging results were also reported for acne and seborrhea.

In a study of 27 patients with a partial-thickness burn wound, treatment with *A. vera* gel was compared with Vaseline gauze. The average time of healing in the aloe gel area was a statistically significant and dramatic 1 week shorter: 11.9 days compared with 18.2 days for the Vaseline gauze–treated wound. Histological evaluation showed early epithelialization in the *A. vera* gel–treated area.[37]

In another double-blind study, the efficacy of *A. vera* cream for partial-thickness burn wounds was studied and compared with that of SSD. Thirty patients with similar types of second-degree burns at two sites on different parts of the body were included in this study. Each patient had one burn treated with topical SSD and one treated with aloe cream, randomly. The rate of reepithelialization and healing of the partial thickness burns was significantly faster in the site treated with aloe than in the site treated with SSD (15.9 vs 18.73 days, respectively; $P < 0.0001$).[38]

Another study compared the therapeutic effects of systemic pentoxifylline with topical *A. vera* cream in the treatment of frostbite. The frostbitten ears of 10 New Zealand white rabbits were assigned to one of four treatment groups: untreated controls, those treated with *A. vera* cream, those treated with pentoxifylline, and those treated with *A. vera* cream and pentoxifylline. The control group had a 6% tissue survival. Tissue survival was notably improved with pentoxifylline (20%), was better with *A. vera* cream (24%), and was best with the combination therapy (30%).[39]

Aloe may also prove useful in more severe tissue injuries, such as those seen in necrotizing fasciitis. Necrotizing fasciitis usually manifests as a low-grade cellulitis that quickly deteriorates to a limb- and life-threatening soft tissue infection. Immediate surgical débridement is essential, followed by aggressive wound management. An interesting report described excellent results in two cases. Case 1 was a 72-year-old female who, upon presenting to the emergency department with a "sore bottom," was diagnosed with five problems:

- Anal-rectal abscess
- Fournier's gangrene
- Ulcerative colitis
- Chronic blood loss/anemia
- Protein caloric malnutrition

After débridement, her anal-rectal wound extended from the labia to the left buttock. Care was multidisciplinary and included applying a water-based aloe gel and saline-soaked gauze twice a day. After 45 days, the wound exhibited a pink base with granulation tissue and contraction of the wound edges.

Case 2 was a 48-year-old male with seroma of the left leg secondary to a crush injury. Within 3 days he developed deep vein thrombosis in that leg, as well as two large seroma cavities on either side of the thigh. Care included packing with aloe gel and saline-soaked sponges. Two weeks after admission, the anterior wound was covered with a split-thickness skin graft, whereas partial closure of the lateral cavity was attempted unsuccessfully with retention sutures. After 5 weeks, healing was complete for the anterior wound and 95% complete for the posterior wound.[40]

A double-blind study also showed that patients with pressure sores responded equally to an acemannan hydrogel wound dressing or a moist saline gauze wound dressing.[41]

Several studies have also shown that topical aloe preparations can accelerate healing from surgical wounds. In one of the more recent studies, 90 women who had undergone cesarean delivery were randomly divided into two groups. In one group, the wound was dressed with aloe vera gel, whereas simple dressing was used in the control group. Wound healing was assessed 24 hours and 8 days after the cesarean operation using a standard scale. A significant difference was observed between the two groups with respect to the wound healing score 24 hours after the operation, with 45 women in the aloe vera group and 35 in the control group obtaining a zero score.[42]

A topical cream containing 0.5% *Aloe vera* juice powder showed benefits posthemorrhoidectomy. Application of the cream on the surgical site was shown to be effective in reducing postoperative pain both on resting and during defecation, healing time, and analgesic requirements in the patients compared with the placebo group.[43]

Oral ingestion of aloe preparations may also help promote wound healing. In particular, sterol-rich extracts. Sterolic fractions of aloe stimulate collagen and hyaluronic acid production in human dermal fibroblasts. In a 12-week, randomized, double-blind, placebo-controlled study an oral aloe sterol supplement was shown to promote very positive effects on skin elasticity, hydration, and the collagen scores in 64 healthy women (age range 30–59 years; average 44.3 years). The improved collagen score was based on the measured collagen content in the dermis by ultrasound.[44]

Psoriasis

Several studies have shown topical treatment with aloe preparations may help psoriasis. One double-blind, placebo-controlled study evaluating the clinical efficacy and tolerability of topical *A. vera* extract 0.5% in a hydrophilic cream obtained impressive results. Sixty patients (36 males and 24 females) aged 18 to 50 years (mean 25.6 years) with slight to moderate chronic plaque–type psoriasis and psoriasis area, and severity index (PASI) scores between 4.8 and 16.7 (mean 9.3) were enrolled and randomized to two groups. The mean duration of the disease before enrollment was 8.5 years (range 1–21 years). Patients self-administered trial medication topically at home three times daily for 5 consecutive days/week (maximum 4 weeks active treatment). Patients were examined on a weekly basis, and those showing a progressive reduction of lesions, desquamation followed by decreased erythema, infiltration, and lowered PASI score were considered healed. The study was scheduled for 16 weeks with 12 months of follow-up on a monthly basis. The treatment was well tolerated by all the patients, with no adverse drug-related symptoms and no dropouts. By the end of the study, the *A. vera* extract cream had cured 25 of 30 patients (83.3%) compared with the placebo cure rate of only 2 of 30 patients (6.6%), resulting in significant clearing of the psoriatic plaques (328 of 396, or 82.8%) versus placebo (28 of 366, or 7.7%), and a decreased PASI score to a mean of 2.2.[45]

In another study, the efficacy of topical *A. vera* was compared with 0.1% triamcinolone acetonide (TA) in mild to moderate plaque psoriasis. After 8 weeks of treatment, the mean PASI score decreased from 11.6 to 3.9 in the *A. vera* group and from 10.9 to 4.3 in the TA group. The mean Dermatology Life Quality Index scores decreased from 8.6 to 2.5 in the *A. vera* group and from 8.1 to 2.3 in the TA group. These results indicated that both treatments had similar efficacy in improving the quality of life of patients with mild to moderate psoriasis.[46]

Radiation Burns

Research into the topical applications of *A. vera* gel began in the 1930s for the treatment of radiation burns. During the 1930s, radiographs were used therapeutically for cancer, eczema, and other skin complaints, and as a depilatory agent. In 1935 Collins and Collins[9] reported

the success of *A. vera* gel in a single case, a woman with a patch of severe x-ray dermatitis on her forehead. The woman had tried various medical treatments for 8 months, only to have her condition worsen. The Collinses were going to perform a skin graft, but as a temporary measure applied a preparation of fresh whole *A. vera* leaves to reduce the itching. The result was that "Twenty-four hours later she reported that the sensation of itching and burning had entirely subsided," and by 5 weeks "there was complete regeneration of the skin of the forehead and scalp, new hair growth, complete restoration of sensation, and absence of scar." Five months after treatment was started, there was complete healing. The following case reports, although not as positive as this initial study, clearly indicated that *A. vera* was effective in some cases.

Until the 1940s most of the studies on aloe were reported case histories.[4] To substantiate these case studies, animal studies began to appear in the literature. Rowe and colleagues[35] performed several studies in rats with radiation-induced ulcers and determined that fresh aloe pulp was effective, whereas dried aloe powder was not.[4,34]

In 1953 Lushbaugh and Hale,[36] working for the US Atomic Energy Commission, produced one of the most convincing studies of the efficacy of *A. vera* gel. Twenty albino rats were exposed to β-radiation, and different treatments were used on quadrants of the affected area of each animal. The treatments used were fresh *A. vera* leaf, a commercial *A. vera* ointment, application of a dry gauze bandage, and an untreated control. Both fresh *A. vera* and the *A. vera* ointment produced clear improvements. At the end of 2 months, the *A. vera*–treated areas were completely healed, whereas the other two areas had not yet healed at the end of 4 months.

A large placebo-controlled, double-blind study cast doubt on the efficacy of aloe for severe radiation burns. Three Phase III randomized trials were reported in this study. The first one was double-blind, used a placebo gel, and involved 194 women receiving breast or chest wall irradiation. The second trial randomized 108 such patients to *A. vera* gel versus no treatment. Skin dermatitis was scored weekly during both trials both by patients and by health care providers. Skin dermatitis scores were virtually identical on both treatment arms during both trials.[47] The aim of the study was to see if topical *A. vera* gel would be beneficial in reducing the identified skin side effects of radiation therapy, including erythema, pain, itching, dry desquamation, and moist desquamation compared with aqueous cream. The secondary aim was to assess the effect of other factors known to predict severity of radiation skin reaction (i.e., breast size, smoking habit, and one or more drainages of lymphocele after surgery) on other skin side effects. The third study involved more than 225 patients with breast cancer after lumpectomy or partial mastectomy who required a course of radiation therapy using tangential fields. Like the other two studies, *A. vera* gel did not significantly reduce radiation-induced skin side effects.[48]

These surprising results might be explained by another study that compared the efficacy of commercially available gels with an acemannan-rich extract from aloe leaves in the treatment of irradiated mice. Male C3H mice received graded single doses of γ-radiation ranging from 30 to 47.5 Gy to the right leg. In most experiments, the gel was applied daily, beginning immediately after irradiation. To determine the timing of application for the best effect, gel was applied beginning on days −7, 0, or +7 relative to the day of irradiation (day 0) and continuing for 1, 2, 3, 4, or 5 weeks. The right inner thigh of each mouse was scored on a scale of 0 to 3.5 for severity of radiation reaction from the seventh to thirty-fifth day after irradiation. Dose–response curves were obtained by plotting the percentage of mice that reached or exceeded a given peak skin reaction as a function of dose. The researchers found that although the acemannan-rich extract gel was highly effective, the commercially available gel showed no improvement over the control. They also found that the aloe gel had to be applied immediately after irradiation and continued for at least 2 weeks. There was no effect if the aloe gel was applied only before irradiation or beginning 1 week after irradiation. Clearly, the quality and concentration of aloe constituents are crucial if clinical results are to be obtained.[53] In addition, the physical form of the preparation (e.g., gel vs. cream) may be important, as a study using a well-defined aloe extract in a cream showed no benefit in protecting against radiation injury to the skin in women being treated for breast cancer.[49]

One area where *A. vera* gel has shown some benefit is in acute radiation-induced proctitis (ARP), a common side effect that affects up to 50% of patients receiving radiotherapy. In a double-blind placebo-controlled trial, 20 consecutive patients with ARP after external-beam radiation therapy of pelvic malignancies were randomized to receive either *A. vera* 3% or placebo ointment, 1 g twice daily for 4 weeks. These patients presented with at least two of the following symptoms: rectal bleeding, abdominal/rectal pain, diarrhea, or fecal urgency. A symptom index and lifestyle effect was calculated by the addition of the scores from a questionnaire. Results showed a significant ($P < 0.05$) improvement in the symptom index for diarrhea, fecal urgency, clinical presentation total, and lifestyle effect. Hemorrhage and abdominal/rectal pain did not improve significantly. The odds ratios for advantage of *A. vera* over placebo for "clinical presentation total" was 3.97.

Gastric Ulcers, Ulcerative Colitis, and Rectal Disorders

Internal use of *A. vera* gel to treat peptic ulcers was first studied in 1963.[50] Twelve patients with x-ray–confirmed duodenal ulcers were given 1 tablespoon of an emulsion of *A. vera* gel in mineral oil once daily. At the end of 1 year, all patients demonstrated complete recovery and no recurrence. On the basis of experimental evidence, the following factors were considered responsible for the effectiveness:

- *A. vera* gel inactivates pepsin in a reversible fashion. When the stomach is devoid of food, pepsin is inhibited by *A. vera* gel; however, in the presence of food, pepsin is released and allowed to digest the food.
- The gel inhibits the release of hydrochloric acid via interference with histamine binding to the parietal cells.
- *A. vera* gel is an extremely good demulcent that heals and prevents aggravating irritants from reaching the sensitive ulcer.

A. vera gel has also been shown to useful for ulcerative colitis. In the double-blind study, 44 patients were randomly given oral *A. vera* gel or placebo, 100 mL twice daily for 4 weeks. Clinical remission, improvement, and response occurred in 9 (30%), 11 (37%), and 14 (47%), respectively, of 30 patients given aloe vera, compared with 1 (7%), 1 (7%), and 2 (14%), respectively, of 14 patients taking placebo. The Simple Clinical Colitis Activity Index and histological scores decreased significantly during treatment with *A. vera* ($P = 0.01$ and $P = 0.03$, respectively), but not with placebo.[51]

A topical cream containing 0.5% *A. vera* juice powder showed benefits in the treatment of chronic anal fissures.[52] The aloe cream was applied by the patients to the wound site three times per day for 6 weeks. There were statistically significant differences ($P < 0.0001$) in chronic anal fissure pain, hemorrhaging upon defection, and wound healing before and at the end of the first week of treatment with the aloe cream compared with the control group. This aloe preparation was also shown to be great benefit after hemorrhoidectomy (mentioned previously).

Oral Mucosal Disorders

The topical benefits of aloe preparations extend to the oral mucosa. According to a systematic review, aloe preparations have been

evaluated in 15 clinical trials ranging in size from 20 patients to 110 patients with clinically diagnosed oral mucosal lesions. Most of the studies showed statistically significant clinical improvement in such conditions as oral lichen planus, submucous fibrosis, burning mouth syndrome, radiation-induced mucositis, candida-associated denture stomatitis, xerostomic patients, and recurrent aphthous stomatitis.[53]

Oral submucosa fibrosis is a chronic, complex, premalignant condition linked most often to betel nut chewing. Given *A. vera's* anti-inflammatory, wound-healing, antioxidant, and antineoplastic activities, it would appear to be an effective intervention. In the most recent study, the clinical response to *A. vera* juice or gel was comparable to that of intralesional injections of hydrocortisone and hyaluronidase combined with oral antioxidant supplementation.[54]

In the treatment of lichen planus, results from five double-blind clinical trials indicate that aloe vera is more efficient than placebo and has a comparable effect to triamcinolone acetonide.[53,55] In the most recent study, 40 patients with lichen planus were randomly divided into two equal groups. Group A patients received aloe vera gel, whereas group B patients received triamcinolone acetonide. When clinical signs and symptoms were observed after 8 weeks of therapy, it was determined that aloe vera gel was more effective than triamcinolone acetonide in the treatment of oral lichen planus.[56]

Acquired Immunodeficiency Syndrome

Although acemannan has demonstrated some direct antiviral activity against HIV-1 by inhibiting glycosylation of viral glycoproteins, its main promise in treating AIDS and HIV may be to enhance the action of azidothymidine (AZT), one of the antiviral drugs used in the treatment of AIDS. In vitro studies have shown that acemannan combined with suboptimal noncytotoxic concentrations of AZT or acyclovir acts synergistically to inhibit the replication of HIV and herpes simplex type 1 (HSV-1).[22] On the basis of these studies, as well as preliminary human studies, researchers believe that the use of acemannan may reduce the amount of AZT required by as much as 90%. In addition to AZT's cost, its use is often associated with severe side effects, including anemia and granulocytopenia resulting from bone marrow suppression.

Preliminary clinical studies have suggested that acemannan and *A. vera* may be beneficial when administered orally in HIV-positive individuals. For example, in one study, 14 HIV patients prescribed oral acemannan (800 mg/day) demonstrated significant increases in circulating monocytes/macrophages. In particular, there were significant increases in the number of large circulating monocytes, indicating improvement in phagocytizing, processing, and presenting cells in the blood.[57] In a study of 15 AIDS patients receiving an oral dose of acemannan (800 mg/day), the average scores of Modified Walter Reed (MWR) Clinical Evaluation scoring, absolute T-4, absolute T-8, and p24 core antigen levels all improved in those surviving (Table 52.2) at the end of 900 days. Two patients died of AIDS, and another committed suicide. From this study and others, it has been suggested that prognostic criteria to determine the most responsive patients are those with an absolute T-4 count greater than 150/mm^3 and p24 levels less than 300.

TABLE 52.2 Acemannan in the Treatment of Acquired Immunodeficiency Syndrome

Test	Pretreatment	After 900 Days
Modified Walter Reed Clinical Evaluation	65	2
Absolute T-4	322/mm^3	324/mm^3
Absolute T-8	469/mm^3	660/mm^3
p24 Core antigen	5/15	4/12

Data from McDaniel HR, Carpenter RH, Kemp M, et al. *Antiviral Res* 1990;13(suppl 1):117.

Unfortunately, a follow-up study did not reproduce these early, promising results. A comprehensive study assessed the safety and efficacy of acemannan as an adjunctive to antiretroviral therapy among 63 male patients (mean age, 39 years) with advanced HIV disease receiving zidovudine (ZDV) or didanosine (ddI).[58] The randomized, double-blind, placebo-controlled trial provided a large dose of acemannan (400 mg orally four times daily). Eligible patients had CD4 counts of 50 to 300/μL twice within 1 month of study entry and had received 26 months of antiretroviral treatment (ZDV or ddI) at a stable dose for the month before entry. CD4 counts were made every 4 weeks for 48 weeks. p24 antigen was measured at entry and every 12 weeks thereafter. Sequential quantitative lymphocyte cultures for HIV and ZDV pharmacokinetics were performed in a subset of patients.

The mean baseline CD4 counts were 165 and 147/μL in the placebo and acemannan groups, respectively; 90% of the patients were receiving ZDV at entry. Six patients in the acemannan group and five in the placebo group developed AIDS-defining illnesses. There was no statistically significant difference between the groups at 48 weeks with regard to the absolute change or rate of decline of the CD4 count. Among ZDV-treated patients, the median rates of CD4 change (ACD4) in the initial 16 weeks were −121 and −120 cells/year in the placebo and acemannan groups, respectively; ACD4 decline from week 16 to 48 was 0 and −61 cells/year in the acemannan and placebo groups, respectively ($P = 0.11$). No statistical difference between groups occurred with regard to adverse events, p24 antigen, quantitative virology, or pharmacokinetics. Twenty-four patients, 11 receiving placebo and 13 receiving acemannan, discontinued study therapy prematurely (none as a result of serious adverse reactions). The decreased, but not statistically significant, rate of loss of CD4 cells in the acemannan group from weeks 16 to 48 provides a possible ray of hope that long-term use, such as reported previously, may be of value, and should be investigated.

Diabetes

A. vera also exhibits a hypoglycemic effect in both normal and alloxan-induced diabetic mice.[59] Research began in humans with a small study of five patients with type 2 diabetes ingested half a teaspoonful of aloe four times daily for 14 weeks. Fasting blood sugar in each patient fell from a mean of 273 to 151 mg/dL with no change in body weight. The authors concluded that aloe lowered blood glucose levels by an unknown mechanism.[60] A more recent and larger study (49 men and 23 women) provided more support for the efficacy of aloe in combination with glibenclamide in diabetes. Although there was no response to glibenclamide alone, the combination was effective.[61] The patients were provided with 1 tablespoon of aloe gel and 5 mg of glibenclamide twice daily, with 5 mg twice daily of glibenclamide serving as the control. After 2 weeks, fasting blood sugar decreased significantly in the treated group, and by day 42 had decreased from an average of 289 mg/dL to a remarkable 148 mg/dL. Although the drop in serum cholesterol was insignificant, serum triglycerides decreased from 223 mg/dL to (again remarkable) 128 mg/dL by day 42.

In a systematic review of five randomized controlled trials with *A. vera* preparations involving 415 participants with prediabetes or early stage type 2 diabetes, results showed that *A. vera* supplementation significantly reduced the concentrations of fasting blood glucose, glycosylated hemoglobin A1c (Hb A_{1c}), total cholesterol, and low-density lipoprotein-cholesterol at the same time increasing serum high-density lipoprotein-cholesterol levels. Only one adverse event was reported

(but not described) in all of these studies combined. The evidence showed that *A. vera* can effectively reduce the levels of FBG, HbA1c, triglyceride, TC, and LDL-C, and increase the levels of HDL-C in these patients. The proposed mechanism is improved insulin sensitivity by activating AMP-activated muscle protein kinase.[62]

Asthma

Oral administration of an extract of *A. vera* for 6 months was shown to produce good results in the treatment of asthma in some individuals of various ages.[63] The exception was the fact that the *A. vera* extract was not effective in patients dependent on corticosteroids. The mechanism of action is thought to be via restoration of protective mechanisms, followed by augmentation of the immune system.

The extract used in the study was produced from the supernatant of fresh leaves stored in the dark for 7 days at 4°C. The dosage was 5 mL of a 20% solution of the aloe extract in saline twice daily for 24 weeks. Eleven of 27 patients (40%) without corticosteroid dependence reported significant improvement at the study's conclusion.

Studies indicate that subjecting the leaves to dark and cold results in an increase in the polysaccharide fraction. One gram of the crude extract obtained from leaves stored in the cold and dark produced 400 mg of neutral polysaccharide, compared with only 30 mg produced from leaves not subjected to cold or dark.

Antioxidant Support

Daily ingestion of an *A. vera* gel extract for 14 days was shown to increase plasma total antioxidant capacity (TAC) in healthy volunteers without any clinical side effects.[63]

Cancer Prevention

Aloe preparations and components have been shown to exert antigenotoxic and chemopreventive effects in a time-course and dose-dependent manner.[64,65] Aloe preparations have also shown efficacy in treatment of spontaneous neoplasms in dogs and cats.[66] These studies suggest *A. vera* may also play a role in humans. One clinical study sought to evaluate whether the concomitant administration of aloe could enhance the therapeutic results of melatonin in patients with advanced solid tumors for whom no effective standard anticancer therapies were available. The study included 50 patients with lung cancer, gastrointestinal tract tumors, breast cancer, or brain glioblastoma who were treated with melatonin alone (20 mg/day orally in the dark period) or melatonin plus *A. vera* tincture (1 mL twice daily). A partial response was achieved in two of 24 patients treated with melatonin plus aloe and in none of the patients treated with melatonin alone. Stable disease was achieved in 12 of 24 and in seven of 26 patients treated with melatonin plus aloe or melatonin alone, respectively. Therefore the percentage of nonprogressing patients was significantly higher in the group treated with melatonin plus aloe than in the melatonin group (14 of 24 vs. 7 of 26; $P < 0.05$). The percentage of 1-year survival was also significantly higher in patients treated with melatonin plus aloe (9 of 24 vs. 4 of 26; $P < 0.05$).[67]

Contraception

An interesting new application of aloe is as a spermicide. Twenty samples of fresh ejaculate from healthy human volunteers between 20 and 30 years of age were treated in vitro with a 1% concentration of zinc acetate combined with lyophilized *A. barbadensis* (at concentrations of 7.5%–10%). The combination of zinc acetate with lyophilized *A. barbadensis* was shown to possess powerful spermicidal and antiviral effects. This was attributed to their concentration of minerals (boron, barium, calcium, chromium, copper, iron, potassium, magnesium, manganese, phosphorus, and zinc), which were toxic to the sperm tail, causing instant immobilization. Studies with rabbit vaginal epithelium showed no irritation. This is important because nonoxynol-9, the active spermicidal ingredient used in vaginal contraception for more than 30 years, appears to cause cell membrane damage in vaginal and cervical epithelium and may possibly have teratogenic effects.[68]

DOSAGE

A. vera gel can be applied liberally for topical applications. A wide range of products are available on the market; however, simple pure *A. vera* gel is sufficient.

A. vera juice can be consumed orally as a beverage or tonic. Although detailed information is currently lacking as to the optimal dose for these types of products, it is recommended that no more than 1 quart be consumed daily.

The dose of acemannan being used in HIV/AIDS patients is 800 to 1600 mg/day. This corresponds to a dose of approximately 0.5 to 1 L/day for most *A. vera* juice products. However, there may be great variation in the amount of acemannan in various products.

TOXICOLOGY

Although rare, hypersensitivity reactions manifesting as generalized, nummular, eczematous, and papular dermatitis have been reported as a result of topically applied *A. vera* preparations. In general, topical aloe preparations are not useful for treating deep vertical wounds such as those produced during laparoscopy.[69]

Oral aloe preparations are extremely well tolerated. There are a few reports of aloe preparations inducing elevations in hepatic enzymes and even acute liver injury.[70] Thus it may be appropriate to perform annual assessment of liver function enzymes. There are also a few case reports of aloe ingestion leading to thyroid dysfunction (reduced serum triiodothyronine).

DRUG INTERACTIONS

Like other stimulant laxatives, excessive use of aloe dried juice/latex may interact with several drugs. Large doses of aloe may increase the risk of toxicity of antiarrhythmic drugs. Theoretically, potential for adverse effects exists when aloe dried juice/latex is used excessively along with herbs containing cardiac glycosides (e.g., black hellebore, Canadian hemp roots, digitalis leaf, pheasant's eye plant, pleurisy root, squill bulb leaf scales, *Strophanthus* seeds) or with cardiac glycoside drugs (e.g., digoxin). Overuse of aloe dried juice/latex can exacerbate the potassium loss caused by corticosteroids, diuretics, horsetail, and licorice root.

As a result of the hypoglycemic effects of internally consumed *A. vera* gel, people using glyburide drugs to control blood sugar (e.g., Diabeta, Micronase, Glynase) should monitor blood glucose levels closely.

Aloe dried juice/latex causes shorter gastrointestinal transit time, so it may reduce the absorption of some drugs.

Concomitant use of aloe with other stimulant laxative herbs might increase the risk of potassium depletion. In addition to senna leaves and pods and cascara bark, the two herbs most widely used for this purpose, stimulant laxative herbs also include wild cucumber fruit *(Ecbolium elaterium)*, blue flag rhizome, alder buckthorn, European buckthorn, butternut bark, castor oil, colocynth fruit pulp, gamboge bark exudate, jalap root, black root, manna bark exudate, podophyllum root, rhubarb root, and yellow dock root.

Angelica Species

Michael T. Murray, ND,* and *John Nowicki, ND*

OUTLINE

Angelica sinensis or polymorpha (family: *Umbelliferae* or *Apiaceae*)
Common names: Chinese angelica, tang-kuei (dong quai)
Angelica acutiloba (family: *Umbelliferae* or *Apiaceae*)
Common name: Japanese angelica
Angelica archangelica (family: *Umbelliferae* or *Apiaceae*)
Common name: European angelica
Angelica atropurpurea (family: *Umbelliferae* or *Apiaceae*)
Common name: American angelica
Angelica silvestris (family: *Umbelliferae* or *Apiaceae*)
Common name: wild angelica

GENERAL DESCRIPTION

Angelica spp. are biennial or perennial plants with hollow fluted stems that rise to a height of 3 to 7 feet. The umbels, or clusters, of greenish-white flowers bloom from May to August (Fig. 53.1AC). The plants are found in damp mountain ravines and meadows, on riverbanks, and in coastal areas; angelica is also a widely cultivated species. In Asia it is grown primarily for its medicinal properties, whereas in the United States and Europe it is cultivated for use as a flavoring agent in most major categories of food products, including alcohol (e.g., bitters, liqueurs, vermouths) and nonalcoholic beverages (e.g., ice cream, candy, gelatins, and puddings). In all species, the roots and rhizomes are the most extensively used portions of the plant.

Angelica sinensis and *Angelica acutiloba*

In Asia the authentic and original angelica species used for medicinal purposes is *A. sinensis* (dong quai), native to China. Although at least nine other angelica species are used in China, dong quai is by far the most highly regarded. For several thousand years, dong quai has been cultivated for medicinal use in the treatment of a variety of disorders. Several hundred years ago, when the supply of Chinese angelica was scarce, the Japanese began to cultivate *A. acutiloba,* an angelica species indigenous to Japan, as a substitute.[1] The two species appear to have similar therapeutic effects despite the following cultural opinions: in China, the Japanese angelica is thought to have no therapeutic value; whereas in Japan, Chinese angelica is thought to have no effect. Experimentally, both species exhibit similar therapeutic effects.

Angelica archangelica and *Angelica atropurpurea*

Historical usage suggests that European angelica *(A. archangelica)* and American angelica *(A. atropurpurea)* have properties different from the Asian species. However, this difference has not been evaluated by chemical analysis.

CHEMICAL COMPOSITION

Angelica sinensis and *Angelica acutiloba*

Although it has been assumed that Chinese and Japanese angelica are similarly composed of various coumarins and flavonoids that are responsible for their medicinal actions, a recent analysis showed that *A. sinensis* contained approximately tenfold higher levels of the key components ferulic acid and Z-ligustilide compared with roots of *A. acutiloba.*[2]

Many medicinal compounds are believed to be present in the essential oil, including the following[3]:

- 3*n*-Butylphthalide
- Cadinene
- Carvacrol
- n-Dodecanal
- Isosafrole

Fig. 53.1 (A) *Angelica* species. (B) *Angelica archangelica* inflorescence. (C) *Angelica dahurica* flower fruit. (A, from JPC-PROD/iStock.com. B and C, from Eric L Yarnell urologynd@gmail.com Also contributor.)

- Linoleic acid
- Palmitic acid
- Safrole
- Sequiterpene
- n-Tetradecanoyl

Angelica archangelica

A. archangelica is also rich in coumarins and is particularly phototoxic. Coumarins including osthole, angelicin, osthenol, umbelliferone, archangelicine, bergapten, and ostruthol are found in significant concentrations, with osthole composing nearly 0.2% of the root. The root is also a good source of flavonoids, including archan-gelenone and caffeic acids. The root contains 0.3% to 1% volatile oil, composed mainly of β-phellandrene, α-pinene, borneol, limonene, and four macrocyclic lactones.[3,4]

HISTORY AND FOLK USE

Angelica sinensis and *Angelica acutiloba*

In Asia, angelica's reputation is perhaps second only to ginseng. Predominantly regarded as a female remedy, angelica has been used to treat dysmenorrhea, amenorrhea, metrorrhagia, and menopausal symptoms, and to facilitate a healthy pregnancy and easy delivery. Angelica is also used in the treatment of abdominal pain, anemia, injuries, arthritis, migraine headache, and many other conditions.[3,5]

Angelica archangelica

One of the most highly praised herbs in old herbal texts, *A. archangelica* was used in all Northern European countries as a protection against contagion, for purifying the blood, and for curing every conceivable malady; it was considered a sovereign remedy for poisons, agues, and all infections. According to one legend, *A. archangelica* was revealed in a dream as a cure for the plague. One explanation for the name is related to its blooming near May 8, the feast day of Michael the Archangel.

A. archangelica has been used for a wide variety of conditions, including flatulent dyspepsia, pleurisy, respiratory catarrh, and bronchitis. The plant was believed to possess carminative, spasmolytic, diaphoretic, expectorant, and diuretic activity.[6] A prospective, open-label trial of Feru-guard, a combination of ferulic acid and an extract of *A. archangelica*, led to significantly reduced subscale scores on the Neuropsychiatric Inventory, indicating that it may be effective for treating the behavioral and psychological symptoms of dementia.[7]

Angelica atropurpurea

American angelica's therapeutic use mirrors that of European angelica. It is most commonly used for heartburn and flatulent colic.[8]

PHARMACOLOGY

The pharmacology of *Angelica* spp. primarily relates to high coumarin content. However, unlike other scientific investigations of botanical medicines, most research on *Angelica* spp. has been done on plant extracts, rather than isolated constituents. The overwhelming majority of studies have been done on the Asian species. Some of the pharmacological activities demonstrated include the following:

- Phytoestrogen activity
- Cardiovascular effects
- Smooth muscle–relaxing effects
- Antioxidant effects
- Analgesic activity
- Antiallergic, immunomodulating, and direct antitumor activity
- Antimicrobial activity

Phytoestrogen Effects

Phytoestrogens (i.e., plant estrogenic substances) are components of many medicinal herbs with historical use in conditions that are now treated by synthetic estrogens. Chinese and Japanese angelica contain weakly active phytoestrogens, much lower in activity than other phytoestrogens, and approximately no more than 1:400 are active as estrogen.[9] This helps explain why angelica was used in conditions of both excessive and deficient estrogen. Phytoestrogens demonstrate an adaptogenic effect by competing with estrogen for binding sites. When estrogen levels are low, they can exert some weak estrogenic activity; when estrogen levels are high, they reduce overall estrogenic activity by occupying estrogen receptor sites. This alterative action of phytoestrogens is probably the basis of the plant's use in amenorrhea and menopause.

Japanese angelica has demonstrated uterine tonic activity, causing an initial increase in uterine contraction followed by relaxation.[10,11] In addition, administration of Japanese angelica to mice resulted in an increase in uterine weight, an increase in the DNA content of the uterus and liver, and an increase in glucose use by the liver and uterus.[1,10] Because of these and other effects, angelica has been referred to as a uterine tonic.

Administration of a standardized ethanol extract in ovariectomized rats exhibited stimulation of the uterine histoarchitecture, a significant cornification in the vaginal epithelium, and a reduction of serum luteinizing hormone concentration, showing the estrogenic nature of the extract. Furthermore, the administration of the extract in intact female rats provoked a significant modification of the vaginal smear in 67% of treated rats.[3,12]

Cardiovascular Effects

Angelica possesses significant hypotensive action largely due to its vasodilator activity.[1,10] Dihydropyranocoumarins and dihydrofuranocoumarins from *Umbelliferous* plants have been shown to possess significant coronary vasodilatory, spasmolytic, and cyclic adenosine monophosphate phosphodiesterase inhibitory properties.[13] The mechanism of action appears to be a result of calcium-channel antagonism. Agents that interact with calcium channels (calcium channel blockers) are involved in the treatment of wide-ranging conditions, including hypertension and angina. Umbelliferous plants, such as angelica, may offer similar effects. Angelica provides additional cardiovascular effects, including negative inotropic and antiarrhythmic action.[1]

Smooth Muscle–Relaxing Activity

Calcium-channel–blocking compounds are also capable of relaxing the smooth muscles of visceral organs. Essential oil of angelica demonstrated relaxing action on the smooth muscles of the intestines and uterus, whereas the water extract produced an initial contraction and then prolonged relaxation.[1,10,11] This confirms its historical use in the treatment of intestinal spasm and uterine cramps. Its action on other smooth muscles could explain its hypotensive action (vascular smooth muscle) and historical use in asthma (bronchial smooth muscle).

Analgesic Activity

Both Chinese and Japanese angelica have demonstrated pain-relieving and mild tranquilizing effects in experimental studies in animals.[1,10,14,15] Angelica's analgesic action was 1.7 times that of aspirin in one study.[15] Several dimetric phthalides, including angesinenolides, exhibit inhibitory activity against COX-2.[16] Its analgesic activity, combined with its smooth muscle–relaxing activity, supports its historical use in such conditions as uterine cramps, trauma, headaches, and arthritis.

Antiallergic, Immunomodulating, and Direct Antitumor Activity

Angelica has a long history of use by Chinese and Japanese herbalists in the prevention and treatment of allergic symptoms in individuals who are sensitive to various substances (e.g., pollen, dust, animal dander, food).[1,17] Its action is related to its ability to inhibit the production of immunoglobulin-E in a selective manner. Because immunoglobulin-E levels in patients with atopic conditions are typically 3 to 10 times greater than the upper limit of normal, angelica may offer some benefit by reducing these elevated antibodies.

Coumarin compounds have demonstrated immune-enhancing activity in both healthy and cancer patients.[18,19] Coumarins have been shown to stimulate macrophages and increase phagocytosis, offering significant protection against metastasis and growth of tumor cells.[18] Upon coumarin administration, macrophages are activated and thus capable of entering the tumor, where a specific destruction of tumor cells may occur.[18,19]

Coumarin compounds of angelica and the polysaccharides of the water extract of Japanese angelica have demonstrated immune-modulating and antitumor activity. They have been shown to possess mitogenic activity to B lymphocytes, interferon-producing activity, antitumor activity, and activation of both classic and alternative complement pathways.[20–24] Chinese angelica has been shown to increase murine interleukin-2 production, stimulate the reticuloendothelial system, and increase the production of tumor necrosis factor.[25–27] The antitumor effects of angelica appear to result from the polysaccharide components because these compounds have been shown to exert antitumor effects on experimental tumor models in vivo and inhibitory effects on invasion and metastasis of cancer cells in vitro.[28–30] The time-effect relation of cytokine response also suggests that macrophages and natural killer cells involved in nonspecific immunity were primarily activated, and helper T cells were secondarily affected by angelica polysaccharides.[31] The effects by coumarins, polysaccharides, and extracts of *Angelica* spp. would seem to support the historical use of angelica as an adjunct in cancer therapy.

Kidney Effects

A 24-week, prospective, multicenter, and randomized controlled trial was performed on 158 patients with primary glomerulonephritis.[32] Compared with patients taking losartan, there was a significant continual decrease of proteinuria in the *A. sinensis* group throughout the 24-week time frame of the study, and from week 16 to week 24, there was a significant reduction in proteinuria.

Antimicrobial Activity

Extracts of Chinese angelica have been shown to possess antibacterial activity against both gram-negative and gram-positive bacteria, whereas extracts of Japanese angelica exhibited no antibacterial action.[9] The inconsistency may be secondary to different essential oil concentrations of the extracts used in the studies. The oil of *A. archangelica* has also exhibited significant antifungal and anthelmintic properties but virtually no antibacterial activity.[4,33,34] Because other herbs have much greater antimicrobial activity, *Angelica* spp. would be considered a less-than-optimum antimicrobial agent.

CLINICAL APPLICATION

Angelica spp. have been used worldwide to treat multiple conditions. At present, *A. archangelica* and *A. atropurpurea* are most indicated as expectorants, antispasmodics, and carminatives in the treatment of respiratory ailments, gas, and abdominal spasm. Chinese angelica (*A. sinensis* or *polymorpha*) and Japanese angelica *(A. acutiloba)* appear most useful in the treatment of disorders of menstruation, menopause

(especially hot flashes), atopic conditions, smooth muscle spasm (e.g., uterine cramps, migraines, abdominal spasm), and possibly as an immunostimulatory adjunct in cancer therapy.

Menopause

By far the most popular use of *Angelica* spp. has been the use of *A. sinensis* in the treatment of menopausal complaints. Although a double-blind, placebo-controlled study in women showed no significant benefit, the preparation used (a dried aqueous extract) was clearly lacking some of the important volatile compounds, although it was standardized for ferulic acid content.[35] A study conducted in China showed that a combination of *A. sinensis, Paeonia lactiflora, Ligusticum monnieri, Atractylodes chinensis, Sclerotium poriae,* and *Alisma orientalis* was effective in roughly 70% of women experiencing menopausal symptoms.[36] In an in vitro study with human bone, the aqueous extract of *A. sinensis* was found to directly stimulate proliferation, alkaline phosphatase activity, protein secretion, and type I collagen synthesis in a dose-dependent manner.[37] Also, in a double-blind study, the combination of 100 mg angelica, 60 mg soy isoflavones, and 50 mg of black cohosh extract significantly reduced menstrual migraines.[38] An herbal product, EstroG-100, containing a combination of standardized extracts of *Cynanchum wilfordii, Phlomis umbrosa,* and *Angelica gigas,* was tested in a randomized, double-blind, placebo-controlled trial on 64 pre-, peri-, and postmenopausal women.[39] The constituting symptoms of vasomotor, paresthesia, insomnia, nervousness, melancholia, vertigo, fatigue, rheumatic pain, and vaginal dryness were significantly improved in the EstroG-100 group, without weight gain or any serious side effects.

The estrogenic aspect of dong quai has been called into question for women with estrogen-dependent breast cancer. In vitro studies have shown that the aqueous extract of dong quai stimulated the growth of breast cancer cells, resulting in the caution against its use in herbal preparations for the treatment of peri- or postmenopausal symptoms, especially in women with breast cancer, pending further study.[40]

DOSAGE

- Dried root or rhizome: 1 to 2 g orally, or by infusion, three times a day
- Tincture (1:5): 1.0 to 2 mL, three times a day
- Fluid extract (1:1): 0.5 to 2 mL, three times a day

TOXICOLOGY

Angelica is generally considered to be of low toxicity. However, it contains many substances that may induce photosensitivity. This should be kept in mind when using any *Umbelliferous* plant. This photoreactive activity can be used therapeutically in the treatment of vitiligo and psoriasis.

Use of *Angelica* spp., particularly *A. sinensis,* in men may lead to gynecomastia.[41]

DRUG INTERACTIONS

Angelica species may interfere with anticoagulants. Although animal studies showed no significant variation in the pharmacokinetic parameters of warfarin after dong quai treatment for either single-dose administration or steady-state concentrations of warfarin, there was a single case report of dong quai possibly being responsible for raising the international normalized ratio in women on long-term coumadin therapy. Therefore, in patients on anticoagulant therapy, caution is advised, and monitoring is necessary.[42]

Artemisia absinthium (Wormwood)

Kathy Abascal, BS, JD, RH(AHG), and *Eric L. Yarnell, ND, RH(AHG)*

OUTLINE

Artemisia absinthium (family: Asteraceae)
Common names: wormwood

GENERAL DESCRIPTION

Artemisia absinthium generally occurs as an aromatic, semiwoody, perennial subshrub reaching up to 1 m tall, particularly in its native Mediterranean habitat. The leaves and flowers are used as medicine (Fig. 54.1A and B).

CHEMICAL COMPOSITION

The aerial parts of wormwood contain two components considered most important to its medicinal activity: 0.15% to 0.4% monoterpenoids and 0.2% to 1.5% sesquiterpene lactones.[1] The monoterpenoids α- and β-thujone are perhaps the most notorious constituents, given their potential neurotoxicity. Alpha-thujone is believed to be much more toxic and is present as 0% to 60% of the volatile oil (mean 5.8%) compared with 0% to 69.7% of β-thujone (mean 12.5%).[2,3] Chemotypes of wormwood depend on growing environment and genetics, and only certain ones contain thujones—others have transsabinyl acetate, cis-epoxyocimen, or chrysanthenyl acetate as primary compounds instead.[4] Major sesquiterpene lactones present are absinthin, artabsin, matricin, and anabsinthin (Figs. 54.2–54.5).

HISTORY AND FOLK USE

Wormwood was used historically as a digestive bitter in traditional herbal systems of various societies around its native Mediterranean habitat. The Ebers papyrus, an Egyptian medical treatise and one of the oldest extant pieces of writing (circa 1550 BC), mentions wormwood. Pliny the Elder discussed the use of wormwood to expel parasites, as reflected in the common name of the plant, in the 1st century AD.

The medicinal aspects of most of the history of wormwood are often overshadowed by development in the late 18th century of absinthe. The standard account of the rise of absinthe, a liqueur derived in part from wormwood, begins with French expatriate Pierre Ordinaire, who allegedly developed the first absinthe recipe in 1792 in Switzerland.[5] Absinthe schnapps, absinthe-infused ale (known as "purl"), absinthe-infused wine, and other absinthe-containing beverages had been in use since Dioscorides' time and probably before. Absinthe was apparently made by infusing wormwood, garden angelica root, anise fruit, and marjoram herb in ethanol; distilling them; and adding other flavorings, including volatile oils.[5] The resulting product was bright green and intensely bitter, formed a white precipitate with water (known as louche), and had a high alcohol content (50%–80%).[6]

Henri Dubied and his son-in-law Henri Louis Pernod purchased Ordinaire's formula and began producing large quantities of absinthe at the Pernod Fils distillery.[6] One client for their product was the French military, which invaded Algeria from 1844 to 1847 and issued absinthe regularly to the troops to help prevent and treat dysentery. These troops apparently returned to France with a taste for absinthe and increased the popularity of the beverage.

Although originally most popular with people in the lower classes, absinthe caught on among the intelligentsia in the 1860s and 1870s, a time of cultural ferment, particularly in Paris. Parisians would gather in cafes to sip absinthe, often diluted by pouring cold water over a sugar cube held in a perforated spoon into a glass containing a shot of absinthe.[7] Numerous famous artists of the time drank absinthe regularly, including Vincent van Gogh, whose insanity has been blamed (without proof) on his absinthe habit.

The growing popularity of absinthe, combined with a fire at the Pernod Fils distillery in 1901, led to a surge of absinthe-like products on the market. Unfortunately, these imitation products were often made as cheaply as possible by simply mixing volatile oils with alcohol, adding various coloring agents to give the appropriate green hue (including

copper sulfate), and adding antimony chloride to create the appearance of the white precipitate formed in true absinthe.[5] At the same time, a new phenomenon termed absinthism was becoming widely known. This syndrome was a result of chronic absinthe overindulgence and included bursts of violent aggressiveness followed by prolonged depression, trembling, hallucinations, seizures, and death.[7] However, the presence of adulterated, low-quality, high-ethanol absinthe products on the market and the inability to distinguish the effects of ethanol abuse from those of other compounds in the mixture made it difficult to be certain exactly what was causing absinthism. The levels of the purported neurotoxins thujones in true absinthe were 2 to 4 mg per drink, far below the 10 mg/kg levels needed to induce neurological damage in numerous animal experiments.[8] In the early 20th century, absinthe was banned in most of Europe and the United States. Absinthe, usually with limits on thujones content, is now legal again in many places, including Europe and the United States.

The Eclectics regarded wormwood as a digestive tonic useful in atonic dyspepsia, as a potential treatment for roundworms, and for topical application to sprains and bruises.[9] The dangers of absinthism were well known to these turn-of-the-century American natural physicians, but they did not seem clear on the various problematic elements in the history of absinthe discussed previously.

PHARMACOLOGY

The study of wormwood has focused on four major actions: digestive effects, antiparasitic effects, endocrine effects, and effects on the central nervous system. Growing evidence suggests it is also a potent tumor necrosis factor-α inhibitor. Various reported effects of isolated α- and β-thujone may also be relevant to wormwood's effects.

Digestive Effects

In a controlled clinical trial, wormwood tincture and thujones-free wormwood tincture were both shown to significantly increase bile and pancreatic enzyme secretion in humans, compared with water.[10] The levels of secretion were assessed intraduodenally. These effects seem to be common to many bitter herbs that contain sesquiterpene lactones. Wormwood extract had a modest antidiarrheal effect in one rat model unrelated to infection.[11]

Hepatic Effects

Pretreatment of mice with 500 mg/kg of wormwood extract decreased the 100% lethality of 1 g/kg acetaminophen to 20%.[12] The toxicity of carbon tetrachloride was also reduced by pretreatment of rats with wormwood. Administering 500 mg/kg wormwood extract to rats 6 hours after toxic but sublethal doses of acetaminophen (but not

carbon tetrachloride) significantly reduced hepatic damage. An aqueous extract of wormwood protected mice against carbon tetrachloride- and immune-mediated liver damage, partly by reducing oxidation and partly by inhibiting tumor necrosis factor (TNF)-α and interleukin-1.[13]

Antiparasitic Effects

Wormwood does not appear to contain the same active constituents as sweet Annie *(Artemesia annua),* notably artemisinin, yet aqueous extracts of wormwood showed antimalarial effects in vitro.[14] In mice, oral administration of extracts using 95% ethanol of wormwood was shown to have a potent schizonticidal effect against *Plasmodium berghei,* although not as potent as chloroquine.[15,16] Activity of wormwood against multidrug-resistant *P. falciparum* has been demonstrated in vitro.[16]

Crude extracts of wormwood have been reported to inhibit other organisms in vitro or in animals, including *Trypanosoma brucei, Trichinella spiralis, Leismania amazonensis, Hymenolepsis nana, Naegleria fowleri,* and *Toxocara cati.*[17–23] Crude extract of wormwood was ineffective at treating infection with the nematode *Haemonchus contortus* in gerbils, although infusions and tinctures were effective at treating this infection in sheep and calves.[24,25] Apparently, research in India has shown an effect for wormwood against *Entamoeba histolytica,* but details of this publication could not be obtained.[26]

Endocrine Effects

Wormwood has repeatedly been shown to be antidiabetic and hypoglycemic in multiple animal models of diabetes.[27–30] Contrary to the picture of thujones as largely harmful, a mixture of α- (70%) and β-thujone (20%) 5 mg/kg/day normalized lipid levels in diabetic rats, with no reported adverse effects.[31] A mixture of green tea and wormwood has been shown to both enhance glycemic control and lower elevated lipid levels.

Neurological Effects

Structural and biosynthetic similarities have long been noted among α- and β-thujone and tetrahydrocannabinol from *Cannabis sativa* (marijuana).[32] Although thujones weakly bind cannabinoid receptors in animals and human receptors in vitro, they do not appear to activate them.[33] Wormwood oil also lacked significant cannabimimetic activity in this assay. Thujones' purported hallucinogenic and epileptogenic effects have been disproven except at extremely high concentrations, and "absinthism" has been largely proven to be a result of alcoholism.[34,35] An 80% ethanol extract of wormwood was a strong muscarinic and nicotinic cholinergic receptor agonist in vitro.[36] Methanol extracts of wormwood at concentrations of 100 to 200 mg/kg significantly reduced memory loss and motor incoordination after middle cerebral artery occlusion in rats.[37]

CLINICAL APPLICATIONS

Wormwood was officially approved by the German Commission E for the treatment of patients with dyspepsia, loss of appetite, and biliary dyskinesia.[38] Human research showing that wormwood could increase digestive secretions supports the use of wormwood for loss of appetite, although much more specific work is necessary for definitive proof of efficacy.[10]

Two preliminary open trials have found wormwood teas effective for reducing symptoms and serum transaminase levels in patients with chronic hepatitis B.[39,40] Neither found adverse effects of using up to 6 g per day for 4 weeks. One randomized, single-blind trial found that wormwood was not more effective than placebo for patients with nonalcoholic fatty liver disease.[41]

A randomized, double-blind clinical trial of Crohn's disease found that wormwood extract, standardized to 0.2% to 0.38% absinthin and 0.25% to 0.52% total volatile oil (without thujone), in a base of rose petal, cardamom, and mastic gum or ginger (500 mg three times per day), was more effective than placebo at preventing relapse at 20 weeks.[42] All patients were tapered off corticosteroids after 2 weeks on the medication. At a dose of 750 mg three times per day, this same extract has been shown to lower TNF-α levels in patients with Crohn's disease over 6 weeks.[43]

In an uncontrolled trial, the same extract mentioned earlier, at a dose of 600 mg three times per day in 10 patients with immunoglobulin-A nephropathy not responding to immunosuppressive medications, was effective at decreasing proteinuria and blood pressure over 6 months.[44] Glomerular filtration rate remained stable, and there were no adverse effects.

Wormwood ointment, liniment, and piroxicam were compared in a double-blind, randomized noninferiority trial in adults with knee osteoarthritis.[45] After application of the assigned medication three times daily for 28 days, all groups had improved significantly compared with baseline; there was no significant difference between the groups on outcome measures (assessment of pain, stiffness, and physical function). All treatments were very safe.

In a small clinical trial, 32 Chinese adults with type 2 diabetes were treated with either *Gymnema sylvestre* (gurmar), *Citrullus colocynthis* (bitter apple), wormwood, or placebo capsules for 30 days, all at a dose of 500 mg twice per day.[46] Blinding and randomization were not described. All three herbs significantly decreased fasting blood glucose compared with placebo, with no significant changes in lipid levels.

DOSAGE

Wormwood is primarily used in three forms—tea, tincture, and capsule. Volatile oil should not be used. A typical dose of tea is 1 g (1–2 tsp) dried leaf and flower per cup of water, steeped for 10 to 15 minutes.[47] The tea should be covered during steeping to retain as many volatile constituents as possible. A cup of tea is sipped before meals three times daily. Thujones are water insoluble, so aqueous extracts of the plant are generally low in thujones. A typical dose of tincture is 0.5 to 1 mL three times daily mixed with 2 to 4 oz water, sipped before meals. A typical capsule dose is 2 to 3 g/day in divided doses.[48] Daily thujone intake should be <0.1 mg/kg/day.[49]

TOXICITY

Although much toxicity is ascribed to wormwood, it now appears that this is largely the result of poor research methodology in the early 20th century and improperly conflating thujones, wormwood volatile oil, and absinthe.[34] Any toxicity attributed to the use of various forms of the beverage absinthe must not be confused with the use of teas or tinctures in medicinal doses. Alpha-thujone is considered a neurotoxin and convulsant compound, although these effects are only seen at supratherapeutic doses.[2,50] Beta-thujone, present in much higher levels in wormwood, is generally considered much less toxic.[51] In mice, α- and β-thujone both antagonized γ-aminobutyric acid-A receptors and induced seizures.[52] Alpha-thujone was a much stronger convulsant than β-thujone in this study. This study confirmed previous findings that thujone is rapidly metabolized by the liver and removed from the body in animals.[53]

A 31-year-old man who drank 10 mL of wormwood volatile oil, mistakenly believing it was identical to absinthe, became agitated, belligerent, and incoherent and developed tonic-clonic seizures.[54] Haloperidol improved his mental function, but acute renal failure and rhabdomyolysis were discovered, becoming worse a day later.

Seventeen days after discharge from the hospital, he had recovered completely. More recently, another case was reported of a 53-year-old woman who drank an unspecified amount of wormwood tea and developed rhabdomyolysis and acute renal failure; she recovered completely.[55] A 31-year-old woman who drank wormwood tea was reported to develop disorientation, amnesia, and fever but recovered completely.[55]

These effects have never been documented to occur in patients being treated with reasonable doses of medicinal extracts of or crude wormwood. In one naturopathic medical practice, nine patients over a 3-year period were identified who had been treated with a bitters formula including 11% tincture of wormwood, generally as a treatment for dyspepsia or malabsorption.[56] Administered at a dose of 1 teaspoon (5 mL) three times daily, patients would have been exposed to approximately 0.5 mL wormwood tincture three times daily for weeks to months. For the eight patients with available laboratory data, there was no evidence of renal, hepatic, or other damage. One patient showed improvement in serum liver enzyme levels while taking the bitters formula. None of the patients developed seizures or other signs or symptoms of neurotoxicity. Although retrospective, this study did support the notion that wormwood in this form and at this dose is safe for use in adults as a digestive aid.

Thujones stimulate 5-aminolevulinate synthase in vitro, leading to large increases in porphyrin levels.[57] Although it seems likely that porphyrogenic levels of thujones could be achieved by drinking large volumes of absinthe or volatile oil, levels of intake of tincture, tea, or capsules of wormwood are far lower and unlikely to lead to such high levels. Porphyrogenic effects have not been clearly documented to be induced by wormwood in humans, although thujones and thujone-containing herbs such as wormwood should be avoided by people with porphyria until more information is available.

DRUG INTERACTIONS

No confirmed drug interactions exist for wormwood. It should be avoided in combination with chronic ethanol abuse due to historic reports pertaining to absinthe. Given the low doses of tinctures used, this should not represent any health threat related to ethanol ingestion. Wormwood could theoretically have synergistic porphyrogenic effects with other drugs that can induce porphyric attacks, including barbiturates, hydantoins, and carbamazepine.

Artemisia annua (Sweet Wormwood)

Kathy Abascal, BS, JD, RH(AHG), and *Eric L. Yarnell, ND, RH(AHG)*

OUTLINE

GENERAL DESCRIPTION

The genus Artemisia is named after the Greek goddess Artemis, who apparently used a plant in the genus and gave her name to it.

CHEMICAL COMPOSITION

Sweet wormwood contains several sesquiterpene trioxane lactones, most notably artemisinin (also known as qinghaosu) but also deoxyartemisinin, artemisinic acid, and arteannuin-B.[1] These compounds give the plant a distinctive bitter taste. A peroxide bridge in artemisinin is vital in the antimalarial effects of the compound.[2] Artemisinin is rapidly and readily reduced to dihydroartemisinin in the body. Dihydroartemisinin appears to be the active metabolite of artemisinin and all synthetic artemisinin derivatives developed to date.[3]

Sweet wormwood also contains several flavonoids.[1] In vitro research suggests these flavonoids potentiate the antimalarial activity of the sesquiterpene lactones.[4]

Three semisynthetic derivatives of artemisinin are widely available for use: artemether, artesunate, and arteether.[3] Artemether is a lipophilic β-epimer of dihydroartemisinin and is administered intramuscularly. Artesunate is a hydrophilic hemisuccinate compound administered orally or by injection. Arteether is an ethyl ether derivative of dihydroartemisinin and is lipophilic.

HISTORY AND FOLK USE

The herb, known to the ancient Chinese as qing hao, was recommended for treatment of fever as early as 341 AD, as written in the handbook for prescription for emergencies, *Zhou Hou Bei Ji Fang* by Ge Heng.[3] On the basis of extant written records, qing hao had been prescribed in traditional Chinese medicine for other problems for at least 500 years beforehand.

Qinghaosu, known as artemisinin in the West, was isolated and identified in qing hao in the 1970s in China.[5] It was thoroughly investigated and determined to have excellent antimalarial activity.

PHARMACOLOGY

Antimalarial Effects

Dihydroartemisinin preferentially accumulates in erythrocytes, and malaria-infected erythrocytes accumulate 300 times as much as uninfected erythrocytes.[6] Because active artemisinin compounds all appear to be converted to dihydroartemisinin in vitro and then act as mentioned previously, all these compounds ultimately end up in erythrocytes.

Artemisinin and related molecules appear to act in part by the generation of free radicals, which then damage the membranes of several parasitical organisms.[7] This leads to the rapid death of all stages of malaria parasites.[8] Because the presence of an oxidizing peroxide bridge appears essential to the activity of artemisinin compounds, the oxidative hypothesis is further supported. The importance of iron to this process is unclear. Some investigators suggest that iron chelators such as desferrioxamine increase the activity of artemisinin in vitro.[9]

Artemisinin compounds are synergistic with many other, but not all, antimalarial drugs. Low doses of mefloquine and artemisinin showed definite synergism in vitro against *Plasmodium falciparum,* whereas higher doses showed additive effects.[10] Mefloquine, chloroquine, primaquine, and tetracycline were all potentiated by artemisinin in mice with malaria; the effects of pyrimethamine, cycloguanil, and sulphonamide antibiotics were all decreased.[11]

Antiparasitic Effects

Besides killing *Plasmodium* spp., artemisinin compounds have shown activity against *Schistosoma* spp. and *Clonorchis sinensis.* Numerous animal studies show that artemether and artesunate can prevent and cure infections by *Schistosoma japonicum, Schistosoma mansoni,* and

Schistosoma haematobium.[12–15] It is not clear if artemisinin or dihydroartemisinin is effective. However, artemisinin and the various available semisynthetic variants were all effective at treating *Clonorchis* infections in rats, with no sign of toxicity.[16]

Antineoplastic Effects

Mounting evidence suggests that artemisinin compounds have potent anticancer activity. Artemisinin and quercetagetin 6,7,3′,4′-tetramethyl ether, a flavonoid found in sweet wormwood, both showed activity against several tumor types in vitro.[17] Dihydroartemisinin and artesunate have also been investigated and found to inhibit cancer cells significantly in vitro.[18,19] The presence of ferrous iron appears to be essential for this activity, and sufficient quantities of iron may be necessary to prevent cancer cells from becoming resistant to artemisinin compounds.[18,20]

A combination of ferrous sulfate and dihydroartemisinin proved effective at limiting the growth of implanted fibrosarcomas in rats.[21] The combination did not appear to cause adverse effects. Ferrous sulfate or dihydroartemisinin administered alone was not effective in this model.

CLINICAL APPLICATIONS

Malaria

A meta-analysis confirmed that artemisinin, dihydroartemisinin, artemether, artesunate, and arteether are potent, effective, and safe in patients with uncomplicated malaria compared with other antimalarial agents.[22] In cases of severe or cerebral malaria, these agents appeared to be at least as effective as quinine.[23] No artemisinin compound has been shown to work better than any other, although there is a relative dearth of studies examining this question. It should be noted that most trials have been conducted in Southeast Asia, an area with a high incidence of multidrug-resistant malaria. Profligate use of artemisinin and derivatives by itself (instead of coupled with other drugs and measures as should be) is associated with rising resistance to these agents (Fig. 55.1).[24] Tú Yōuyōu won the Nobel prize for medicine and physiology for her part in the discovery of artemisinin for malaria—the first Chinese woman to win any Nobel prize, and she did so without a postgraduate degree, without ever working outside of China, and without belonging to any scientific academies.

Rising artemisinin resistance, which occurs for a wide range of reasons including widespread sales of counterfeit drug, use of single artemisinin instead of combination therapy, and the expense of the drug, has led to a new approach to malaria. This approach uses whole sweet wormwood and not artemisinin, and as will be shown, has shown it is more effective.

Based on several prior small trials,[25,26] a large double-blind trial was conducted, involving 957 patients aged 5 years and older with malaria in the Democratic Republic of the Congo.[26a] Of these, 943 completed the trial. Participants were randomized to artesunate 4 mg/kg and amodiaquine 10 mg/kg (ASAQ) once daily for three days, an infusion of sweet wormwood providing at most 8.5 mg artemisinin per day, or an infusion of *Artemisia afra* (African wormwood), which had minimal artemisinin. Both infusions were made by adding 5 g of stem and leaf of the respective herbs to 1 L of boiled water and letting it infuse for 10 minutes. It was then strained and drunk in three equal portions throughout the day for 7 days. The dose was the same for children and adults. All patients therefore received some active treatment. They simultaneously received either a placebo tablet (in the herbal infusion groups) or a placebo infusion (made using just 0.2 g of herb, in those taking active ASAQ).

On every clinical measure that matters, sweet and African wormwood were significantly superior to artesunate-amodiaquine. Cure (defined as absence of parasitemia after 28 days) was seen in 89% of African and 96% of sweet wormwood patients, significantly superior compared to just 34% of those receiving ASAQ. Fever resolution occurred within 24 hours with either herb, compared to the significantly longer 48 hours for ASAQ. After 14 days, no patient taking sweet or African wormwood had detectable gametocytes in their blood, while 2% of the drug group did not have clearance. Adverse effects occurred in significantly fewer patients taking wormwood than those taking drugs (5% vs. 43% respectively).

This study calls into question the entire idea of approaching infectious diseases using single molecules. A significant shift of focus of research on malaria treatment and prevention should now go towards complex medicines as are found in herbs. It is particularly notable that the dramatic reduction in gametocytes could open a completely new approach to preventing malaria, as this is the form of the parasite that gets into mosquitos, completing the plasmodial life cycle.

Schistosomiasis

Several double-blind trials conducted in China, the Ivory Coast, and Egypt proved that artemether is effective in reducing the risk of developing schistosomiasis compared with placebo.[27–29] Similar to the work with malaria cited above, a large double-blind trial has assessed the efficacy of sweet and African wormwood in 800 patients with schistosomiasis in the Democratic Republic of the Congo.[29a] Of these, 780 completed the trial. Patients were randomized to either take praziquantel 60 mg/kg daily for 3 days or the same dose of the herbal infusions described in the malaria section. All subjects taking praziquantel also took low-dose herb infusions (0.2 g/L) as a placebo, or if they were taking the herbal infusions at full strength, a placebo tablet. The teas were again administered for 7 days.

All subjects in both herb groups had 100% elimination of eggs in their stools by day 14; this was significantly faster than by day 21 in the praziquantel group. Egg counts dropped by 91% in both herb groups, significantly better than the 67% reduction achieved by the drug. Melena and serum eosinophil levels declined equally well in all groups; hemoglobin levels rose significantly better in the praziquantel and African wormwood groups compared to those taking sweet wormwood. Vomiting, abdominal pain, and headache were common (16% -27% incidence) in the praziquantel group while none of the wormwood groups suffered any significant adverse effects. These herbs should now be considered the standard of care for schistosomiasis, as they are clearly superior in every way to praziquantel based on this very large, rigorous trial.

Cancer

An early case study in a 72-year-old Indian man found that artesunate intramuscularly (IM) 60 mg daily for 15 days followed by artesunate 50 mg once daily by mouth for 6 weeks reduced the size of a laryngeal squamous cell carcinoma by 70% and resolved symptoms.[30] Several other case studies appeared in 2002, including patients with lymphoma, lung, breast, and skin cancer, suggesting that artemisinin and/or artesunate resulted in dramatic improvement.[31] Two cases of metastatic uveal melanoma progressing under conventional chemotherapy had disease stabilization, and one was alive for over 4 years at the time of publication, when artesunate was added to their programs.[32] A case series of 15 patients with prostate cancer (5 postprostatectomy) found that 7 had improvements in their prostate-specific antigen (PSA) levels; all were still alive and without metastasis with an average 9-month follow-up.[33]

The only known double-blind, randomized trial involved 20 patients with resected colorectal cancer treated with oral artesunate

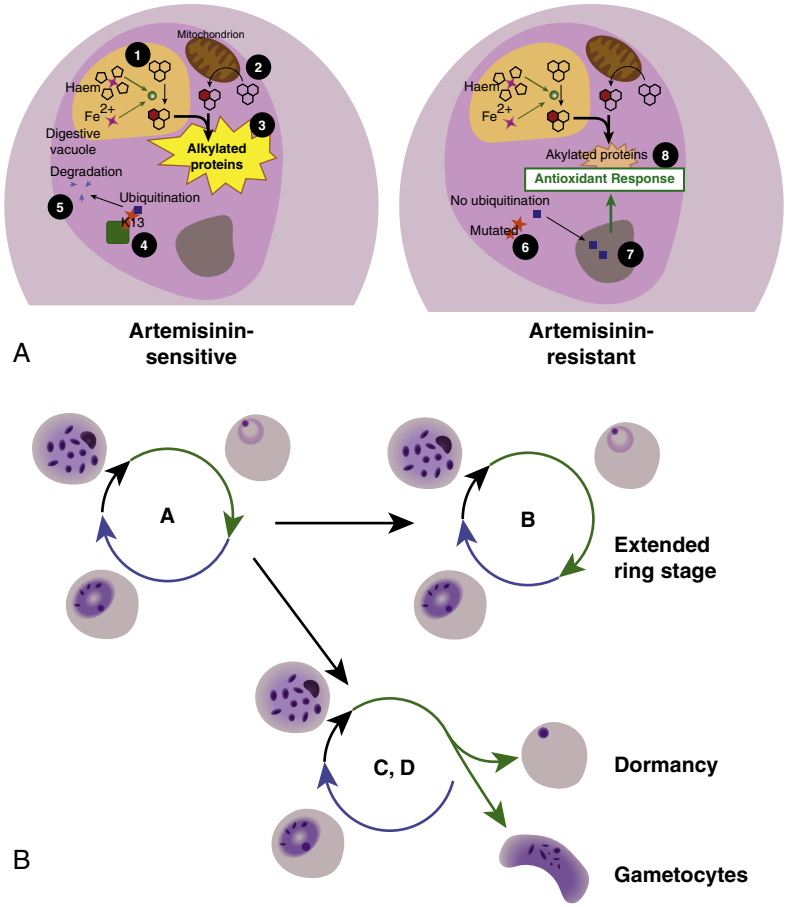

Fig. 55.1 Proposed mechanisms of artemisinin resistance. (A) Relevant biochemical pathways. In ring-stage parasites, artemisinin is primarily activated by heme produced in the process of hemoglobin digestion *(1)* although heme biosynthesis in mitochondria may also contribute *(2)*. Activated artemisinins alkylate nearby proteins in an indiscriminate manner, leading to cell death *(3)*. In artemisinin-sensitive parasites, a transcriptional factor with the potential to upregulate protein turnover and oxidative damage responses is bound via the K13 adaptor *(4)*, leading to its ubiquitination and proteolysis *(5)*. K13 mutation disrupts this binding *(6)*, allowing the factor to enter the nucleus *(7)*, with upregulation of a range of transcriptional responses that can mitigate the downstream consequences of artemisinins *(8)*. (B) Proposed phenotypes associated with artemisinin resistance. The overall length and proportion of time spent in each stage appear relatively fixed in a given strain *(A)*. By extending their ring stage *(B)*, parasites increase the period of reduced vulnerability to artemisinins. An alternative is to increase the proportion of parasites entering dormancy *(C)*, a natural phenomenon observed in all parasite strains that allows escape from relatively short-duration artemisinin exposures in patient treatments. Finally, increasing the proportion of parasites that differentiate into gametocytes *(D)* at a given timepoint could improve the chances of transmission before treatment is administered. (From Woodrow CJ, White NJ. The clinical impact of artemisinin resistance in Southeast Asia and the potential for future spread. *FEMS Microbiol. Rev.* 2017;41[1]:34–48.)

200 mg daily or placebo for 14 days before surgery and found a significantly reduced risk of cancer recurrence in those treated with artesunate.[34] More randomized controlled trials are certainly warranted to determine the optimal dosing and efficacy of artemisinin and artesunate for cancer patients.

ARTHRITIS

In a controlled trial (blinding was not described), 159 patients with rheumatoid arthritis were randomized to take leflunomide and methotrexate alone or coupled with 30 g of sweet wormwood extract daily for 48 weeks.[35] All measures of symptomatic relief and objective measures of inflammation, including C-reactive protein and citrullinated protein antibody levels, were improved significantly more in the sweet wormwood group compared with controls. Corticosteroids were able to be used less in the sweet wormwood group compared with controls, and there were fewer adverse effects as well.

A supercritical carbon dioxide extract of sweet wormwood was tested in 42 patients with knee or hip osteoarthritis.[36] This double-blind, randomized trial compared 75 mg or 150 mg twice daily of the extract with placebo over 12 weeks. Only the low-dose extract group had significant improvements in symptoms, particularly pain, compared with baseline. Between-group comparisons were unfortunately not provided, raising concerns that neither dose of the extract may have been superior to placebo. In an open-label extension of this trial, 28 patients completed an additional 6 months of treatment, and it was found that the benefits seen in the double-blind portion were maintained, with no significant adverse effects.[37]

DOSAGE

The historical dosage of sweet wormwood tea is 5 g/1 L water in three to four divided doses, although doses of up to 30 g daily have also been used.[20,35] The dose of a 1:5 tincture of dried leaf is difficult to extrapolate because a higher ethanol concentration (60%–70%) could be used, which would greatly improve the ability of the solvent to draw artemisinin into the final product. A rough estimate would be 1 to 3 mL three times a day for a healthy adult. The usual dose of isolated artemisinin as a prescription drug for uncomplicated malaria is 500 to 1000 mg/day for 5 days.[20,38] Food does not appear to significantly affect the absorption of artemisinin.[39] Artemisinin and sweet wormwood should not be used for more than 5 to 7 days continuously because they stop being absorbed and stop working at that point.

TOXICITY

The only common adverse effects from the use of sweet wormwood are nausea, loss of appetite, and dizziness.[38] Vomiting is rare. Neurotoxic effects have been observed in experimental animals treated with artemisinin derivatives and in a small handful of humans.[40] These effects have not been observed during the use of whole sweet wormwood or its extracts. Sweet wormwood should be avoided in pregnancy and lactation until more data are available regarding its safety in these situations. Artemisinin derivatives have frequently been used safely in children, particularly when administered by suppository.[41] A single case of encephalopathy has been reported in one breast cancer patient being treated with artemisinin.[42]

DRUG INTERACTIONS

Artemisinin compounds generally show more rapid parasite clearance and fever reduction when combined with mefloquine than either agent given by itself, according to a meta-analysis of clinical trials.[18] Mefloquine's neurological toxicity does not appear to be altered by combination with artemisinin compounds, although the tendency to induce severe vomiting may be slightly lessened.

Artemisinin compounds can be combined safely with doxycycline and tetracycline, according to the results of two clinical trials, although at least one of these trials suggested the combination was less effective than artemether combined with mefloquine.[43,44] Another double-blind trial found that the combination of artesunate and tetracycline was equally effective and much safer than quinine and tetracycline.[45]

Artemisinin may interfere slightly with sulfadoxine-pyrimethamine. In one trial, artemisinin by itself led to insignificantly more rapid parasite clearance than artemisinin combined with sulfadoxine-pyrimethamine.[46] Fever relief was achieved equally rapidly, and adverse effects were absent in both groups. Further research is necessary to determine for certain if there is any negative effect from combining these two agents.

Grapefruit juice initially increases the bioavailability of oral artemether, although it does not stop the inevitable decline in bioavailability of this compound that occurs with repeated dosing over a few days.[47]

Single case studies suggest that artesunate may increase the risk of hepatotoxicity in cancer patients being treated with the drug temozolomide.[48]

Bee Products—Pollen, Propolis, and Royal Jelly

Michael T. Murray, ND

OUTLINE

GENERAL DESCRIPTION

Historically, one of the most valued groups of natural medicines is that of bee pollen, propolis, and royal jelly.

Bee pollen comes from the male germ cell of flowering plants. As the honeybee travels from flower to flower, it fertilizes the female germ cell. Honeybee pollination enables the reproduction of more than 80% of the world's grains, fruits, vegetables, and legumes. The pollen is collected and brought to the hive, where the bees add enzymes and nectar to the pollen.

Propolis is the resinous substance collected by bees from the leaf buds and barks of trees, especially poplar and conifer trees. The bees use the propolis, along with beeswax, to construct the hive. Propolis has antimicrobial activities that help the hive block out viruses, bacteria, and other organisms.

Royal jelly is a thick, milky substance produced by worker bees to feed the queen bee. The worker bees mix honey and bee pollen with enzymes in the glands of their throats to produce royal jelly. Royal jelly is believed to be a useful nutritional supplement because of the queen bee's superior size, strength, stamina, and longevity compared with other bees.

CHEMICAL COMPOSITION

Bee pollen is often referred to as "nature's most perfect food" because it is a complete protein (typically containing 10%–35% total protein), meaning it contains all eight essential amino acids, and it also provides B vitamins, vitamin C, carotenes, minerals, DNA, RNA, numerous flavonoid molecules, and plant hormones.

Propolis and royal jelly have similar nutritional qualities to pollen but considerably higher levels of different biologically active compounds.[1,2] Royal jelly contains approximately 12% protein, 5% to 6% lipids, and 12% to 15% carbohydrates.

HISTORY AND FOLK USE

The use of bee products for medicinal purposes is as old as beekeeping itself. Chinese texts more than 2000 years old include many mentions of bee products. Hippocrates also wrote about them. Honey was so valued during Roman times that it was often used instead of gold to pay taxes.

Of the bee products, propolis was the most valued as a medicinal agent. Hippocrates prescribed propolis to help heal sores, and external and internal ulcers. Propolis-making bees were also depicted on vases from ancient Egypt, where the sign of the bee was often interwoven with the titles of the kings and used as the motif on ornaments presented as rewards for valor. The ancient Egyptians looked upon bees and their propolis as the source of eternal health and life. In the 17th century, propolis was a major ingredient of healing ointments in the European pharmacopoeia.

PHARMACOLOGY AND CLINICAL APPLICATIONS

The health benefits of bee products are much heralded but insufficiently researched. Some overlap exists in the clinical uses of pollen, propolis, and royal jelly. The following discussion notes the principal uses for each of these bee products, as shown in Box .62.1. This list is likely to grow with continued research.

Bee Pollen

Little research has been done on bee pollen, probably because the financial rewards to justify such an investment are lacking. The research that does exist is limited but impressive. For example, studies in animals show that pollen can promote growth and development, protect against free radical and oxidative damage, and protect against the effects of harmful radiation and toxic exposure to chemical solvents.[3–5] A pollen extract has also been shown to produce significant improvement in menopausal symptoms (headache, urinary incontinence, vaginal dryness, decreased vitality) in double-blind studies.[6] The improvements were achieved although the pollen extract produces no estrogenic effect, an important consideration for women who cannot take estrogens of any kind.[7]

BOX 56.1 Clinical Applications for Bee Products

Bee Pollen
- Allergies
- Antioxidant support
- Energy enhancement
- Menopausal symptoms
- Support for chemotherapy and radiation therapy

Propolis
- Common cold
- Gastrointestinal infections
- Immune enhancement
- Topical anti-inflammatory
- Upper respiratory tract infections
- Vaginitis

Royal Jelly
- Elevated cholesterol levels
- Energy enhancement

Propolis

The primary use of propolis has been in immune system enhancement and infections. Propolis has inherent antimicrobial activity that protects the hive block from viruses, bacteria, and other organisms. Propolis has shown considerable antimicrobial activity in in vitro studies.[8–10] Propolis also stimulates the immune system, according to preliminary human studies.[11,12] In vitro and animal studies have also shown that propolis exerts some antioxidant, liver-protecting, anti-inflammatory, and anticancer properties.[13–17]

A key use of propolis is protecting against and shortening the duration of the common cold. A preliminary human study reported that propolis extract (PE) reduced upper respiratory infections in children.[11] In a double-blind study of 50 patients with the common cold, the group taking PE became symptom-free far more quickly than the placebo group.[18]

Another possible application of propolis is in the treatment of inflammatory bowel diseases like Crohn disease and ulcerative colitis. An anecdotal article described an interesting case of ulcerative colitis that responded to propolis therapy.[19] The author suggested that the antimicrobial and anti-inflammatory properties of propolis might be of value in the treatment of inflammatory bowel diseases.

The antimicrobial properties of propolis may also help protect against parasitical infections in the gastrointestinal tract. One preliminary study of children and adults with giardiasis showed a 52% rate of successful parasite elimination in children and a 60% rate in adults in those given PE (amount not stated).[20] However, these results are not as impressive as those achieved with conventional drugs used against giardiasis, so propolis should typically not be used alone for this condition.

Propolis may also have an effect on vaginal infections. In one study, 97 vaginal yeast strains were evaluated for susceptibility to nystatin and PEs. All the yeasts tested were inhibited by low concentrations of PE (maximum of 393.19 mcg/mL of the total flavonoid content), including an isolate resistant to nystatin, regardless of the clinical conditions of the women and the species of yeast isolated.[21]

Propolis has exerted many positive effects on the oral cavity in clinical studies. This includes its use as a mouthwash, showing benefits in reducing dental plaque[22] and gingivitis,[23] healing oral wounds,[24] improving periodontal pocket depths in type 2 diabetics,[25] and reducing the severity and promoting the resolution of oral mucositis associated with chemotherapy.[26] In the study on oral mucositis, on day 7 of the study, there were significant differences in the incidence rates of oral wounds, mucositis, and oral cavity erythema between the propolis group and the placebo group, with 65% of the propolis group having complete healing.

Propolis has also been shown to exert some benefit in type 2 diabetes in terms of improvement in blood sugar control, periodontal health, antioxidant activity, and healing of foot ulcers (topical use). However, the degree of absolute improvement in any of these areas is not sufficient on its own. For example, in one double-blind study, a dosage of 900 mg per day of propolis showed statistically significant advantage over the placebo, but after 12 weeks, the fasting blood sugar only dropped from an average of 152 to 134 mg/dL, and the glycosylated hemoglobin A1C only dropped from 8.2% to 7.4%.[27] Neither of these improvements reached targeted goals in type 2 diabetes. Similar results were seen in another study using a dosage of 400 mg per day of a propolis product.[25] Nonetheless, propolis appears a useful adjunctive therapy for patients with problems with blood sugar control.

Finally, one of the key components of propolis, caffeic acid phenethyl ester, has been shown to exert selective estrogen-receptor modulation.[28] This action, along with inhibition of receptor activator nuclear factor-κB ligand (RANKL)-activated signaling, implied that it might be an effective agent against osteoporosis. RANKL is essential for osteoclast differentiation, activation, and survival. Low concentrations of caffeic acid phenethyl ester (<1 mcM) dose-dependently inhibited RANKL-induced osteoclastogenesis in cell and bone marrow macrophage cultures, as well as decreasing the capacity of human osteoclasts to resorb bone.[29]

Royal Jelly

Some research on royal jelly found a cholesterol-lowering effect. Specifically, 11 human studies have been published, 8 of which were double blind.[30,31] Of the double-blind studies, only three used an oral preparation. An injectable form was used in the other studies. The results of a detailed analysis of the double-blind studies indicated that with oral preparations, despite shortcomings in the design of the studies and lack of standardization with commercial preparations used, royal jelly decreased total cholesterol levels by about 14% in patients with moderate to severe elevations in blood cholesterol levels (initial values ranging from 210–325 mg/dL). Better results may be achieved when using higher-quality royal jelly products.

DOSAGE

- Bee pollen: usually 1 to 3 tablespoons a day
- Propolis: 100 to 500 mg three times a day
- Royal jelly: 50 to 250 mg of royal jelly one to two times a day

TOXICITY

Allergic reactions are the most common adverse reactions. If there is a known allergy to conifer and poplar trees, the use of bee products should be avoided. Allergic reactions can range from mild (e.g., mild gastrointestinal upset) to severe (e.g., asthma, anaphylaxis [shock], intestinal bleeding, and even death in people who are extremely allergic to bee products).[32]

DRUG INTERACTIONS

No drug interactions have been reported.

Beta-Carotene and Other Carotenoids

Michael T. Murray, ND, and *Bob Capelli**

OUTLINE

INTRODUCTION

The carotenoids represent the most widespread group of naturally occurring pigments in nature. They are a highly colored (red and yellow) group of fat-soluble compounds, composed of hydrocarbons (carotenes) and their oxygenated derivatives (oxycarotenoids or xanthophylls). The basic carotenoid structure consists of eight isoprenoid units with a series of conjugated double bonds. All photosynthetic organisms, whether bacteria or plants, contain carotenoid pigments. These compounds not only function as auxiliary pigments in photosynthesis but also play a crucial role in protecting the organism or plant against photosensitization by its own chlorophyll.

More than 600 carotenoids have been characterized, but only about 30 to 50 are believed to have vitamin A activity, and some 20 are found in human plasma and tissues. The biological activity of a carotenoid has historically been considered synonymous with its corresponding vitamin A activity. Beta-carotene has been termed the most active of the carotenoids because of its higher provitamin A activity (Fig. 57.1). However, recent research suggests that this function of carotenoids has been overemphasized because they have been found to exhibit many other important physiological activities. For a carotenoid to have vitamin A activity, it must have an unaltered β-ionone ring with an attached polyene side chain containing 11 carbon atoms. In contrast, apocarotenoids are compounds that have been shortened by the removal of at least one end of the molecule beyond a designated location (e.g., β-Apo-8′-carotenal has been cleaved at the 8′ carbon). Apocarotenes and xanthophylls have reduced or no vitamin A activity, but many have been shown to have significant antioxidant activity, physiological benefits, and the ability to produce meaningful clinical effects.[1–3] Also, approximately 25% of Caucasians do not effectively convert β-carotene to vitamin A.

DIETARY SOURCES

Among the richest sources of carotenes are green leafy vegetables. The carotenoids in green plants are found in the chloroplasts with chlorophyll, usually in complexes with a protein or lipid. Beta-carotene is the predominant form in most green leaves. In general, the greater the intensity of the green color, the greater the concentration of β-carotene. Orange-colored fruits and vegetables (e.g., carrots, apricots, mangoes, yams, squash) typically have higher concentrations of provitamin A carotenoids, the provitamin A content again paralleling the intensity of the color. Yellow vegetables have higher concentrations of xanthophylls and hence lower provitamin A activity. In orange and yellow fruits and vegetables, β-carotene concentrations are high, but other provitamin A carotenoids typically predominate. Red and purple vegetables and fruits, such as tomatoes, red cabbage, berries, and plums, contain large portions of non–vitamin A–active pigments, including flavonoids. Legumes, grains, and seeds are also significant sources of carotenoids. Carotenoids are also found

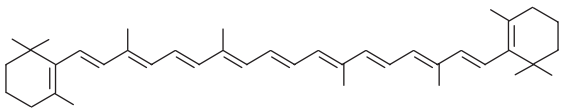

Fig. 57.1 Beta-carotene.

TABLE 57.1 Provitamin A Carotenoids and Food Sources

Carotenoid	Vitamin A Activity (%)	Food Sources
Beta-carotene	100	Green plants, carrots, sweet potatoes, squash, spinach, apricots, green peppers
Alpha-carotene	50–54	Green plants, carrots, squash, corn, watermelons, green peppers, potatoes, apples, peaches
Gamma-carotene	42–50	Carrots, sweet potatoes, corn, tomatoes, watermelons, apricots
Beta-zeacarotene	20–40	Corn, tomatoes, yeast, cherries
Cryptoxanthin	50–60	Corn, green peppers, persimmons, papayas, lemons, oranges prunes, apples, apricots, paprika, poultry
Beta-apo-8′-carotenal	72	Citrus fruit, green plants
Beta-apo-12′-carotenal	120	Alfalfa meal

TABLE 57.2 Non–Provitamin A Carotenoids and Food Sources

Carotene	Vitamin A Activity (%)	Food Sources
Lycopene	0	Tomatoes, carrots, green peppers, apricots, pink grapefruit
Zeaxanthin	0	Spinach, paprika, corn, fruits
Lutein	0	Green plants, corn, potatoes, spinach, carrots, tomatoes, fruits
Canthaxanthin	0	Mushrooms, trout, crustaceans
Crocetin	0	Saffron
Capsanthin	0	Red peppers, paprika
Astaxanthin	0	Salmon, trout, lobster, shrimp, krill

in various animal foods such as salmon and other fish, egg yolks, shellfish, milk, and poultry. Carotenoids are also frequently added to foods as colorants. Table 57.1 lists carotenoids with provitamin A activity found in common food sources, whereas Table 57.2 lists some important carotenoids that have no vitamin A activity. The structures of two of these, lycopene and zeaxanthin, are illustrated in Figs. 57.2 and 57.3.

According to a detailed analysis of the levels of carotenoids in 120 fruits and vegetables, lycopene is found in few.[4] Table 57.3 lists the foods that contained lycopene. These values indicate that lycopene levels are retained in food processing.

Astaxanthin is a vibrantly deep red pigment found predominantly in marine life. When microalgae rich in astaxanthin are consumed by salmon, lobster, shrimp, krill, and other sea life, the intense red pigmentation results in these animals having red or pink flesh or outer shells. Salmon is the richest source, with different species having different levels. Here are the levels per 6-ounce serving:

Wild Sockeye salmon 6.4 mg
Wild Coho salmon 3.6 mg
Farmed Atlantic salmon 1.6 mg
Pink salmon 1.2 mg

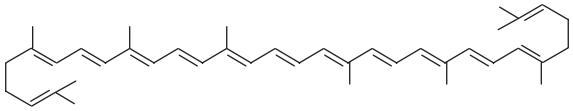

Fig. 57.2 Lycopene.

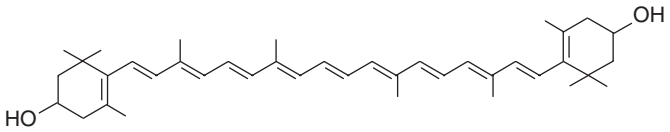

Fig. 57.3 Zeaxanthin.

TABLE 57.3 Lycopene Content of Common Foods

Food	Lycopene (mg/100 g)
Apricot, canned	0.06
Apricot, dried	0.8
Grapefruit (pink and raw)	3.4
Guava juice	3.3
Tomato, raw	3.1
Tomato juice, canned	8.6
Tomato paste, canned	6.5
Tomato sauce, canned	6.3
Watermelon, raw	4.1

METABOLISM

Absorption

Various factors are known to influence the absorption efficacy of vitamin A and carotenoids. Although retinol does not require bile acids to assist absorption, carotenoids do. Other factors that affect vitamin A and carotenoid absorption include the following:

- The presence of fat, protein, and antioxidants in the food
- The presence of bile and a normal complement of pancreatic enzymes in the intestinal lumen
- The integrity of the mucosal cells

The absorption efficiency of dietary vitamin A is usually quite high (80%–90%), with only a slight reduction in efficiency at high doses. In contrast, β-carotene's absorption efficiency is much lower (40%–60%), and it decreases rapidly with increasing dosage. Carotene supplements are better absorbed than the carotenes from foods.[5] Supplying only β-carotene, whether natural or synthetic, may exert a detrimental effect on the absorption of other carotenes. For example, β-carotene supplementation has been shown to inhibit the absorption of lutein.[6] Studies in humans have shown that with β-carotene supplementation, the absorption of lutein can drop by more than 50%.[7] Interestingly, the absorption of lutein from vegetables is five times greater than that of β-carotene.[8]

Transformation in the Intestinal Mucosa

As stated earlier, of the more than 600 carotenoids that have been reasonably well characterized, only about 30 to 50 are believed to have provitamin A activity. However, carotenoids provide the majority of dietary vitamin A for those who have the genetics for conversion. Provitamin A carotene conversion to vitamin A depends on diverse factors:

- Genetics
- Protein status
- Thyroid hormones
- Zinc
- Vitamin C

TABLE 57.4 Distribution of Carotenoids in Some Human Tissues (milligrams per kilogram)

Tissue	Carotenoids	Beta-Carotene
Adrenal	20.1 ± 11.9	10.8 ± 5.5
Liver	8.3 ± 21.3	—
Testis	5 ± 7.7	4.7 ± 2
Fat	3.9 ± 6	1.3 ± 1.1
Pancreas	2.3 ± 1.2	1.1 ± 1
Spleen	1.6 ± 2.2	1.2 ± 0.5
Lung	0.6 ± 1.0	—
Thyroid	0.6 ± 0.4	—

The conversion diminishes as carotene intake increases and when serum retinol levels are adequate. Beta-carotene and other provitamin A carotenes were originally believed to be cleaved by carotene dioxygenase at the 15,15' double bond, which would yield two molecules of all-trans retinal. However, it has been established that the dioxygenase enzyme nonspecifically attacks any one of the double bonds of the β-carotene, resulting in the formation of a corresponding apo-β-carotenal or retinal.[9] The apocarotenal formed can either be degraded to retinal or absorbed. The retinal formed is then converted to retinol by retinaldehyde reductase.

Uncleaved provitamin A carotenoids, apocarotenoids, and non–provitamin A carotenoids, like retinol, are transported in the chylomicra.

Genetics of Conversion of Carotenoids to Vitamin A

Evolving research is showing that many humans are not very effective converting beta-carotene into vitamin A. The enzyme 15,15′-monooxygenase (BCMO1) responsible for converting beta-carotene to vitamin A has six common single-nucleotide polymorphisms (SNPs) that result in the production of a slow to almost completely ineffective BCMO1.[10–12]

Transport, Storage, and Excretion

No specific carrier protein exists in the plasma for carotenoids. These compounds are typically transported in human plasma in association with the plasma lipoproteins, particularly by low-density lipoprotein (LDL). As a consequence, patients with high serum cholesterol or LDL levels tend to have high serum carotene levels. The concentrations found in the plasma usually reflect the dietary concentration, with β-carotene typically comprising only 20% to 25% of the total serum carotene level.[13]

Lycopene is the most predominant carotenoid in human plasma, accounting for more than 50% of the carotenoids in human serum. Owing to its lipophilic nature, lycopene is found to concentrate in the LDL and very-low-density lipoprotein fractions and not in the high-density lipoprotein (HDL) fractions of the serum cholesterol. Interestingly, although trans-lycopene constitutes the predominant isomer in food sources, in human plasma, 50% of the total lycopene has been found as cis isomers. Whether this is due to in vivo isomerization or preferential absorption of cis-lycopene is still unclear. Little is known about in vivo metabolism of lycopene.

Carotenes may be stored in adipose tissue, the liver, other organs (the adrenals, testes, and ovaries have the highest concentrations), and the skin (Table 57.4). Deposition in the skin results in carotenodermia. This is a benign (and probably beneficial) state. Carotenodermia not directly attributable to dietary intake or supplementation, however, may indicate a deficiency in a necessary conversion factor (e.g., zinc, thyroid hormone, vitamin C, or protein).

Astaxanthin behaves differently than other carotenoids due to its unique structural and chemical properties.[14] Astaxanthin possesses six qualitative features that are important to distinguish:

- It can span the entire depth of the cell membrane to protect both the external and internal cell membranes.
- It crosses the blood–brain and blood–retinal barriers to provide its protective properties to the eyes and brain.
- It is more easily incorporated into many cells, including skin, muscle, and nerves.
- It does not become a prooxidant and increase free radical proliferation.

PHYSIOLOGICAL ROLES AND PHARMACOLOGICAL ACTIVITY

Antioxidant Activity

In general, carotenes exert significant antioxidant activity, whereas the antioxidant activity of vitamin A is relatively minor.[1] However, its antioxidant actions are specific in that they are involved primarily in scavenging singlet molecular oxygen and, to a much lesser extent, peroxyl radicals. The efficacy of the various carotenoids for physical quenching is related to the number of conjugated double bonds present in the molecule, determining their lowest triplet energy level. The most efficient singlet oxygen-quenching carotene is the open-ring carotenoid lycopene,[15] whereas even more potent is the xanthophyll astaxanthin.[16]

The antioxidant activity of carotenes is thought to be responsible for their anticancer effects. Because aging is associated with free radical damage, a hypothesis developed that carotenes may protect against aging as well. Evidence seems to support this hypothesis. It appears that tissue carotenoid content is the most significant factor in determining the maximal life-span potential (MLSP) of mammalian species ($r = 0.835$ for 12 mammalian species, and for primates alone, $r = 0.939$).[17] For example, the human MLSP of approximately 90 years correlates with a serum carotene level of 50 to 300 mg/dL, whereas other primates, such as the rhesus monkey, have an MLSP of approximately 34 years, correlating with a serum carotene level of 6 to 12 mg/dL.

Although β-carotene has received most of the attention, many carotenoids that have either low or no vitamin A activity exert much greater protection compared with β-carotene. For example, β-carotene generates vitamin A much more efficiently than α-carotene, but α-carotene is approximately 38% stronger as an antioxidant and 10 times more effective in suppressing liver, skin, and lung cancer in animals compared with β-carotene. Even more powerful are lycopene, lutein, and astaxanthin. Studies have shown astaxanthin to exhibit the highest overall antioxidant activity.[16] In singlet oxygen quenching, astaxanthin is 11 times stronger than beta-carotene. In total free radical elimination, natural astaxanthin is:

- 14 times stronger than vitamin E
- 18 times stronger than proanthocyanins
- 21 times stronger than synthetic astaxanthin
- 54 times stronger than beta-carotene

The antioxidant effects of carotenoids are believed to be a key mechanism of action for their role as a protective factor against in aging-related, chronic degenerative diseases such as atherosclerosis, heart disease, strokes, cancer, macular degeneration, and neurodegenerative diseases. Numerous epidemiological studies have shown the association with an increased intake or higher blood levels of various carotenoids and lower incidence of these diseases and aging-related disorders.

Anti-inflammatory Activity

In addition to their antioxidant effects, many carotenoids also act directly and indirectly on many aspects of inflammation that include cellular signaling cascades, such as nuclear factor κB (NF-κB), mitogen-activated protein kinase (MAPK), and nuclear factor erythroid 2–related factor 2 (Nrf2).[18] In particular, astaxanthin has shown significant anti-inflammatory effects.[19] These effects were quite evident in a double-blind, placebo-controlled study in people with rheumatoid arthritis. Subjects took either astaxanthin (12 mg per day) or placebo for 8 weeks. Results showed a steady trend toward improvement in both pain levels and daily satisfaction from the beginning of the study to a midway point after 4 weeks, and then increasing improvement during the last 4 weeks of the study. By the end of 8 weeks, the pain scores had dropped by 35% in the group taking astaxanthin, and the satisfaction scores improved by 40%.[20] These effects were also studied in soccer players.[21] In a double-blind study, 40 male soccer players were randomly assigned to astaxanthin (4 mg daily) and placebo groups. After 90 days, results showed a number of benefits with astaxanthin, including a rise of salivary secretory IgA levels, a decrease in prooxidant-antioxidant balance, a decrease in muscle enzymes levels, and a significant blunting of the systemic inflammatory response as noted by C-reactive protein.

Immune System

Carotenoids have demonstrated significant effects in enhancing immune function.[22] Some of these effects are probably related to an ability to prevent stress-induced thymic involution, as well as promote thymus growth and function and increase interferon's stimulatory action on the immune system.[23] Interferon is a powerful immune-enhancing compound that plays a central role in protection against viral infections.

Reproduction

Beta-carotene reportedly has a specific effect in fertility distinct from its role as a precursor to vitamin A. In bovine nutritional studies, cows fed β-carotene–deficient diets exhibited delayed ovulation and an increase in the number of follicular and luteal cysts.[24,25] The corpus luteum has the highest concentration of β-carotene of any organ measured.[26] The carotene cleavage activity changes with the ovulation cycle, with the highest activity occurring during the midovulation stage. It has been speculated that a proper ratio of carotene to retinol must be maintained to ensure proper corpus luteum function.

Because the corpus luteum produces progesterone, inadequate corpus luteum function could have significant deleterious effects. Inadequate corpus luteum secretory function is one of the characteristic features of infertile or irregular menstrual cycles, or both.[27] Furthermore, reduced corpus luteum function and an increased estrogen-to-progesterone ratio has been implicated in various clinical conditions, including ovarian cysts, premenstrual tension syndrome, fibrocystic breast disease, and breast cancer.[28] Because supplemental β-carotene given to cows significantly improves corpus luteum function in cows and reduces the incidence of ovarian cysts (42% in control group vs. 3% in the β-carotene group), it may have similar effects in humans.

Astaxanthin has also shown benefit in improving reproductive function in animals. Human research has focused exclusively on male fertility and its effects on sperm to date. A double-blind, placebo-controlled, randomized study was done in 30 couples who had been unsuccessfully trying to conceive for more than 12 months. In each couple, the men were diagnosed as being infertile according to World Health Organization (WHO) guidelines, whereas the women showed no signs of infertility. The men in the treatment group were administered 16 mg per day of natural astaxanthin along with other antioxidants, and the men in the control group received placebos. At the end of the study, significant differences between the two groups included the following:

- Sperm linear velocity increased in the astaxanthin group.
- Reactive oxygen species decreased in the astaxanthin group.
- Of the astaxanthin-treated couples, 54.5% got pregnant, versus 10.5% of the placebo couples.

The researchers commented that the results in this trial were better than those in similar trials in which other antioxidants were used. "Functional improvement may be related to the reduction of reactive oxygen species resulting in enhancement of linear velocity and reduction of DNA damage."[29]

Photoprotection

Photo-oxidative processes play a role in the pathology of light-exposed tissues, including the eyes and skin. Age-related macular degeneration affects the macula lutea of the retina, the area of maximal visual acuity. It is a major cause of irreversible blindness among the elderly in the United States. Macular pigments protect against the photo-oxidative processes, which may be related to the antioxidant activities of the macular carotenoids or their light-filtering effects. Lutein and zeaxanthin are responsible for the coloration of the macula lutea. It is important to point out that neither lycopene, α-carotene, or β-carotene is found in this tissue. Lutein supplementation has proven particularly beneficial in offering protection against macular degeneration, as well as improving visual acuity in the early stages of the disease.[30]

In regard to protecting the skin against oxidative damage, although clinical applications have focused on β-carotene (discussed later in the chapter), there is evidence indicating that lycopene and astaxanthin may be better suited for this application.[31,32] For example, in a double-blind trial, lycopene completely inhibited UVA1- and UVA/B-induced upregulation of genes in the skin that are indicators of oxidative stress, photodermatoses, and skin aging.[31]

COMMERCIAL FORMS

Six primary sources of carotenes are on the market:

- Synthetic all-trans β-carotene
- Beta- and α-carotene from the algae *Dunaliella*
- Mixed carotenes from palm oil
- Lutein
- Lycopene
- Astaxanthin

Of the three sources of β-carotene, mixed carotenes from palm oil carotenes seem to be the best form (Table 57.5). Palm oil carotenes appear to give much better antioxidant protection compared with either synthetic or algal derived beta-carotene. The carotene complex of palm oil closely mirrors the pattern in high-carotene foods. In particular, whereas the synthetic version only provides the trans configuration of β-carotene, natural carotene sources like palm oil provide β-carotene in both a trans and cis configuration:

- 60% β-carotene (both trans and cis isomers)
- 34% α-carotene
- 3% γ-carotene
- 3% lycopene

Palm oil carotenes are absorbed about 4 to 10 times better than synthetic all-trans β-carotenes.[32–35] Carotenes from *Dunaliella* have also been shown to be well absorbed.[36] The widespread health concerns over the use of "tropical oils" like palm and coconut do not apply to carotene products extracted from palm oil because the fat content is minimal. In addition, the real problem with palm oil occurs when it is processed (i.e., partially hydrogenated).

TABLE 57.5 Antioxidant Potential of Different Carotene Products (Per 25,000 IU of Vitamin A Activity)

Source	Carotenoid	Quenching Rate	% In source	mg/25,000 IU	Antioxidant Potential
Antioxidant potential	Alpha-carotene	1.9	33	7.36	2.6
	Beta-carotene	1.4	63	14.04	3.66
	Gamma-carotene	2.5	2.5	0.56	0.26
	Lycopene	3.1	0.1	0.02	0.01
	TOTAL				6.53
Algal	Alpha-carotene	1.9	4	0.61	0.22
	Beta-carotene	1.4	96	14.69	3.83
	TOTAL				4.05
Synthetic	Beta-carotene	1.4	100	14.97	3.9
	TOTAL				3.9

Lutein is derived primarily from marigold flowers, whereas lycopene is derived from tomato extracts. Astaxanthin is most often derived from *Haematococcus pluvialis,* an astaxanthin-rich type of algae. Although astaxanthin is found in certain fish oil supplements such as salmon, herring roe, or krill oil, the amounts in these sources are much lower than those provided from extracts of *H. pluvialis.* For example, the level of astaxanthin naturally occurring in a capsule of salmon or krill oil is in the range of 100 mcg (0.1 mg). That amount is not much compared with the 4 to 12 mg per capsule found in most astaxanthin supplements derived from *H. pluvialis.* There are other sources of astaxanthin on the market, but these forms are produced from either chemical synthesis or from genetically modified yeast (*Xanthophyllomyces dendrorhous,* formerly *Phaffia rhodozyma*). These synthetic forms are approved as feed additives and are often fed to salmon in fish farms to give them red flesh, but the synthetic forms differ in stereochemistry and esterification. The synthetic form is also 20 times less effective as an antioxidant, so it is unlikely to have the same benefits as natural astaxanthin.[37]

CLINICAL APPLICATIONS

The primary clinical applications of carotenoids are as follows:

- Prevention of cancer
- Prevention of cardiovascular disease
- Prevention of cognitive decline and dementia
- Macular degeneration and visual processing (see Chapter 195, Macular Degeneration)
- Immune enhancement
- Vaginal candidiasis
- Photosensitivity disorders

Although there is great overlap, it is important to understand that each carotenoid that may exert greater benefit in specific clinical indications.

Prevention of Cancer

Most epidemiological studies have demonstrated a strong inverse correlation between dietary beta-carotene intake and various cancers, especially those involving epithelial tissues (e.g., lung, skin, uterine cervix, gastrointestinal tract, and breast cancer).[38–42] The epidemiological association is much stronger for beta-carotene than for vitamin A. This may reflect beta-carotene's superior antioxidant, immune-potentiating, and anticarcinogenic activity.

Here is an important consideration. Although most of the epidemiological studies employed dietary questionnaires to determine intake, when blood levels were used instead, the results were even better for carotene intake reducing cancer risk. In a systematic review and meta-analysis of prospective studies of dietary intake and blood concentrations of carotenoids and breast cancer risk, beta-carotene intake as determined by dietary questionnaire was associated with a reduced breast cancer risk with a relative risk (RR) of 0.95. In contrast, the summary RR for blood concentrations of 50 µg beta-carotene/dL was 0.82. Interestingly, only beta-carotene was associated with a reduction in RR of the six dietary carotenes assessed in this analysis (alpha-carotene, beta-carotene, beta-cryptoxanthin, lycopene, lutein/zeaxanthin, and total carotenoids).

Although there is no argument that a diet high in carotenes protects against cancer, the big question is: "Can β-carotene supplementation reduce the risk of cancer?" The answer appears to be that synthetic β-carotene supplementation does not. Three highly publicized reports on cancer prevention trials featuring synthetic all-*trans* β-carotene in high-risk groups produced negative results. Taking a close look at each of these studies is important to help put things into perspective.

The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study Group

This study's population was 29,000 men in Finland who smoked and drank alcohol.[43] The men were given β-carotene (20 mg/day) or vitamin E, or both. The results of this study indicated an 18% increase in lung cancer in the β-carotene group. This result was not totally unexpected, as studies in primates demonstrated that when animals were fed alcohol and β-carotene, they experienced an increase in liver damage as a result of oxidative damage.[44] Other researchers have pointed out that β-carotene is susceptible to oxidative damage.[45] The protection against the oxidative damage of β-carotene is the presence of other antioxidant nutrients.[46] The absence of these protective nutrients could result in the formation of cancer-causing compounds, stressing the importance of relying on foods and broader-spectrum nutritional antioxidant support. Adding support to this statement is the fact that the group receiving both β-carotene and vitamin E did not show an increase in cancer. In the group not receiving β-carotene supplements, there was a strong protective effect of high dietary β-carotene and blood carotene levels against lung cancer. Altogether, these data strongly suggest that the protection offered by β-carotene is only apparent when other important antioxidant nutrients are provided and may not be provided by the synthetic forms.

Carotene and Retinol Efficacy Trial

The second trial reporting on the role of β-carotene in a high-risk group is the Carotene and Retinol Efficacy Trial (CARET).[47] This study comprised more than 18,000 U.S. male and female smokers and

asbestos workers. It was halted 21 months prematurely in January 1996 after 4 years of intervention indicated that β-carotene supplementation (30 mg/day) increased lung cancer by 28% and overall deaths by 17%. Although this appears dramatic, a closer look at the numbers and percentages puts them into proper perspective. Among active smokers, the risk of lung cancer during the CARET study was 5 per 1000. The 28% increase found with β-carotene supplementation increased this number to roughly 6 per 1000.[47]

Interestingly, once again in the group not taking β-carotene, the lowest rate of cancer was found among individuals with the highest blood β-carotene levels, and in former smokers, β-carotene supplementation actually reduced cancer risk by 20%.

The Physician's Health Study

The Physician's Health Study was composed of 22,071 U.S. male physicians who took either 50 mg of β-carotene or a placebo every other day for 12 years. Results demonstrated no significant effect—positive or negative—on cancer or cardiovascular disease, even in the group (11%) that smoked.[48]

General Comments on the "Negative" Studies

Although scientific research is clear that diets high in antioxidants are protective against many cancers, the data are not as solid with antioxidant supplements. Three main points should be kept in mind when discussing research with antioxidants:

- The antioxidant system of the body relies on a complex interplay of many different dietary antioxidants.
- Taking any single antioxidant nutrient is not enough. Total protection requires a strategic, comprehensive dietary and supplement program.
- Although dietary supplements are important, they cannot replace the importance of consuming a diet rich in antioxidants.

A shortcoming of many dietary studies is that researchers often focus on the effects of just one factor. In a way, this is like judging an entire symphony by listening to a single trombone. Such research has its value, but it is not complete and often raises more questions than it answers.

Another issue is that not all antioxidants are created equal. When it comes to quenching free radicals, each may have a somewhat different (and usually narrow) range of activity. For example, β-carotene is an effective quencher of a free radical known as singlet oxygen but is virtually powerless against the dozens of other types of free radicals. As a result, it has a narrow range of benefit and is susceptible to being damaged itself and forming a free radical without additional antioxidant support. Most antioxidants require some sort of "partner" antioxidant that allow them to work more efficiently. Additionally, research has shown that β-carotene itself can become damaged if used alone (i.e., without its partner antioxidants vitamin C, vitamin E, and selenium). For example, although studies showed that synthetic β-carotene supplements given alone actually increased the risk of cancer in smokers, when β-carotene was given along with vitamin E and selenium, it reduced cancer deaths by a significant 13%.[43] Damaged β-carotene is extremely toxic to the liver, the lining of the arteries, and the lungs. This fact alone may explain some of the disappointing results from recent β-carotene studies.

The results of these three studies indicate that synthetic β-carotene supplementation may have adverse effects in high-risk groups for cancer and cardiovascular disease. These studies do not invalidate the hundreds of studies showing the preventive effect of a diet rich in carotenes and nutritional antioxidants against cancer and cardiovascular disease. These results seem to indicate the need for a diet high in carotenes, and if carotene supplementation is desired, people should not smoke, natural forms should be used, and the β-carotene needs to be protected against the formation of toxic derivatives by taking extra vitamins C and E and selenium. That said, even studies with β-carotene supplementation that also used additional vitamins C and E failed to show a protective effect against either cancer or cardiovascular disease.[49,50]

Other Prospective Cancer Prevention Studies

In addition to these three highly publicized studies, several prospective and double-blind studies have shown promising results. In particular, β-carotene supplementation is especially effective in the treatment of early cancerous lesions of the oral cavity and esophagus.[51,52] Although β-carotene has been shown to exert these benefits on its own (in dosages ranging from 15–180 mg/day), one of the most positive studies showing a reduction in cancer risk with supplemental β-carotene to date is one that featured a broader supplement program. The Linxian Cancer Chemoprevention Study was a prospective study of 30,000 rural Chinese adults. In one substudy, subjects received one of four supplement programs:

- Retinol and zinc
- Riboflavin and niacin
- Vitamin C and molybdenum
- Beta-carotene, vitamin E, and selenium (dosages one to three times greater than the U.S. recommended daily allowance)

The latter group demonstrated a 13% decrease in cancer deaths and a reduction of 9% in overall deaths.[53,54] These results again support the notion that a combination of antioxidants is superior to high levels of any single antioxidant.

Lycopene in Prostate Cancer

In one of the first detailed studies of lycopene protection against cancer, Harvard researchers discovered that men who consumed the highest levels of lycopene (6.5 mg/day) in their diet showed a 21% decreased risk of prostate cancer compared with those eating the lowest levels.[55] Men who ate two or more servings of tomato sauce each week were 23% less likely to develop prostate cancer during the 22 years of the study than men who ate less than one serving of tomato sauce each month. In addition to a protective effect, lycopene may exert a therapeutic effect as well. In a study of patients with existing prostate cancer, lycopene supplementation (15 mg/day) was shown to slow tumor growth, shrink the tumor, and lower the level of prostate-specific antigen (PSA), a marker of cancer activity, by 18%.[56]

In another study, the efficacy of lycopene (4 mg/day) plus orchidectomy was compared with orchidectomy alone in the management of advanced prostate cancer.[57] Fifty-four patients with histologically confirmed metastatic prostatic cancer and a performance status of 0 to 2 (WHO) were entered into the trial. At 6 months there was a significant reduction in PSA level in both treatments, but it was more marked in the lycopene group (mean 9.1 and 26.4 ng/mL). After 2 years, these changes were more consistent in the lycopene group (mean 3.01 and 9.02 ng/mL). Eleven (40%) patients in the orchidectomy-alone group and 21 (78%) in the lycopene group had a complete PSA response, with a partial response in 9 (33%) and 4 (15%) and progression in 7 (25%) and 2 (7%), respectively. Bone scans showed that in the orchidectomy arm, only 4 (15%) patients had a complete response versus 8 (30%) in the lycopene group, with a partial response in 19 (70%) and 17 (63%) and progression in 4 (15%) and 2 (7%), respectively. Of the 54 patients who entered the trial, 19 (35%) died: 12 (22%) in the orchidectomy group and 7 (13%) in the lycopene group. Researchers concluded that adding lycopene to orchidectomy produced a more reliable and consistent decrease in serum PSA level; it not only shrunk the primary tumor but also diminished the secondary tumors, providing better relief from bone pain and lower urinary tract symptoms

and improving survival compared with orchidectomy alone. Lycopene appears to be most useful in the early stages of prostate cancer because no clinically relevant benefits were shown for patients with advanced stages of the disease in one clinical trial. Lycopene also does not appear to be effective for androgen-independent prostate cancer.[58] Lycopene does, however, appear to be helpful in benign prostate hyperplasia (BPH). In one double-blind, placebo-controlled trial involving 40 patients with histologically proven BPH free of prostate cancer were randomized to receive either lycopene at a dose of 15 mg/day or placebo for 6 months.[59] The primary end point of the study was the inhibition or reduction of increased serum PSA levels. Symptoms of the disease, as assessed via the International Prostate Symptom Score questionnaire, were improved in both groups, with a significantly greater effect in men taking lycopene supplements.

In a 6-month repeat-biopsy randomized trial among men with high-grade prostatic intraepithelial neoplasia (HGPIN), 58 participants consumed a placebo or lycopene (30 mg/day). Pre- and posttreatment biopsies were immunostained and digitally scored. Pathologists blindly reviewed each biopsy to score histologic features. There were no meaningful differences between the groups in PSA, IGF-1, or IGF-binding protein 3 concentrations, nor any significant differences in expression of MCM-2 or p27 in epithelial nuclei or prevalence of cancer. However, more extensive atrophy and less extensive HGPIN was more common in the lycopene group.[57] Despite large differences in serum lycopene after intervention, no treatment effects were apparent on either the serum or benign tissue end points. Larger studies are warranted to determine whether changes observed in the extent of HGPIN and focal atrophy can be replicated.

Prevention of Cardiovascular Disease

Just as in the case of cancer prevention, although a high intake of carotene-rich foods appears to be protective, the same may not be true for supplementation with synthetic β-carotene.[1–3,60,61] Double-blind trials wherein people were supplemented with β-carotene alone or placebo have not found benefit for synthetic β-carotene supplementation.[61] Three of four trials reported a higher risk of cardiovascular disease in the β-carotene groups compared with those receiving placebo.

Again, a major issue with much research on carotenes in cardiovascular disease protection has been the focus on β-carotene. It may not be the most important marker of protection. A large clinical study evaluating the relationship between carotene status and heart attack (acute myocardial infarction) found that lycopene, but not β-carotene, was protective.[62] Lycopene, lutein, and astaxanthin exert greater antioxidant activity compared with β-carotene in general but specifically against LDL oxidation.[63–65]

Beta-carotene is likely of less importance compared with many other carotenes, especially lycopene, astaxanthin, and lutein, because it does not get incorporated into LDL effectively, although it may help protect the endothelium. These other carotenoids exert more significant effects. For example, lutein is especially important in protecting against LDL oxidation. On the basis of analysis of the different subtypes of LDL, it has been found that lycopene, β-carotene, and cryptoxanthin were mainly located in the larger, less dense LDL particles, whereas astaxanthin, lutein, and zeaxanthin were found preferentially in the smaller, denser LDL particles.[63,66] Because the smaller, denser LDL subtype is most easily oxidized, astaxanthin, lutein, and zeaxanthin are particularly important in protecting against damage to LDL cholesterol.

Despite the focus on protecting LDL cholesterol from damage, it appears that the protective effect of carotenoids against the development of atherosclerosis does not occur early in the progression (i.e., they exert little effect on protecting against oxidative damage to LDL cholesterol) but, rather, later on by some undetermined mechanism. This conclusion is based on studies indicating that carotenoid-enriched diets are associated with less atherosclerotic plaque formation.

Prevention of Cognitive Decline and Dementia

Astaxanthin exerts a number of key protective mechanisms against age-related decline in cognitive function. Because astaxanthin can cross the blood–brain barrier, and because it is a strong and high-quality antioxidant and has anti-inflammatory actions as well, it is logical that it should help prevent neurologic impairment associated with aging because these conditions are directly related to oxidation and inflammation in the brain. Astaxanthin also promotes neurogenesis and plasticity, factors that decline with aging. Neurogenesis is now widely accepted to occur throughout adulthood, primarily in the hippocampus, the key area of the brain essential for learning and memory.[67]

This ability to directly affect neurogenesis and plasticity in the hippocampus is an emerging explanation for some of the observed effects with astaxanthin supplementation. Effects include not only delaying or ameliorating the cognitive impairment associated with normal aging but also improving cognitive function as well. For example, in one double-blind, placebo-controlled clinical trial, 96 healthy middle-aged or elderly subjects were randomly to take either placebo, 6 mg of astaxanthin per day, or 12 mg of astaxanthin per day for 12 weeks. Improvements in the CogHealth battery score were found in the 12-mg group after 12 weeks. Improvements were noted earlier in the Groton Maze Learning Test in both the 6-mg and 12-mg groups.[68]

Immune Enhancement

Carotenes demonstrated a number of immune-enhancing effects in recent studies.[27] However, these effects were demonstrated as far back as 1931, when it was found that a diet rich in carotenes, as determined by blood carotene levels, was inversely related to the number of school days missed by children.[69] Originally, it was thought that the immune-enhancing properties of carotenes were due to their conversion to vitamin A. Now it is known that carotenes exert many immune system–enhancing effects independent of any vitamin A activity.

In one study, the relationship of plasma concentrations of six major carotenoids (β-carotene, α-carotene, β-cryptoxanthin, lycopene, lutein, and zeaxanthin) with the incidence and severity of acute respiratory infections was determined.[70] The incidence rate ratio of acute respiratory infections at high β-carotene status was 0.71 (95% confidence interval [CI] 0.54–0.92) compared with the group with a low β-carotene concentration. Interestingly, α-carotene, β-cryptoxanthin, lycopene, lutein, and zeaxanthin were not related to the incidence or severity of infections, indicating that β-carotene may exert the most significant immune-enhancing effects.

One of the most impressive studies with supplemental β-carotene was conducted on normal human volunteers.[71] Results demonstrated that oral β-carotene (180 mg/day, approximately 300,000 international units [IU]) significantly increased the frequency of OKT4+ (helper/inducer T cells) by approximately 30% after 7 days and the frequency of OKT3+ (all T cells) after 14 days.[47] Because T4+ lymphocytes play a critical role in determining host immune status, this study indicates that oral β-carotene may be effective in increasing the immunologic competence of the host in conditions characterized by a selective diminution of the T4 subset of T cells, such as the acquired immunodeficiency syndrome and cancer.

However, rather than supplementing the diet with synthetic β-carotene, it may be more advantageous to use natural carotene sources or to increase the intake of carotene-rich foods. In another study, 126 healthy college students were randomly assigned to one of the following groups:

- Group A, the control group
- Group B, a group that used a 15-mg (25,000 IU) β-carotene supplement daily

- Group C, a group that consumed approximately 15 mg β-carotene per day from carrots

Better results (i.e., increase in white blood cell number and function) were achieved in the group eating the carrots versus those taking the carotene supplement.[72]

Astaxanthin also demonstrates significant immune-enhancing effects. In one double-blind clinical trial in healthy, young women averaging just over 20 years old, the women were separated into three different groups: the control group took a placebo, and the two treatment groups took either 2 mg of astaxanthin per day or 8 mg per day over 8 weeks. Results showed that at either dosage, astaxanthin[19]:

- Increases the total number of antibody-producing B cells
- Amplifies the cytotoxic activity of natural killer cells
- Leads to increased numbers of T cells
- Stimulates lymphocyte (white blood cell) counts
- Significantly increases delayed-type hypersensitivity response
- Dramatically decreases DNA damage
- Reduces C-reactive protein (CRP), the key marker for systemic inflammation

Vaginal Candidiasis

It is a well-established fact that women are more susceptible to vaginal candidiasis when the immune system is depressed, which may be due to low carotene levels. Beta-carotene levels were determined in exfoliated vaginal cells in 22 women with vaginal candidiasis and compared with vaginal cells from 20 controls. The β-carotene level per 1 million cells in the women with vaginal candidiasis was 1.46 ng compared with 8.99 ng in the control group (i.e., one-sixth that of normal).[73]

These results, coupled with β-carotene's known effects on enhancing the immune system, suggest that a low tissue level of β-carotene is associated with vaginal candidiasis, and a high dietary or supplemental intake of β-carotene may be protective against vaginal candidiasis.

Photosensitivity Disorders

Beta-carotene has become the treatment of choice for photosensitivity disorders. It is most effective in the treatment of erythropoietic protoporphyria (EPP).[74] Its effectiveness in other photosensitivity disorders such as polymorphous light eruption, solar urticaria, and discoid lupus erythematosus is significant but not as great.[75–79] Beta-carotene also has a small but significant effect in increasing the exposure at which manifestations of sunburn begin, thus allowing some subjects the opportunity to stay in the sun long enough to get a "tan" for the first time.[79]

Patients with EPP are characterized by elevated levels of porphyrins in blood, feces, and skin and by sensitivity to visible light. This sensitivity manifests after exposure to sunlight as a burning sensation followed by swelling and redness. Topical sunscreens are of no value. The photosensitivity is due to excitation of the porphyrin molecule by ultraviolet radiation, resulting in the production of free radicals that are deleterious to the skin. Direct cell damage results in the release of chemical mediators, which in turn damage other cells, resulting in the manifestations of itching, burning, redness, and swelling.

In EPP, it appears that carotene levels must be maintained in the blood at 600 to 800 mg/dL for optimum effects and that the protective effect is not usually observed until after 4 to 6 weeks of therapy. The actions of β-carotene and other carotenes in human tissue are similar to their action in plant cells (i.e., they function as a cellular screen against sunlight-induced free radical damage).

DOSAGE

Beta-carotene: A daily dosage of 25,000 IU (15 mg of β-carotene) appears to be reasonable for general health. Again, for the best clinical effect, it appears that natural mixed forms of carotene should be used in conjunction with a broad range of other natural antioxidants (see Chapter 108). In the treatment of EPP, the dosage is based on maintaining blood carotene levels between 600 and 800 mg/dL.

- Lycopene: 15 to 30 mg daily.
- Lutein/zeaxanthin: 10 mg of lutein and 2 mg zeaxanthin
- Astaxanthin: 4 to 12 mg daily.

TOXICITY

Supplementing the diet with β-carotene has not been shown to result in any significant toxicity despite its use in high doses in the treatment of numerous photosensitivity disorders (see discussion on "Photosensitivity Disorders"). Occasionally patients complain of loose stools, which usually clears spontaneously and does not necessitate stopping treatment. Elevated carotene levels in the blood do not lead to vitamin A toxicity, nor do they lead to any other significant disturbance besides yellowing of the skin (carotenodermia).

The ingestion of large amounts of carrots or carrot juice (0.45–1 kg/day of fresh carrots for several years) has, however, been shown to cause neutropenia, as well as menstrual disorders.[80,81] Although the blood carotene levels of these patients did reach levels (221–1007 mg/dL) similar to those of patients taking high doses of β-carotene (typically 800 mg/dL), the disturbances are due to some other factor in carrots because neither of these effects nor any others have been observed in subjects consuming high doses of pure β-carotene (e.g., 300,000–600,000 IU/day [180–360 mg β-carotene], which is equivalent to 4–8 lb of raw carrots) over long periods of time.[82–85] Doses up to 1000 mg/kg have been given to rats and rabbits for long periods of time, with no signs of embryotoxicity, toxicity, tumorigenicity, or interference in reproductive functions.[86]

There are no significant side effects or concerns with recommended levels of lycopene, lutein, or astaxanthin.

DRUG INTERACTIONS

One study showed that β-carotene in combination with selenium, vitamin C, and vitamin E appeared to decrease the effectiveness of the combination of simvastatin (Zocor) and niacin. The researchers proposed that this inhibition of hydroxymethylglutaryl coenzyme-A reductase inhibitors could reduce the effectiveness of similar drugs, such as atorvastatin (Lipitor), fluvastatin (Lescol), lovastatin (Mevacor), and pravastatin (Pravachol).[87]

Boron[94]

Joseph E. Pizzorno, ND

OUTLINE

INTRODUCTION

Boron is a ubiquitous constituent of the environment, typically occurring in nature as inorganic borates with minerals replacing the hydrogen ions seen in Fig. 58.1. In human tissues, boron is found as the borate anion and boric acid, predominantly the latter form, with a concentration primarily reflecting dietary intake.[1,2] In trace amounts, boron is essential for the growth of many plants, and although it has yet to be recognized as an essential nutrient for humans, growing data from animal and human studies continue to suggest that boron is important for many life processes. These include embryogenesis; bone growth and maintenance; immune function; regulation of inflammation; psychomotor skill; mineral metabolism; brain function and performance; and the prevention of osteoporosis, osteoarthritis, and prostate, lung, and cervical cancer.[3] It also has been shown to affect the metabolism or action of many biological compounds, including glucose, S-adenosylmethionine, amino acids, triglycerides, macrominerals, and a number of hormones, including vitamin D, insulin, testosterone, and estrogen.[4,5]

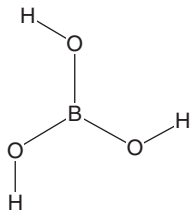

Fig. 58.1 Boric acid.

Sources

Because boron in plants depends on the availability of boron in the soil, the same food crop can vary greatly in boron content depending on where and how it is grown. In general, soils exposed to high degrees of precipitation have decreased levels of boron.[6] Heavy rainfall leaches the highly soluble boric acid from the soil, whereas in more arid regions, evaporation of groundwater results in higher concentrations of boron solutes. Food processing results in additional loss of boron, and the use of high-phosphate and high-potash fertilizers reduces its uptake by plants.[7,8] Foods of plant origin, such as leafy vegetables, noncitrus fruits (e.g., apples), nuts, legumes (peanut butter), avocados, and sea vegetables are considered the best sources of boron.[1,9] Wine has also been shown to contribute appreciable amounts of boron to the diet, and water intake may also be a significant source of total intake.[10] A diet containing an abundance of these items would provide 2 to 6 mg/day of boron.[9,11]

Daily intake of boron depends on several variables. The concentration of boron in water varies considerably according to the geographical source. In some areas, boron in drinking water and water-based beverages may account for most of the total dietary boron intake. Individual food preference greatly influences the daily intake of boron. Fruits, vegetables, tubers, and legumes have higher concentrations of boron than do cereal grains or animal tissues. For adults and seniors, though, the largest source of boron turns out to be instant regular coffee.[12] Given the poor dietary intake of produce in the United States, the top two boron contributors to adult boron intake, coffee and milk, are actually deficient in this nutrient (Table 58.1)[13] compared with other,

TABLE 58.1 Top Contributors of Dietary Boron in the American Diet

Food	Boron (mg/mL)
Coffee, from ground beans	0.029
Milk, whole	0.018
Apples, raw	0.36
Beans, refried	0.4
Potatoes, from French fries	0.11
Orange juice	0.072
Peanut butter	1.145
Wine	0.61
Apple juice	0.18
Cola	0.013

more nutritious foods. Nevertheless, these make up 12% of the total boron intake by virtue of the volume consumed.[13] Boron has also been determined to be a notable contaminant or major ingredient of many personal care products, and it (boric acid) is occasionally used as a food preservative.[14]

In Sydney, Australia, 32 subjects aged 20 to 53 years old were assessed over a 7-day period for their dietary intake of boron. The average boron intake in male and female subjects was found to be 2.28 ± 1.3 and 2.16 ± 1.1 mg/day, respectively.[10] The boron content of selected Australian foods has been found to correlate with values in Finnish and U.S. Food and Drug Administration tables and is presented in Table 58.2 (note, however, the large variations between countries and even regions of a country).[10] Regional differences are certainly important. An analysis of nearly 300 foods that are commonly consumed in Korea found considerable discrepancies with values reported elsewhere. For example, the boron content in Korean apples was found to be one-twelfth that found in German apples. The foods found to be richest in boron (in micrograms/100 g) included buckwheat flour (828), soybeans (1642), mung beans (818), almonds (917), cocoa (2026), coffee powder (approximately 1530), and oolong and green tea powder (1274 and 1316, respectively).[15]

TABLE 58.2 Concentration of Boron in Selected Australian[a] Foods

Food	Boron (mg/100 g)
Almonds	2.82
Apples (red)	0.32
Apricots (dried)	2.11
Avocados	2.06
Bananas	0.16
Beans (red kidney)	1.4

METABOLISM

Chemical Properties

Elemental boron was first isolated in 1808. It is the first member (atomic number 5) of the metalloid or semiconductor family of elements, including silicon and germanium, and is the only nonmetal of the group IIIA elements. Like carbon, boron has a tendency to form double bonds and macromolecules.[16] Boron, as boric acid, acts as a Lewis acid, accepting hydroxyl (OH^-) ions and leaving an excess of protons.[17] Because boron complexes with organic compounds containing hydroxyl groups, it interacts with sugars and polysaccharides, adenosine-5-phosphate, pyridoxine, riboflavin, dehydroascorbic acid, and pyridine nucleotides.[18] Given boron's affinity for hydroxyl groups, it is possible that it interacts with glycoproteins and glycolipids found in cellular membranes. Animal studies have supported a role for boron in maintaining cellular membrane structure and function, with boron deprivation causing pathological changes in both zebrafish and frogs.[19] Dietary magnesium and essential fatty acids, both of which are involved in cell membrane function, also influence the response to boron deprivation, lending further support for a role for boron. For example, in an animal-based study, boron deprivation was found to alter animal behavior in ways that were modifiable by varying the composition of dietary fatty acids, and vice versa, possibly by altering the fluidity of cellular membranes.[20]

Biochemistry

Boron in food, sodium borate, and boric acid are well absorbed from the digestive tract.[21] However, homeostatic mechanisms for maintaining serum levels of boron exist, with urinary levels mirroring intake.[8] A boron transporter has been identified (NaBC1), and dietary supplementation of boron has been shown to alter its genetic expression.[4,22] Compounds of boron are also absorbed through damaged skin and mucous membranes; however, they do not readily penetrate intact skin.[23]

No accumulation of boron has been observed in soft tissues of animals fed long-term low doses of boron; however, in acute poisoning incidents, the amount of boric acid in brain and liver tissue has been reported to be as high as 2000 ppm. Within a few days of consumption of large amounts of boron, levels in blood and most soft tissues quickly reach a plateau.[24] Tissue homeostasis is maintained by the rapid elimination of excess boron, primarily in the urine, with bile, sweat, and breath also contributing as routes of elimination.[18]

Evidence suggests that supplemental boron does accumulate in bone; however, cessation of exposure to dietary boron results in a rapid drop in bone boron levels. The half-life of boric acid in animals is estimated at about 1 day.[24]

Biological Functions

Boron contributes to living systems by acting indirectly as a proton donor and exerting an influence on cell membrane structure and function.[25] Although the absolute essentiality of boron for plants as well as two animal species (zebrafish and frogs) is well documented, studies to date have not shown it to be unequivocally essential for other species or humans. However, boron supplementation has been shown to affect certain aspects of animal physiological function. In general, supplemental dietary boron has its most marked effects when the diet is deficient in known nutrients.[26]

Recent animal-based data suggest boron may in some way affect the utilization or production of S-adenosylmethionine, which in turn influences homocysteine metabolism, as well as other molecules involved in cellular signaling and differentiation. Rats deprived of boron had increases in plasma cysteine and homocysteine as well as decreases in hepatic S-adenosylmethionine and the related compounds S-adenosylhomocysteine and spermidine. It is possible that many of boron's biological effects are mediated through this mechanism because S-adenosylmethionine is involved in many methylation reactions, including DNA methylation, as well as methylation of other neurotransmitters, phospholipids, and signaling molecules, and is also used frequently as an enzyme substrate.[27]

Evidence suggests that boron might also have an effect on decreasing fasting serum glucose concentrations in postmenopausal women.[28]

Embryo Maturation

Research has shown that boron is an important player in the early stages of life.[3] Boron deficiency negatively affects reproductive ability, as well as embryo development, in both the African clawed frog *(Xenopus laevis)* and the zebrafish. Experimentation with *Xenopus* noted that dietary boron deprivation elicited necrotic egg increases combined with a high frequency of abnormal gastrulation, causing adverse effects during gametogenesis, gamete maturation, embryonic development, and larval maturation.[19] In the zebrafish model, 45% of boron-deprived embryos died during the early postfertilization period. Conversely, only 2% of boron-supplemented embryos died. Other studies with rats and mice corroborated that low boron status might affect reproduction in mammals, although the conclusions from these studies were not as clear.

Life Span

Boron in an animal model has been shown to affect life span, although the process is undefined. Extremes in dietary boron, both a deficiency and an excess, appear to affect the median life span of *Drosophila.* Adding excess during the adult stage decreased life span by as much as 69%, whereas supplementing the diet with low levels of boron increased life span by 9.5%.[29] No research exists for other species.

Brain Function and Performance

Although limited data exist for boron's influence on brain function, existing research is "among the most supportive in demonstrating that boron is a beneficial bioactive element for humans."[30] Brain electrophysiology and cognitive performance were assessed in response to dietary manipulation of boron (approximately 0.25 vs. approximately 3.25 mg boron/2000 kcal/day) in three studies with healthy older men and women. A low boron intake was shown to result in a decrease in the proportion of power in the α-band and an increase in the proportion of power in the δ-band, effects similar to those induced by heavy metals and nonspecific malnutrition, as well as mental drowsiness and reduced alertness. Other changes in left–right symmetry and brain-wave coherence were noted in various sites, indicating an influence on brain function. When contrasted with the high boron intake, low dietary boron resulted in significantly poorer performance ($P < 0.05$) on tasks emphasizing manual dexterity, eye–hand coordination, attention, perception, encoding, and short- and long-term memory. Collectively, the data from these studies indicate that boron may play a role in human brain function, alertness, and cognitive performance.[31]

Interestingly, as mentioned previously, essential fatty acid composition may interact with boron status to influence brain function. A number of biomarkers for low activity were observed in boron-deficient rats when given safflower oil, but fish oil negated these deficits.[20]

Hematologic

Boron supplementation to human subjects who had previously followed a dietary regimen deficient in boron increased blood hemoglobin concentrations, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration. It lowered hematocrit, red blood cell count, and platelet count.[32] As discussed in the "Toxicology" section, boron may inhibit the enzyme δ-aminolevulinic acid dehydratase.

Hepatoprotection

Studies of fulminate hepatic failure in Wistar rat models showed that boron pretreatment significantly reduced lipid peroxidation, as well as decreased serum liver enzymes, in these animals. Boron pretreatment also increased the peroxide-metabolizing enzymes' levels of glutathione peroxidase and catalase, as well as glutathione itself.[33,34]

Mineral Metabolism

Boron also affects mineral metabolism as well as related hormones in human subjects. In the first nutritional study with humans involving boron,[23] postmenopausal women first were fed a diet that provided 0.25 mg boron/2000 kcal for 119 days and then were fed the same diet with a boron supplement of 3 mg boron/day for 48 days. The boron supplementation reduced the urinary excretion of calcium and magnesium and elevated the serum concentrations of 17 β-estradiol and testosterone.[9]

In a study designed to determine the effects of boron supplementation on blood and urinary minerals in athletic subjects on Western diets, findings suggested that boron supplementation modestly affected mineral status.[35]

DEFICIENCY SIGNS AND SYMPTOMS

Information on boron deficiency is limited, especially in humans. It is thought that insufficient intake of boron becomes obvious only when the body is stressed in a manner that enhances the need for it. When the diets of animals and humans are manipulated to cause functional deficiencies in nutrients such as calcium, magnesium, vitamin D, essential fatty acids, and methionine, a large number of responses to dietary boron occur.[36] Evidence suggests that more than 21 days on a boron-deficient diet is required to demonstrate detectable effects in humans.[37] The variables that are changed due to a boron-deficient diet abruptly improve about 8 days after boron supplementation is introduced.[9] Evidence indicates that hemodialysis results in an excessive decrease in serum boron compared with controls.[38] Although blood urea is by no means pathognomonic for a boron deficiency, it has been found to be slightly elevated during boron depletion.[39]

NUTRIENT INTERACTIONS

Vitamin D

Considerable evidence indicates that dietary boron alleviates the perturbations in mineral metabolism that are characteristic of vitamin D_3 deficiency.[40] In one study, chicks fed a diet inadequate in vitamin D exhibited decreased food consumption and plasma calcium concentrations and increased plasma concentrations of glucose, β-hydroxybutyrate, triglycerides, triiodothyronine, cholesterol, and alkaline phosphatase activity after 26 days. Supplemental boron returned plasma glucose and triglycerides to concentrations exhibited by chicks fed a diet adequate in vitamin D.[41]

In rachitic chicks, boron elevated the numbers of osteoclasts and alleviated distortion of the marrow sprouts of the proximal tibial epiphysial plate, a distortion characteristic of vitamin D_3 deficiency.[40,42] Higher apparent balance values of calcium, magnesium, and phosphorus have been observed for rats fed a vitamin D–deprived diet if the diet was supplemented with boron.[26]

After supplementation with 3.25 mg boron daily, plasma levels of vitamin D_2 increased in men older than age 45 and postmenopausal women on low-magnesium and low-copper diets.[43] In a very small human study ($n = 8$), healthy male volunteers were given 10 mg boron per day for 1 week, resulting in a nonsignificant 7% rise in vitamin D levels.[5] Inhibition of 24-hydroxylase, the enzyme that catabolizes vitamin D, has been speculated to be the possible mechanism of action, although this has not been demonstrated.[44]

Calcium

Boron supplementation may have a favorable effect on calcium metabolism. A boron supplement of 3 mg/day affected several indexes of mineral metabolism of seven women consuming a low-magnesium diet and five women consuming a diet adequate in magnesium; the women had consumed a conventional diet supplying about 0.25 mg boron per day for 119 days. Boron supplementation modestly reduced the urinary excretion of calcium when dietary magnesium was low.[9]

In men older than age 45 and postmenopausal women, changes caused by boron supplementation included an increased concentration of ionized plasma and total calcium, as well as reduced serum calcitonin concentration and urinary excretion of calcium.[43] A 1993 study demonstrated that a low-boron diet elevated urinary calcium excretion. The high level of calcium excretion was maintained throughout the 6-week study; however, it remained elevated even after boron supplementation began.[45]

Animal studies suggest that boron deprivation does not markedly affect the concentration of calcium (and phosphorus) in bone, but rather, it does affect the concentration of other nutrients associated with osteoblast and osteoclast function, such as magnesium, potassium, copper, and zinc.[30]

Copper

Supplemental boron acts to increase serum levels of both copper and copper-dependent enzymes in humans. Boron supplementation (3 mg/day) to five men older than age 45, four postmenopausal women, and five postmenopausal women on estrogen therapy who had been fed a low-boron diet (0.23 mg/2000 kcal) for 63 days resulted in higher erythrocyte superoxide dismutase, serum enzymatic ceruloplasmin, and plasma copper.[43] In a subsequent study, these same variables were again found to be higher during boron repletion than while subjects were fed a diet low in boron.[46]

Magnesium

When magnesium deprivation is severe enough to cause typical signs of deficiency, a significant interaction between boron and magnesium is found.[16] A combined deficiency of boron and magnesium causes detrimental changes in the bones of animals. Supplemental boron elevates plasma magnesium concentrations and enhances growth.[42]

Boron supplementation resulted in increased serum magnesium concentrations in human female subjects.[24] Boron supplementation increased red blood cell magnesium concentrations.[47] It has been shown that serum magnesium concentrations are greater in sedentary females whose diets are supplemented with boron than in exercising female athletes who are supplemented with boron.[48] This finding, although unexplained to date, may indicate an increased loss of boron through urine and perspiration during exercise.

Phosphorous

Supplemental boron seemed to lower serum phosphorus concentrations in female subjects 20 to 27 years old.[48] However, exercise training diminished these changes,[24] again possibly indicating increased losses or an increased need for boron as a result of exercise. A low-magnesium status, along with supplementation of boron, may depress the urinary excretion of phosphorus. This does not occur in women with an adequate magnesium intake.[9]

Methionine and Arginine

In experimental animals, a beneficial effect is consistently observed after boron supplementation when the diet contains marginal methionine and excessive arginine. Among the signs exhibited by rats fed on a diet marginal in methionine and magnesium are depressed growth and bone magnesium concentration and elevated spleen weight/body weight and kidney weight/body weight ratios. Findings indicate that the severity of these symptoms is alleviated with boron supplementation.[49]

Essential Fatty Acids

Several studies have emerged that suggest some interaction between essential fatty acids and boron. As previously mentioned, boron deprivation was shown to decrease the activity of rats and alter their brain composition, yet supplementation with fish oil (vs. safflower oil) minimized these effects.[20] Similarly, boron deprivation in rats was shown to impair both bone trabecular microarchitecture and cortical bone strength. Interestingly, the use of fish oil instead of safflower oil was also shown to benefit both of these structural markers through a distinct mechanism, yet the benefit of fish oil was limited only to the group receiving adequate boron. In other words, a boron deficiency prevented the normal benefit of fish oil to bone.[50] Lastly, as mentioned previously, boron deprivation was shown to decrease S-adenosylmethionine levels in rats. Feeding them corn oil instead of fish oil had similar effects, although they were likely mediated by a different mechanism.[50]

HORMONE INTERACTIONS

In rats, supplemental dietary boron substantially depressed plasma insulin, plasma pyruvate concentrations, and creatine kinase activity and increased plasma thyroxine (T4) concentrations. Boron supplementation also decreased plasma aspartate transaminase activity.[51] In animal experiments, boron supplementation offset the elevation in plasma alkaline phosphatase caused by vitamin D deficiency.[39] Boron supplementation in rats has also been shown to reduce plasma insulin levels, likely by increasing insulin sensitivity.[52]

An increase in the dietary intake of boron from 0.25 to 3.25 mg/day has been reported to increase plasma 17 β-estradiol by more than 50% and to more than double plasma testosterone levels in postmenopausal women. The elevation seemed more marked when dietary magnesium was low.[9] In a subsequent study of healthy men, boron supplementation resulted in an increase in the concentrations of both plasma

estrogen and testosterone; however, not all published trials support these observations.[10]

Ten male bodybuilders, 20 to 26 years old, were given a 2.5-mg boron supplement for 7 weeks, whereas nine male bodybuilders, 21 to 27 years old, were given a placebo. Because both groups demonstrated significant increases in total testosterone ($P < 0.01$), lean body mass ($P < 0.01$), one-repetition maximum squat ($P < 0.001$), and bench pressing ($P < 0.01$), the authors concluded that the gains were a result of 7 weeks of bodybuilding, not of boron supplementation.[53] However, in a small study of male volunteers, 10 mg supplemental boron per day was associated with an increase in plasma free testosterone and a decrease in mean plasma estradiol levels. A decrease in the inflammatory markers C-reactive protein, tumor necrosis factor-α, and sex hormone–binding globulin was also seen.[5]

One researcher hypothesized that boron might be required for the synthesis of steroid hormones, as well as vitamin D. Because the biosynthesis of steroids such as vitamin D, testosterone, and 17 β-estradiol involves one or more hydroxylation steps, and because of boron's ability as a Lewis acid to complex with hydroxyl groups, boron may assist the addition of hydroxyl groups to the steroid structures.[9] It has also been suggested that boron may act in an unspecified manner to protect hormones from rapid inactivation.[9] The current hypothesis suggests that boron can inhibit a range of microsomal enzymes that insert hydroxyl groups near existing hydroxyls in steroids. These enzymes include those that catabolize 25-hydroxyvitamin D.[54]

Table 58.3 lists boron's effect on selected hormones in either animals or humans. Some of these interactions have only been demonstrated in animal models, whereas others have not been demonstrated unequivocally to date in all age and gender segments of the human population.

CLINICAL APPLICATIONS

Osteoporosis

A considerable body of evidence has shown that both the compositional and functional properties of bone are affected by boron status.[55] In experimental animals, histological findings suggest that supplemental boron enhances maturation of the growth plate.[39] Boron has also been found at the highest concentrations in growing and calcifying areas of long bones.[9] In two human studies, boron deprivation caused changes in indexes associated with calcium metabolism in a manner that could be construed as being detrimental to bone formation and maintenance; these changes were enhanced by a diet low in magnesium.[9,39] The author concluded that boron and magnesium are apparently necessary for optimal calcium metabolism and are thus necessary to prevent the excessive bone loss that often occurs in postmenopausal women and older men.[39]

At the cellular level, in vitro studies have shown that boron may play a role in the regulation of proteins in the morphogenesis of bone, including BMP-4, -6 and -7, as well as the mRNA expression of several extracellular matrix proteins.[56] This is consistent with animal-based studies that suggest boron deprivation causes deficits in bone modeling and remodeling by inhibiting bone formation.[57,58]

Osteoarthritis, Rheumatoid Arthritis, and Regulation of Inflammation

A dietary boron deficiency may be a contributing factor in some cases of arthritis.[59] In areas of the world where boron intake is routinely 1 mg/day or less, the estimated incidence of arthritis ranges from 20% to 70%, whereas in areas where boron intake ranges from 3 to 10 mg/day, the estimated incidence of arthritis ranges from 0% to 10%.[59]

Analytic evidence indicates that persons with arthritis have lower boron concentrations in femur heads, bones, and synovial fluid compared with persons without this disorder.[7]

In 1961 the first anecdotal evidence suggesting that boron may be beneficial for osteoarthritis was presented when one patient had reduced swelling and stiffness and remained symptom-free for 1 year after supplementation with 3 mg of elemental boron twice daily for 3 weeks. A human study also offered evidence that boron supplementation might be beneficial in the treatment of this condition. In a double-blind, placebo-controlled trial of 20 subjects with osteoarthritis, 50% of subjects receiving a daily supplement containing 6 mg of boron noted a subjective improvement in their condition. Only 10% of those receiving placebo improved during the same time interval. Greater improvement was noted in the condition of all joints ($P < 0.01$), as well as less pain on movement ($P < 0.001$), in subjects receiving the boron supplementation.[60]

Clinical observations indicate that children with juvenile arthritis (Still disease) improve with boron supplementation (6–9 mg/day) in 2 to 3 weeks, whereas adults with osteoarthritis may require 2 to 4 months of supplementation before benefits are detected. Persons with rheumatoid arthritis may experience an aggravation of symptoms for 1 to 3 weeks but generally notice improvement within 4 weeks of beginning boron supplementation.[7]

Boron also has been implicated as a potential regulator of inflammatory and immune responses, possibly explaining its benefit for arthritic conditions. For example, boric acid has been shown to inhibit lipopolysaccharide-induced tumor necrosis factor-α formation.[61] Other animal-based studies support an anti-inflammatory role for boron.[62,63]

Prostate, Lung, Breast, and Cervical Cancer

Given that boron may act as a possible modifier of the hormones testosterone and estrogen, some studies have investigated its possible role in prostate cancer. One controlled case study compared the boron intake of 95 prostate cancer cases with that of 8720 male controls. After controlling for age, race, education, smoking, body mass index, dietary caloric intake, and alcohol consumption, this epidemiological screening found the risk of prostate cancer to be inversely proportional to dietary intake of boron in a dose-responsive manner.[64] A more recent study compared the prevalence of prostate cancer among those with high exposure to boron to control populations, and although no significant difference in prevalence was found, they did find a lower prevalence of elevated prostate-specific antigens (PSAs). The authors concluded that boron may interfere with processes related

TABLE 58.3 Boron's Observed Effect on Selected Hormones

to hyperplasia and carcinogenesis.[65] This is consistent with previous research that purported that boron may act as an inhibitor of PSA. It is thought that uninhibited PSA cleaves insulin-like growth factor binding protein-3, providing increased local levels of insulin-like growth factor 1, which then leads to tumor growth. Most epidemiological studies support a preventative effect of higher dietary boron, although not all do (the only exception used a different database for the boron content of foods).[66–68]

Some in vitro research observed that boric acid inhibits the proliferation of both the hormone-dependent and hormone-independent human prostate cancer cell lines in a dose-dependent manner.[69] In one study, three groups of 10 mice were implanted subcutaneously with human prostate adenocarcinoma cells. Two of the murine groups were given boric acid solutions (at 1.7 or 9 mg/kg of boron per day) by gavage, whereas the control group received only water. After 8 weeks, tumor sizes in the boric acid groups decreased by 38% and 25%, respectively, and serum PSA levels decreased by 88.6% and 86.4%, respectively, compared with the control group. Additionally, significantly less mitotic figures were seen in the boric acid groups. Immunohistochemical studies demonstrated significantly less expression of insulin-like growth factor 1 levels, although circulating levels were unchanged among the groups.[70]

Multiple mechanisms in addition to PSA inhibition have been suggested for boron's chemopreventative properties, including inhibition of stored calcium release from ryanodine receptor agonist sites and induction of apoptosis.[71,72]

This may explain its reported benefit for other cancers as well, for in addition to prostate cancer, diets with greater amounts of boron have been associated with reduced risks of cervical cancer (cytopathologic findings) and lung cancer among women.[73] A dose-dependent risk for lung cancer was seen among women, with those consuming the lowest amounts of boron having a nearly twofold greater risk compared with those in the highest quintile. Additionally, a diet low in boron heightened the risk for lung cancer among those using hormone replacement therapy.[74]

A double-blind, placebo-controlled study of 47 women with invasive ductal carcinoma treated with radiotherapy found that a boron-based gel statistically significantly relieved the pain and discomfort of radiation-induced dermatitis.[75]

Multiple cell-culture, animal, and pilot human studies have found benefit directly or as an adjunct in inhibition of tumor-induced angiogenesis, induction of cancer-cell apoptosis, treatment of multiple myeloma and non-Hodgkin lymphoma, and decreasing the adverse effects of chemotherapy.[76]

For these many reasons, boron-containing compounds are increasingly being used for cancer care, based on a variety of mechanisms.[77] Further human research is needed to determine the full clinical benefits of this interesting element in cancer prevention and treatment.

Wound Healing

Boron has been shown to significantly improve wound healing in humans. Application of a 3% boric acid solution to deep wounds reduced time in intensive care by two thirds.[78] In vitro research showed that a boric-acid solution improved wound healing through action on the extracellular matrix.[79] These beneficial effects are apparently due to the promotion of the activity of elastase, trypsin-like enzymes, collagenase, and alkaline phosphatase.

Dysmenorrhea

In a triple-blind randomized clinical trial study of 113 university students, 10 mg/day of boron from 2 days before the menstrual flow until its third day resulted in significant reduction in severity and duration of pain. The study followed the women for only two cycles, which is unfortunate because the improvement increased by cycle, suggesting that further benefit above the 20% found in the second cycle may be possible.[80]

DOSAGE

The optimal dose of boron for the prevention of osteoporosis and proper physiological function appears to be between 1 and 6 mg/day. It is best to obtain boron by means of a diet abundant in fruits, vegetables, legumes, and nuts, but persons whose diets are limited may need a supplement containing 1 to 3 mg of elemental boron. In patients with either osteoarthritis or rheumatoid arthritis, a trial period of 2 to 4 months with a dose of 3 mg of boron two to three times daily seems to be indicated.

TOXICOLOGY

Although boron is potentially toxic to all organisms and, as boric acid and borax, has been used as a pesticide and food preservative, higher animals usually do not accumulate boron because of their ability to rapidly excrete it.[17] Authenticated cases of poisoning in humans have been few and have primarily been the result of accidental ingestion of insecticides and household products containing borates or use of large amounts of boric acid in the treatment of burns.[81]

Improper use of boric acid–containing antiseptics is still one of the most common causes of toxic accidents in newborns and infants. Because boric acid is readily absorbed through damaged skin, it should not be applied topically to extensive wounds.[21]

In animals, long-term low-level boron exposure has been shown to cause reduced growth, cutaneous disorders, and suppression of male reproductive system function.[82] Studies indicated that male rodents developed testicular atrophy with dietary exposure to boric acid above 4500 ppm and had decreased sperm motility at all exposure levels above 1000 ppm.[83]

Humans given 100 mg of boron intravenously or 270 mg of boric acid orally reported no discomfort and showed no obvious signs of toxicity.[84,85] Drinking water with high boron concentrations in Turkey has not been shown to cause untoward effects in humans exposed over multiple generations.[86] Airborne exposures to boron oxide and its hydration product, boric acid, have been reported to cause respiratory and eye irritation.[87] A fatal outcome was reported after ingestion of 1 g of boric acid by a child; however, adults have survived acute intakes of nearly 300 g.[88] The Food and Nutrition Board of the Institute of Medicine has established a Tolerable Upper Intake Level for boron of 20 mg/day for adults over 18 years of age and as low as 3 mg for children between 1 and 3 years of age.[89] One author suggested that plasma or serum concentrations greater than 300 ng/mL indicate an intake in excess of what is needed to prevent deficiency, whereas levels more than 1 mcg/mL indicate toxicity.[50]

Boron may also have the potential for toxicity during pregnancy. A study in a population of newborns exposed to normal environmental boron levels through pregnancy found a negative relationship between whole blood δ-aminolevulinic acid dehydratase activity and placental boron levels. This is certainly concerning given the neurotoxic effects caused by lead's inhibition of this same enzyme.[90]

Common signs and symptoms of acute boron toxicity (largely based on animal data) include nausea, as well as vomiting and diarrhea that are blue–green in color.[8,88] Other symptoms seen with acute exposure are abdominal pain, an erythematous rash involving both the skin and mucous membranes, stimulation or depression of the central nervous system, convulsions, hyperpyrexia, renal tubular damage, abnormal

liver function, and jaundice.[21] Increased urinary riboflavin excretion has also been reported subsequent to acute boric acid ingestion.[91] Symptoms of long-term intoxication include anorexia, gastrointestinal disturbances, debility, confusion, dermatitis, menstrual disorders, anemia, convulsions, and alopecia.[21] In three cases of work-related exposure, alopecia signs were reversed when boric acid exposure was reduced or eliminated.[92] Because it is excreted primarily in urine, caution should be used for those with impaired renal function.

Because of its ability to increase the excretion of boron, in cases of toxicity, *N*-acetylcysteine is the preferred intervention.[93]

DRUG INTERACTIONS

Boron supplementation may increase serum magnesium, testosterone, and estrogen levels. However, no adverse clinical effects have been reported.

SUMMARY

Although the skeletal response to boron is modified by other nutritional variables, such as calcium, magnesium, vitamin D, methionine, essential fatty acid intake, and arginine, considerable evidence indicates that both the compositional and functional properties of bone are affected by boron status at least somewhat independently of other variables.

Findings suggest that boron is an important nutrient not only for mineral metabolism but also for varied aspects of optimal health in humans, including influences on lipid membrane integrity and cellular signaling pathways. Although all published trials are not in agreement on the effect of boron supplementation on levels of 17 β-estradiol and testosterone, evidence strongly suggests that boron deficiency results in decreased levels in postmenopausal women, whereas supplementation tends to normalize levels in these same women. Boron's effect on sex hormones in other segments of the population is still equivocal, although recent evidence suggests it may increase free testosterone levels at least in men. Topically it has shown clinical benefit for treating some forms of vaginitis (see Chapter 224, Vaginitis, Vulvovaginitis and Vulvodynia). As the mechanisms for its action are more thoroughly understood, which now include influencing S-adenosylmethionine metabolism and regulation of osteogenesis and cellular signaling pathways, therapy with boron may become more targeted and specific.

On the basis of available information, boron appears to offer benefits in the prevention of osteoporosis and arthritis, as well as cancer prevention. It is also a safe and potentially effective mineral to consider in any treatment regimen for both rheumatoid and osteoarthritis, as well as several cancers.

Bromelain[107]

Anthony J. Cichoke Jr., BS, BS, MA, MA, PhD, DC, DACBN

OUTLINE

Proteolytic enzyme of *Ananas comosus* (family: Bromeliaceae)
Synonyms: bromelin, plant protease concentrate

INTRODUCTION

Bromelain is a proteolytic (protein-lysing) enzyme found in the stem and the fruit of the pineapple plant *(Ananas comosus)*. Other proteolytic enzymes found in pineapple include ananain and comosain,[1] and there are several nonproteolytic enzymes, such as amylase, peroxidase, and acid phosphatase.[2]

Most bromelain on the market is stem bromelain (which itself is composed of perhaps up to six different types of enzymes, including bromelain A and B).[3] Bromelain is widely used in food processing to prepare precooked cereals, produce protein hydrolysates, chill-proof beer, and tenderize meat; in cosmetics; in diagnostic laboratories; in pharmaceuticals; and in over-the-counter nutritional supplements. Best known as a digestive aid, bromelain supplements, when used systemically, are also used to treat the degenerative effects of aging (including osteoarthritis),[4] several types of cancer,[5–11] circulatory disorders,[5,12–18] dysmenorrhea,[19] immune disorders,[20,21] infections,[22–25] inflammatory diseases and conditions,[26–39] and respiratory tract diseases.[42–45] Topical applications include cosmetics and skin debridement formulations.

Bromelain is a sulfur-containing enzyme, with an optimum pH activity between 3.0 and 8.0.[46] Bromelain has endoproteolytic and catalytic activity and predominantly splits peptides, amides, and ester bonds involving lysine, alanine, tyrosine, glycine, and other basic amino acids.[47]

The extraction of bromelain is usually accomplished by fractionated ultrafiltration and subsequent lyophilization of the juice pressed from the stem of ripe pineapples (frequently from *Ananas comosus* of the cayenne variety). However, cores, leaves, and other waste products remaining after pineapple processing also yield a certain amount of the enzyme.[48]

Bromelain activity within the stem of the pineapple can vary widely depending on the age of the plant, as well as on the storage duration and conditions. A Thai study found that 3-year-old peeled pineapple stems contained substantially more activity than second- and first-year stems as measured in casein-digesting units (CDUs)—48.76% compared with 32.0% and 19.3%, respectively.[49] In addition, storage duration before considerable loss of activity occurred was limited to 3 days at room temperature or 2 weeks in a room cooled to 5°C (41°F).[49]

BROMELAIN SUPPLEMENTS

Hundreds of medical articles on bromelain's therapeutic applications have been published since it was introduced as a medicinal agent in 1957.[50,51] Initially, many studies employed Ananase (Rorer; Washington, PA), an enterically coated bromelain tablet. Since then, studies have included bromelain in virtually every available form including tablets, chewable tablets, capsules, powder, and ointment. In addition, many studies use bromelain in combination with other enzymes or with various vitamins, minerals, and herbs, for wider application.

Bromelain activity is measured in "units," and there are several types of units currently in use. Most bromelain supplements sold in the United States are measured in gelatin-dissolving units (GDUs), although milk-clotting units (MCUs), Fédération Internationale du Pharmaceutiques units (FIPs), and CDUs are also used. However, these measurement methods are neither interchangeable nor comparable. In addition, the activity of any bromelain supplement might be expressed per tablet or capsule or per gram, making comparison between different supplements difficult.

BROMELAIN AS A DIGESTIVE AID

Bromelain has a long history of use as a digestive aid. By the time Columbus and his men arrived in America, natives of Central and

South America were already using bromelain-rich pineapple juice to cure bellyaches and improve digestion. As a proteolytic enzyme, bromelain aids in the digestion of protein foods. Because of bromelain's wide pH activity, it is effective on substrates in the acidic stomach as well as the alkaline small intestine. To aid in digestion, bromelain supplements should be taken with, or just before, a meal. Enzyme supplements are also effective against numerous diseases and conditions when taken between meals in a method referred to as systemic enzyme therapy.

SYSTEMIC ENZYME THERAPY

Bromelain—when taken systemically—can help slow many of the degenerative effects of aging[4,51]; inhibit cancer growth and metastasis[5–10]; prevent the aggregation of blood platelets[5,12–18] and thereby help prevent heart attacks, strokes, and other cardiovascular conditions; improve digestive problems[51–53]; treat dysmenorrhea[19,54]; improve the symptoms of immune conditions[38]; fight infections[22–24,26,55]; effectively speed up healing from inflammatory diseases and conditions[26–39]; fight sinusitis and other respiratory tract diseases[44,45]; and improve antibiotic absorption.[54–56]

To be effective systemically, many enzymes are enterically coated to prevent them from breaking down in the acidic stomach. Enzymes with wide pH, such as bromelain, can also be taken between meals. In this way, they are able to move through the digestive system and into the small intestine, pass through the brush border into the circulatory system, and be used by organs and cells in the body. To be most effective, systemically, it is essential to take enzymes on an empty stomach, approximately 1.5 hours before or after a meal (when used for digestive therapy, enzymes should be ingested approximately 30 minutes before meals). See the "Dosage" section of this chapter.

In the past, it was widely assumed that large protein molecules—such as enzymes—could not survive the digestive process and be reabsorbed intact. However, numerous studies have demonstrated that bromelain—and other proteolytic enzymes—can be absorbed by the small intestine through a number of routes, pass into the bloodstream, and ultimately circulate throughout the body.[57–59] Oral administration is effective, as is parenteral administration.[26,59–61]

Research on dogs indicated that levels of bromelain (after oral administration) peaked at 10 hours and were still detectable after 48 hours, whereas intravenous infusion peaked in 50 minutes and was detectable for 5 hours.[60]

A randomized, controlled, double-blind study on humans demonstrated that the highest plasma concentration of bromelain was achieved at approximately 48 hours.[57,58] A study of 19 men given 3 grams of oral bromelain daily indicated that the enzyme had a plasma half-life of 6 to 9 hours. Researchers estimated that within the 3- to 50-hour period, an average of 10.8 mcg of bromelain was present in plasma.[57] In both animals and humans, studies indicated that up to 40% of the absorbed orally administered bromelain was absorbed intact.[59–61] For an in-depth discussion of enzyme absorption, please refer to Chapter 100 on pancreatic enzymes.

CLINICAL APPLICATIONS

When used in systemic enzyme therapy, bromelain exerts a wide variety of therapeutic effects[26,50,51]:

- Fights many of the disorders associated with aging (e.g., digestive problems,[51] osteoarthritis,[4] and cancer[5–10])
- Assists digestion[51–53]
- Prevents and treats cancer[5–10,62]
- Inhibits blood platelet aggregation[5,12–18]
- Reduces pain[17,63–65]
- Relaxes smooth muscles[12]
- Stimulates the immune system[20,21]
- Fights inflammation[26–33]
- Reduces swelling[28,63,64]
- Improves wound healing[29]
- Relieves sinusitis[44,45]
- Debrides burns and wounds[66–68]
- Improves antibiotic absorption[54–56]

Aging

Unfortunately, the process of aging is accompanied by an increasingly wide variety of health problems, including chronic disorders, cancer, cardiovascular disease, osteoporosis, and arthritis. Further, the number of Americans over 65 is increasing every year. According to the US Census Bureau, over 20% of the American population will be age 65 or older by the year 2050. That figure was only 12% in 2008.[69]

Most commonly, the body loses resiliency as it ages and various degenerative diseases manifest. This is accompanied by a decline in hormone secretion,[70,71] immune system function,[71,72] and enzyme production,[73,74] thus reducing the body's effectiveness at fighting off foreign invaders. The symptoms of aging could be, at least partially, the consequence of these enzymatic reductions. For example, the graying of hair has been attributed to a lack of tyrosinase or a loss of its activity level.

Unlike the known serious side effects of most prescription drugs, bromelain has been shown to effectively fight many of the disorders associated with aging, including digestive problems,[49] osteoarthritis,[4] and cancer,[5–10] but without the serious and long-term side effects of many drugs.

Bromelain is also widely incorporated into lotions, creams, scrubs, facial masks, and other skin care products, where it is believed to improve the skin's appearance by removing dead skin cells.

Cancer

The standard of care for treating cancer has long included surgery, chemotherapy, and radiation, although hormone therapy, stem cell transplantation, and biological therapy (which includes immunotherapy) are increasingly being used. Treatment with bromelain is one form of biological therapy showing considerable promise in the treatment of cancer by preventing its growth,[5] delaying or preventing its metastasis,[6–9] and in some cases, exhibiting a cytotoxic effect on cancer cells.[9,10] In addition, in vitro studies show that bromelain can enhance the therapeutic value of several chemotherapeutics[8,62,75] and can alleviate some of the side effects of hormone therapy in patients with breast cancer.[76]

Skin cancer is the most common form of cancer in the United States.[77] To determine whether bromelain could prevent skin cancer, researchers gave hairless mice 20 mg of bromelain per kilogram of body weight per day for 1 year and then subjected them to ultraviolet light for 15 minutes three times per week for the same period[11] (it is generally agreed that exposure to ultraviolet rays increases an individual's risk of skin cancer). After 1 year, only 40% of the bromelain group developed skin cancer (as opposed to 100% of the control group). In addition, it took the bromelain group twice as long to develop lesions. Another study, conducted over a 6-month period, found that mice receiving 80 mg of bromelain per kilogram of body weight did not develop any abrasions after 2 months.[5]

Bromelain also appears effective at reducing cancer metastasis. An in vitro study on bromelain and glioma (primary brain tumor) cells

found that bromelain significantly and reversibly reduced the migration, adhesion, and invasion of glioma cells.[6] In this study, bromelain did not appear to have a cytotoxic effect, even after a 3-month treatment period.

An in vitro study on four different gastrointestinal cancer cell lines found that treatment with bromelain significantly inhibited their spread.[7] Another study determined that a combination of bromelain and N-acetylcysteine (NAC) was significantly more effective at inhibiting the growth and spread of cancer cells than either bromelain or NAC alone.[8]

A study on human cholangiocarcinoma (CC) cell lines found that bromelain treatment reduced cancer cell viability and inhibited the ability of those cells to migrate and invade.[9] Treatment with bromelain also induced apoptosis, an important function of most, if not all, cancer therapies.[78]

Particularly encouraging are animal studies suggesting antimetastatic properties and inhibition of platelet aggregation associated with metastasis, as well as inhibition of invasiveness and growth of tumor cells. For example, an in vivo study on mice found that bromelain significantly increased the animals' survival time in five of the six tumor lines evaluated.[79] Researchers transplanted the tumor cell lines (leukemia P-388, sarcoma S-37, Ehrlich ascites tumor cells [EAT], Lewis lung carcinoma cells [LLC], M-B16F10 [MB-F10] melanoma, and ADC-755 mammary adenocarcinoma cells) into the mice and 24 hours later administered bromelain either intraperitoneally, intramuscularly, or subcutaneously (depending on tumor type). The life expectancy of the mice treated with bromelain increased compared with the untreated mice or those treated with the control (5-fluorouracil) in all cases except those transplanted with MB-F10 melanoma (the researchers considered bromelain's effect on this tumor cell line to be a nonsignificant increase in survival).

Pharmacological and preclinical studies indicate that bromelain acts as an immunomodulator by inducing the production of distinct cytokines (such as interleukin[IL]-1β, IL-6, and IL-8, as well as tumor necrosis factor-γ), and by raising the impaired immunocytotoxicity of monocytes against tumor cells.[10,26,80–83] These findings were partially confirmed in a study involving 16 mammary tumor patients.[80] In that study, bromelain had a significant effect on monocytes, natural killer cells, and lymphocytes. In those patients who responded to bromelain treatment, monocyte cytotoxicity increased from 7.8% to 54% in b-macrophage-activated killer cells (bMAK-cells) and 16% to 47% in macrophage-activated killer cells (MAK-cells). Another study on breast cancer cell line MCF-7 found that treatment with bromelain significantly decreased the viability of the MCF-7 cells.[84] The researchers found that bromelain's strength was similar to that of taxol.

Bromelain appears to work synergistically with chemotherapeutics and improves their therapeutic efficacy.[62,75] Researchers conducted an in vitro study on gastrointestinal cancer and found that bromelain in combination with N-acetylcysteine potentiated the effect of numerous chemotherapeutics.[75]

An in vitro study on breast cancer cell line MDA-MB-231 found that bromelain in combination with cisplatin induced apoptosis to a higher degree than either bromelain or cisplatin when used as a single agent.[62] Most encouraging was the determination that the addition of bromelain significantly enhanced the activity of cisplatin, allowing for a reduction in the necessary dose of cisplatin, thereby potentially reducing its sometimes-serious side effects.

In addition to its effect on cancer cell growth and metastasis, bromelain may relieve some of the adverse side effects of hormone therapy in the treatment of breast cancer.[76,85] Bromelain in combination with papain, sodium selenite, and *Lens culinaris* lectin was given to 680 women receiving hormone therapy as an adjuvant treatment for breast cancer.[77] After 4 weeks of therapy, those suffering from adverse effects of the hormone therapy (which often include arthralgia and mucosal dryness) experienced a significant reduction in the severity of their symptoms.

A number of mechanisms may be responsible for bromelain's effect on cancer. Some researchers believe that bromelain's proteolytic activity may be responsible for its effect on tumor cells,[6,84] whereas others believe its effectiveness may be due to its other components.[10,26,80]

Circulatory Disorders

Research shows that bromelain is a potent inhibitor of platelet aggregation, both in vivo and in vitro.[5,12–18] Platelet aggregation is a major factor in atherogenesis and can result in heart attack, stroke, acute thrombophlebitis, transient ischemic attack, nightly leg cramps, edema, deep venous thrombosis, ecchymosis, and cellulitis. Bromelain's action could be due to its plasmin-increasing effects (plasmin is a proteolytic enzyme produced by the body whose job is to dissolve fibrin, a protein involved in blood clot formation).[86] Further, research demonstrates that bromelain (in conjunction with potassium and magnesium) can be effective in treating angina pectoris.[18,87]

An ex vivo study on rats found that bromelain offers cardioprotective activity.[88] The rats received an intraperitoneal injection of bromelain twice daily for 15 days before their hearts were removed and ischemia was induced in the heart. Researchers concluded that the bromelain treatment reduced the size of the infarct, limited injury to the myocardium, and thereby, enhanced cardiac function.

Researchers employed bromelain as an adjunct to analgesics in a double-blind study involving 73 patients with acute thrombophlebitis.[17] All symptoms of inflammation, including pain, swelling, tenderness, redness, disability, and elevated skin temperature, decreased. The common daily dose of bromelain (in this study and others) was 60 to 160 mg of 1200 MCU bromelain. Other researchers believe that doses of 400 to 800 mg are necessary in treating patients with thrombophlebitis (and many other conditions as well).[18]

Digestive Disorders

As mentioned previously, when taken with or just before meals, bromelain supplements can regulate digestion. As a proteolytic enzyme, bromelain improves the digestion of protein-containing food. When taken systemically, bromelain is effective in treating pancreatic insufficiency (and is a proven substitute for trypsin or pepsin in cases of pancreatic insufficiency and postpancreatectomy).[51] Researchers in one study found that nearly 22% of subjects over the age of 60 years had pancreatic exocrine insufficiency.[74] Double-blind studies determined that bromelain is particularly effective at treating pancreatic insufficiency when combined with ox bile and pancreatin.[52,53]

Dysmenorrhea

Bromelain in combination with papain is an effective treatment for dysmenorrhea.[19] Bromelain decreases the spasms of a contracted cervix in tested patients, so it is believed to be a smooth muscle relaxant. As-yet-unidentified substances in bromelain may be more beneficial in this regard than the bromelain protease; when isolated and purified, the protease failed to produce a similar effect. Bromelain increases levels of prostaglandin-E (PGE_1)-like compounds while decreasing prostaglandins of the 2-series (e.g., PGE_2 and PGF_{2a}), which is hypothesized to be the basis for bromelain's muscle-relaxing ability.[50]

Endometriosis is a frequent cause of dysmenorrhea and occurs when endometrial tissue grows outside of the uterus. Researchers conducted in vitro and in vivo tests to assess the effect of a combination of N-acetyl cysteine, alpha-lipoic acid, and bromelain on endometriosis.[54] The study results showed that the combination not only

resulted in the developed of fewer and smaller cysts but also had an anti-inflammatory effect by inhibiting the activation of vascular cell adhesion protein 1 (VCAM-1).

Immune Disorders

Bromelain appears to have immunomodulatory effects on immune and autoimmune disorders.[20,21] Understanding and treating immune disorders is becoming increasingly important because these disorders include many chronic conditions. (Please see the "Respiratory Tract Diseases" section of this chapter for a discussion of bromelain and respiratory conditions, including asthma.)

Two of the most devastating immune disorders are immune complex hypersensitivities (e.g., rheumatoid arthritis and glomerulonephritis) and autoimmune disorders (e.g., systemic lupus erythematosus). Immune complex hypersensitivities occur when antigens and antibodies bind, forming a cluster that can lodge in tissues or circulate throughout the body, leading to inflammation and tissue damage. Circulating immune complexes seem to be a major component of numerous immune disorders. Various factors inhibit cellular immunity, but the most important elements seem to be these "blocking factors" (i.e., immune complexes) that cause immune suppression. Autoimmune disorders occur when the body's immune system mistakenly attacks healthy cells. There are dozens of such conditions, including type 1 diabetes mellitus, multiple sclerosis, myasthenia gravis, and systemic lupus erythematosus. Crohn's disease and ulcerative colitis are two types of autoimmune disease, collectively referred to as inflammatory bowel disease (IBD). Researchers conducted an in vitro study to measure the effect of bromelain on the secretion of proinflammatory cytokines in IBD.[38] They determined that bromelain treatment significantly decreased the secretion of cytokines (including granulocyte colony-stimulating factor [G-CSF], interferon gamma [IFN-γ], and tumor necrosis factor [TNF]) and chemokines (including macrophage inflammatory protein-1ß [MIP-1ß]). According to the researchers, the secretion of these proinflammatory substances was due to bromelain's proteolytic activity.

Systemic enzyme therapy can stimulate the body's own defenses, accelerate the inflammatory process, and break down pathogenic immune complexes from the tissues, bringing them into the bloodstream for elimination. It is important to note that because enzyme use liberates immune complexes from the tissues, increasing their presence in the bloodstream, symptoms may actually increase in severity; however, this is only temporary. When used in sufficient quantities, the enzymes can then degrade the immune complexes in the bloodstream (sometimes within a few hours), and the disease symptoms should subside.

Infections

Infections caused by bacteria, viruses, fungi, and parasites can frequently be the most challenging conditions to treat. Bromelain has proven effective in fighting numerous infections, ranging from *Escherichia coli* to bronchitis (see the "Respiratory Tract Diseases" section later in this chapter).

The O157:H7 strain of *E. coli* is a particularly severe and potentially life-threatening bacterial infection that causes nausea, vomiting, and bloody diarrhea in humans and can lead to kidney failure and death. The *E. coli* enterotoxins gain a foothold by adhering to receptors on the intestinal mucosa. Preventing the attachment could also prevent the resulting diarrhea. Researchers administered a single dose of enterically coated protease granules (containing bromelain) to rabbits and then inoculated the animals with different strains of *E. coli*.[22] Of those rabbits given the enzyme mixture and strain H10407, only one animal died, and none of the remaining rabbits developed diarrhea. In the group not inoculated with the enzyme mixture, 87% either developed severe diarrhea or died.[22]

Comparable results were obtained with other bacterial infections. For example, similar studies with bromelain have been conducted on piglets inoculated with K88 positive *E. coli,*[24] and an in vitro study on rabbit ileum found that bromelain was also 51% effective against cholera toxin.[23]

Antibiotics are often the drug of choice to treat bacterial infections. Some studies indicate that bromelain may be as effective as antibiotics in treating numerous infectious processes, including bronchitis, perirectal abscess, pyelonephritis, and cutaneous staphylococcus infection.[26,55] In addition if, and when, treatment with antibiotics becomes necessary, studies show that bromelain can increase serum levels of several antibiotics (including tetracycline, amoxicillin, and penicillin) in different body fluids (including blood, cerebral spinal fluid, mucus, sputum, and urine) and tissues (including appendix, gallbladder, ovary, epithelium, and uterus).[54–56]

Bromelain also shows effectiveness against antibiotic-resistant bacteria, including strains of *Staphylococcus aureus*.[89] *S. aureus* is a gram-positive bacterium responsible for a number of infections, including skin infections (staph infections). Drug-resistant strains of *S. aureus*, including methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant *S. aureus* (VRSA), have rendered the infection particularly difficult to treat. Researchers evaluated the effect of bromelain and other enzymes on drug-resistant *S. aureus* biofilms and found that, after a 2-hour treatment with bromelain, the *S. aureus* biomass had been reduced by up to 98%.[89] The researchers concluded that treatment with enzymes may be a beneficial therapy against infections caused by drug-resistant bacteria.

Tuberculosis (TB) is another bacterial infection that appears to respond to bromelain treatment.[25] In an in vitro study, researchers evaluated stem bromelain's effect on murine and human macrophages infected with *Mycobacterium tuberculosis,* the bacterium responsible for TB.[25] Study results show that bromelain treatment reduced the production of foamy macrophages and inhibited the bacteria's viability. Foamy macrophages are produced as part of the inflammatory response and may play an important role in the progression of TB.[90]

Bromelain may also play a role in preventing periodontal disease.[91] An in vitro study found that a bromelain solution restricted the growth of several pathogens, including *Streptococcus mutans, Enterococcus fecalis, Aggregatibacter actinomycetemcomitans,* and *Porphyromonas gingivalis,* implicated in the formation of periodontal disease.[91] The researchers hypothesized that bromelain may have prevented the pathogens from adhering to periodontal tissues.

Inflammatory Diseases and Conditions

The ability of bromelain to decrease inflammation has been documented in various clinical studies and experimental models.[26–39] This anti-inflammatory action is beneficial because the inflammatory process is involved in numerous conditions, including injuries, infections, respiratory tract diseases, and arthritis (many of these conditions are covered separately within this chapter). In addition, numerous studies have noted bromelain's ability to reduce pain, swelling, and bruising and improve the rate of healing after various surgical procedures.[26–30,92] Unlike the majority of nonsteroidal anti-inflammatory drugs (NSAIDs), there seems to be no indication that bromelain promotes bleeding; however, because bromelain inhibits platelet aggregation, it is logical to assume that it *might* increase the risk of bleeding, so care should be exercised (see the section on drug interactions in this chapter).

Some of the earliest studies on bromelain involved athletic injuries. A 1960 study of boxers highlighted bromelain's rehabilitative effects.[29]

Within 4 days of initiating bromelain treatment, 58 of 74 boxers experienced complete resolution of all signs of bruising. Complete clearance of bruising occurred in 8 to 10 days in the remaining 16 boxers receiving bromelain. At the end of 4 days, only 10 boxers in the control group demonstrated complete clearance of bruising, whereas clearance in the remaining 62 in the control group required 7 to 14 days. It is important to note that bromelain's effect on pain reduction is probably not due to any direct analgesic effect but rather to its ability to reduce tissue edema and inflammation.

Fifty-nine patients with muscle strains, contusions, ligament tears, and other injuries to the musculoskeletal system received 500 mg of bromelain three times daily, 30 minutes before meals.[31] Results from this study and others indicate that the use of bromelain led to a rapid improvement of pain at rest and during motion, swelling, inflammation, and tenderness on palpation.[63,64]

Seventy-seven otherwise healthy subjects completed a study investigating bromelain's effect on mild acute knee pain of less than 3 months' duration.[32] Two validated questionnaires (the Psychological Well-Being Index and the Western Ontario and McMaster Universities [WOMAC] Knee Health Index) were completed as a baseline and after 1 month of bromelain treatment (200 or 400 mg/day, allocated randomly to volunteers). In both bromelain groups, all WOMAC symptom scores decreased significantly compared with baseline. Reductions in the total symptom score were 41% for the low-dose group of bromelain recipients and 59% in the high-dose group. Additionally, those receiving 400 mg/day of bromelain experienced significantly greater improvement in total symptom score plus stiffness and physical function dimensions compared with those receiving low-dose (200 mg/day) bromelain. Both bromelain groups experienced a significant improvement in overall psychological well-being compared with baseline (researchers noted a dose-dependent relationship).

Researchers in a study on knee osteoarthritis found that 500 mg per day of bromelain (2000 GDU) taken for 4 weeks was as effective as diclofenac (a commonly prescribed NSAID) in reducing WOMAC scores.[4] The diclofenac arm of the study was terminated at week 4 because of ethical reasons relative to side effects, whereas the group receiving bromelain continued the study for 16 weeks. The researchers deemed bromelain treatment to be safe.

Surgery

Numerous studies indicate bromelain's effectiveness at reducing postsurgical inflammation.[28,30,93,94] A double-blind study of patients who underwent oral surgery found that bromelain was significantly superior to placebo in reducing swelling (3.8 days compared with 7 days for the placebo).[28] In addition, the duration of pain decreased to 5.1 days in the bromelain group compared with 8.1 days for the placebo group.[27,28] The researchers concluded that although postsurgical medication alone was effective, a regimen of presurgical and postsurgical bromelain was recommended to enhance the healing process.

Bromelain is also effective at relieving the pain and edema that typically follow wisdom tooth extraction.[65,94] Researchers in a study of 40 patients found that 70% experienced reduced swelling and pain after taking bromelain.[65] Researchers in another study of 46 patients found that bromelain was as effective as ketoprofen (an NSAID).[94]

Similar observations were made in studies of episiotomy cases. Several studies show that bromelain reduced pain and edema after episiotomy.[30,92,93] In addition, preoperative administration of bromelain improved the potential positive effects.[30,93]

Anti-inflammatory Action of Bromelain

Bromelain may function as an anti-inflammatory by (1) activating proteolytic activity at the inflammation site, (2) lysing fibrin at the site (fibrin is a protein required for blood clotting), (3) depleting kininogen (a kinin precursor; kinin causes blood vessels to dilate), and (4) inhibiting the biosynthesis of prostaglandins and the induction of prostaglandin E_1 accumulation (which, thereby, inhibits vasodilation).[33,48,81]

Bromelain's proteolytic activity demonstrates a delayed analgesic effect that involves the action of two mechanisms: (1) bromelain cleaves inflammatory mediators, including the kinins and prostaglandins, which directly stimulate the pain receptors; and (2) bromelain supports the breakdown of plasmin protein and immune complexes that stem from the tissues by cleaving them directly and by stimulating their phagocytosis. The reduction of edema that subsequently follows leads to a relief of pressure and, secondarily, a reduction in pain, thus inhibiting bradykinin formation (a chemical mediator of inflammation) at the inflammation site.

Of these processes, the primary pharmacological effects of bromelain are most likely plasmin activation and the decrease in kinin levels. As mentioned in the "Cancer" section, bromelain functions as an immunomodulator and effectively increases the levels of some cytokines while reducing the levels of others, thus leading to cytokine homeostasis and a reduction in inflammation.

Bromelain also exhibits anti-inflammatory activity when applied topically. Products are available containing bromelain (typically in combination with chondroitin and glucosamine) for the treatment of arthritis and joint/muscle pain. Other combinations containing bromelain are marketed for the relief of dry skin and eczema, back pain, and other inflammatory conditions.

Respiratory Tract Conditions

Respiratory tract conditions, including asthma, bronchitis, and sinusitis, are marked by increased mucus production, inflammation, and resulting pain. Bromelain has shown effectiveness against each of these symptoms.[42–44]

A double-blind study on patients with acute sinusitis found that 87% of those receiving bromelain experienced good to excellent results in symptom relief compared with 68% of the placebo group.[44] Most notable was the reduction of mucosal inflammation (83%–52%) and difficulty breathing (78%–68%) in the bromelain group compared with the placebo group. An epidemiological cohort study on children with acute sinusitis compared the symptom recovery time of those treated with bromelain, standard therapy (which included antibiotics, antihistamines, anti-inflammatories, and analgesics), or bromelain in combination with standard therapy.[45] The results of the study indicate that treatment with bromelain led to a statistically significant faster recovery time than with standard treatment or bromelain combined with standard treatment.

When given by intraperitoneal injection, bromelain has been found to exert anti-inflammatory effects in allergic airway disease in numerous studies involving murine models,[95–97] but it is also effective when given orally. Researchers hypothesize that bromelain may be beneficial in treating human asthma, as well.

In addition to its anti-inflammatory activity, bromelain may be effective in the treatment of respiratory tract conditions because of its mucolytic activity.[43] Bromelain appears to reduce sputum viscosity and possesses an antitussive effect in patients with chronic bronchitis. Spirometric examination of patients before and after bromelain treatment indicated increased FEV_1 (a measurement of the amount of air exhaled in a forced exhalation) and vital capacity, whereas residual volume was reduced. These favorable results were believed to be due to bromelain's ability to function as a mucolytic and decrease bronchial secretions, thereby reducing respiratory congestion.

Cosmetic and Dermatological Applications

Although bromelain supplements are effective against numerous conditions, bromelain's applications are not limited to its oral use. A number of topical bromelain preparations, including skin care products, dentifrices, and skin debridement formulations are available over the counter and also by prescription.

As a proteolytic enzyme, bromelain degrades proteins, including the dead cells in the stratum corneum—the outer layer of the epidermis. This ability is particularly beneficial in skin care products, including cosmetics, exfoliants, and shaving lotions.

Bromelain is also used in dentifrices for its tooth-whitening properties. Researchers in a study on bovine teeth found that treatment with a gel containing papain and bromelain effectively removed the stains that resulted after the teeth had soaked for 1 week in a coffee solution.[98] The researchers noted that unlike peroxide-based gels, which are commonly used in clinical dental bleaching products, the enzyme mixture does not produce reactive oxygen species (ROS), which can deleteriously affect the teeth and surrounding soft tissues.[99]

In another study, researchers subjected the enamel portions of human teeth to a mixture of human saliva, tea, instant coffee, areca nut, betel leaf, lime, tobacco leaf, smokeless tobacco, and chlorhexidine.[100] After 24 hours, the tooth portions were treated with either a control toothpaste (Colgate Regular) or with the test toothpaste (a commercial product containing papain, bromelain, miswak *[Salvadora persica]*, neem *[Azadirachta indica]*, and fluoride). Compared with the control product, the lightness value of the teeth treated with the bromelain-containing toothpaste had improved to a statistically significant level. According to the researchers, the enzymes' proteolytic activity removed the protein component of the plaque on the teeth to which the stains are known to bind.

Bromelain products are also effective in debriding dead and damaged tissue resulting from severe burns.[66–68] It is important to remove necrotic tissue because it can interfere with healing and potentially contaminate the wound. Debriding the damaged tissue exposes healthy tissue, promotes healing, and provides a clear foundation for skin grafting, when necessary.

One such enzyme formulation is a bromelain-based gel dressing. Several studies confirm its safety and efficacy in burn debridement.[66–68] Unlike surgery and chemical or biological methods, enzymatic debridement rapidly removes necrotic tissue without damaging underlying and adjacent healthy tissue.[66,68] Skin debridement with bromelain products is typically conducted in a burn center or other clinical setting.

A Brazilian study found that emulsion-based bromelain products remained more stable than gels and that heat and light had adverse effects on shelf life.[101]

DOSAGE

When used as a digestive aid, bromelain should be taken just before a meal (no more than 30 minutes before eating). When used systemically, bromelain should be taken between meals, on an empty stomach (about 1.5 hours before or after a meal). Because supplement potency varies by manufacturer, it is best to follow the recommendations on the label for dosage. Most bromelain currently marketed in the United States is between 600 and 2400 GDUs.

Bromelain is a hydrolytic enzyme, so supplements should be taken with plenty of water to place the enzyme into solution. As with all enzymes, bromelain's activity can be inhibited by cold or increased by heat; however, excessive heat will denature the enzyme, so avoid drinking hot liquids when taking bromelain supplements.

SIDE EFFECTS AND CONTRAINDICATIONS

High doses (nearly 2 g) of bromelain have been administered with no apparent side effects.[104] No lethal dose 50 (LD_{50}) exists up to 10 g/kg, so it is deemed to be virtually nontoxic.[103] Long-term use seems to be well tolerated. As with most therapeutic agents, allergic reactions may occur with prolonged occupational exposure or in sensitive individuals; however, no significant side effects have been noted.[103,106]

No teratogenic studies have been conducted in humans, so bromelain should not be used by pregnant women. In addition, studies have not been conducted on the safety of using bromelain in nursing mothers.

Although no anaphylactic reactions have been reported, bromelain can induce gastrointestinal allergic and immunoglobulin-E–mediated respiratory reactions, as well as cross-react with papain, rye flour, wheat flour, birch pollen, and grass pollen.[103,106] Although side effects are infrequently observed, bromelain sensitivity as manifested by skin rash or urticaria has occurred. Other possible but unconfirmed reactions include vomiting, nausea, metrorrhagia, menorrhagia, and diarrhea. Researchers hypothesize that bromelain's ability to inhibit platelet aggregation may increase the risk of bleeding[40]; however, there are no studies to support this assertion. Eckert et al. administered 3000 FIP units daily to patients with breast cancer, with no significant alterations in their prothrombin time or plasminogen.[80]

DRUG INTERACTIONS

There are few known interactions between bromelain and other medications. However, because bromelain is a potent inhibitor of platelet aggregation (both in vivo and in vitro),[5,12–18] caution should be exercised when used with anticoagulants (e.g., warfarin) as well as over-the-counter NSAIDs, including aspirin and ibuprofen. In addition, certain botanicals, including garlic, ginkgo biloba, and ginseng, may increase bleeding risk, so patients should be monitored when these are used in conjunction with bromelain.

Clinical studies show that bromelain can increase serum levels of several antibiotics (including tetracycline, amoxicillin, and penicillin) in body fluids and tissues.[54–56] This can be helpful when attempting to improve an antibiotic's efficacy; however, it is possible that there could be instances where elevated serum levels of antibiotics would be deleterious.

Any foods that contain protease inhibitors have the potential to decrease the proteolytic activity of bromelain. However, most of these foods (e.g., potatoes and soybeans) are rarely eaten raw (heat inactivates the protease inhibitors). In addition, many of the protease inhibitors found in these (and other) foods are actually trypsin inhibitors (bromelain contains no trypsin).

CONCLUSION

The future of oral enzyme therapy is already here; however, the rate at which this knowledge is used in restoring health to millions is deplorably slow. This concerns those scientists, doctors, biochemists, and pharmacists who recognize the potential of enzyme therapy. This chapter on bromelain and Chapter 100 on pancreatic enzymes have been written in the hope of hastening the day when enzyme therapy will be employed as a matter of course for every disorder in which it can be of assistance.

Bromelain has proven to be effective in treating the following diseases and conditions:

Angina[18,87]
Arthritis[4]
Athletic injuries[29]
Bronchitis[55]

Camellia sinensis (Green Tea)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

Camellia sinensis (family: Theaceae)
Common name: green tea

GENERAL DESCRIPTION

Both green tea and black tea are derived from the same plant, *Camellia sinensis* (Fig. 60.1). The tea plant originated in China but is now grown and consumed worldwide. *C. sinensis,* an evergreen shrub or tree that can grow up to a height of 30 feet, is usually maintained at a height of 2 to 3 feet by regular pruning. The shrub is heavily branched, with young hairy leaves. The parts used are the leaf bud and the two adjacent young leaves together with the stem, broken between the second and third leaves (Fig. 60.2). Older leaves are considered of inferior quality.

Green tea is produced by lightly steaming the freshly cut leaf, whereas black tea is produced by allowing the leaves to oxidize. During oxidation, enzymes present in the tea convert many polyphenolic therapeutic substances to compounds with much less activity. With green tea, oxidation is not allowed to take place because the steaming process inactivates these enzymes. Green tea is high in polyphenols with potent antioxidant and anticancer properties. Oolong tea is a partially oxidized tea.

Of the nearly 2.5 million tons of dried tea produced each year, only 20% is green tea. India and Sri Lanka are the major producers of black tea. Green tea is produced and consumed primarily in China, Japan, and a few countries in North Africa and the Middle East (Table 60.1). Consumption is increasing in the United States.

CHEMICAL COMPOSITION

The chemical composition of green tea varies with climate, season, horticultural practices, and age of the leaf (i.e., position of the leaf on the harvested shoot). The major components of interest are the polyphenols.[1,2] The major polyphenols in green tea are the following flavonoids:

- Catechin
- Epicatechin
- Epicatechin gallate
- Epigallocatechin gallate (EGCG)
- Proanthocyanidins

EGCG is viewed as the most significant active component (Fig. 60.3). The leaf bud and the first leaves are richest in EGCG. The concentration of total polyphenols in dried green tea leaf is around 8% to 12%.

Other compounds of interest in dried green tea leaf include the following:

- Caffeine (3.5%)
- Theanine (one half of the total amino acid content, which is usually 4%)
- Lignin (6.5%)
- Organic acids (1.5%)
- Protein (15%)
- Chlorophyll (0.5%)

One cup of green tea contains about 300 to 400 mg of polyphenols and between 50 and 100 mg of caffeine. Commercial preparations that have been decaffeinated and have concentrated total polyphenols to between 60% and 80% are available.

PHARMACOLOGY

The primary pharmacological actions center around the antioxidant effects of the green tea polyphenols.[3] The degree of antioxidant protection produced by green tea is clearly dose dependent and requires a threshold dose. In a randomized crossover study, 15 healthy volunteers consumed 500 mL of green tea with different solid contents (1.4, 1.6, 1.8, and 2.0 g/L). Ingestion of the lowest dose produced no change in plasma antioxidant capacity. At the highest dose, the effects increased the plasma antioxidant capacity the greatest at 1 and 4 hours after ingestion.[4] This study is significant because it indicates that some in vivo studies that fail to demonstrate the increasing antioxidant activity of green tea may be due to insufficient dose.[5,6]

(–)-Epigallocatechin-3-gallate
(EGCG)

Fig. 60.2 Structure of epigallocatechin gallate (EGCG).

TABLE 60.1 World Tea Production by Type

Type	Dry Weight (×1000 tons)
Black	1940
Green	515
Oolong	60
Total	2515

In addition to exerting antioxidant activity on its own, green tea may increase the activity of antioxidant enzymes. In mice, oral feeding of a polyphenolic fraction isolated from green tea in drinking water for 30 days resulted in significantly increased activities of antioxidant and detoxifying enzymes (glutathione peroxidase, glutathione reductase, glutathione-S-transferase, catalase, and quinone reductase) in the small intestine, liver, lungs, and small bowel.[7]

Several in vitro and experimental models of cancer have shown that green tea polyphenols may offer significant protection.[8,9] Specifically, green tea polyphenols inhibit cancer via inhibition of metalloproteinases, various protein kinases, proteins that regulate DNA replication and transformation, tumor proteasomal activity, and the formation of cancer-causing compounds such as nitrosamines. Green tea polyphenols also upregulate or maintain intercellular–gap junction communication and increase apoptosis. Green tea acts as a carcinoma blocker by modulating the signal transduction pathways involved in cell proliferation, transformation, inflammation, and metastasis. The consumption of flavonoid-containing botanicals, like green tea, has demonstrated clear antioxidant benefit, and a diet high in polyphenols has demonstrated effectiveness at lowering 8-OHdG levels.[10]

L-Theanine

L-theanine (*N*-ethyl-L-glutamine) or theanine is a major amino acid uniquely found in green tea. In animal models, L-theanine increases brain serotonin, dopamine, and γ-aminobutyric acid (GABA) levels and has micromolar affinities for various brain receptor sites, including α-amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA), kainate, and *N*-methyl-D-aspartic acid (NMDA). Theanine has been shown to exert neuroprotective effects in animal models, possibly through its antagonistic effects on group 1 metabotropic glutamate receptors. Behavioral studies in animals suggest improvement in learning and memory. Clinical studies demonstrated that L-theanine reduces stress, improves the quality of sleep, diminishes the symptoms of premenstrual syndrome, heightens mental acuity, and reduces the negative side effects of caffeine.[11,12] These clinical effects are directly related to L-theanine's ability to stimulate the production of α-brain waves (a state often achieved by meditation and characterized by relaxation with greater mental focus and mental alertness) as well as reduce β-waves (associated with nervousness, scattered thoughts, and hyperactivity).

L-theanine is a popular ingredient in functional foods and beverages as well as dietary supplements designed to produce mental and physical relaxation without inducing drowsiness. L-theanine is fast-acting. Generally, the effects are felt within the first 30 minutes and have been shown to last up to 8 to 12 hours. Based on the results of clinical studies, it has been established that L-theanine is effective in the range of 50 to 200 mg.

CLINICAL APPLICATION

The primary clinical applications for green tea are in the prevention of cancer and heart disease, as well as aiding weight loss. It may also offer benefit to bone health and may protect the skin from sun damage.

Cancer

Epidemiological studies demonstrate that green tea consumption might offer significant protection against many forms of cancer. However, epidemiological correlations regarding the relationship between tea consumption and human cancer are confounded by numerous variables. The forms of cancer that appear to be best prevented by green tea are those of the gastrointestinal tract, including cancers of the stomach, small intestine, pancreas, and colon. Green tea may also provide protection against lung and estrogen-related cancers, including most breast cancers, skin cancer, and prostate cancer.[13–18] It is generally held that a desirable green tea intake is 3 to 5 cups/day, providing a minimum of 250 mg/day catechins. However, based on clinical data, this dosage level may not be sufficient once neoplasia develops or in high-risk individuals.

Although a population-based study of women in Shanghai found that among nonsmokers, the consumption of green tea was associated with a clearly reduced risk of lung cancer, in a dose-dependent manner, 17 studies showed little benefit in antioxidant effects in smokers even at significant dosage levels (i.e., more than 3 grams green tea polyphenols per day).[19]

In preventing breast cancer, the main anticancer mechanism may be inhibition of the interaction of estrogen with its receptors in breast tissue. Polyphenol compounds in green tea extracts also block the interaction of tumor promoters, hormones, and growth factors with their receptors in breast tissue. Experimental and epidemiological studies demonstrated a protective effect against breast cancer,

and clinical results confirmed that green tea might be helpful for early-stage breast cancer. In an observational study, 1160 surgical cases of patients with invasive breast cancers were followed for 9 years. During a review of 5264 person-years follow-up, 133 subjects (12%) had a documented recurrence of breast cancer. A decreased hazard ratio for recurrence adjusted for stage was observed with the consumption of 3 or more cups a day of green tea. Particularly in Stage I, the hazard ratio was decreased quite significantly. A similar tendency was observed for Stage II subjects but was not present among more advanced stages.[20]

The coadministration of tamoxifen with green tea catechins may be an appealing strategy, especially in the case of estrogen receptor (ER)–negative breast cancer, where green tea catechins have been reported to reactivate ER. Indeed, it has been observed that the treatment of ER-alpha-negative breast cancer cells with green tea polyphenols led to the reactivation of ER-alpha expression.[21] Experimental trials suggest a synergistic interaction of green tea catechins with tamoxifen or raloxifene in the treatment of ER-positive and ER-negative breast cancer through ER-dependent and ER-independent mechanisms. No evidence of an interaction of green tea catechins with aromatase inhibitors or fulvestrant has been reported.[22]

Topical and oral treatments of green tea flavonoid components have also been explored to treat human papillomavirus (HPV)–related cervical cancer. A randomized, controlled clinical trial of 51 patients with cervical lesions, including chronic cervicitis, mild dysplasia, moderate dysplasia, and severe dysplasia, were divided into four treatment groups, whereas 39 untreated patients served as controls. Green tea components such as EGCG were shown to have antiproliferative properties through the induction of apoptosis and cell-cycle arrest in cervical cancer cell lines.[23]

A second trial used a polyphenol ointment made with EGCG applied locally to 27 patients twice a week for 12 weeks; 200 mg of the ointment or an EGCG capsule was taken orally every day for 8 to 12 weeks. Overall, a 69% response rate (35 of 51 patients) was noted for treatment with green tea extracts, with each treatment showing a similar response, compared with a 10% response rate (4 of 39 patients) in untreated controls. A response was considered positive when pretreatment and posttreatment biopsies and Pap smears detected an elimination of abnormal cells, and there was a decrease in or complete elimination of HPV or a decrease in the size of the cervical lesion. The authors of this study concluded that green tea extracts might be a potential therapy regimen for patients with HPV-infected cervical lesions.[24]

In vitro and in vivo studies showed that EGCG produces marked inhibition of both hormone-sensitive and hormone-insensitive prostate cancer cells. To demonstrate concentration within the prostate of EGCG after oral intake, men with clinically localized prostate cancer consumed six cups of green tea daily or water for 3 to 6 weeks before undergoing radical prostatectomy.[25] Using high-performance liquid chromatography, green tea polyphenols were not detected in prostate tissue or urine from men consuming water preoperatively. In contrast, both the methylated and nonmethylated forms of EGCG were detectable in prostate tissue and urine in men consuming green tea.

In an additional study of men undergoing radical prostatectomy for prostate cancer, subjects were given 1300 mg of green tea polyphenols daily until surgery. Serum was collected before initiation of the drug study and on the day of prostatectomy. Serum biomarkers, including hepatocyte growth factor, vascular endothelial growth factor, insulin-like growth factor (IGF), IGF binding protein-3, and prostate-specific antigen (PSA), were analyzed by enzyme-linked immunosorbent assay (ELISA). The results showed a significant reduction in serum levels of PSA, hepatocyte growth factor, and vascular endothelial growth factor in men with prostate cancer after brief treatment with green tea.[26] Even at this relatively high dosage of polyphenols, there was no elevation in liver enzymes.

A proof-of-principle clinical trial was designed to assess the safety and efficacy of green tea polyphenols for the chemoprevention of high-grade prostate intraepithelial neoplasia developing prostate cancer within 1 year after repeated biopsy.[27] Sixty volunteers with high-grade prostate intraepithelial neoplasia were given either a placebo or 600 mg of green tea polyphenol extract (GTPE) daily. After 1 year, only one tumor was diagnosed among the 30 GTPE-treated men (incidence, approximately 3%), whereas nine cancers were found among the 30 placebo-treated men (incidence, approximately 30%). Total PSAs did not change significantly between the two arms, but GTPE-treated men showed values constantly lower with respect to placebo-treated ones. The International Prostate Symptom Scores and quality-of-life scores of GTPE-treated men with coexistent benign prostate hyperplasia improved, reaching statistical significance in the case of International Prostate Symptom Scores. As a secondary observation, administration of GTPE also reduced lower urinary tract symptoms, suggesting that these compounds might also be of help for treating the symptoms of benign prostate hyperplasia. No significant side effects or adverse effects were documented.

Cancer Risk and Black Tea Consumption

In contrast to green tea, population studies analyzing black tea consumption are not as clear regarding cancer protection. Some early studies even indicated that black tea consumption might increase the risk for certain cancers (e.g., rectum, gallbladder, endometrium).[28,29]

For example, in one study, the relationship between black tea consumption and cancer risk was analyzed using data from an integrated series of case-control studies conducted in Northern Italy between 1983 and 1990.[28] The data set included 119 biopsy-confirmed cancers of the oral cavity and throat, 294 of the esophagus, 564 of the stomach, 673 of the colon, 406 of the rectum, 258 of the liver, 41 of the gallbladder, 303 of the pancreas, 149 of the larynx, 2860 of the breast, 567 of the endometrium, 742 of the ovary, 107 of the prostate, 365 of the bladder, 147 of the kidney, 120 of the thyroid, and a total of 6147 controls admitted to the hospital for acute noncancerous conditions. After allowance for age, sex, area of residence, education, smoking, and coffee consumption, results indicated an increased risk with tea consumption for cancers of the rectum, gallbladder, and endometrium. There was no association with cancers of the oral cavity, esophagus, stomach, bladder, kidney, prostate, or any other site considered.

In another study, data on black tea consumption from 1965 to 1968 were clinically examined in 7833 men of Japanese ancestry.[29] Since 1965, hundreds of newly diagnosed cancer cases have been identified: 152 colon, 151 lung, 149 prostate, 136 stomach, 76 rectum, 57 bladder, 30 pancreas, 25 liver, 12 kidney, and 163 at other (miscellaneous) sites. Compared with almost-never drinkers, men who habitually drank black tea more than once a day had a four-times-greater chance of developing rectal cancer.

Cardiovascular and Liver Disease

Epidemiological, clinical, and experimental studies have established a positive correlation between green tea consumption and cardiovascular health. Green tea polyphenols exert vascular protective effects through multiple mechanisms, including antioxidative, antihypertensive, anti-inflammatory, antiproliferative, antithrombogenic, and lipid-lowering effects.[30] The underlying mechanisms for these effects are listed in Table 60.2.

In a double-blind, placebo-controlled study, 111 healthy adult volunteers were given either a green tea preparation (GTP) containing 100 mg of L-theanine together with 200 mg of a decaffeinated catechin green tea extract twice a day or a placebo.[31] Before and after 3 weeks, blood

TABLE 60.2 Correlation Between Green Tea Consumption and Cardiovascular Health

Cardioprotective Effects	Mechanisms	Molecular targets
Antioxidant effect	Scavenge free radicals	↓ $O2^{\bullet-}$, $NO^{\bullet}$, 1O2, ONOO–
	Chelate metal ions	Chelate copper and iron
	↓ Redox active transcription factors	↓ NF-κB, AP-1
	↓ Prooxidant enzymes	↓ iNOS, XO
	Upregulate antioxidant enzymes	↑ Catalase, GPx, SOD
	Sparing of antioxidants	Sparing tocopherol
Improvement of lipid metabolism	↓ Cholesterol synthesis	↓ Squalene epoxidase
	↑ Cholesterol excretion	Bind to cholesterol
	↓ Cholesterol absorption	Bind to cholesterol
	↓ Triglycerides	↓ Phospholipase
	↓ Fatty acid synthesis	↓ Acetyl-CoA carboxylase
		↓ β-ketoacyl reductase of FAS
Improvement of endothelial function	↑ NO-dependent vasodilation	↑ eNOS
	↑ NO-independent vasodilation	↑ Prostacyclin
		↑ Cytosolic cAMP, cGMP
Anti-inflammatory effect	↓ Adhesion of leukocytes to ECs	↓ VCAM, MCP-1
	+ Apoptosis of monocytes	↑ Caspase 8 and 9
Antiproliferative effect	↓ VSMC growth	↓ PCNA
		↓ PDGF
	↓ VSMC migration	↓ MMP-2
Antiplatelet and antithrombotic effects	↓ Platelet aggregation	↓ Cytoplasmic Ca^{2+} release
		PAF
	↓ Thrombosis	↓ Thromboxane A2 synthase
		Scavenge free radicals

ApoA1, Apolipoprotein A1; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *CoA,* coenzyme A; *EC,* endothelial cells; *eNOS,* endothelial nitric oxide synthase; *FAS,* fatty acid synthase; *GPx,* glutathione peroxidase; *iNOS,* inducible nitric oxide synthase; *MCP-1,* monocyte chemotactic protein-1; *MMP,* matrix metalloproteinase; *NF-κB,* nuclear factor-κB; *NO,* nitric oxide; *O2•–,* superoxide anion; *1O2,* singlet oxygen; *ONOO–,* peroxynitrite radical; *PAF,* platelet activating factor; *PCNA,* proliferating cell nuclear antigen; *PDGF,* platelet-derived growth factor; *SOD,* superoxide dismutase; *VCAM-1,* vascular cell adhesion molecule-1; *VSMC,* vascular smooth muscle cells; *XO,* xanthine oxidase.

pressure, serum lipids, serum amyloid-α (a marker of chronic inflammation), and serum malondialdehyde (a marker of oxidative stress) were measured. After 3 months, systolic blood pressure remained significantly lower. GTP lowered serum amyloid-α by 42% and lowered malondialdehyde by 11.9%. In men, there was a 9-mg/dL reduction in low-density lipoprotein cholesterol (LDL-c) and a 10-mg/dL reduction in total cholesterol (TC). In all subjects with a baseline LDL-c level greater than 99 mg/dL, there was a 9-mg/dL decrease of TC and LDL-c. A second double-blind, placebo-controlled trial enrolled 60 mildly hypercholesterolemic subjects (180–220 mg dL^{-1}) and divided them into three groups: catechin-enriched green tea (CEGT), catechin-enriched oolong tea (CEOT), or placebo. The subjects were instructed to drink 2 × 300 mL of CEGT (780.6 mg of catechin), CEOT (640.4 mg of catechin), or placebo beverage for 12 weeks. Drinking CEGT and CEOT significantly decreased subjects' body weight, fat, body mass index (BMI), lipid peroxidation, and lipid profile (TC, LDL-c, high-density lipoprotein cholesterol [HDL-c], and triglycerides [TG]). CEGT and CEOT also significantly improved ($p < 0.05$) the oxidative indices (TEAC and GSH) and antioxidant enzymes (SOD, CAT, GPx, and GR). Furthermore, ultrasound examination endorsed the hepatoprotective activity of CEGT and CEOT by reverting mild fatty liver to the normal hepatic condition because of antioxidant and hypolipidemic activities.[32]

Just as in the studies with cancer, cigarette smoking may nullify some of these protective effects against cardiovascular disease. A study from the Netherlands evaluating inflammatory markers, such as interleukin-6, interleukin-1β, tumor necrosis factor-α, C-reactive protein, and fibrinogen, found no benefit for 59 healthy smoking volunteers who drank tea with regard to inflammation, hemostasis, and the endothelial cardiovascular risk factors measured.[33] Given other studies of green tea that showed little protection for smokers and the strong body of literature regarding its efficacy in nonsmoking populations, it is possible that the level of oxidative damage sustained by regular smoking may be too great for tea's demonstrated antioxidant capacities. However, it may also be that the dosage of green tea polyphenols must be much higher in smokers. In one double-blind study, 30 healthy male smokers were divided into three groups and given green tea beverages containing 0 mg (control group), 80 mg (medium-dose group), or 580 mg (high-dose group) of green tea polyphenols daily for 2 weeks.[34] Endothelial-dependent and endothelial-independent vasodilatation were investigated by measuring the forearm blood flow (FBF) responses to acetylcholine and sodium nitroprusside using venous occlusion strain-gauge plethysmography. The FBF response to acetylcholine significantly increased at 2 hours and at 1 and 2 weeks after green tea polyphenol intake in the high-dose group, but no increase was observed in the other groups. FBF responses to sodium nitroprusside did not alter in any group at any time point. A significant increase in plasma nitric oxide and a decrease in asymmetrical dimethylarginine, malondialdehyde, and 4-hydroxynonenal, C-reactive protein, monocyte chemotactic protein-1, and soluble CD40 ligand levels were detected after long-term consumption of high-dose green tea polyphenol. This study indicates that higher dosages might be required to overcome the oxidative stress of cigarette smoke.

Weight Loss

The effects of green tea extracts on weight loss appear to require both the catechins and caffeine. Extracts containing both ingredients

decreased BMI (−0.55), body weight (−1.38 kg), and waist circumference (−1.93 cm) compared with caffeine alone. Studies that evaluated green tea catechins without concomitant caffeine administration did not show benefits on any of the assessed anthropometric end points. Green tea catechin and caffeine mixtures promote weight loss through thermogenesis and fat oxidation.[35,36]

Bone Health

Epidemiological evidence demonstrates an association between green tea consumption and the prevention of age-related bone loss in elderly individuals. There are five proposed mechanisms through which green tea protects bone health: (1) by mitigating bone loss through antioxidative stress action, (2) by mitigating bone loss through anti-inflammatory action, (3) by enhancing osteoblastogenesis, (4) by suppressing osteoclastogenesis, and (5) through its high content of fluoride and vitamin K_1.[37]

Neuroprotective Effects

EGCG has gained a lot of attention as a potential therapeutic agent for preventing neurodegenerative diseases, mostly attributed to the antioxidant, free-radical-scavenging, metal-chelating, antiapoptotic, and anti-inflammatory properties.[38] In support of this, a 13 year-long Finnish study with 30,000 adults aged 25 to 74 years reported a nearly 60% reduced risk of Parkinson's disease when 3 or more cups of tea were consumed per day.[39] In addition, a large-scale cohort 20-year follow-up analysis with approximately 50,000 men and 80,000 women showed that EGCG intake was associated with a 10% to 25% lower risk of Parkinson's, particularly in men.[40]

Animal research on EGCG suggests there may be potential in promoting healthy aging by improving the morphological and functional alterations that occur in a natural aging brain, suppressing cognitive dysfunction, increasing learning ability, and reducing oxidative damage in the brain.[41] Although EGCG shows promise as an iron-chelating, brain-permeable antioxidant agent, there is a need for examining this neuroprotective effect in depth through more human clinical trials.

PHOTOPROTECTIVE EFFECTS

Topical treatment or oral consumption of green tea polyphenols inhibits chemical carcinogen or ultraviolet (UV) radiation–induced skin tumorigenesis in different animal models. In one study, volunteers were treated with an extract of green tea or one of its constituents and subsequently exposed to graded doses of UV radiation 30 minutes later.[42] UV-treated skin was examined clinically for UV-induced erythema, looking histologically for the presence of sunburn cells or Langerhans cell distributions for UV-induced DNA damage. On histological examination, skin treated with green tea extracts had a reduced number of sunburn cells and protected epidermal Langerhans cells from UV damage. In a dose-dependent manner, EGCG and EGCG polyphenols proved to be the most efficient at inhibiting erythema. It was noted that the epigallocatechin and epicatechin fractions showed almost no effect. Green tea extracts also reduced the DNA damage that formed after UV radiation.

ORAL CAVITY DISEASES

Inflammatory gingival reactions, tooth decay, and oral cancer may also benefit from the use of green tea. By studying the amount of dental plaque present, as well as a bleeding index, green tea chews and rinses have been shown to positively affect the level of gum inflammation.[43] One trial evaluated volunteers who held 2 grams of brewed black tea or unbrewed green tea leaves in the mouth for 2 to 5 minutes. Results showed that this simple use of tea leaves, acted upon by salivary esterases, released high levels of catechins and theaflavin gallates into the oral cavity.[44] A controlled, clinical, double-blind, crossover study conducted to assess the efficacy of tablets containing green tea extract (equivalent of 1 mg polyphenols for three tablets) on oral volatile sulfur-containing compounds (VSCs) demonstrated statistically significant reductions in oral VSC levels immediately (55% reduction) and after 30 minutes (26% reduction).[45] Routine prophylaxis, as well as treatment of gum disease, may be well served by the addition of green tea support to standard brushing, flossing, and dental care regimens.

DOSAGE

The normal amount of green tea consumed by Japanese and other green tea–drinking cultures is about 3 cups daily or about 3 grams of soluble components, providing roughly 240 to 320 mg of polyphenols. For a green tea extract standardized for 80% total polyphenol and 55% EGCG content, this would mean a daily dose of 300 to 400 mg.

When selecting commercial green tea extracts, it is important to look for the level of EGCG as well as total polyphenol content.

TOXICITY

Green tea is not associated with any significant side effects or toxicity. As with any caffeine-containing beverage, overconsumption may produce a stimulant effect (e.g., nervousness, anxiety, insomnia, irritability). Consumption of green tea is not associated with liver damage in humans, and green tea infusion and GTE-based beverages are considered safe in the range of historical uses. Use of no-observed-adverse-effect-levels (NOAELs) from bolus administration to derive a tolerable upper intake level applying the margin-of-safety concept results in acceptable EGCG-doses lower than those from 1 cup of green tea. In clinical intervention studies, liver effects were not observed after intakes below 600 mg EGCG/person/day. Thus as a measure of safety, a tolerable upper intake level of 300 mg EGCG/person/day has been proposed for food supplements.[46]

DRUG INTERACTIONS

Populations with marginal or deficient iron status have been shown to have lower serum ferritin or hemoglobin levels, or both, presumably due to iron binding.[47] Theoretical concerns have been raised for interactions with several drug classes, including amphetamines and anticoagulants due to the caffeine content of green tea, but no interactions have been reported in humans.

Cannabis (Marijuana) and Cannabinoids

Roy Upton, RH

OUTLINE

Cannabis spp. (family: Cannabaceae)
Common name: cannabis

GENERAL DESCRIPTION

Cannabis consists of the dried inflorescences and remains of subtending leaves of pistillate Cannabis plants (Fig. 61.1). It is an herbaceous annual growing from a taproot. Male and female flowers primarily occur on separate plants, but rarely male and female flowers occur on the same plant. There is considerable academic and practical debate regarding speciation of the genus, with some authorities recognizing a single highly varied species (*Cannabis sativa, C. sativa* var. *sativa; C. sativa* var. *indica;* etc.) and others recognizing separate species, specifically *C. sativa, C. indica,* and *C. ruderalis,* this latter species being a wild progenitor from central Asia. Species are often designated as narrow-leaf or broadleaf, botanically referring to *C. sativa* and *C. indica,* respectively, or fiber and drug types, respectively. Cannabis hemp types are generally nonintoxicating, yielding very low levels of the primary intoxicating cannabinoid tetrahydrocannabinol (THC) and, rather, yielding relatively high amounts of the nonintoxicating cannabidiol (CBD). (Technically, the forms in the raw, unprocessed plants are precursors THCA and DBDA.) Conversely, cannabis drug types yield much higher concentrations of THC. Many of the distinctions differentiating *C. sativa, C. indica,* narrow-leaf, broadleaf, drug type, and fiber type are no longer supported due to interbreeding, predominantly breeding for high-THC cultivars.

Based primarily on chemical analysis, three types of cannabis are generally recognized, irrespective of botanical origin or morphological characters, namely, drug type (THC precursor predominating), fiber types (CBD precursor predominating), and intermediate cultivars between the two. The manner in which the species is lumped or split has implications commercially and regulatorily, especially when making a distinction between intoxicating and fiber (hemp) types, a discussion that is beyond this review. For a detailed discussion of the taxonomic debate regarding the monotypic versus polytypic classification of cannabis, see Clarke and Merlin *Cannabis—Evolution and Ethnobotany* (2016).[1]

Confusing the popular nomenclature more is the manipulation of terpenes, which give cannabis its sensory characteristics of taste, feel, and aroma, giving rise to distinctive names such as "train wreck," "silver haze," "kush," "skunk," "lemon haze," and "lemon skunk," to name only a very few. Despite the many different descriptors appearing in cannabis trade, most of these can be categorized between types that yield one of several predominant terpene profiles (see "Constituents"). Although terpenes, and perhaps other compounds, can have a modulating effect on cannabinoids, the concentration and contributions of the activity of CBD or THC are generally far greater than the relatively small concentrations of individual terpenes. Still, most involved in the

medicinal use of cannabis believe the effectiveness of the botanical is due to the entourage effects of all compounds present, including the numerous other cannabinoids beyond CBD and THC. For a detailed discussion of the concept of *entourage effects,* see Russo (2011).[2]

REGULATORY FRAMEWORK

Although recreational and medicinal use of cannabis is federally illegal, numerous states allow for its use. The federal scheduling of cannabis as a controlled substance is based on the legal grounds that the U.S. government considers cannabis (1) to have a high potential for abuse, (2) to have no accepted medical use, and (3) to be unsafe for use under medical supervision. None of these assertions has a scientific basis. The extensive historical medical use, modern clinical and pharmacological data supporting numerous uses of cannabis, its safety when used appropriately, and the recent approval by the U.S. Food and Drug Administration (FDA) of the cannabis drug Epidiolex (GW Pharmaceuticals, United Kingdom; 98% CBD) for the treatment of rare seizure disorders demonstrate that there is little evidence supporting such a prohibition—and likely never was. It is also clear that the recreational use of cannabis is far safer than that of other restricted, but allowed, substances such as cigarettes and alcohol, similarly suggesting such prohibitions based on safety are not scientifically based. Unfortunately, the U.S. prohibition against cannabis has influenced the manner in which the botanical is regulated in other countries and, more importantly, has limited meaningful research from taking place in North America. Fortunately, numerous states have minimally recognized the potential medical use of cannabis, and a few others have recognized the ability to use it safely recreationally. The laws governing the use of cannabis differ state by state and change frequently. Similarly, as evidenced by the FDA approval of Epidiolex, the regulatory framework of cannabis is evolving, making it necessary to refer to individual state laws and federal policies for current legal status.

HISTORICAL USE

Numerous medicinal preparations of cannabis have been used and prescribed since the earliest written records of medical history, including their formal recognition by medical authorities in official pharmacopeias, dispensatories, and *materia medicas*. Despite this, the plant has remained a source of controversy, possessing a reputation as both a pariah and medical panacea, depending on one's viewpoint. Fueling the former philosophy is the intoxicating nature of cannabis, which, historical and modern use demonstrates, has negative effects when

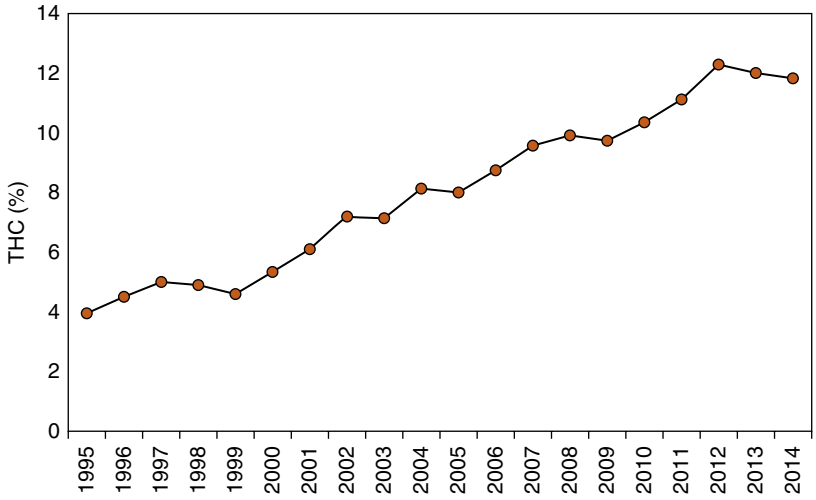

Fig. 61.2 Change in THC content over past two decades. (From ElSohly MA, Mehmedic Z, Foster S, et al. Changes in cannabis potency over the last 2 decades [1995–2014]: Analysis of current data in the United States. *Biol Psychiatry.* 2016 Apr 1;79[7]:613-61–9.)

used in excess and has been the subject of intense political and social demonization and religious prohibition. Representing the more positively biased side of the cannabis story is the discovery of the endocannabinoid system (ECS). The ECS is an integral part of human biology consisting of endogenous cannabinoids, most notably *anandamide,* named after the Sanskrit *ananda* for "bliss" or "joy" coupled with *amide,* and the widespread distribution of endocannabinoid receptors throughout the body (CB1 and CB2 receptors).

Endocannabinoid receptors occur in the central and peripheral nervous systems, including the brain, as well as the pancreas, uterus, bones, and liver.[3] Through a wide array of network signaling, cannabinoids have a modulating effect on many physiological systems that are both excitatory and inhibitory. There is a biphasic nature to the effects of cannabinoids on human physiology that is at least partially dependent on the receptor status of patients, that is often unpredictable until cannabis is administered. Anandamide is a neurotransmitter derived from arachidonic acid and is also synthesized in the uterus in pregnancy, eliciting a modulating effect at various stages of the developing embryo. The widespread distribution of cannabinoid receptors leads to the conclusion by some that anything that can modulate the ECS is beneficial for a myriad of diseases. Although this is mostly accurate, it leads lay advocates to believe that cannabis is a beneficial medicine for all people all the time in all diseases. In reality, beyond the general use of self-medicating with cannabis for the temporary relief of specific symptoms or long-term management of disease states (e.g., epilepsy), cannabinoid therapy should be tailored for individual needs, using preparations that favor specific cannabinoid profiles (i.e., CBD or THC prominence). Cannabis, as with other medications, should be integrated with lifestyle, behavioral, emotional, and/or other botanical or conventional medications that support cannabis therapy and normal physiology. Unfortunately, many resort to cannabis as a symptomatic Band-Aid to cope with mild to serious diseases, in the same manner as conventional drugs are used without addressing underlying or lifestyle factors that contribute to the disease state. That being said, aside from the ideal of using cannabis within the context of an integrative medical approach, it is a highly safe and effective medicine, with profound pharmacological activities that can be used to positively provide symptomatic relief and, in some cases, alter pathological states.

One important consideration regarding reference to the historical use of cannabis is the fact that the THC content of THC-prominent strains was historically much lower than plant material today. For example, in the 1960s and 1970s, the average percentage of THC in herbal cannabis was less than 1%, although anomalous samples reaching 9.5% were reported,[4] although this also has to be questioned based on analytical methodologies that were less well developed than they are today. In 1980 the average total THC concentration was approximately 1.5%,[5] which rose to approximately 3.3% in 1983 and 1984, fluctuated around 3% until 1992, and increased to 4.2% (average) in 1997. Since 1997, due to the increasing prevalence of cross-breeding for psychotropic effects, THC yields have steadily increased to today's average of approximately 13%.[6] In the same time period, other cannabinoid concentrations (e.g., CBD) remained relatively stable.[7,8] Another consistent theme reflected in the traditional herbal medical literature is that the efficacy of cannabis typically was evident below intoxicating doses, and much of the historical literature suggests that, if unwanted psychotropic effects occurred, too much was given (Fig. 61.2).

Another consideration in interpreting the therapeutic benefit of cannabis preparations is the differentiation between subjective and objective metrics of benefit and between short-term feelings of well-being that last only until the psychotropic effects of cannabis wear off (typically a few hours) and require repeated dosing versus long-term positive changes in physiology that last beyond the acute effects of cannabis. For example, the psychotropic effects of cannabis often contribute to a higher tolerance of or disassociation from subjective symptoms such as pain or depression but may not demonstrably alter pathology or lead to a worsening of symptoms. For integrated medical practitioners working with clients for whom cannabis may be used or indicated, these are important considerations. There are many potential benefits from the appropriate therapeutic use of cannabis and many more to be discovered. Following are the primary areas of application, but this discussion is by no means comprehensive.

Use in Traditional Healing Systems

Cannabis has been used throughout the world wherever consumers and medical practitioners had access to it. Its use dates to ancient times in Africa, China, Egypt, Greece, India, Rome, and Mesopotamia. The earliest writings of the medical use of cannabis occur on cuneiform bones. Some from approximately 800 BCE in Assyria record it as an ingredient in prescriptions. In Assyria, cannabis was named *gan-zi-gun-nu* ("the drug that takes away the mind") or *azallu* when used therapeutically.[9] During this time, cannabis was used to treat nocturnal epilepsy, a use relevant to clinical practice today.

Use in Traditional Chinese Medicine

The seed of *Cannabis* was discussed in China's earliest known text dedicated to medicinal therapies, the *Shennong Bencao Jing* (*Divine Farmer's Materia Medica*). In this *materia medica,* the psychotropic effects of cannabis were recognized in the statement that "excessive consumption causes one to see ghosts and walk frenetically." It was further recorded that consuming cannabis over a prolonged time "frees the spirit light and lightens the body."[10] In a 5th-century annotated edition of the *Shennong Bencao Jing,* the Taoist priest Tao Hongjing reported that *Cannabis* flower was "toxic," relieved pain due to "impediment," and was rarely used in formulas or by healthcare practitioners. Li Shizhen, regarded as the greatest compiler of Chinese *materia medica,* in his 16th-century *Bencao Gangmu,* recorded the use of cannabis for "hundred diseases of wind-withdrawal,"[11] which is a reference to mental disorders, a traditional category of mental illness characterized by either extreme withdrawal, mania, or both. The flowers, seeds, leaves, and stalk were later referenced in a number of other important historical Chinese texts on medicinals, but the vast majority of these and modern textbooks focus only on the use of the seeds.

In the modern era, the *Zhongyao Daci Dian* (Great Encyclopedia of Chinese Medicinals) is arguably the most complete single reference on all parts of the *Cannabis* plant. In this text, the following uses for the flowers were given: "pain wind," "withdrawal and mania," insomnia, and panting and cough. Although the seed is ubiquitous in modern Chinese *materia medica* and formula literature, relatively few texts include other parts of the *Cannabis* plant, and no other parts of the plant are commonly used today as part of traditional Chinese medicine (TCM) practice, either in the People's Republic of China or Taiwan. Some TCM specialists in North America are integrating the medical use of *Cannabis* into their practices based on the plant's modern use, however, not always according to TCM theory.

Use in Ayurveda

According to modern authorities,[12,13] cannabis is not featured in the foundational texts of Ayurveda, namely, *Caraka Samhita, Suśruta Samhita,* and *Vāgbhata's Aṣṭāngahrdayasamhitā.* The use of the leaves medicinally in oral preparations in India was definitively established around the 11th to 12th century CE in *Vangasena's Cikitsāsārasamgraha.* This text reports on the combination of opium and cannabis as a *vyavayin:* "a substance which pervades the whole body before being metabolized." The same text, naming the herb *indrāsana* ("food of Indra") and *tribhavanavijaya,* includes cannabis as an ingredient in two longevity formulas.

The pharmacodynamics of cannabis in Ayurveda *(dryavaguna)* is most consistently described in the historical literature. In the *Mahendrabhogika's Dhanvantarīyanighantu* of around the 11th century, cannabis is described as removing humoral phlegm, to be sharp, to aid digestion, and to be light. It is written that because cannabis is sharp and heating, it increases *pitta* (humorous bile) and provokes delusions, slows speech, and increases the digestive fire.[13] The *Rajanighantu* of the 13th century characterized cannabis properties and functions as acrid, astringent, heating, and pungent; as removing wind and phlegm, promoting speech, giving strength, and inspiring of mental power; and being an excellent excitant.[14] In Ayurveda, cannabis was used as a treatment for fevers to cool heated blood, soothe the overwakeful to sleep, give beauty, and secure length of days. It was also used to treat dysentery and sunstroke, clear phlegm, quicken digestion, sharpen the appetite, make the tongue of the lisper plain, freshen the intellect, and give alertness to the body and gaiety to the mind. In underscoring the need for appropriate doses, it was also stated that in moderation, cannabis is the best of gifts, but in excess, it causes abscess and even madness.[15]

The leaves of *Cannabis* are included in modern editions of the *Ayurvedic Pharmacopoeia of India* (2001)[16] under the name *vijayā,* where it is recorded for "sluggishness of the digestive fire" *(agnimāndya),* which often refers to dyspepsia and loss of appetite, acute diarrhea *(atisara),* digestive disturbances *(grahanīroga),* malabsorption, impotence *(klabiya),* and insomnia *(anidra).*

Use in Western Medical Traditions

Although cannabis is mentioned in the earliest writings of ancient Western medicine, detailed records of its clinical uses are lacking, focusing predominantly on its use for textiles, ropes, the seed as a cereal grain and providing fewer reports of its intoxicant and medical effects.

Irish physician William O'Shaughnessy, who learned of the herb's use in India, introduced cannabis into Western medical practice in the early 19th century. O'Shaughnessy provided detailed records and personal accounts of the effects and clinical use of cannabis that remain some of the most detailed guidance to date, which included the use of cannabis for relieving tetanus, rheumatic pain, cholera, and infantile convulsions. In this latter use, O'Shaughnessy's experience led him to believe that the anticonvulsant properties of cannabis had no equal and that it was the safest of the powerful narcotics of the time, for example, compared with opium.[17] The general effects of cannabis on humans as reported by O'Shaughnessy include alleviation of pain, antispasmodic, a remarkable increase in appetite, unequivocal aphrodisiac, great mental cheerfulness, and at the extreme continuum, delirium and a cataleptic state.

Cannabis came into use by the eclectic physicians of the United States around 1855 as practitioners learned of its use, partly from German physicians. The primary earliest actions were noted as anodyne, hypnotic, nervine, digestive, and antispasmodic, with indications including rheumatic pain accompanied by spasms and contraction that was only marginally responsive to other agents, as a narcotic to induce sleep, for menorrhagia, as a mind-altering drug, and even its use for "insanity" and reducing symptoms of withdrawal (delirium tremens), among other uses. As an anodyne, its action was considered to be less certain than opium but without the common side effects of opium or morphine,[18] a use of considerable importance today. This subsequently led to the inclusion of a comprehensive discussion of the herb's use in Felter and Lloyd's *King's American Dispensatory*,[19] in which both the inebriating and medicinal qualities of cannabis are noted. This foundational Eclectic work refers to cannabis as "one of the most important of our remedies" and additionally notes "but, like our best agents, it must not be used indiscriminately," providing sage advice for its medicinal use today. Cannabis was subsequently entered into the pharmacopeias of many European countries and the United States, where it was officially recognized as a medicinal agent, again attesting to the lack of scientific basis for today's current scheduling.

CHEMICAL COMPOSITION

There is a large number and variety of compounds in cannabis, most notably, cannabinoids and terpenes. There are more than 100 cannabinoids that potentially contribute to the activity of cannabis, of which several are prominent, the most well known being THC and CBD, accompanied by tetrahydrocannabivarin (THCV), cannabigerol (CBG), cannabichromene (CBC), and delta-8-tetrahydrocannabinol (delta-8-THC) and degradation compounds such as cannabinol (CBN). These compounds occur in the plant in carboxylic acid forms (e.g., as THC acid [THCA], CBD acid [CBDA], etc.) that are often considered to be relatively inactive but should be considered to possess a weaker or different activity than the decarboxylated forms of the parent compounds. Although possessing

some activity, conversion of the acids to their decarboxylated forms, usually by heating, is necessary for their full potential to be reached. For example, THCA lacks intoxicating effects and requires decarboxylation to the psychoactive THC. This conversion readily occurs in smoking or baking. Conversely, THCA possesses anti-inflammatory activity.[20]

Terpenes are volatile compounds that give cannabis its characteristic aroma, taste, and overall sensory characteristics. Although cannabis contains more than 200 terpenes and sesquiterpenes, like the cannabinoids, several predominate, most notably myrcene (reminiscent of cloves with hints of citrus), α- and β-pinene (pine aroma), and β-caryophyllene (reminiscent of pepper). Additional terpenoid chemovars include those containing limonene (citrus aroma), linalool (floral or sweet aroma), and humulene (reminiscent of hops), to name the primary types (for a more complete discussion, see Giese et al. [2015]).[21] Each terpene chemovar is generally believed to offer a unique suite of compounds beneficial for specific conditions and may modulate the effects of cannabinoids. To date, preference for one over another chemovar is highly subjective, based on patient or practitioner perspectives.

Whereas the cannabinoid profile and content in a particular chemovar are primarily genetically predetermined, terpenes are much more subject to variability through environmental and growing conditions, giving rise to the wide variety of chemovars, fanciful names, and sensory subtleties that exist in the market.

There is a host of additional compounds that occur in *Cannabis* that may contribute to the overall activity of the species. These include carbohydrates (monosaccharides, disaccharides, polysaccharides, sugar alcohols, cyclitols, and amino sugars), amino acids, amines (piperidine, hordenine, ammonia), noncannabinoid phenols (spiroindan-type, dihydrostilbene-type, cannabidihydrophenanthrene derivatives, simple phenols, simple phenolic glycosides, and phenol methyl esters), simple alcohols, aldehydes, ketones, acids, esters, lactones, steroids (phytosterols and brassinosteroids), vitamins, xanthones, coumarins, pigments, and alkaloids.[22]

Tetrahydrocannabinol

Heating THCA, the form found in the raw plant, results in decarboxylation to tetrahydrocannabinol (THC), which affects behavior by influencing both inhibitory GABAergic and excitatory glutamatergic terminals in the brain in a dose-dependent fashion. Gamma-aminobutyric acid (GABA) is a neurotransmitter involved in the communication between the brain and nervous system and is primarily responsible for promoting calmness by inhibiting neuronal activity. This has significant clinical implications for anxiety, depression, insomnia, various behavioral disorders, cognition, modulation of stress responses, and maintenance of muscle tone. GABA is also expressed in the immune system, where it has a modulating effect on immune responses and thus implications in autoimmune disease.[23,24]

In contrast to the inhibitory nature of the GABAergic system, the gluatmatergic system is excitatory, with glutamine being the primary excitatory neurotransmitter in the nervous system. Glutamate receptors are distributed throughout the spinal cord and brain in neurons and are linked to numerous other neurotransmitter pathways. There is also a close biological relationship between the GABAergic and glutamatergic systems in that GABA is synthesized by L-glutamic acid carboxylase, suggesting that, from an evolutionary perspective, the two systems work in tandem in modulating nervous system function between inhibitory and excitatory states.[25] There are various clinical implications of the effects of cannabinoids on the endocannabinoids system.

Cannabidiol

Like THC, CBD is not a naturally occurring cannabinoid in the raw *Cannabis* plant but rather has to be decarboxylated, usually by heat, from the acid form (CBDA) to CBD. Unlike THC, CBD does not possess the intoxicating activity of THC and is often referred to as lacking psychotropic activity. However, this compound has a marked effect on anxiety, so it can be considered to possess psychotropic effects but lacks the "high" that comes with THC consumption.

Like THC, CBD acts on both CB1 and CB2 receptors but to a much lesser degree than THC[26] and is often cited as potentially modulating the intoxicating effects of THC. Part of the activity of CBD is its ability to preserve the activity of the endogenous cannabinoid anandamide, either by preventing its degradation or increasing its uptake. Anandamide effects memory,[27] eating, sleep, and pain[28,29]; inhibits breast cancer cell proliferation[30]; and may be at least partially responsible for "runner's high."[30] Increasing the amount of anandamide in the brain has implications in the treatment of anxiety and depression.[31,32] CBD may also play a role in anxiety and depression through its effect as a serotonin (5HT1A) agonist, on pain through its interaction with TRP receptors, and in reducing inflammation through its ability to inhibit adenosine inactivation.[26,33–35] One primary area of investigation is the potential for CBD to positively affect numerous neurological and seizure disorders such as psychosis, multiple sclerosis, epilepsy, Dravet syndrome, Lennox-Gastaut syndrome, Huntington's disease, Tourette's, and numerous other neurological conditions. The use and often-remarkable effects of CBD for seizure disorders in children were popularized by the use of the CBD preparation Charlotte's Web (Stanley Brothers, Colorado) and the recently FDA-approved CBD preparation Epidiolex.

Other Nonintoxicating Cannabinoids

There is a host of other cannabinoids that, like CBD, lack the intoxicating effects associated with THC, including cannabigerol (CBG), cannabichromene (CBC), D9-tetrahydrocannabivarin (D9-THCV), and cannabidivarin (CBDV) and their acid forms D9-tetrahydrocannabinolic acid (D9-THCA) and cannabidiolic acid (CBDA).[36] These compounds occur in lower concentrations than THC and CBD and are often overshadowed by the more pronounced effects of THC and CBD. However, they are pharmacologically active compounds affecting both the endocannabinoid system, as well as systems outside of endocannabinoids, and they undoubtedly contribute to the entourage effect. CBN, for example, possesses approximately 10% of the activity of THC; D9-THCV is abundant in hashish from Pakistan and is reported to antagonize the effects of THC; and CBG effects a family of receptors (TRP) involved with sensations such as pain, hot, and cold but also exhibits antitumor activity and displays activity at very low doses. For a discussion of these minor compounds, see Izzo et al. (2009)[36] (Table 61.1).

PHARMACOLOGY

There are many indications for which cannabis is and can be used. Historically, the most common actions of cannabis were as an anesthetic, antidepressant, anodyne, calmative, appetite stimulant, and sedative. Based on these actions, cannabis was used for a wide array of conditions, including depression, pain management, spastic symptoms, acute mania, menorrhagia and dysmenorrhea, and wasting syndromes. Cannabis was also used topically for swelling, pain, bruises, burns, hemorrhoids, and fungal infections, applications not commonly employed today.

TABLE 61.1 Primary Compounds of Cannabis and Their Activity

 Delta-9-tetrahydrocannabinol (THC)	Primary psychotropic compound of cannabis Analgesic via CB1 and CB2 agonism (active at 20–40 nM)[191]; antiemetic[192,193]; anti-inflammatory, antioxidant[194]; antipruritic, cholestatic jaundice[195]; benefits duodenal ulcers[196]; bronchodilatory[197]; muscle relaxant[205]; reduces symptoms of Alzheimer's[199,200]
 Cannabidiol (CBD)	Anandamide (AEA) reuptake inhibitor,[29] analgesic,[201] anticonvulsant,[202] antidepressant in rodents,[203] antiemetic (5HT1A agonist; 5 mg/kg ip),[204] antifungal,[205] anti-inflammatory,[206] antagonizes effects of THC in humans,[207] antioxidant, anxiolytic via 5HT1A agonism,[34,208,209] decreases sebum/sebocyte proliferation,[210] effective against methicillin-resistant *Staphylococcus aureus* (MRSA),[211] increases adenosine A2A signaling,[35] proapoptotic against breast cancer cell lines,[212] treatment of addiction,[213] treatment of psychosis[214]
 Myrcene	Analgesic,[215,216] anti-inflammatory,[216] muscle relaxant,[217] sedative[218]

Most states that allow for the medical use of cannabis include cancer, HIV/AIDS, multiple sclerosis, glaucoma, and seizures/epilepsy as among the most commonly accepted of medical indications,[37,38] usually as adjuvants to other therapies and primarily for relieving symptoms associated with these conditions. Other surveys provide further evidence of additional uses of cannabis in states with medical marijuana laws and include pain, spasticity associated with multiple sclerosis, nausea, posttraumatic stress disorder, cachexia, glaucoma, and degenerative neurological conditions.[39,40] To date, the most comprehensive evidence-based reviews of cannabis use come from the National Academy of Science (NAS)[26] and the Canadian government (Health Canada).[41] The NAS review concluded there was conclusive evidence for an antiemetic effect in chemotherapy-induced nausea and vomiting; substantial evidence for moderate reduction of self-reported spasms; limited evidence for effect on clinician-measured spasms; limited evidence for reduction of depressive symptoms; moderate evidence for improvement of short-term sleep outcomes; and limited evidence for increasing appetite and decreasing weight loss in HIV. The NAS review failed to find supporting evidence for many of the other indications for which cannabis is popularly used.

The Health Canada review reports there are varying levels of evidence supporting the use of cannabis or cannabinoids in a myriad of conditions, including pain; movement disorders (epilepsy, multiple sclerosis, Parkinson's, Tourette's); adjunctive cancer and HIV care; mood, sleep, and psychiatric disorders; alcohol and opioid withdrawal; Alzheimer's; some gastrointestinal conditions; and potential anticancer activity.

Anecdotal reports of efficacy for use in conditions such as posttraumatic stress syndrome, cancer, and spastic conditions other than multiple sclerosis continue to drive cannabis use, and although lacking in strong formal evidence, these remain consistent uses for which the plant is employed.

The Endocannabinoid System

Cannabinoid receptors are often described as being separated between CB1 receptors in the central nervous system and CB2 receptors predominantly in the peripheral system. However, although both are preferentially concentrated in different tissues, both are broadly distributed throughout the body. CB1 receptors are highly concentrated in the brain and affect most areas and functions of the brain, affect neurotransmitters, and are highly expressed at GABAergic and glutamatergic neurons. CB1 is also highly expressed in nonneuronal tissues, including the gastrointestinal, reproductive, and cardiovascular systems, as well as in fat cells, the liver, the pancreas, and skeletal muscle (see Ligresti et al. [2016] and references therein).[42]

CB2 receptor expression and its functional physiological effects are less well understood than those for CB1 expression and activity. CB2 is highly expressed in various tissues of the immune system, including the spleen, intestines (gut lymphatic tissue), and lymph, and is also found in the brain and retina. One challenge in determining the specific tissue distribution and subsequent physiological activity of cannabinoid receptors is due to the fact that CB receptor expression can change with physiological stresses and disease states. For example, greater CB2 expression can occur in inflammatory conditions of the retina, more so than in healthy tissues.[42,43] Both receptor types have the ability to activate multiple signaling pathways that affect multiple systems and have the potential to positively influence numerous disease states. The endocannabinoids system has marked effects on neuronal activity, brain development in all stages of development, memory, emotions, appetite, and pain. Other cannabinoid receptors are also present (see Ligresti et al. [2016]),[42] and botanicals other than cannabis (e.g., echinacea) can influence cannabinoid receptors,[44] although both receptor types are highly activated specifically by the psychoactive THC and, to a lesser extent, the relatively minor cannabinoid cannabinol (CBN).

CLINICAL APPLICATIONS

Appetite Stimulation, Nausea, and Vomiting

Cannabis is well known for its ability to stimulate the appetite and is often used to sustain weight or promote weight gain in anorexia or weight loss associated with acquired immunodeficiency disorders (AIDS) and cancer. To date, no well-designed studies on the effects of cannabis on weight gain have been conducted. There is evidence for appetite stimulation, weight preservation, and weight gain from uncontrolled studies in patients with AIDS[44–47] and cancer,[48] and animal studies suggest that greatest efficacy is seen with relatively low doses[50] because the intoxication that accompanies high-dose cannabis use can impair the ability to initiate feeding. Some small investigational

studies suggest that smoking cannabis can increase caloric intake by 40%.[49,50] Other reports note that the increase in calories is mostly from snack foods, not increases in mealtime eating. This is predictable because CB1 receptors are highly expressed in sweet taste receptors.[51] Other investigations show an increase in caloric intake but no corresponding weight gain.[52] Numerous studies have shown efficacy for appetite stimulation and weight gain for synthetic THC (e.g., Jatoi et al. [2002],[53] Nelson et al. [1994],[54] Regelson et al. [1976],[48] Strasser et al. [2006],[55] Struwe et al. [1993], and Timpone et al. [1997][56] among others), but sometimes to a lesser degree than other therapies (e.g., megestrol acetate).[53,56] Most studies used orally consumed cannabis, whereas at least one study[47] reported comparable effects with smoked cannabis.

Cannabis is frequently used to allay nausea and vomiting, with THC generally considered as the primary active ingredient. The formal evidence regarding efficacy is reported as mixed and potentially positively biased, although cannabinoids are more effective than placebo and equally effective as conventional antiemetics.[26] Despite the potential for a positive bias in studies, the NAS review reported that there is conclusive or substantial evidence for the effectiveness of cannabis for allaying chemotherapy-induced nausea and vomiting. In one study, smoking was found to be more appropriate as a treatment option than pills, due to the inability to ingest oral forms when nauseous, but also due to higher blood levels of THC that are achieved with smoking.[57]

Synthetic cannabinoids (nabilone and dronabinol) were initially approved in 1985 for treating nausea and vomiting associated with cancer chemotherapy in patients who failed to respond adequately to conventional antiemetics. However, a number of studies and reviews since then report that THC or crude cannabis preparations are more effective than these approved THC analogs and are often equally effective as or more effective than other conventional antiemetic agents (for reviews, see NAS [2017],[26] Chang et al. [1979],[58] Lauritsen et al. [2016],[59] and Whiting et al. [2015][59]).

One important note regarding the use of cannabis as an appetite stimulant is that an increase in calories does not always result in an increase in weight gain because calories are often increased with simple sugars and snack foods, rather than increases at mealtime. Although weight gain has been reported in patients with HIV/AIDS using cannabis, cannabinoids are also reportedly less effective than progesterone megestrol acetate in improving appetite.[26]

The use of cannabis for allaying morning sickness has also been reported and is regarded by some as safe and others as contraindicated due to mixed evidence on the potential negative effects of cannabis on the developing fetus (see "Use in Pregnancy").

Neurological Disorders

Dravet and Lennox-Gastaut Syndromes

Cannabis, and in particular, CBD, has gained fame in recent years for its ability to dramatically decrease the severity of seizure disorders in children, conditions that in one third of cases are not effectively treated with conventional therapies. The use was stimulated by parental medication of their children with a CBD preparation (initially Charlotte's Web), in some cases with an almost complete control of seizures in some children with Dravet syndrome.

One group of investigators evaluated 214 patients with intractable Dravet and Lennox-Gastaut syndromes.[56] A 39% and 50% reduction in motor seizures was observed in subjects with Dravet and Lennox-Gastaut, respectively. There was a mean reduction in motor seizures of 30% over the 12-week period. The same research group[60] reported a 50% reduction in seizures in 43% of subjects with Dravet syndrome. At the end of the therapy, a small percentage (5%) was completely seizure-free. In subjects with Lennox-Gastaut syndrome, an almost 69% reduction in average monthly atonic seizures was observed, with 21% of subjects free of atonic seizures and 3% completely free of seizures during the last 4 weeks of therapy. The majority of caregivers (62%) reported improvement in the overall condition of the children given Epidiolex, compared with 34% of caregivers in the placebo group. There was no significant reduction in nonconvulsive seizures. Adverse effects were reported in 93% of treatment subjects, 89% of which were mild or moderate, and 75% of which were attributed to the medication. Some of the adverse effects were due to a potentiation of the effects of other medications taken. The most common adverse effects included sleepiness, vomiting, fatigue, elevated body temperature, decreased appetite, diarrhea, and elevated liver enzymes.[60]

In 2018 Epidiolex, a concentrated CBD oil (>98% CBD), was approved in the United States for the treatment of Dravet and Lennox-Gastaut syndromes that are resistant to standard treatments.

Epilepsy

Cannabis is widely employed in other types of seizure disorders, such as epilepsy, a long-standing historical indication[61] and an approved indication under the U.S. *compassionate drug use* program, in which select patients in the program are provided legally obtained cannabis as a seizure management tool. Numerous studies of a variety of designs demonstrate the efficacy of cannabis in reducing the incidence of epileptic seizures. In a case series of patients treated in U.S. epilepsy centers, a reduction in seizures of 36.5% was observed compared with baseline over a 12-week treatment period. In Israel, where the medical benefits of cannabis have been extensively studied for decades, 18% of children with epilepsy experienced a 75% to 100% reduction in seizure frequency, 34% experienced a 50% to 75% reduction, 12% reported a 25% to 50% reduction, and 26% reported a reduction of less than 25%. Aggravation of seizures was reported in 7% of subjects and led to a discontinuation of the treatment.[62] Tzadok et al.[63] reported on the use of cannabis in the treatment of seizure disorders represented by 272 cases in Washington state and California. Of these cases, cannabis was ineffective at reducing seizures in 14% (37) of subjects, 15% (29) experienced a 1% to 25% seizure reduction, 18% (60) a 26% to 50% reduction, 17% (45) a 51% to 75% reduction in seizures, 28% (75) a 76% to 99% reduction, and 10% (26) experienced a complete clinical response. Across patients studied in this review, 86% experienced some clinical benefit. Generally speaking, adverse effects were mild, and 4% of patients experienced an exacerbation of seizures. In these subjects, there was a wide range of effective cannabinoid doses, ranging from 0.05 to 9 mg/kg/day, and effective serum levels of CBD ranging from 1.8 to 80 ng/mL, showing a wide variation that makes it challenging to determine the most appropriate dose, which is highly individualized.[63] Some patients also included THC or THCA in their treatments. A similar reduction (84%) in seizures was reported in another survey of parents of children with seizure disorders who administered cannabinoid preparations to the children. Other beneficial effects included increased alertness, better mood, and improved sleep. Side effects included drowsiness and fatigue.[64] In a different report, seizures were exacerbated in 18% of subjects using a cannabis preparation[62] (see "Adverse Effects").

Although cannabis preparations are not effective for all subjects with seizure disorders, for those in which it is effective, the benefits can be remarkable. However, different subjects respond to different preparations and dosages. Although CBD has received a considerable amount of attention, some subjects require at least small amounts of THC. Others appear to respond to noncarboxylated preparations dominant in the nonpsychoactive THCA, whereas others may respond best to chemovars that favor one terpene over another (e.g., linalool).

Not treating patients who could benefit from cannabis as a novel therapy, treating with illicit or poorly characterized products in states where cannabis prohibition is still in place, and not having appropriate guidance in how to dose all carry a wide array of consequences in which the benefits must be weighed against the risk. One key consideration is the fact that cannabis has been widely effective in relatively large numbers of people, including children, with refractory seizure disorders. Their parents, often against great odds and with tremendous personal risk, are responsible for raising awareness about its potential benefit. For a more comprehensive review of the use of cannabis in seizure disorders and the pharmacological mechanisms involved, see Devinsky et al. (2016, 2017),[59,60] Russo (2017),[61] Stockings et al. (2018),[65] and Whalley (2014),[66] among others.

Multiple Sclerosis

Approximately 20% of patients with multiple sclerosis (MS) use cannabis for reducing MS symptoms,[67] and MS is one of the most commonly accepted diseases for the use of the plant in states where medical cannabis is approved. The NAS review concluded there was conclusive evidence for improving patient-reported symptoms associated with MS spasticity symptoms and limited clinical evidence for improvement of clinician-measured MS spasticity symptoms.[26] There is preclinical evidence of potential objective benefit based on anti-inflammatory properties associated with cannabis, with specific evidence suggesting a protective effect on neurons in MS models in mice.[68] Conversely, clinical evidence regarding the ability of cannabis to change disease progression is lacking.[69]

In formal clinical trials, the majority of evidence for efficacy is based on the investigation of the cannabis preparation Sativex, which is used as an oromucosal spray delivering 2.7:2.5 mg/100 μL THC:CBD, respectively. Most authoritative, evidence-based reviews report that information regarding the potential benefits of cannabis for MS is limited and that cannabis may be effective for relieving some symptoms (pain, spasticity, lack of bladder control, sleep) of MS.[69,198]

Other Movement Disorders

There are limited data on the use of cannabis in other movement disorders, including Huntington's disease,[70–72] Tourette's,[73] Parkinson's disease,[74–76] and amyotrophic lateral sclerosis.[77] Most evidence for these conditions comes from individual case reports, surveys, or pilot studies and is limited to a reduction of symptoms associated with these conditions, including anxiety, depression, obsessive-compulsive disorder, spasms, spastic rigidity, and mild psychosis. As a point of historical interest, a cannabis tincture (Squire's Extract) was used for the relief of symptoms in patients with Parkinson's disease beginning in the 1800s.

Pain

Cannabis has been used for the treatment of pain since as early as the 12th century. Formal reviews report there is conclusive or substantial evidence that cannabis or cannabinoids are effective for the treatment of chronic pain in adults. Pain is one of the most common conditions resulting in medical marijuana prescriptions, and an oromucosal spray (Sativex) of a whole *Cannabis* plant extract (THC:CBD, approximately 1:1) is approved for use in Europe, the United Kingdom, and Canada, specifically for the treatment of pain and spasticity associated with multiple sclerosis.[26]

Most studies, including a meta-analysis, investigating the use of cannabis in relieving pain, are in patients also suffering from other conditions, such as cancer, HIV/AIDS, or MS, and cannabis seems to be most effective for neuropathic pain.[78] Preclinical research on cannabis and pain has been carried out since 1899, at which time dogs exposed to cannabis inhalation failed to respond to pin-prick stimuli.[79] Relief of pain by cannabis appears to be due to multiple mechanisms that include direct analgesia, anti-inflammatory activity, and modulation of neurotransmitters and endogenous opioids.[80] Several studies, most with a placebo as a comparator and using different preparations, including smoking and extracts, reported significant reduction in neuropathic pain. Some subjects respond positively to low doses, whereas in others, high doses that are accompanied by intoxication were needed. Perhaps the most poignant observation suggesting the widespread efficacy of cannabis in pain management is the use of cannabis resulting in a 64% reduction in opioid use[81] and an almost 25% reduction in opioid fatalities in states with medical marijuana laws.[82]

Cancer

Cannabis is frequently used by cancer patients, both for allaying the symptoms associated with the disease, such as appetite loss, chemotherapy-induced nausea, depression, insomnia, and pain, as well as in an attempt to reduce tumor growth, based on a plethora of anecdotal reports and preclinical research suggesting direct anticancer activity (for reviews, see McAllister et al. [2015],[83] Patil et al. [2015],[84] Ramer and Hinz [2016],[85] Soliman et al. [2016],[86] Velasco et al. [2016][87]).

Cannabis is clearly beneficial for allaying symptoms associated with cancer and conventional cancer therapies.[88] Regarding pain control, the studies that have been conducted suggest that cannabis (smoked and vaporized) can alleviate chronic pain and can be effective when conventional therapies have failed. A single large-scale cohort study (the California Men's Health Study [CMHS]) reported an approximately 45% reduction in the incidence of bladder cancer in male subjects who reported cannabis use versus those who did not. The cohort included more than 82,000 subjects who were followed for 11 years. Conversely, an increase in bladder cancer incidence was reported in those who reported smoking tobacco only.[89] Although causality could not be ascertained, the results are suggestive of a potential protective effect of cannabis on the incidence of bladder cancer. Results of an open-label longitudinal study demonstrated that patients with chronic pain that was resistant to conventional therapies found relief with cannabis oil. As is typical of historical medical dosing, patients started at a low dose of one drop daily, increasing in increments of one drop per dose, three times daily, until satisfactory analgesia was achieved or until side effects appeared. In these oil preparations, the THC concentrations ranged from 11% to 19% and 0.5% to 5.5% CBD.[90] In some studies, plant extracts were reported to be preferred over synthetic cannabinoids.[88]

Numerous preclinical studies demonstrate that a number of cannabinoids (e.g., THC, CBD, CBG, CBC, CBDA) can inhibit cancer cell growth in vitro and also elicit a variety of antineoplastic effects in vivo. However, the in vivo doses used are generally magnitudes higher than is typically consumable to be clinically relevant.

A formal evidence-based review of the cannabis literature concluded there was substantial or conclusive evidence for the use of cannabinoids in chemotherapy-induced nausea.[26] There are mechanistic data suggesting that cannabis has direct anticancer activity, but there are no formal trials supporting a clinically relevant benefit. Conversely, there is widespread belief that cannabis holds great potential as an anticancer compound, leading to the popularization of high-dose THC protocols (e.g., Rick Simpson protocol) in an attempt to decrease tumor growth. No formal investigations of these protocols have been conducted.

Topical cannabis preparations are also popularly used for skin cancers but lack any formal evidence regarding efficacy.

Glaucoma

Glaucoma was one of the earliest conditions for which medical marijuana was approved in the United States in the compassionate drug

use program. There is an abundance of cannabinoid receptors in the tissues of the eyes. There is some evidence that THC reduces the intraocular pressure in the eye that accompanies glaucoma, but the effects seem to be transient (a few hours), and tolerance to the beneficial effects seems to develop over time.[91,92] Benefits were observed with an oral mucosal spray delivering 5 mg sublingual and up to 20 mg THC, and sublingual administration of 40 CBD caused a similarly transient increase in intraocular pressure.[93]

Addiction

Although cannabis has its own dependence-causing potential, both clinical and preclinical trials demonstrate it also has therapeutic application in the treatment of addictions to alcohol, cigarettes, cocaine, opioids, and stimulants, including the use of CBD (200–800 mg) for the treatment of cannabis dependence,[94] although the results of the available studies are mixed.

Anxiety, Depression, Posttraumatic Stress Disorder

There is a wide variety of evidence supporting the anxiolytic activity of cannabis. Although a small subset of the population experiences paranoia or agitation with cannabis use, and inexperienced users are more susceptible to agitation than experienced users, a large segment of the population experiences an anxiolytic effect. The benefit is especially evident for those suffering from other conditions, such as HIV/AIDS, cancer, and MS. Both THC-predominant chemovars and CBD are used. Some of the effects of THC are dose dependent, with low doses eliciting anxiolytic and mood-elevating effects and high doses and chronic use resulting in anxiety and an increased propensity for depression.

There are numerous anecdotal reports of the potential for both CBD and cannabis in general to relieve the symptoms of PTSD and, in some cases, to act as a reset that allows those with PTSD to reexperience joy and happiness, although again, results are mixed. Some investigations reveal that those with PTSD have relatively low concentrations of circulating endocannabinoids.[95] Much of the clinical work that is available was done with synthetic cannabinoids and shows benefit. A few studies investigated both THC and CBD.

In one study, patients with PTSD who received 2.5 to 10 mg THC mg experienced improvements in symptom severity, sleep quality, frequency of nightmares, and PTSD hyperarousal symptoms.[96] Targeting the endocannabinoid system has been described "as a possible ideal therapeutic target to treat both the emotional and cognitive dysfunctions characterizing PTSD."[97] The use of cannabis for PTSD is an approved indication in a number of states with medical marijuana laws, and there is generally a higher frequency of cannabis use in those suffering from PTSD, primarily for improving sleep.[98] Conversely, subjects with excessively high consumption of high-potency cannabis preparations, such as butane hash oil, report higher rates of anxiety and depression and are also prone to greater use of other illicit drugs and higher levels of physical dependence compared with those using crude high-potency herbal cannabis preparations.[99]

There is a biological relationship between cannabinoids and mental health. Anandamide levels in the cerebrospinal fluid and blood of patients are elevated in patients in early-stage psychosis, and there is an abundance of evidence of either a causal or associative relationship between excessive THC-predominant cannabis use and increased risk of psychosis and schizophrenia. There are numerous anecdotal reports of cannabis relieving the symptoms associated with schizophrenia, most notably for mood elevation and relief of anxiety and boredom.[100] However, despite subjective temporary relief of symptoms, ongoing cannabis use contributes to a worsening of schizophrenia, whereas cannabis cessation is associated with improved general health and cognition and a reduction in depression and psychotic symptoms.[101]

The negative effect of cannabis on psychosis and schizophrenia appears to be predominantly due to THC. Perhaps of greater relevance is that evidence suggests that substance abuse and symptoms associated with schizophrenia share similar neurological imbalances, making it difficult to determine whether the relationship is causal or associative.[102,103] Still, the available data suggest that cannabis use in those with schizophrenia or psychotic disorders results in a greater likelihood of relapse, longer hospital admissions, poorer adherence to treatment protocols, and greater need for psychiatric care, and the association is dose dependent, with strong strains producing the worst outcomes.[104] Conversely, CBD appears to lessen the negative effects of THC and even be of therapeutic benefit in relieving symptoms associated with psychosis and schizophrenia.[105–108]

In preclinical investigations, CBD at doses equivalent to 1.25 to 10 mg/kg in humans reduced the psychotic-producing effects of THC.[109,110] Similar effects were reported in human studies where increasing concentrations of CBD relative to THC (2:1 ratio of CBD:THC) reduced the intensity of the psychoactive effects of THC.[103] Another human study demonstrated that CBD blocked a number of negative effects associated with THC alone, including depersonalization, disconnected thoughts, paranoid ideas, and anxiety.

Alzheimer's Disease and Dementia

In recent years there have been reports of the potential use of cannabis for reducing symptoms associated with Alzheimer's and dementia, primarily based on preclinical research and case reports of symptomatic improvement. There is a relatively strong physiological basis for a potential benefit of cannabis in Alzheimer's because the brains of deceased patients with Alzheimer's contain lower levels of anandamide compared with matched control subjects.[111] A number of other physiological mechanisms associated with THC have been proposed as potential targeted therapies in Alzheimer's disease, including the ability of low-dose THC to stimulate mitochondrial activity.[112] In one animal study, CBD (2.5 and 10 mg/kg/day) inhibited inflammatory mediators in an experimental model of Alzheimer's-related neuroinflammation.[113] Conversely, a 2009 formal review of the use of cannabis for dementia found insufficient evidence of clinical efficacy,[114] whereas a more recent study of a medicated cannabis oil preparation reported a reduction of symptoms of delusions, agitation/aggression, irritability, apathy, sleep, and caregiver distress in patients with dementia.[115]

Sleep Disorders

Cannabis has been used to promote sleep for centuries. There is evidence that suggests the endocannabinoid system has a role in sleep. THC is associated with changes in slow-wave sleep, which is critical for learning and memory consolidation, both of which factor into normal sleep cycles. The effects of cannabis are dose dependent, decreasing time to sleep onset at low doses and increasing time to sleep onset at higher doses.[116] Most of the research has been conducted with synthetic cannabinoids. According to the NAS review (2017),[26] there is moderate evidence that cannabis or cannabinoids are effective for improving short-term sleep outcomes in individuals with sleep disturbance associated with obstructive sleep apnea syndrome, fibromyalgia, chronic pain, and multiple sclerosis, primarily synthetic THC.

DOSAGE

The dosing of cannabis preparations is highly variable.[117–119] Complicating the dosage determination is differentiating between the chemovar, terpene type and concentration, THC concentration, biphasic effects (low doses—1 mg THC or less—may stimulate, whereas larger doses can decrease activity, and vice versa), and the ratio of THC

TABLE 61.2 Typical Dosages of Cannabis and CBD Products[a,b]

Smoking	680 mg to 3 g dried herb
Vaporized	Dried herb: 1.5 g daily Concentrate: 5 puffs at 2 mg THC/CBD per puff
Tincture (1:5)	15–40 drops in single or divided doses[117–119] up to the equivalence of 1.5 g cannabis[119]
Fluid extract (1:1)	1 drop to 3–5 drops depending on extract
Tea	Equivalence of 1.5 g cannabis
Edible preparations	Equivalence of 1.5 g cannabis
Oil (1 g cannabis in 6.6 g oil)	13.9–16.5 g
Sativex	2.7 mg THC/2.5 mg CBD; titrate up as directed by a physician.
Epidiolex	Starting dose of 2.5 mg twice daily for 1 week; 5 mg twice daily week 2; titrate up as directed by a physician.

[a]Based on average medical use from a variety of demographics or as directed by physicians.
[b]Many of the effects of cannabis are biphasic and vary greatly in different individuals. Low doses are often stimulatory, whereas high or long-term use can decrease activity. It is best to start at the lowest possible dose and titrate up as tolerance and desired effect allow.
CBD, Cannabidiol; *THC,* tetrahydrocannabinol.

to CBD. Responses to cannabis are highly variable as well and very much dose dependent. When prescribing cannabis therapeutically, the dosage should start low (e.g., 1 mg THC) and move up as needed. Surveys of self-use suggest the average consumer taking cannabis for medicinal purposes uses from 1 to 3 g daily.[41] The U.S. national average for cannabis is 13% THC; this equates to a potential 130 mg to 390 mg of THC, although not 100% of the available THC is consumed. This is an extremely high dose compared with historical dosing regimens. Formal clinical trials of standardized preparations provide more exact doses for modern use.

The onset of effects differs between different preparations. The average time of onset for the various preparations is as follows:

- Smoking/vaporizing 6.5 to 7 minutes
- Tea 29 minutes
- Edibles and tinctures 46 minutes

However, response and detoxification rate vary widely. Another challenge is determining the dosage, which is greatly affected by form, concentration, and species. There is great variation in the literature between research studies and community use. In addition, the actual amount of THC and CBD in a product varies widely in the various types of extracts. Table 61.2 lists dosing regimens based on historical literature and surveys of typical use across studies internationally. These should be taken as relative guidelines. Individual patients and practitioners are recommended to start at the lowest dose and increase according to the desired effect and subject tolerability.

SAFETY

Adverse Effects

Historically, *Cannabis* was considered a safe herb to use for appropriate medical indications and with appropriate caution. Historical writers often reported that if symptoms of intoxication occurred, too much was given and the dose should be reduced. A similar observation has been made by experienced clinicians who often observe benefits at doses below intoxication thresholds (Sulak, personal communication, unreferenced). The safety profile of cannabis has changed over the decades as intensive interbreeding has increased THC levels from a historical concentration of 3% or less to a U.S. national average of 13%. Some preparations available today can be as high as 60% THC, which changes the landscape of cannabis safety with the side-effect potential first and foremost dose dependent and correlated with increasing THC concentrations. Despite increasing THC concentrations, when used with appropriate caution, cannabis is safe both when self-medicating and prescribed. The same adverse-effect profile is not evident with the use of nonintoxicating cultivars or preparations of cannabis, such as those based predominantly on hemp or CBD.

Details of the mechanisms associated with adverse effects are provided in the primary literature. Following is a basic overview of the primary safety considerations regarding cannabis. For more detailed and comprehensive information, refer to the primary literature.

The primary adverse effects that are correlated with THC intoxication include dizziness, sedation, euphoria, cognitive impairment, transient impairment of sensory and perceptual functions, clumsiness, dry mouth, hypotension, or increased heart rate. Most of these adverse effects are tolerable in healthy adults. The seriousness of most cannabis-induced adverse effects is similar to those experienced with other medications and is manageable with appropriate observation and care. More serious adverse effects associated with excessive THC exposure include panic attacks, severe anxiety, cannabis hyperemesis syndrome, psychosis, paranoia, hallucinations, and convulsions.[41]

Traditional Cautions

In the traditional Ayurvedic literature *(Ananadakanda),* nine stages of cannabis side effects were recognized: (1) red eyes and hot breath with dry tongue, lips, palate, and nose; (2) closed eyes and rigid body; (3) burning feeling in the feet, hands, eyes and a choking voice; (4) hunger and thirst, sleepy eyes, and rolling eyes; (5) a choking voice and forgetfulness of recent events; (6) complete amnesia; (7) weakness in upper limbs and body and prostration; (8) disorientation and weeping; and finally, (9) shouting, fainting, coma, eructation, groaning, rolling on the ground, difficulty speaking, incoherence, disclosure of secret feelings, misery, and collapse.[120] In traditional Chinese medicine, excessive consumption was said to cause one to see ghosts and walk frenetically.[10] In early American herbal traditions, the noted Eclectic physician John Uri Lloyd[117] described cannabis as "one of the most important of our remedies . . . but, like our best agents, it must not be used indiscriminately." Thus a number of the major herbal traditions recognized both the benefit and potential for adverse effects inherent in the use of cannabis. Acute symptoms subside with discontinued use. However, psychomotor impairment, specifically regarding attention and critical task performance, remain impaired despite three weeks of abstinence.[121]

Intoxication (the "High")—Typical Use

The most common effects that can be considered either desired or adverse, depending on the user and intent, are associated with intoxication when using THC-predominant strains. Short-term intoxication effects of recreational use include euphoria, relaxation, and loss of inhibition; time- and spatial distortion; and intensification of sensory experiences, such eating or listening to, music followed by a depressant period.[122,123] Cannabis use is associated with impaired function in a variety of cognitive and short-term memory tasks and can result in significant impairment of motor functions, such as slowed or distorted reaction times. Some experience dysphoria, agitation, anxiety, depression, and paranoia.[124] Increased appetite and rapid heart rate are relatively common physiological effects.[125–128]

Intoxication (the "High")—Excessive Chronic High-Dosage Use

There are significant adverse effects associated with high-dose chronic use of cannabis that persist beyond acute intoxication and have

anatomical, physiological, and psychological consequences. In addition to negative respiratory effects, excessive use of cannabis can result in structural changes in the white and gray matter of the brain,[129–131] increased risk of pancreatitis,[132] sperm abnormalities,[133] downregulation of CB1 receptors,[134] and dependence. Some of these changes reverse with discontinuation of cannabis use. However, the developing nervous system of young people is more susceptible to adverse effects. Psychologically, high-dose chronic cannabis use is associated with anxiety, depression, bipolar disorders, cognitive dysfunctions, and in adolescent users, increased risk of schizophrenia in subjects predisposed to schizophrenic disorders. Again, negative effects generally reverse quickly, although cognitive deficits can persist for up to 1 year.[135–139]

Respiratory Effects—Smoking

There are mixed data on the effects of cannabis smoking on the lungs. Some studies report that cannabis smoking has similar negative effects on the lungs as cigarette smoking, with the exception that there seems to be no definitive correlation between cannabis smoking and lung cancer. However, some studies suggest that smoking marijuana leaves is more carcinogenic than smoking tobacco leaves, and some studies report clear lung damage (e.g., Aldington [2007][140]). The comprehensive review of the available studies by Health Canada[41] reports there is no definitive risk, although the review provides a caution that smoking should generally be avoided. The most common respiratory symptoms self-reported for cannabis smoking by cannabis smokers include chronic bronchitis, cough, and phlegm.[141,142] Other respiratory symptoms that have been reported include shortness of breath and wheezing[143,144] and unusual conditions that include spontaneous pneumothorax,[145] bullous lung disease,[144] and barotrauma,[144,146] all of which are rare and for which causation is not definitive.[145] These unusual conditions are thought to result from the deep inhalation and holding of smoke in the lungs associated with cannabis smoking and are confounded by other factors, such as cigarette smoking. The holding of smoke in the lungs is linked to higher concentrations of tar, carbon monoxide, and THC in the lungs.[147] To date, no concerns have been reported for negative respiratory effects associated with nonsmoking exposure, and inhalation using a clean-technology vaporizer can minimize some of the risks of smoking.

Pediatric Intoxication (Intentional/Unintentional)

An unintended consequence with changing laws regarding cannabis has been an increased frequency in exposure to cannabis in children, or at least the reporting of such events. Perhaps the incidence of childhood exposure was the same before legalization, but the criminality of cannabis may have prevented parents from reporting accidental exposures. In children, the most common symptoms reported after acute ingestion include central nervous system (CNS) depression (e.g., lethargy, coma), confusion, agitation, and ataxia. Nausea and vomiting have also been reported, as well as drowsiness/lethargy, ataxia/dizziness, agitation, vomiting, tachycardia, dystonia/muscle rigidity, respiratory depression, bradycardia/hypotension, and seizures.[148] Exposures can be related to both medical use and, more commonly, unintentional consumption of edible preparations, which is of particular concern with children.[149] Unintentional exposures are primarily due to lack of supervision or poor product storage controls of parents. According to a review of poison control center data, the majority of exposures are provided palliative treatments, evaluated, and released without intensive medical care, although some are referred to intensive care for intubation. To date, there are no reports of unintentional intoxications causing permanent disability or death in children, and symptoms generally subside as the effects of cannabis wear off, usually within a few hours.

Effects on Driving

Cannabis significantly impairs motor functions, the impairment of which is proportional to the THC exposure and effects experienced, which are highly variable between consumers. There are mixed data regarding the incidence and fatalities associated with car accidents in states in the years following cannabis legalization. Some data suggest increases in accidents and fatalities, whereas others suggest decreases. In comparison, the risk of an accident is 5 to 30 times greater with impairment due to alcohol.[150]

The available data must also be interpreted cautiously. The incidence of cannabis-related accidents may be underestimated due to the time lapse between an accident, especially those that are fatal, and analysis of blood THC levels.[151] Conversely, the detection of small amounts of THC in the blood does not mean the driver was impaired or that cannabis was the cause of or contributed to an accident.

Results of laboratory experiments demonstrate that chronic use of cannabis negatively affects the long-term psychomotor and cognitive performance of drivers; the effects improve after 3 weeks of abstinence, but users do not recover completely.[152]

Cannabis Hyperemesis Syndrome

Chronic use of cannabis has been associated with severe cyclic vomiting in a small subset of cannabis users, leading to the development of a new clinical condition known as cannabinoid hyperemesis syndrome (CHS). Most subjects experiencing this are chronic heavy users smoking a few times weekly to several times daily. CHS is divided into three stages: (1) morning nausea, fear of vomiting, normal eating patterns, and abdominal discomfort that can last for years, as well as continued cannabis use, sometimes due to the belief that cannabis will reduce their nausea (preemetic or prodromal phase); (2) sudden onset of intense, profuse, persistent, and incapacitating nausea and vomiting up to five times per hour, with some patients reporting abdominal pain and weight loss (hyperemetic phase). When presenting to the emergency room, these subjects are generally dehydrated. (3) Treatment with antiemetics and fluids usually results in the cessation within 48 hours (recovery phase). Patients also often learn that frequent hot bathing provides temporary relief from the acute hyperemesis.[153] The mechanism associated with CHS is not definitively known but is related to a derangement of cannabinoid receptor signaling, and complete resolution of the condition with cannabis cessation has been reported.[154,155] Some patients experience relief by application of topical capsaicin (0.075% preparation) to the abdomen.[156]

Edibles—Special Caution

Oral consumption of cannabis in edible preparations requires particular caution due to a 35-minute to 2-hour latency between consumption and effects and effects that can last for up to 8 hours.[26] Unlike smoking, in which the effects occur within minutes and can be self-titrated, oral consumption can result in overconsumption of THC concentrations that are higher than expected or desired, resulting in negative adverse effects that can be severe, such as acute psychotic effects. Additionally, analytical methodologies for testing the THC concentration in edibles is not well established, and so the THC concentration of edible preparations may not be accurately disclosed, or the amount of THC delivered in edibles may have poor homogeneity control. Particular care must be taken when consuming edibles because fatalities with the consumption of edibles, predominantly due to psychotic episodes, have occurred.[156–158]

Treatment of Intoxication

In most cases, no treatment of cannabis intoxication is needed. Mild intoxication is primarily only troublesome for inexperienced users,

and the most marked effects wear off relatively quickly (typically 1.5 hours), requiring no more than reassurance and supportive therapy. More marked intoxication may benefit from pharmacological support with benzodiazepines. Severe intoxication, such as can occur with edibles, may require restraint in individuals experiencing acute psychotic episodes to prevent them causing harm to oneself or others.

Adverse Effects Based on Clinical Trials

The most detailed reports of adverse events associated with formal medical use can be discerned from controlled clinical trials conducted with standardized preparations and administered under medical supervision. In a review of cannabinoid studies over a period of 40 years, dizziness was reported as the primary adverse effect experienced by patients. In these studies, almost 97% of adverse effects experienced were considered nonserious.[162] Other common side effects experienced with cannabis use include lightheadedness, sleepiness, gastrointestinal upset, and dry mouth in short-term studies. In longer-term studies, many of these side effects subside, which is typical as patients become accustomed to (tolerant of) the effects of cannabis. A certain degree of tolerance for some of the symptoms associated with cannabis intoxication can occur in 4 to 10 days.[163] However, gastrointestinal (GI) upset and negative cognitive effects can persist, and subjects can experience more pain compared with those taking placebo.[64,159,160] Adverse events typically occur within 20 minutes of dosing and resolve completely within 3.5 hours.

According to one report, seizures were exacerbated in 18% of subjects using a cannabis preparation.[62] Inability to sleep, drowsiness, fatigue, loss of appetite, and GI upset were other common adverse effects, with an overall mean adverse-effects incidence of approximately 11% of subjects.[62] Assessing adverse events in children is particularly challenging, as is the use of illicit preparations in states where medical cannabis is not allowed.

Cannabis Dependence

There are a number of adverse effects that can occur with long-term excessive cannabis use. As with excessive use of other drugs, there is a potential for abuse, dependence, and withdrawal in some heavy users, which is most commonly designated as cannabis use disorder (CUD). Dependence has both physical and psychological aspects and is very much individualized between those with a propensity for dependence and those without such a propensity. There is evidence for both physical and psychological dependence to occur with excessive cannabis use, and dependence can be mild to severe. Mild withdrawal symptoms can include headache, lack of appetite, and restlessness; stronger withdrawal symptoms can include anxiety, insomnia, and depression, whereas more severe symptoms can include sweating, fever, chills, and hallucinations.[161] Mild symptoms usually subside in only a few days.[162]

Although there are no formally approved pharmaceutical therapies for the treatment of withdrawal, interestingly, there is evidence that CBD is potentially beneficial for cannabis dependence.[94]

Amotivational Syndrome

Long-term excessive cannabis use has been reported to contribute to amotivational syndrome, characterized by apathy and an inability to function effectively and, in some, long-term depression. Conversely, it can be debated that many excessive cannabis users are predisposed to exhibit amotivational tendencies rather than cannabis being causative, although abstinence results in a resolution of some symptoms.[163]

Toxicity of Cannabidiol

Most adverse effects associated with cannabis are both THC and dose dependent, with side effects worsening with excessive use of THC-rich preparations. In formal trials with the CBD preparation (Epidiolex), adverse events were reported in 75% to 93% of patients. The majority of these (89%) were reported as mild or moderate in severity. Adverse events reported with CBD (20 mg/kg body weight) in one study included diarrhea, vomiting, fatigue, increased body temperature, sleepiness, and abnormal results on liver-function tests, although some of these may have been associated with concomitant antiseizure medications.[60] A thorough review of CBD safety was published by Iffland and Grotenhermen (2017),[164] who report that CDB has a generally favorable side-effect profile and possesses less side effects than standard antiseizure medications and, because of this, helps in improving compliance with standard treatments.

Use in Pregnancy and Childhood Development

There is a long history of the use of cannabis in pregnancy, primarily for allaying morning sickness and facilitating childbirth by promoting labor, although in labor reportedly accompanied with much pain.[165] Cannabis is often used to help allay the nausea and vomiting due to morning sickness, with an estimate that 5% of pregnant women in the United Kingdom[166] and one in 20 pregnant women in the United States use cannabis.[167] In small doses for the acute relief of labor pain and nausea, cannabis use is generally believed to be safe for the mother. A formal investigation of the effects of low-dose cannabis in the neonate from conception to beyond delivery has not been undertaken.

Data suggest that pregnant women who use cannabis during pregnancy are more likely to be daily users and are more likely to meet the criteria for cannabis use disorders than nonpregnant women.[168,169] Those using cannabis during pregnancy also have numerous other behaviors that make the interpretation of effects difficult, such as other drug use or high-risk sociodemographic status. However, when such factors are taken into account, risks remain. Expectant mothers using cannabis are also reported to gain more weight than nonusers.[170]

THC can cross the placental barrier, raising the concern that excessive cannabis exposure can have a negative effect on the developing fetus.[171,172] In some studies, excessive cannabis exposure in pregnancy was associated with lower-than-average birth weight, height, and head circumference[170,173–175]; the differences were small but statistically significant.[176] Other studies confirmed the lower-than-average birth weight but failed to show changes in head circumference and height.[177] Other evidence suggests that using cannabis two or more times per week can increase the risk of premature birth.[174,178]

There are a number of studies establishing negative neonatal effects associated with excessive cannabis use, although the data are also mixed and of poor quality, making interpretation difficult. There is evidence to suggest that in utero cannabis exposure may negatively affect long-term growth and neurodevelopment, particularly in terms of cognition and behavior. Some of the primary adverse effects reported include lower memory scores, attention problems, hyperactivity and impulsivity in early childhood, problems with executive functioning later in life, and a greater likelihood of developing emotional and behavioral problems, such as depression and delinquent behavior.[168]

In the most comprehensive review to date, data on the developmental effects of cannabis from pregnancy ("first hit to the endocannabinoid system") to 22 years of age was summarized.[179] In one study, the gestational age of the neonate was decreased, whereas in another, cannabis exposure was associated with changes in birth length and weight in the first and third trimesters, respectively, but the findings between the studies were contradictory. In newborns, there was a decreased response to light and an increase in startle response and tremors, as well as a decrease in body length. The most effects were seen in the developing infant to 6 years old, with increases in motor skills, impulsivity, hyperactivity, nocturnal arousals, wake time after sleep onset,

delinquency, and aggression in girls and decreases in memory, verbal reasoning, mental development, short-term memory, sleep efficiency, concentration, IQ scores, and attention. The nature of these studies does not allow for definitive conclusions to be drawn. However, considering that the endocannabinoid system is integral to neurological development, it is not surprising that neurodevelopment changes can occur with exposure to cannabinoids.

Risk of Psychosis and Schizophrenia

In addition to the developmental effects reported previously, there appears to be a strong association between heavy adolescent cannabis use and an increased risk of schizophrenia. Some studies suggest there is a sixfold risk with heavy cannabis exposure, and there appears to be a greater risk for those genetically predisposed to schizophrenia.[180] Some consider cannabis an independent risk factor for psychosis as well, although there is evidence that also suggests that cannabis users who experience an initial psychotic episode have fewer neurological abnormalities than nonusers.[181] Animal data demonstrate that chronic exposure of cannabinoid agonists during the periadolescent period causes persistent behavioral alterations in adult animals. Although it is clear that cannabis can be used to provide symptomatic relief of symptoms associated with schizophrenia and psychosis, other researchers have continued to build a body of evidence suggesting caution in its use.[182]

One of the more interesting findings in the literature on cannabis and reproductive issues is an association with heavy prenatal, gestational, and postnatal cannabis use in males and an increased risk of sudden infant sudden syndrome (SIDS).[183] The reason for this has not been definitively ascertained. Cannabis use in pregnancy does not increase teratogenicity, stillbirths, or fetal distress, nor does it appear to elicit negative postnatal effects up to 1 year of age.[169,176,184,185]

One important principle in reviewing the childhood development data is to look at investigations at different stages of a child's life because certain cognitive deficits may not be evident, for example, until a child reaches school age. Over time, compensatory mechanisms can result in normalization after a cannabis-induced developmental deficit, followed by other developmental issues that become evident, such as an increased incidence of psychosis in susceptible populations, later in life. These cautions notwithstanding, the evidence for harm is more suggestive than definitive and must be interpreted carefully.

Because the endocannabinoid system plays a critical role in neurological development, there is concern that exposure to cannabinoids at critical times of gestational development can cause alterations that can have long-term negative consequences. This seems to be supported by animal data showing that exposure to low doses of THC during prenatal development can negatively affect cortical development in mice.[186]

Child Protection

There is a need to protect young children from accessing cannabis unintentionally. Reports of pediatric ingestion show that drowsiness, lethargy, "coma" that wears off as the effects of cannabis wear off, the need for respiratory intubation, agitation, an inability to walk, vomiting, respiratory depression, and aspiration pneumonia are among the most common adverse effects observed.[187] The dangers of accidental ingestion should also not be exaggerated because most children unintentionally exposed to cannabis recover from symptoms as the effects of cannabis wear off. Unlike opioids, which cause a depression in CNS function that can lead to respiratory failure, cannabis does not have the same effect. Although accidental ingestions do occur and reports to poison control centers increase in incidence in states in the first few years after states enact medical marijuana laws, the overwhelming majority of events resolve without the need for treatment, and relatively few serious events occur.[188–190] Even these reports of incidence must be considered carefully because increased reporting of unintentional ingestions does not necessarily mean there are more accidental ingestions in states where cannabis is legal but can also mean that there is a greater willingness to seek treatment, whereas before legalization, such reports carried a greater threat of childhood endangerment or neglect suspicions that may have caused parents to not seek medical care.

TOXICITY

Despite the widespread use of cannabis, including by youth, in the immunocompromised, and in pregnancy, there are no reports of death due to cannabis overdose.[41] This is predominantly due to the fact that, unlike opioids, cannabis use does not result in marked depression of respiratory and cardiovascular functions. When overdose does occur, subjects, even experienced users, can feel as if they have died or are at serious risk of dying, which can be very traumatic, and with edibles, this event can last for several hours, but full recovery can be expected. Conversely, there are individual reports of overdose resulting in psychotic behavior resulting in death. In at least two cases, edible preparations were implicated. In one, a young inexperienced user consumed a cannabis edible, did not feel as if any effect was occurring, due to the lag time between consumption and effects, and consumed many times the amount that he should have. This resulted in erratic behavior and his throwing himself over a balcony, falling to his death. His blood THC level was reported at 7.3 ng/mL, a little over the legal driving limit of 5 ng/mL. In another case, only a small amount of an edible preparation was eaten along with pain medications, causing a man to act erratically, asking his wife to get his gun and "kill him." While the wife called 911, the man got his gun and shot her. In the first case, causality appears clear. In the second case, a single case report such as this does not provide the entire picture of what could have contributed to this behavior. However, while on the call, the wife expressed that she had never seen her husband act in that manner and said he was acting more drunk than violent. There was a history of schizophrenia in the man's family, causing his defense attorneys to suggest he was particularly prone to cannabis-induced psychosis, a claim that was neither proven nor disproven.

There is a single case report of an 11-month-old who died of myocarditis subsequent to cannabis exposure, likely due to an edible preparation. Although causation cannot be assured, the physicians attempted to rule out other causes. Blood THC levels were 7.8 ng/mL,[220] which is very high for an 11-month-old, considering the 5-ng/mL limit established for adult intoxication. Cannabis also has marked cardiovascular-related effects, with tachycardia being one of the most physiological relevant effects of cannabis intoxication.[123] This still does not establish causality, but it is not unreasonable to consider cannabis as a contributing factor to such events.

As these reports suggest, the greatest risk of toxicity is with edible preparations because of the delay in onset of effects, and the risk is THC dependent. In contrast, the relatively immediate effects of respiratory administration allow consumers to self-regulate, and with the physical incapacitation that occurs in most users, it is very difficult to reach concentrations that would represent toxic overdose events.

Despite its relative safety, cannabis does result in reports to poison control centers and visits to emergency rooms, primarily due to dread of death, paranoia, anxiety, or convulsions. Although there are a number of pharmaceutical and mechanical interventions, the best policy is to provide support and reassurance to those suffering from excess cannabis use until the most acute effects wear off.

Based on rodent toxicology studies, the equivalent lethal dose of THC in humans has been extrapolated to be more than 15,000 mg or the equivalent of ingesting 7500 g of cannabis that contains 20% THC.[41]

DRUG INTERACTIONS

The most significant clinically relevant interactions can occur when cannabis is taken with CNS depressant drugs such as sedative-hypnotics or alcohol. THC is metabolized by a number of cytochrome enzymes (CYP2C9, 2C19, and 3A4) that are involved in the metabolization of the majority of conventional medications. Any substance that inhibits CYP enzymes can increase the bioavailability and action of THC and THC-related adverse effects. Concomitant use of cannabis with tricyclic antidepressants, amphetamines, and anticholinergic agents (e.g., antihistamines) has resulted in increased heart rate (tachycardia), high blood pressure, drowsiness, and cardiotoxicity. Substances that increase CYP activity can, conversely, potentially decrease the efficacy of cannabis. Of most clinical significance considering the recent approval of Epidiolex is the potential for interactions with antiseizure medications such as clobazam. CBD has been shown to inhibit the metabolization of this medication, resulting in a positive interaction associated with increases in plasma levels of clobazam metabolites and the ability to maintain seizure control with lower-than-normal clobazam doses. Conversely, CBD has been reported to decrease the anticonvulsive activity of other antiseizure medications.

Perhaps the most significant potential benefit of cannabis to date in relationship to other drug use is the reduction in opioid-related fatalities. In those states that enacted medical marijuana laws, a 24.8% reduction in opioid-related fatalities was observed.[82] Clinically, the use of cannabis resulted in a 64% reduction in opioid use.[81] In contrast, the intoxicating effects of cannabis can sometimes be enhanced with concomitant use of opioids.[41]

Capsicum frutescens (Cayenne Pepper)

Michael T. Murray, ND

OUTLINE

Capsicum frutescens (family: Solanaceae)
Common names: cayenne pepper, capsicum, chili pepper, red pepper, American pepper

GENERAL DESCRIPTION

Cayenne pepper (also known as chili or red hot pepper) is the fruit of *Capsicum annuum,* a shrubby, tropical plant that can grow up to 3 feet high. The fruit is technically a berry (Fig. 62.1). Paprika is a milder and sweeter-tasting fruit produced from a different variety of capsicum. Although cayenne pepper is native to tropical America, it is now cultivated in tropical locations throughout the world and has found its way into the cuisine of many parts of the world, particularly Southeast Asia, China, southern Italy, and Mexico.

CHEMICAL COMPOSITION

The most important constituents of cayenne pepper are the pungent compounds, with capsaicin being the most prominent (Fig. 62.2). Typically, cayenne pepper contains about 1.5% capsaicin and related principal components. Other active constituents present include carotenoids, vitamins A and C, and volatile oils.

HISTORY AND FOLK USE

The folk use of cayenne pepper is quite extensive. It has been used for the following:

- Asthma
- Fever
- Sore throats and other respiratory tract infections
- Digestive disturbances
- Poultices
- Cancer

It has also been used as a counterirritant in the topical treatment of arthritis and neuralgia.

PHARMACOLOGY

The pharmacology of cayenne pepper centers around its capsaicin content. Interestingly, capsaicin, although hot to the taste, has been shown to lower body temperature by stimulating the cooling center of the hypothalamus.[1] The ingestion of cayenne peppers by cultures native to the tropics may offer locals a way to deal with high temperatures.

When taken internally, cayenne pepper exerts several beneficial effects on the cardiovascular system. In addition to possessing antioxidant compounds, studies have shown that cayenne pepper reduces the likelihood of developing atherosclerosis by reducing blood cholesterol, triglyceride levels, and platelet aggregation, as well as increasing fibrinolytic activity.[2–4] (For the significance of these effects, see Chapter 149.) Cultures consuming large amounts of cayenne pepper have a much lower rate of cardiovascular disease.

When topically applied to the skin or mucous membranes, capsaicin is known to stimulate and then block small-diameter pain fibers by depleting them of the neurotransmitter substance P.[5] Substance P is thought to be the principal chemo-mediator of pain impulses from the periphery. In addition, substance P has been shown to activate inflammatory mediators into joint tissues in osteoarthritis and rheumatoid arthritis.[6]

CLINICAL APPLICATIONS FOR ORAL PREPARATIONS

Gastrointestinal Disorders

Cayenne pepper exerts several beneficial effects on gastrointestinal function, including acting as a digestant and carminative.[7] In addition, constituents of capsicum increase gastric emptying; stimulate gastromucosal defense and absorption; enhance permeability to micronutrients; and stimulate salivary, intestinal, hepatic, and pancreatic secretions.[8] Traditionally, *C. annuum* has been used against various gastrointestinal complaints, including dyspepsia, loss of appetite, gastrointestinal reflux disease (GERD), and gastric ulcer. Red pepper has been used therapeutically in atonic dyspepsia and flatulence because it increases the motility in the gastric antrum, duodenum, proximal jejunum, and colon.[9] Capsicum has been used as an antiseptic, counterirritant, appetite suppressor, antioxidant, and immunomodulator in the gastrointestinal system.

Double-blind studies show that red pepper consumption protects against aspirin-induced stomach damage and improves epigastric pain, fullness, and nausea scores in people with nonulcer dyspepsia.[10–12] In one study, the digestive-enhancing effects of capsicum were determined in 30 patients with functional dyspepsia and without GERD and irritable bowel syndrome (IBS). Patients randomly received 2.5 g/day of red pepper powder or placebo before meals for 5 weeks in a double-blind manner. Starting from the third week, overall symptom score and epigastric pain, fullness, and nausea scores were significantly lower than the placebo group. The decrease reached about 60% at the end of treatment in the red pepper group, whereas placebo scores decreased by less than 30%.

Capsicum does, however, lower the threshold for GERD, presumably by direct effects on sensory neurons, and may produce symptoms of GERD.[13,14] The therapeutic use of chili pepper and capsaicin may therefore act as a double-edged sword in many physiological circumstances, and further studies are warranted to determine the dose ceiling for their use as gastroprotective agents.

Fig. 62.1 *Capsicum annuum* fruit.

Thermogenic Aid

Capsicum ingestion may prove to be helpful in promoting weight loss in obese individuals. The antiobesity effects of capsicum occur via several mechanisms, including thermogenesis, satiety, fat oxidation, elevation of the basal metabolic rate, reduction of caloric intake, prevention of adipogenesis, restriction of the activity of lipoprotein lipase and pancreatic lipase, stimulation of lipolysis in adipose tissue, inhibition of the differentiation of adipocytes, and modulating adipokine release from adipose tissues.[15]

A study of 13 Japanese females showed that adding red pepper to high-fat meals increased diet-induced brown adipose tissue thermogenesis and lipid oxidation.[16] In a clinical trial, capsaicinoids from *Capsicum* were administered to subjects (age 42 years and body mass index [BMI] 30.4) for 12 weeks at a dose of 6 mg/day. At the end of the study, subjects in the treatment group had an average abdominal adiposity reduction of 21.1% compared with 20.2% in the placebo group,

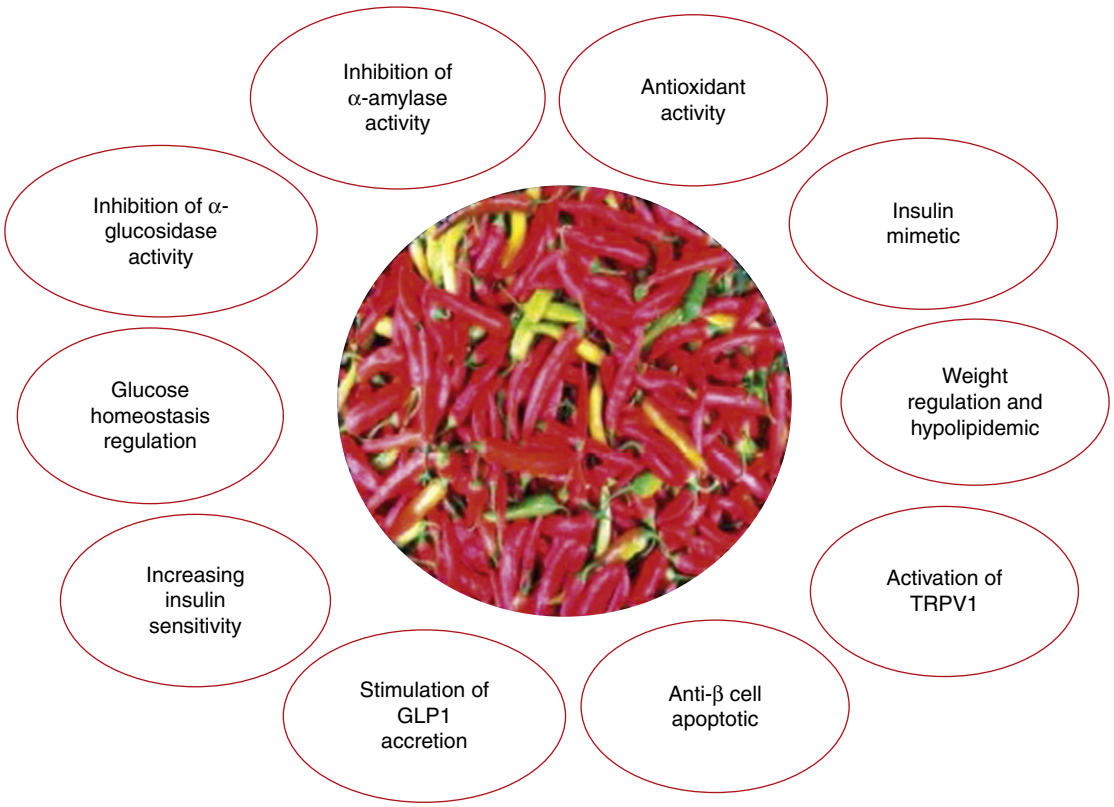

Fig. 62.2 Capsaicin.

and these effects were positively correlated with the change in body weight.[17] Researchers have also evaluated the effects of dietary red pepper added to high-fat and high-carbohydrate meals on subsequent feeding behavior and energy intake.[18] After ingesting a standardized dinner on the previous evening, the subjects ate one of the following for breakfast: a high-fat meal, a high-fat meal with red pepper (10 g), a high-carbohydrate meal, or a high-carbohydrate meal with red pepper (10 g). The addition of red pepper reduced appetite and hunger before lunch, and diet-induced thermogenesis was significantly enhanced by the addition of red pepper to either meal, but especially the high-fat meal. In another study, 40 women and 40 men (mean age of 42 years and BMI of 30.4) were randomly assigned to a capsinoid (6 mg/day) or placebo group.[19] Mean weight change was 0.9 and 0.5 kg in the capsinoid and placebo groups, respectively. There was no significant group difference in total change in adiposity, but abdominal adiposity decreased more in the capsinoid group (−1.11%) than in the placebo group (−0.18%), and this change correlated with the change in body weight. Changes in resting energy expenditure did not differ significantly between groups, but fat oxidation was higher at the end of the study in the capsinoid group.

Cardiovascular Disease and the Metabolic Syndrome

Capsicum exerts several effects beneficial in the prevention of cardiovascular disease, including inhibiting low-density lipoprotein cholesterol oxidation, acting as an antioxidant, inhibiting platelet aggregation, promoting fibrinolysis, and improving arterial function.[20] A randomized, double-blind, placebo-controlled clinical trial on hyperlipidemic subjects ingesting a traditional fermented red pepper paste (kochujang) for 12 weeks demonstrated significant reductions in total cholesterol (215.5 ± 16.1 mg/dL–194.5 ± 25.4 mg/dL) and LDL cholesterol (133.6 ± 14.8 mg/dL–113.5 ± 23.1 mg/dL) in the kochujang-supplemented group compared with placebo.[21] Capsaicin consumption 1 hour before low-intensity exercise is a valuable supplement for the treatment of individuals with hyperlipidemia and/or obesity because it improves lipolysis.[22] Besides being cardioprotective, the beneficial hypocholesterolemic influence of capsaicin extend to include the prevention of cholesterol gallstones and protection of the structural integrity of erythrocytes under conditions of hypercholesterolemia.[23]

It is known that insulin-like growth factor-1 (IGF-1) reduces arterial blood pressure. Because administration of capsaicin and isoflavone increases serum levels of IGF-1 by sensory neuron stimulation in subjects with alopecia, a study was conducted to evaluate the effects of capsaicin and isoflavone on blood pressure in patients with hypertension.[24] Systolic and diastolic blood pressure and serum levels of IGF-1 were measured before and at 1, 3, and 5 months after the administration of capsaicin and isoflavone. Although blood pressure was unaffected in normotensive subjects, systolic and diastolic blood pressure were significantly reduced in hypertensive volunteers after administration of capsaicin and isoflavone, and IGF-1 levels were significantly increased.

In healthy human subjects, a single meal with capsaicin caused an increase in postprandial GLP1 concentration while decreasing postprandial ghrelin concentration.[25] Chili consumption also lowers postprandial hyperinsulinemia.[26] In addition to the effects of capsaicin in type 2 diabetes, a randomized, double-blind, placebo-controlled trial on 44 pregnant women with gestational diabetes indicated that 5 mg/dL capsaicin for 4 weeks improved fasting lipid levels, improved postprandial hyperglycemia, improved hyperinsulinemia, and decreased the incidence of large-for-gestational-age newborns.[27] Fig. 62.3 describes several of the known mechanisms associated with the antidiabetic effects of *C. annuum*.

Transient receptor potential vanilloid subtype I (TRPV1) is the receptor for capsaicin and is widely expressed in the brain, sensory nerves, dorsal root ganglia, bladder, gut, and blood vessels. TRPV1

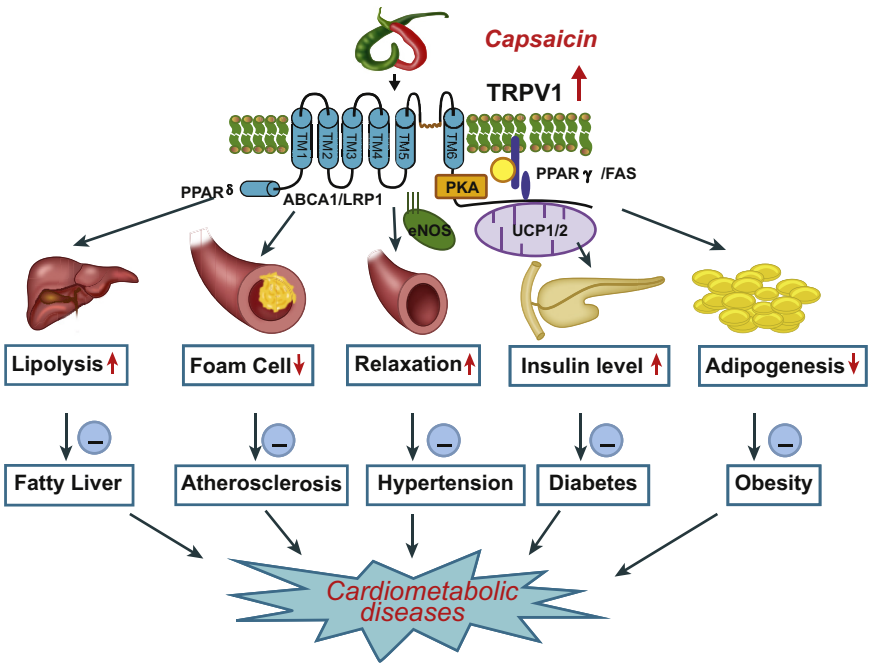

Fig. 62.3 Antidiabetic effects of *Capsicum annuum*. *GLP1,* glucagon-like peptide 1; *TRPV1*, transient receptor potential vanilloid subtype 1. (From Sanati S, Razavi BM, Hosseinzadeh H. A review of the effects of *Capsicum annuum L.* and its constituents, capsaicin, in metabolic syndrome. *Iran J Basic Med Sci.* 2018;21[5]:439–448.)

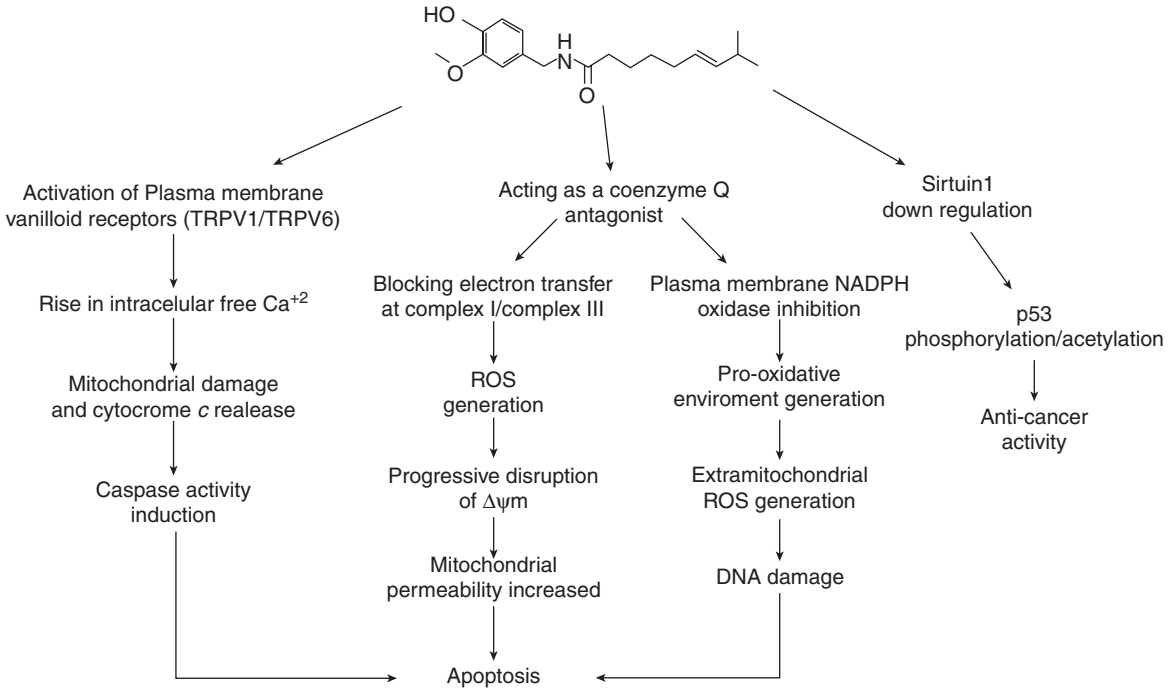

Fig. 62.4 Effects of capsaicin on cardiometabolic disease. (From Sun F, Xiong S, Zhu, Z. Dietary capsaicin protects cardiometabolic organs from dysfunction. *Nutrients*. 2016;8[5]:E174.)

is involved in inflammation, oxidative stress, and pain sensation and likely plays a critical role in the regulation of cardiovascular function and metabolic homeostasis. Activation of TRPV1 by capsaicin has been shown to prevent obesity, improve glucose homeostasis, alleviate hypertension, and antagonize dysfunction of cardiometabolic organs (Fig. 62.4).[28] This receptor provides a common link between the conditions associated with the metabolic syndrome and may be an optimal target for capsaicin in the treatment and management of cardiometabolic diseases.

Cancer

The preponderance of the data strongly indicates significant anticancer benefits of capsaicin. Capsaicin has been shown to alter the expression of several genes involved in cancer cell survival, growth arrest, angiogenesis, and metastasis. Capsaicin targets multiple signaling pathways, oncogenes, and tumor-suppressor genes in various types of cancer models. In addition, data suggest several benefits of combinational use of capsaicin with other dietary or chemotherapeutic compounds, leading to synergistic anticancer activity.

Capsicum has shown an antiproliferative effect on various human cancer cell lines. Capsaicin induced significant cytotoxicity with increases in oxidative stress, PARP cleavage, and apoptosis in gastric cancer cells (SNU-1).[29] Capsaicin-induced apoptosis in SNU-1 cells was associated with down-regulation of tumor-associated NADH oxidase (tNOX) mRNA and protein. This is significant because in cells in which tNOX was scarcely affected, capsaicin exhibited little apoptosis and low cytotoxicity. However, in tNOX-knockdown sensitized cells, capsaicin induced apoptosis and decreased growth, demonstrating that tNOX is essential for cancer cell growth. A similar mechanism was demonstrated in a study of human bladder cancer cells that indicated that capsaicin inhibits the growth of multiple bladder cancer cell phenotypes by inhibiting tNOX and SIRT1 (a deacetylase important in multiple cellular functions), thereby reducing proliferation, attenuating migration, and prolonging cell-cycle progression.[30]

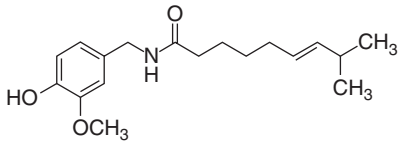

Fig. 62.5 Summary of apoptotic mechanisms and anticancer activity of capsaicin. (From Chapa-Oliver AM, Mejia-Teniente L. Capsaicin: from plants to a cancer-suppressing agent. *Molecules*. 2016;21[8]:E931.)

The various signaling pathways involved in capsaicin-mediated cellular responses include oxidative stress, which is known to trigger apoptosis. Capsaicin was shown to induce apoptosis in pancreatic cancer cells in association with a reduction in Complex I and Complex III activity, leading to reactive oxygen species (ROS) generation and mitochondrial damage.[31] The suppression of cyclooxygenase (COX), an ROS-generating enzyme, was shown to be involved in capsaicin-induced apoptosis of human neuroblastoma cells.[32] The plasma membrane–resident NADPH oxidase also responds to capsaicin, and the NADPH oxidase-mediated generation of ROS may be essentially involved in the mechanism of capsaicin-induced apoptosis in human hepatoblastoma cells.[33]

Other pathways are also relevant to capsaicin-mediated apoptosis. Caspase activation and nitric oxide (NO) elevation were found to be induced by capsaicin stimulating p53 and the apoptotic Bax expression through Mdm2 down-regulation, thus increasing mitochondrial-dependent apoptosis in colon carcinoma cells.[34] The transcription factor signal transducer and activator of transcription 3 (STAT3) has been closely linked with tumorigenesis. Capsaicin was found to inhibit the activation of STAT3 and alter protein expression of Bcl-2, Bcl-xL, and survivin in multiple myeloma cells, demonstrating a potential role in the prevention and treatment of multiple myeloma and other cancers.[35] Furthermore, in urothelial carcinoma cells, capsaicin exerts its apoptotic activity through overexpression of TRPV1.[36] Fig. 62.5 provides a summary of the apoptotic mechanisms and anticancer activity of capsaicin.

The development of resistance to anticancer drugs is a common clinical issue in the treatment of patients with cancer, and methods to address this complication are continuously sought. One solution is the coadministration of substances (chemosensitizers) that can reverse the resistance to anticancer drugs. Capsaicin not only exhibits apoptotic and preventive properties in cancer, but it has also shown significant potential as a chemosensitizing agent. Capsaicin significantly and synergistically increases the cytotoxicity of several chemotherapeutic drugs, including but not limited to doxorubicin,[37] sorafenib,[38] platinum drugs (e.g., cisplatin),[39] and vinblastine.[40]

CLINICAL APPLICATIONS FOR TOPICAL PREPARATIONS

Clinical use of cayenne pepper has focused on topical capsaicin-containing preparations. Commercial ointments containing 0.025% or 0.075% capsaicin are available over the counter. These preparations may offer significant benefits in many conditions, including pain disorders, diabetic neuropathy, cluster headache, osteoarthritis, and rheumatoid arthritis. In addition, topically applied capsaicin may be useful in psoriasis.

Postherpetic Neuralgia

The first studies and approved use for topically applied capsaicin were in relieving postherpetic neuralgia. Numerous studies now document this U.S. Food and Drug Administration (FDA)–approved application. For example, in one study, 39 patients with chronic postherpetic neuralgia (average duration 24 months) were treated with 0.025% capsaicin cream for 8 weeks.[41] During therapy, the patients rated their pain. Nineteen patients (48.7%) substantially improved after the 8-week trial; 5 (12.8%) discontinued therapy due to side effects, such as intolerable capsaicin-induced burning sensations (4) or mastitis (1); and 15 (38.5%) reported no benefit. The decrease in pain ratings was significant after 2 weeks of continuous application. Of the responders, 72.2% still reported improvement 10 to 12 months after the study, with most continuing to apply the cream regularly.

Higher concentration (0.075% vs. 0.025%) might produce better results (as high as 75% response).[42] Capsaicin responders were characterized by higher average daily pain, higher allodynia ratings, and relatively preserved sensory function at baseline compared with nonresponders.[43] In three of the "capsaicin responders," the area of allodynia expanded into previously nonallodynic and nonpainful skin that had normal sensory function and cutaneous innervation. A multicenter, randomized, double-blind, controlled study was conducted to confirm the efficacy, tolerability, and safety of NGX-4010, an 8% capsaicin dermal patch (capsaicin 640 μg/cm^2) in patients with postherpetic neuralgia.[44] In this study, 418 patients were randomized to receive a single 60-minute application of NGX-4010 or a 0.04% capsaicin control patch. NGX-4010 recipients had a significantly greater mean reduction from baseline in pain during weeks 2 to 8 compared with the control group (32.0% vs. 24.4%). Pain was significantly lower in the NGX-4010 group by week 2, and greater pain reduction was maintained throughout the remaining 12-week study period. In a 4-week, double-blind study, patients with postherpetic neuralgia were randomized to receive NGX-4010 or a control patch.[45] Efficacy was evaluated using a numerical pain rating scale (NPRS) scores. During days 8 to 28 after the double-blind treatment, NGX-4010 patients had a mean change in NPRS scores from baseline of –32.7% compared with –4.4% for control patients. Mean changes in NPRS scores from baseline during weeks 2 to 12 was –33.8% for NGX-4010 and +4.9% for control recipients. In both studies, transient increases in application site pain were adequately managed, and no increases in application reactions or adverse events were observed with repeated treatments. Capsaicin 8% patch is an effective, tolerable, and generally safe treatment in cases of postherpetic neuralgia.

Trigeminal Neuralgia

Topically applied capsaicin may be effective in reducing the pain of trigeminal neuralgia. In one study, 12 patients were followed up for 1 year after the topical application over the painful area of capsaicin 3 times a day for several days.[46] Six patients had complete and four patients had partial relief of pain; the remaining two patients had no relief of pain. Of the 10 patients who were responsive to therapy, 4 had relapses of pain within 95 to 149 days. No relapses followed the second therapy for the remainder of the year. These results are promising for a condition that usually does not respond to any therapy, short of surgery.

Postmastectomy Pain

Topically applied capsaicin may help in the relief of pain after breast reconstruction or mastectomy. In one double-blind study, 23 patients with postmastectomy pain syndrome applied either capsaicin (0.075%) or vehicle (placebo) only cream 4 times daily for 4 to 6 weeks.[47] There was a significant difference in jabbing pain, in category pain severity scales, and in overall pain relief scales in favor of capsaicin. Five of 13 patients on capsaicin were categorized as having good-to-excellent responses, with 8 patients (62%) having 50% or greater improvement. Only 1 of 10 cases had a good response to the vehicle, with 3 rated as 50% or better.

In another study, 14 patients with postmastectomy pain had significant pain relief after application of 0.025% capsaicin cream four times daily for 4 to 6 weeks.[48] Unpleasant or painful sensations to light touch or pressure in the painful area (hyperesthesia, allodynia) were also improved.

Mouth Pain Due to Chemotherapy or Radiation

In a study conducted at the Yale Pain Management Center, capsaicin was shown to dramatically reduce the pain from mouth sores resulting from chemotherapy or radiation treatment.[49] An interesting feature in this study was the vehicle used to deliver the capsaicin—taffy. The researchers chose taffy because it could be held in the mouth long enough to desensitize the neurons. The sugar decreased the initial burning sensation, and its soft edges would not aggravate sore mouths like a hard candy. All 11 patients in the Yale study had decreased pain, and in 2 cases the pain stopped entirely after eating the capsaicin-laced candy.

Diabetic Neuropathy

Topically applied capsaicin has been shown to be of considerable benefit in relieving the pain of diabetic neuropathy in numerous double-blind studies.[50–55] In one large double-blind, 8-week study, investigators at 12 sites enrolled 277 men and women with painful diabetic neuropathy of the hands and feet.[56] 69.5% of the group applying the capsaicin cream (0.075%) showed improvement compared with 53.4% in those applying only the vehicle cream.

In another study, 40 patients applied either 0.075% capsaicin cream or placebo to their affected extremities daily. After 4 weeks, 76% of treated patients had some pain relief compared with 50% of placebo patients. In addition, those responding to capsaicin had a 50% reduction in pain, whereas those in the placebo group averaged between 15% and 20% relief in pain symptoms.

A randomized, double-blind, placebo-controlled 12-week study evaluated the efficacy and safety of an 8% capsaicin patch versus placebo in patients with painful diabetic peripheral neuropathy.[57] In this

study, 369 patients were randomized to one 30-minute treatment with either capsaicin 8% patch or placebo to painful areas of the feet. The change in average daily pain score from baseline to between weeks 2 through 8 was statistically significant for the capsaicin patch versus placebo (–27.4% vs. –20.9%). In addition, patients treated with capsaicin 8% patch had a shorter median time to treatment response (19 vs. 72 days) and modest improvements in sleep interference scores compared with placebo. Results confirm the clinical utility of the capsaicin 8% patch in the diabetic population.

Nondiabetic Peripheral Neuropathy

Multiple studies have demonstrated the capsaicin 8% patch is an effective treatment option in patients with peripheral neuropathic pain (PNP) arising from different etiologies. The capsaicin 8% patch provides rapid and sustained pain reductions in patients with PNP and a significant reduction in prescribed concomitant neuropathic pain medications. In nondiabetic patients with PNP, an open-label, randomized, multicenter trial demonstrated the capsaicin 8% patch provided noninferior pain relief versus pregabalin, with a more rapid onset of pain relief and fewer systemic side effects.[58] A 12-week, noninterventional study of a single capsaicin 8% patch treatment demonstrated effectiveness for preexisting PNP and suggested that early initiation of topical treatment (within 6 months of diagnosis) may benefit patients to a greater extent than patients with a longer history of pain.[59] A prospective, open-label, observational safety study in patients with postherpetic neuralgia, posttraumatic or postsurgical nerve injury, HIV-associated distal sensory polyneuropathy, or other peripheral neuropathic pain concluded that capsaicin 8% patch repeat treatment over 52 weeks was well tolerated, with variable alteration in sensory function (newly emergent hyperesthesia or allodynia apparent in 1.1%–3.6% of cases) and minimal chance of complete sensory loss.[60]

ASCEND was an open-label, noninterventional study of patients with nondiabetes-related PNP who received capsaicin 8% patch treatment and were followed for ≤52 weeks.[61] Following the first treatment with the capsaicin 8% patch, there was an overall 26.6% reduction in mean NPRS "average pain" score from baseline to weeks 2 and 8. Overall, patients had a 24.5% reduction in their mean NPRS score from baseline to week 2 and a 37.0% reduction to week 52. A total of 44.4% and 26.2% of patients were classified as ≥30% and ≥50% responders, respectively, after the first treatment. Of responders at week 8, 86.9% retained responder status at week 12 after the first treatment. Patients had a median time from the first to second treatment of 191 days and a median time from the second to third treatment of 301 days.

Together, these studies confirm that the capsaicin 8% patch provides consistent pain relief in a broad range of PNP etiologies. A multicenter, randomized, semidouble-blind study indicated that 0.625% capsaicin patch may prove to be an effective and safe alternative with which to treat patients with PNP and could replace the high-concentration (8%) patch.[62] However, further studies are needed to definitively establish efficacy.

Cluster Headaches

Several studies found that intranasal application of capsaicin ointment by a physician might relieve cluster headaches. In one double-blind study, patients with acute cluster headaches were randomized to receive either capsaicin or placebo in the nostril for 7 days.[63] Patients recorded the severity of each headache for 15 days. Headaches on days 8 to 15 of the study were significantly less severe in the capsaicin group versus the placebo group. There was also a significant decrease in headache severity in the capsaicin group on days 8 to 15 compared with days 1 to 7. Episodic patients appeared to benefit more than chronic patients.

Arthritis

Topically applied capsaicin may be effective in relieving the pain of osteoarthritis and rheumatoid arthritis. One study showed it to be more effective in osteoarthritis, whereas another study showed more benefit for patients with rheumatoid arthritis.

In the double-blind study showing more effect in osteoarthritis, 7 patients with rheumatoid arthritis and 14 patients with osteoarthritis who had painful involvement of the hands applied either capsaicin 0.075% or vehicle-only cream to the hands four times daily. Capsaicin reduced tenderness and pain associated with osteoarthritis but not rheumatoid arthritis.[64]

In the study showing greater benefit for rheumatoid arthritis, 70 patients with osteoarthritis and 31 with rheumatoid arthritis received capsaicin or placebo for 4 weeks.[65] The patients were instructed to apply 0.025% capsaicin cream or its vehicle (placebo) to painful knees four times daily. Significantly more relief of pain was reported by the capsaicin-treated patients than the placebo patients throughout the study; after 4 weeks of capsaicin treatment, patients with rheumatoid and osteoarthritis demonstrated mean reductions in pain of 57% and 33%, respectively. These reductions in pain were statistically significant compared with those reported with placebo. According to overall evaluations, 80% of the capsaicin-treated patients experienced a reduction in pain after 2 weeks of treatment.

Psoriasis

Excessive substance P levels in the skin have been linked to psoriasis. This finding prompted researchers to study the effects of topically applied capsaicin. In one double-blind study, 44 patients with symmetrically distributed psoriasis lesions applied topical capsaicin to one side of their body and a placebo to the other side.[66] After 3 to 6 weeks, significantly greater reductions in scaling and redness were observed on the capsaicin side. Burning, stinging, itching, and skin redness were noted by nearly half of the patients initially, but these diminished or vanished upon continued application.

In a later study, 197 patients applied capsaicin 0.025% cream or placebo cream 4 times a day for 6 weeks.[67] Efficacy was based on a physician's evaluation and a combined psoriasis severity score, including scaling, thickness, erythema, and pruritus. Capsaicin-treated patients demonstrated significantly greater improvement at the physician's evaluation and in pruritus relief, as well as a significantly greater reduction in combined psoriasis severity.

Pruritus Ani

Pruritus ani is a common condition that can be difficult to treat. Results from a double-blind study indicated that capsaicin was a safe and highly effective treatment for severe, intractable idiopathic pruritus ani.[68] This study involved two 4-week treatment phases separated by a 1-week washout phase. Forty-four patients were randomized to receive locally either active capsaicin (0.006%) or placebo (menthol 1%) ointment over a 4-week period. After 4 weeks of treatment and a 1-week washout period, the placebo group began to receive capsaicin, whereas the treated group received placebo (menthol 1%), for another 4 weeks. At the end of the controlled study, responders from both groups continued with capsaicin treatment in an open-label manner. Results indicated that 31 of 44 patients experienced relief during capsaicin treatment periods and did not respond to menthol; all patients who did not respond to capsaicin also did not respond to menthol. In 13 patients, treatment with capsaicin was unsuccessful: 8 patients did not respond to capsaicin treatment, 1 responded equally to capsaicin and placebo, and 4 others dropped out because of side effects.

DOSAGE

Cayenne pepper can be used liberally in the diet. Creams containing 0.025% or 0.075% capsaicin or poultices can be applied to affected areas up to four times daily.

TOXICITY

Capsicum is generally recognized as safe by the U.S. Food and Drug Administration. Contraindications to oral ingestion include aggravation or appearance of GERD or other sensitivity. Studies showed that consumption of 3 g of red chilies per day during the postoperative period after hemorrhoidectomy or surgery for anal fissures increased the intensity of typical postoperative symptoms, stool frequency, and the consumption of analgesics.[69,70]

Topically applied capsaicin may produce a local burning sensation; however, this effect goes away with time and rarely is severe enough to warrant discontinuation of use of the cream.

DRUG INTERACTIONS

Although several theoretical interactions have been postulated, no clinical cases have been documented. The use of capsicum has been cautioned in patients on anticoagulants or antiplatelet therapy.

Carnitine

Angela Sadlon, ND, and *Michael T. Murray, ND*

OUTLINE

INTRODUCTION

Carnitine is an essential nutrient for the transport of long-chain fatty acids into the mitochondrial matrix. Carnitine (β-hydroxy/γ-butyrobetaine) was originally isolated from meat extracts in 1905, and its exact chemical structure was determined in 1932 (Fig. 63.1). However, despite extensive physiological and pharmacological studies in the 1930s, no physiological role for carnitine was determined until 1955.[1–3]

The compound was virtually forgotten until Carter et al.[4] created new interest in carnitine in 1952 when they established it as a growth factor for the mealworm *Tenebrio molitor* (hence carnitine's other name, "vitamin BT"—*B* for the family of vitamins and *T* for *T. molitor*). When other species of organisms were also shown to be dependent on carnitine, researchers began to reexamine its role in humans.

Researchers soon found that carnitine was essential in the oxidation of lipids.[1–3] When the first carnitine-deficient human subjects were described in 1973, it stimulated greater investigation.[5]

BIOSYNTHESIS

Carnitine is synthesized in humans from lysine and methionine. In nonmammalians, carnitine synthesis begins with stepwise methylation of free lysine by S-adenosylmethionine to produce trimethyllysine. In mammals, however, protein-bound trimethyllysine, rather than free lysine, appears to be the major precursor for carnitine synthesis.[1–3]

Trimethyllysine is then converted through a series of enzymatic reactions (occurring in the liver, kidney, brain, heart, and skeletal muscle) to butyrobetaine. However, the conversion of butyrobetaine to carnitine can only occur in the liver, kidney, and brain because the enzyme required, butyrobetaine hydroxylase, is only present in these tissues.[1–3]

The synthesis of carnitine is largely controlled by the activity of butyrobetaine hydroxylase. This enzyme appears to be age dependent. In infancy, the activity of butyrobetaine hydroxylase has been shown to be only 12% of the normal adult mean. By 2.5 years, the activity is 30% of the adult mean, and by 15 years, the level is within a standard deviation of the adult mean.[1–3] These data would seem to indicate the importance of preformed carnitine in breast milk.

As apparent from Fig. 63.2, two essential amino acids (lysine and methionine), three vitamins (ascorbate, niacin, and vitamin B_6), and a metal ion (reduced iron) are required for the synthesis of carnitine. Obviously, a deficiency of any one of these nutrients would result in significantly impaired carnitine synthesis.[1–3] However, research using knockout mice unable to synthesize vitamin C endogenously showed normal carnitine values (comparable to their vitamin C–synthesizing counterparts), although they were vitamin C deficient. The researchers suggested that adequate levels of glutathione and glutathione peroxidase might compensate for or replace the deficient vitamin C in the carnitine biosynthesis pathway.[6]

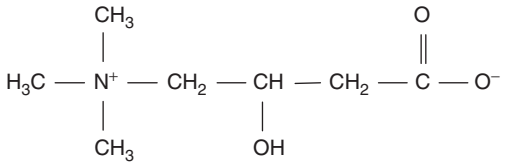

FIG. 63.2 Biosynthesis of carnitine.

METABOLISM

Pharmacokinetics

The heart and skeletal muscles, as well as many other tissues, depend primarily on fatty acid oxidation as a source of energy. Because they cannot synthesize carnitine, its transport into these tissues is of critical importance.

Specific carnitine-binding transport proteins were identified for several tissues (e.g., cardiac muscle, skeletal muscle, epididymis, liver, kidney) taking the serum carnitine into the cell.[1,3] Through this active transport mechanism, the tissues can concentrate carnitine up to 10 times greater than the concentration found in plasma.

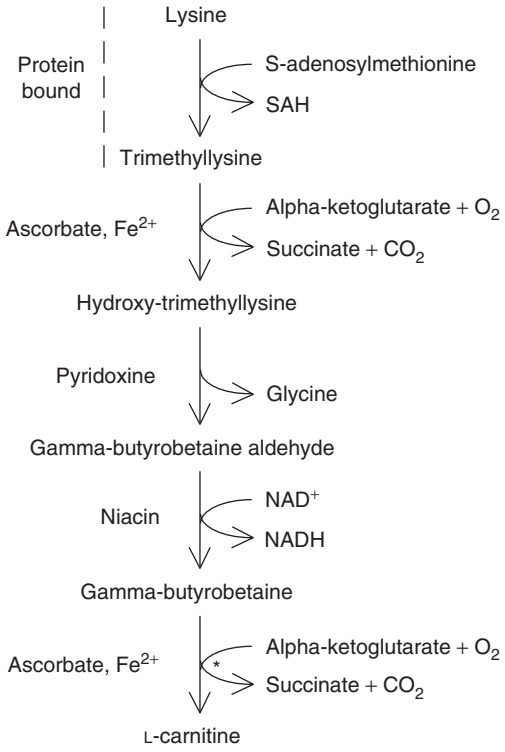
A small in vivo study measured the pharmacokinetics of carnitine in Chinese men and women participants. A 2000-mg single oral dose of L-carnitine (LC; Fig. 63.3) had a half-life of approximately 60.3 hours compared with L-acetylcarnitine (LAC) at 35.9 hours and L-propionylcarnitine (LPC) at 25.7 hours. The maximum plasma concentration of LC, LAC, and LPC occurred at 3.4, 2.4, and 3.8 hours after ingestion, respectively, and at quantities of 84.7, 12.9, and 5.1 µmol/L, respectively. The researchers found comparable levels of carnitine absorption and metabolism between men and women, suggesting that gender should not affect dosage.[7]

Urinary excretion of unchanged carnitine is the major route of elimination of carnitine. Because the tubular reabsorption of carnitine by the kidneys is extremely efficient, the daily turnover of carnitine is estimated to be only 4% to 6% of the total body pool of the healthy individual.[1–3,7] Factors that increase carnitine excretion and degradation are discussed later in the section on deficiency.

PHYSIOLOGICAL FUNCTIONS

Carnitine's basic function is in the transport of long-chain fatty acids into the mitochondrial matrix and the facilitation of β-oxidation.[1,3] Because acyl-coenzyme A formed in the endoplasmic reticulum or outer mitochondrial membrane cannot penetrate the inner mitochondrial membrane to the site of fatty acid β-oxidation, the acyl group must be transferred from coenzyme A to carnitine. The acyl-carnitine molecule then transports the fatty acid molecule to the mitochondrial surface of the inner mitochondrial membrane and releases the fatty acid into the matrix, where β-oxidation occurs. Fig. 63.4 summarizes this process.

Carnitine has several other physiological functions, including oxidation of the ketoacid analogs of the branched-chain amino acids valine, leucine, and isoleucine.[1–3] This function is extremely important during fasting, starvation, and exercise.



*In humans, the enzyme catalyzing this reaction occurs only in the liver, kidney, and brain

FIG. 63.3 L-carnitine.

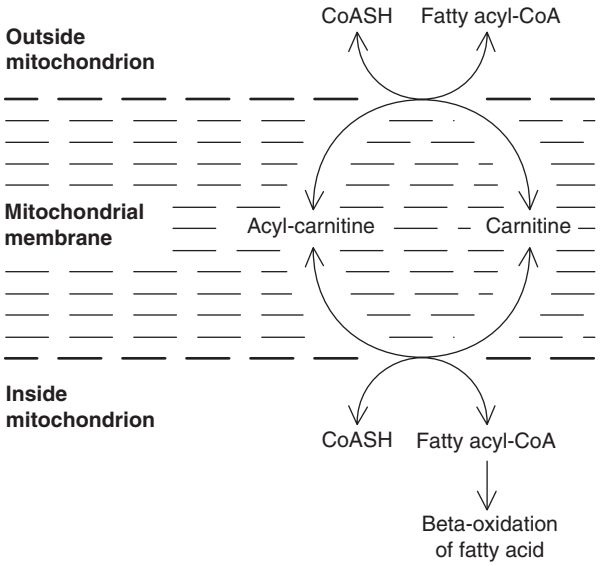


FIG. 63.4 Role of carnitine in the transport of long-chain fatty acids through the inner mitochondrial membrane.

DEFICIENCY

Carnitine deficiency may arise from several causes, as listed in Box 63.1.

Carnitine deficiency states have been classified into two major groups:

- Systemic carnitine deficiency
- Myopathic deficiency

Diagnosis of systemic carnitine deficiency can be made using serum or 24-hour urine samples. Total, free, and esterified carnitine levels should be determined. In myopathic carnitine deficiency, diagnosis requires skeletal muscle biopsy.[8]

BOX 63.1 Causes of Carnitine Deficiency

- Dietary deficiency of the precursor amino acids lysine and methionine
- Deficiency of any cofactor (e.g., iron, ascorbic acid, pyridoxine, niacin) required by the enzymes of the lysine to carnitine pathway
- Genetic defect of carnitine biosynthesis
- Defective intestinal absorption of carnitine
- Liver or kidney dysfunction that impairs carnitine synthesis
- Increased metabolic losses of carnitine due to catabolism, impaired tubular resorption, or genetic defect
- Defective transport of carnitine from tissues of synthesis to tissues where it is maximally used
- Increased carnitine requirement due to a high-fat diet, drugs (e.g., valproic acid), metabolic stress, or disease

Until the late 1990s, there were no documented reports of patients with primary systemic carnitine deficiency. The systemic deficiency has always been secondary to some other factor rather than a defect in carnitine synthesis.[1–3,8,9] However, mutations in the organic cation/carnitine transporter gene *(OCTN2)* were identified in an infant. The infant presented with Reye-like symptoms including encephalopathy, hypoketotic hypoglycemia, elevated liver enzymes, and steatosis. Treatment with intravenous carnitine and then oral LC (200 mg/kg/day) produced a rapid recovery.[10] There are at least a half dozen more papers since then referencing the *OCTN2* gene mutation producing primary carnitine deficiency.

The consequences of systemic carnitine deficiency are impaired lipid metabolism and lipid accumulation in the skeletal muscles, myocardium, and liver. Progressive muscle weakness with lipid storage myopathy is found in all patients.[1–3,8] In adults, auxiliary nonmitochondrial oxidation mechanisms are apparently stimulated, resulting in some degree of adaptation. This adaptation occurs in starvation, diabetes, high-fat diets, and other causes of secondary carnitine deficiency. Systemic carnitine deficiencies usually respond dramatically to orally administered supplemental LC.[8,9]

Children are apparently unable to adapt to low carnitine levels as well as adults can.[8] Several cases of carnitine deficiency in children, presenting a clinical picture resembling Reye's syndrome (acute encephalopathy associated with altered liver function due to lipid accumulation), have been reported.[9,11,12]

The clinical presentation of secondary carnitine deficiency in children includes hypotonia, failure to thrive, recurrent infections, encephalopathy, nonketotic hypoglycemia, and cardiomyopathy.[8] Several fatal cases of systemic carnitine deficiency have been reported.[9,13]

In primary myopathic carnitine deficiency, there is an inborn error of carnitine metabolism that is limited to skeletal muscle.[8,9] The defect appears to be in the transport of carnitine into the skeletal muscle as serum carnitine; the carnitine levels in other tissues are normal. Severe lipid storage myopathy is the result. Supplemental carnitine is generally of no value in myopathic carnitine deficiency. Rather, improvements have been noted using diets high in medium-chain triglycerides and low in long-chain triglycerides.[8]

CARNITINE AS A NUTRIENT

Analysis of several hundred foods for carnitine content indicates that meat and dairy products are the major dietary sources of carnitine.[3] In general, the redder the meat, the higher the carnitine content. Cereals, fruits, and vegetables contain little or no carnitine. Preliminary studies indicate that the daily diet contains 5 to 100 mg of carnitine.[3] There is no evidence that a vegetarian or vegan diet promotes deficiency and would need supplementation. As long as the liver and kidney are able to synthesize carnitine from lysine and methionine, deficiency of carnitine typically does not occur.

Carnitine in the Infant Diet

Oxidation of long-chain fatty acids, which requires carnitine, is well known to be critical to the survival and normal development of the newborn.[3] Carnitine concentrations in fetal and umbilical cord blood are higher than in maternal blood, suggesting the placenta may actively transport carnitine to the fetus because carnitine synthesis is not fully developed.[3] The initial carnitine concentration in the newborn depends on maternal carnitine concentration.

Supplementation of carnitine during pregnancy may be necessary to ensure adequate tissue concentrations in the fetus, as well as the mother. Serum carnitine levels are typically lower in pregnant women than nonpregnant women, presumably due to increased excretion.[14,15]

The newborn infant is almost entirely dependent on external sources of carnitine.[3] Breastfed infants have the best chance of achieving optimal carnitine concentrations. The bioavailability of carnitine from breast milk is significantly greater than that in cow's milk–based formulas,[16] and soy-based infant formulas contain no detectable carnitine.[3] Formula feeding may necessitate supplemental carnitine to achieve normal carnitine concentrations in these infants.

Carnitine administration to preterm infants has potentiated weight gain and growth.[17] In preterm infants, serum values of carnitine decrease dramatically due to limited storage capacity coupled with a decreased ability to synthesize carnitine. Administration of LC to preterm infants is considered important.

CLINICAL APPLICATIONS

Many disease states, in addition to classic as well as secondary carnitine deficiency, may benefit from carnitine administration. Evidence supports the assertion that supplemental carnitine may benefit the conditions listed in Box 63.2 and discussed later.

Carnitine is available in several different forms. The form being used must be LC alone or bound to either acetic (LAC) or propionic acid (LPC). The D form of carnitine (discussed later in the section on "Toxicology") should never be used. The reason for using carnitine will dictate the form used. For Alzheimer's disease and brain and neurological effects, it appears that LAC may provide the greatest benefit. For angina, ulcerative colitis, and wound healing, LPC may be the best choice because the myocardium appears to prefer it to LAC, followed by LC.[18,19]

Cardiovascular Disease

Normal heart function is critically dependent on adequate concentrations of carnitine. A deficiency of carnitine in the heart would be similar to trying to run an automobile without a fuel pump. Despite plenty of fuel, there is no way to get it to the engine. Although the normal heart stores more carnitine than it needs, if the heart does not have a good supply of oxygen, carnitine levels quickly decrease. This lack of oxygen leads to decreased energy production in the heart and increased risk for angina and heart disease.

Oral LAC therapy (1 g twice daily) for 6 months showed a gradual but significant decrease in blood pressure in insulin-resistant participants who had higher risk factors for cardiovascular disease (hypertension, hypertriglyceridemia, obesity, and/or family history of diabetes type 2). In the patients with greater insulin resistance, the insulin sensitivity was significantly increased. The overall adiponectin values increased. These benefits were slowly reversed during an 8-week follow-up after LAC discontinuation. There were no changes to participants' diet or lifestyle during this study. LAC was well tolerated in all participants.[20] It appears that LAC can improve aspects that are characteristic of metabolic syndrome, but without lifestyle and dietary modifications, the patient may potentially need long-term supplementation with carnitine.

Carnitine exerts a beneficial effect on blood lipids by lowering triglycerides (TGs) and total cholesterol levels while raising high-density

BOX 63.2 Conditions That May Benefit From Carnitine Supplementation

- Acquired immunodeficiency syndrome
- Acute myocardial infarction
- Alcohol-induced fatty liver disease
- Alzheimer's disease, senile depression, and age-related memory defects
- Androgenetic alopecia
- Angina pectoris
- Arrhythmias and cardiotoxicity induced by drugs
- Beta thalassemia major
- Cardiac myopathy
- Cardiovascular diseases
- Celiac disease—fatigue
- Chronic obstructive pulmonary disease
- Congestive heart failure
- Depression
- Diabetes
- Down syndrome—visual memory and attention
- Elevated cholesterol levels
- Elevated triglyceride levels
- Enhancing physical performance
- Familial endocardial fibroelastosis
- Glutaric aciduria
- Hepatic cirrhosis—muscle cramps
- Hyperthyroidism
- Idiopathic mitral valve prolapse
- Inborn errors of amino acid metabolism
- Isovaleric acidemia
- Kidney disease and hemodialysis
- Liver cirrhosis
- Liver diseases
- Low sperm counts and decreased sperm motility
- Methylmalonic aciduria
- Muscular dystrophies
- Myocardial necrosis
- Neuropathy
- Organic aciduria
- Propionic acidemia
- Toxicity from various drugs
- Ulcerative colitis
- Wound healing

lipoprotein cholesterol (HDL-c). After 4 months of therapy with LC in patients with elevated blood lipids, typical changes observed were a 20% reduction for total cholesterol, a 28% decrease in TGs, and a 12% increase in HDL levels.[21,22] Due to the higher cost of carnitine compared with other natural agents (e.g., inositol hexaniacinate, garlic, berberine, and guggulipid), its use should be reserved for those cases unresponsive to these more cost-effective measures.

A study comparing LC (2 grams/day) with simvastatin (20mg/day) or simvastatin alone was conducted on patients with hyperlipidemia and elevated lipoprotein (a) (Lp[a]) levels. The results showed a significant reduction in Lp(a) with the combined therapy (LC + statin) versus simvastatin monotherapy. Both treatment groups lowered total cholesterol, low-density lipoprotein cholesterol (LDL-C), apolipoprotein B, and TGs significantly.[23]

Angina and Recovery From Myocardial Infarction

Carnitine is useful in angina due to its ability to improve oxygen usage and energy metabolism by the myocardium. As a result of improving fatty acid usage and energy production, carnitine also prevents the production of toxic fatty acid metabolites.[24] These compounds are extremely damaging because they disrupt cellular membranes. Changes in the properties of cell membranes throughout the heart are thought to contribute to impaired contraction of the heart muscle, increased susceptibility to irregular beats, and eventual death of heart tissue. Supplementing with carnitine increases heart carnitine levels and has been shown to prevent the production of toxic fatty acid metabolites, as well as boost antioxidant enzyme levels. In addition to angina, all of these effects make carnitine beneficial in recovery from a heart attack, cardiomyopathies, arrhythmias, and congestive heart failure.[25,26]

Numerous clinical trials demonstrated that carnitine improves angina and heart disease (note that all three commercial forms have been used).[25,27–34] Improvements were noted in exercise tolerance and heart function. The results indicated that carnitine is an effective alternative to drugs in cases of angina.

LPC may offer the greatest benefit in angina, as well as in other cardiovascular conditions. LPC is taken up by myocardial cells much more rapidly than other forms of carnitine.[18] In one study, LPC (15 mg/kg intravenously) significantly diminished myocardial ischemia as demonstrated by a significant 12% and 50% reduction in ST-segment depression and left ventricular end-diastolic pressure, respectively, during the atrial pacing test.[35] Left ventricular ejection fraction increased by 18%. Recovery of heart function after exercise occurred much quicker in the LPC group compared with the placebo group.

LC and LAC also showed good results. In one of the larger studies, 200 patients with exercise-induced stable angina received either standard therapy alone (e.g., nitroglycerin, calcium channel blockers, β-blockers, antihypertensives, diuretics, digitalis, antiarrhythmics, anticoagulants, hypolipidemics) or in combination with 2000 mg/day of LC over a 6-month period.[36] Compared with the control group, the patients on LC exhibited a significant reduction in premature ventricular contractions at rest, as well as an increased tolerance to exercise as demonstrated by an increased maximal cardiac frequency, increased maximal systolic blood pressure, cardiac output, and reduced ST-segment depression (70% reduction in the LC group versus no change in the control group). Reductions in LDL-c (8%) and TGs (12%) were also noted. These results are highly significant and provide a strong rationale for the inclusion of carnitine in patients using standard medical therapy.

In Italy, a large study involving 472 patients showed additional benefits.[37] The study was performed to evaluate the effects of LC administration on chronic left ventricular dilation in patients with acute anterior myocardial infarction. Placebo or LC was given at a dose of 9 g/day intravenously for the first 5 days and then 6 g/day orally for the next 12 months. Left ventricular volumes and ejection fraction were evaluated on admission, at discharge from hospital, and at 3, 6, and 12 months after acute myocardial infarction. A significant attenuation of left ventricular dilation in the first year after acute myocardial infarction was observed in patients treated with LC compared with those receiving placebo. The percent increase in both end-diastolic and end-systolic volumes from admission to 3-, 6-, and 12-month evaluation was significantly reduced in the LC group.

Congestive Heart Failure

Several double-blind clinical studies showed that carnitine (again, LPC appeared to be more effective than LC or LAC) improved cardiac function in patients with congestive heart failure.[25,38,39] In one double-blind study of LPC versus placebo in a group of 60 patients with mild to moderate (New York Heart Association [NYHA] classes II and III) congestive heart failure, LPC produced demonstrable benefit.[38] The group was made up of men and women between 48 and 73 years old

receiving long-term treatment with digitalis and diuretics for at least 3 months and who still displayed symptoms. Thirty of these patients were chosen randomly and for 180 days received 500 mg of LPC three times a day in addition to their usual treatment. At basal conditions and after 30, 90, and 180 days, the maximum exercise time was evaluated using an exercise tolerance test performed on an ergometer bicycle, and the left ventricular ejection fraction was tested by echocardiography. After 1 month of treatment, the patients treated with LPC, compared with the control group, showed significant increases in the values of both tests, increases that became even more evident after 90 and 180 days. At the stated times, the increases in the maximum exercise time were 16.4%, 22.9%, and 25.9%, respectively. The ventricular ejection fraction increased by 8.4%, 11.6%, and 13.6%, respectively.

Even more obvious benefits were seen in a 3-year study of 80 patients with moderate to severe heart failure (NYHA class III to IV) caused by dilated cardiomyopathy. After a period of stable cardiac function of up to 3 months, patients were randomly assigned to receive either carnitine (2 g/day orally) or placebo. After a mean of 33.7 months of follow-up (range 10–54 months), 70 patients remained in the study: 33 in the placebo group and 37 in the carnitine group. At the time of analysis, 63 patients were alive. Six deaths occurred in the placebo group, and one death in the carnitine group. Survival analysis showed that patients' survival was statistically significant in favor of the carnitine group.[40]

Peripheral Vascular Disease

All three forms of carnitine (2–4 g/day) were shown to improve the walking distance without pain in patients with intermittent claudication. Presumably this improvement was the result of improved energy metabolism within the muscle because carnitine was not shown to improve blood flow to the calf. LPC appeared to offer better effects than either LC or LAC.[41,42] However, in one double-blind study, LC at a dosage of 2 g twice daily demonstrated a 75% increase in walking distance after only 3 weeks of therapy.[43]

In the largest study with LPC, 485 patients with intermittent claudication were randomized to placebo or LPC (2 g/day) for 12 months. Maximal walking distance increased by 62% on LPC and by 46% on placebo in all patients. However, when only those patients with more severe disease status were analyzed, the maximal walking distance increased by 98% in the LPC group compared with only 54% in the placebo group.[44]

Enhancing Physical Performance and Relieving Fatigue

The ability to enhance exercise tolerance and physical performance with carnitine may not be limited to patients with cardiovascular disease because carnitine supplementation was also shown to be of benefit in healthy subjects and athletes. Efficient use of fatty acids by skeletal muscle, like the myocardium, also depends on an adequate supply of carnitine.

Carnitine supplementation (usually 2 g two to three times daily) resulted in significant improvements in cardiovascular function in response to exercise in several double-blind studies in both athletes and normal subjects.[45–47] Compared with control groups, the subjects on carnitine showed not only improvements in exercise intensity over time but also evidence of improved energy metabolism within the muscle (lowered blood lactic acid and free fatty acid levels). Obviously, the improved production of energy by the exercising muscle, as well as improved heart function, could be responsible for carnitine's ability to enhance physical performance.

Although at least three studies showed the benefits of carnitine on exercise performance to be of no more value than a placebo, carnitine supplementation should still be viewed as beneficial, especially in endurance-related events.[48–50] The reason behind this statement is the fact that studies demonstrated that carnitine improves energy-producing enzyme levels in long-distance runners.[51] These athletes received either a placebo or 2 g of LC twice daily for 4 weeks. Runners receiving LC showed a significant increase in enzymes involved in energy production (cytochrome C reductase and cytochrome oxidase). In contrast, there were no changes in the placebo group.

One study examined the influence of L-carnitine L-tartrate (LCLT) at a dosage of 2 g/day for 3 weeks on markers of purine catabolism, free radical formation, and muscle tissue disruption after squat exercise. Exercise-induced increases in plasma markers of purine catabolism (hypoxanthine, xanthine oxidase, and serum uric acid) and circulating cytosolic proteins (myoglobin, fatty acid-binding protein, and creatine kinase) were significantly reduced by LCLT supplementation. Exercise-induced increases in plasma malondialdehyde returned to resting values sooner during LCLT therapy compared with placebo. The amount of muscle disruption from magnetic resonance imaging scans during LCLT was 41% to 45% of the placebo area. These data indicated that LCLT supplementation was effective in assisting recovery from exercise.[52]

Interestingly, normal subjects taking carnitine have improved cardiovascular function and a more rapid return of heart rate to the resting rate after exercise.[53] The significance of these improvements is that carnitine apparently mimics the benefits in heart and vascular function produced by regular exercise training without working up a sweat.

Carnitine supplementation appeared to be beneficial in elderly subjects complaining of muscle fatigue.[54,55] In one double-blind study, 84 elderly subjects with onset of fatigue after even the slightest physical activity were randomized to receive carnitine 2 g twice daily or a placebo for 30 days. Fatigue scores decreased significantly by 40% (physical) and 45% (mental) in subjects taking carnitine, compared with 11% and 8%, respectively, in the placebo group. Other parameters improved significantly, including total fat mass, total muscle mass, total cholesterol, LDL cholesterol, HDL cholesterol, TGs, apolipoprotein-A1, and apolipoprotein-B.[54] In a similar study, researchers reported 2 g/day of LC given to centenarians had a comparable trend when looking at similar parameters.[55] The difference was 2 g twice daily showed greater improvement in most parameters measured.

Few clinical trials have been published regarding carnitine and fatigue relief in multiple sclerosis patients. Some studies reported significant benefit,[56,57] whereas another suggested better designed studies were needed to determine efficacy.[58] Because LC is well tolerated, it may be beneficial to try.

Cancer-Related Fatigue

A notable percentage of cancer patients are deficient in carnitine (serum total and free carnitine levels). Researchers have given a wide dosage range of LC and measured subjective results of fatigue with mixed results.[59–63]

An open-label, Phase I/II clinical trial of LC supplementation in carnitine deficient patients with advanced cancer was done. The results showed significant improvement in free carnitine levels. There were 27 patients and 7 treatment groups (250 mg/d, 750 mg/d, 1250 mg/d, 1750 mg/d, 2250 mg/d, 2750 mg/d, and 3000 mg/d) for 7 days. After the trial, all patients but two requested to continue treatment. The results showed "most of the patients who received LC experienced reduced fatigue and improved mood and sleep. The improvement in fatigue was dose dependent within the subgroup that received 7 days of supplementation and experienced a rise in carnitine-associated laboratory values."[60]

A small 2018 study used 500 mg three time daily for 8 weeks in cancer patients undergoing chemotherapy. There was improved

general fatigue in all cancer patients, and LC possibly improved the ability of cancer patient to cope with chemotherapy. Also, LC seemed to maintain the plasma levels and lymphocyte counts during chemotherapy, enabling patients to continue chemotherapy without dosage reduction.[63]

Another small study of LC supplementation in patients with advanced cancer and carnitine deficiency found no significant change in fatigue after 2 weeks. The patients were given a titrating dosage of LC (500 mg/day for 2 days, then 1 g/day for 2 days, then 2 g/day for 10 days). All carnitine deficiency normalized. The patients were then included in another 2-week open-label phase, and the patients who started the LC supplementation group reported significant improvement in fatigue, functional well-being, and performance status compared with the original placebo patients. Also, after the trial was over, 12 of 17 patients requested to stay on carnitine.[61]

Celiac Disease

Celiac disease can be considered a secondary cause of carnitine deficiency due to the characteristic malabsorption component.[64] In a small double-blind, placebo-controlled study ($n = 47$), tests were performed on participants with newly diagnosed celiac disease before and after 6 months of either a gluten-free diet (placebo) or a gluten-free diet plus LC (1 g twice daily; treatment group). Serum carnitine levels were significantly improved from baseline in both groups after implementing a gluten-free diet. In the treatment group, serum levels were comparable to the nonceliac control group. The LC group had significant improvement in fatigue compared with the placebo group as measured by the visual analog scale. The measurement of OCTN2 (cell membrane transport protein with strong specificity for carnitine) by intestinal biopsies increased by 83% in all celiac patients on a gluten-free diet; however, the amount was still significantly less than that in the nonceliac controls.[65]

Even with asymptomatic celiac disease, the individual breakdown of the serum carnitine esters may be significantly decreased, with LAC sometimes decreased by 50% to 80%.[66]

Ulcerative Colitis

Patients with ulcerative colitis (UC) showed similar levels of plasma LC compared with healthy controls; however, the levels of LPC were significantly lower.[66] Because short-chain fatty acids are the major fuel substrate for enterocytes and are theorized to be less available in UC, LPC has been studied as a potential treatment.[68–70]

One study of 10 males with mild UC used LPC enemas (6 g in 200 mL saline solution) twice daily for 14 days. Each enema took 120 minutes. Significant improvement was noted in all patients, both symptom-wise (abdominal pain, diarrhea, and/or mucus or blood in stool) and histologically (mucosal erosions, distortion of crypt architecture, epithelium inflammation, and interstitial inflammation). No adverse side effects were reported.[68]

In a multicenter, Phase II, double-blind, parallel-group trial of mild to moderate UC, patients using stable oral aminosalicylate or thiopurine therapy were also given oral LPC for 14 days. The group receiving 500 mg twice daily (1 hour before breakfast and dinner) produced the best effect. Seventy-five percent of patients saw improvement, and 55% had remission of disease, with the majority having mild UC.[69] A 2014 study used patients from the latter study to perform microscopical analysis of intestinal biopsies before PLC and after 4 weeks. The results showed a reduction of intestinal acute and chronic inflammation and amelioration of the damaged microvascular endothelium. The higher oxidative stress in UC was presumably from the intestinal microvascular endothelial dysfunction. The antioxidant effect of LPC mediates the reduction of inflammation.[70]

Thyroid Disease

L-carnitine's effect on thyroid hormone and its benefit in hyperthyroidism are reported in the literature as early as 1966 by Gilgore and De Felice.[71,72]

Since 1966, more researchers studied the benefit of LC on hyperthyroidism, regardless of the cause.[71–78] According to researchers, LC does not affect the thyroid gland itself; its action takes place in the peripheral cells. It inhibits thyroid hormone entry into the cell nucleus.[73,78] This may explain why patient symptoms (palpitations, tremors, nervousness, etc.) improve significantly, but the blood levels continue to be elevated. Dosages of oral LC ranged from 500 to 4000 mg daily.

In one study of 19 patients with subclinical hyperthyroidism (thyroid-stimulating hormone [TSH] = 0.1–0.4 mIU/L and positive antibodies), subjects took a combined daily oral dosage of 500 mg LC and 83 mcg selenium for 1 month. The results showed a drop in the score on a 9-item symptom scale from 25.61 ± 1.19 to 12.11 ± 1.15. The symptoms most improved included palpitations, tremor, and nervousness. However, after discontinuing the therapy, the symptom score increased to 23.33 ± 1.35 after 1 month. There were no significant changes in the TSH, free T3, or free T4 values throughout the study. The thyroid antibodies (TgAb and TPO Ab) had a drop of at least 100 points after 1 month of treatment and returned to pretreatment levels after discontinuing the treatment.[77]

L-carnitine prevented and reversed liver enzyme (alkaline phosphatase [ALP], aspartate transaminase [AST], alanine transaminase [ALT]) damage produced by the elevated thyroid hormone.[75]

L-carnitine was administered intravenously (75 mg/kg/d) to an 80-year-old man for severe hyperthyroidism with coma, induced by amiodarone. His Glasgow score was 8. The patient fully recovered 24 hours after starting intravenous (IV) LC administration. Even though he was asymptomatic, the thyroid profile was still classified as hyperthyroid. L-carnitine was administered for 2 months along with propylthiouracil and avlocardyl. The major improvement occurred when LC was administered.[76]

In another case report, a 24-year-old male was given 1 g of LC orally every 12 hours and low-dose methimazole (10–15 mg/d) for a thyroid storm. The LC reversed and prevented his hyperthyroid symptoms. While on the LC and methimazole, he had two more thyroid storms, which were preceded by triggering factors (influenza, emotional stress). Therefore it seems that LC does not prevent relapses of thyrotoxicosis. However, the second and third storms were clinically milder. The LC and methimazole were stopped 6 months after his third thyroid storm, and the patient was still euthyroid 10 months later.[74]

Alzheimer's Disease, Senile Depression, and Age-Related Memory Defect

Much research has been conducted over the past 20 years with LAC in the treatment of Alzheimer's disease, senile depression, and age-related memory defects. As described previously, LAC is a molecule composed of acetic acid and LC bound together. This reaction occurs naturally in the human brain; therefore it is not exactly known how much greater an effect is noted with LAC versus LC or LPC. However, LAC is thought to be substantially more active than these other forms of carnitine in conditions involving the brain.[79,80]

LAC is structurally related to acetylcholine, a major neurotransmitter responsible for memory and proper brain function. In Alzheimer's disease and, to a lesser extent, the normal aging human brain, there is a defect in the use of acetylcholine. The close structural similarity between LAC and acetylcholine led researchers to begin testing LAC in Alzheimer's disease. The results have been encouraging.

Researchers showed that LAC does mimic acetylcholine and is of benefit not only in patients with early-stage Alzheimer's disease but also in elderly patients who are depressed or who have impaired memory.[80] It has also been shown to act as a powerful antioxidant within the brain cell by stabilizing cell membranes, improving energy production within the brain cell, and enhancing or mimicking the function of acetylcholine.[81] In 2008, a study done on rats revealed a significant increase in the brain tissue's kinesin light-chain 1 gene expression with LAC administration. When the kinesin light-chain 1 gene was downregulated, amyloid deposition was accelerated.[82]

The results in delaying the progression of Alzheimer's disease have been promising. The studies have been well controlled and extremely thorough.[79,83–85]

Memory impairment need not be as severe as in Alzheimer's disease for LAC to demonstrate benefit.[86–88] In one double-blind study of 236 elderly subjects with mild mental deterioration, as evidenced by detailed clinical assessment, the group receiving 1500 mg of LAC daily demonstrated significant improvement in mental function, particularly in memory and constructional thinking.[88]

Many of the elderly have depression not only as a result of experiencing a great deal of loss in their lives but also because of the biochemical changes in the brain associated with aging. LAC was shown to improve depression in elderly subjects in double-blind studies using assessment scales standard to scientific research of antidepressant drugs (e.g., Hamilton Depression Scale, Clinical Global Impression, Sandoz Clinical Assessment). The usual dosage was 500 mg three times daily but has been researched as high as 3 g daily.[89–91] Elderly subjects with the highest depression scores were usually the ones who benefited the most from LAC.[89,91]

LAC also appears helpful in enhancing the effects of acetylcholinesterase inhibitors. In one open study of oral LAC (2 g/day for 3 months), 23 patients with mild Alzheimer's disease (unresponsive to donepezil or rivastigmine alone) showed an increased response rate with LAC treatment as an addition to the acetylcholinesterase inhibitor (38% vs. 50%, respectively). The response rate was a measurement of cognitive function, functional status, and behavioral symptoms.[92] This additive effect may be useful whenever a patient does not respond to either treatment alone.

Depression

Recently, animal studies examined the antidepressive activity of LAC.[93,94] LAC was shown to preserve brain plasticity in chronic restraint stress and to grow primary and secondary dendrites. Also, after LAC treatment, "dendrites of the medial amygdala stellate neurons were more complex and longer compared with the chronic restraint stress group that received just the vehicle." Behaviorally, LAC appears to enhance resilience to stress by reducing passive behavior and increasing the social interaction ratio in the social avoidance test. There was no change in behavior in nonstressed animals receiving LAC.[93]

A mouse model showed that LAC had an effect on the type 2 metabotropic glutamate receptors and improved depression symptoms within 3 days of daily dosing. No tolerance to dosage was seen by 21 days. The benefit from LAC lasted 2 weeks after discontinuation.[94]

There are many other theories as to the mechanism of action of LAC and depression. A thorough review can be found in Chiechio's review article.[95] In general, LAC seems to work as well as classic antidepressants, but in less time and without the adverse events. It was also reported that LAC is more effective in the older population compared with younger patients.[95]

Down Syndrome

Given that both Down syndrome and Alzheimer's disease are characterized by a deficit in cholinergic transmission, a study was conducted to assess the effect of a 90-day treatment with LAC in individuals with Down syndrome.[96] Treated patients with Down syndrome showed statistically significant improvements in visual memory and attention, both in absolute terms and in comparison with the other groups. No improvement was found in mentally deficient non–Down syndrome subjects, so the favorable effect of LAC appears to be specific for patients with Down syndrome. An effective dosage is 20 mg of LAC per 2 lb of body weight. The action of LAC in these pathologies may be related to its direct and indirect cholinomimetic effects.

Kidney Disease and Hemodialysis

Carnitine supplementation is much indicated in kidney diseases because the kidney is a major site of carnitine synthesis. Carnitine supplementation can be renoprotective. In one study, high amounts of dietary fructose had adverse effects (higher cholesterol and TGs, lower levels of antioxidants and hypertrophy) on rat kidneys, and concurrent carnitine supplementation (300 mg/kg per day intraperitoneal) was able to prevent the damage either partially or fully.[97]

Damage to the kidney or reduced kidney function has a profound effect on carnitine metabolism. It is well established that patients undergoing hemodialysis have carnitine deficiency due to the loss of considerable quantities of carnitine during dialysis, as well as decreased synthesis. Serum carnitine levels drop nearly 80% during hemodialysis.[1–3] Supplementation with LC (15 mg/kg of intravenous LC at the end of each hemodialysis) helps maintain carnitine status.[98]

Carnitine-treated dialyzed patients have also shown additional benefits, including the following[99–104]:

- Disappearance of angina pectoris and arrhythmias occurring during dialysis
- Reduction of muscle symptoms, including muscle cramps
- Increased muscle mass
- Significant improvement in chronic anemia, as demonstrated by increased hematocrit, hemoglobin, and red blood cell count
- Improved insulin sensitivity and reduced stress on pancreatic β cells
- Decreased serum C-reactive protein (29%) and serum interleukin-6 (61%) values

Since the early 1990s, a major advancement in the treatment of anemia associated with hemodialysis is recombinant human erythropoietin therapy. However, this therapy is expensive and has side effects. In one study, LC 1 g intravenously after every dialysis session for 6 months led to a significant reduction in dosage, as well as improvements in membrane fragility and endogenous erythropoietin secretion.[105] Given the high cost of erythropoietin, if doctors are unwilling to follow this procedure, insurance companies should get involved and force dialysis units to employ LC.

Diabetes

Patients with diabetes typically have deficient carnitine status. Studies revealed relationships between low carnitine status and increased plasma fatty acids, which negatively affect insulin action, so it has been recommended that free carnitine determinations should be made even if the patient has good metabolic control.[106] Given the risk of atherosclerotic cardiovascular disease and reduced kidney and liver function found in patients with diabetes, it may simply be more rational to supplement all patients with diabetes with LC.

Carnitine supplementation was shown to greatly improve peripheral vascular function, as well as nerve function, in patients with diabetes.[107–110] Carnitine supplementation might also affect blood lipids in patients with type 2 diabetes, particularly lipoprotein(a). In a study in type 2 diabetes, 2000 mg of carnitine daily lowered lipoprotein(a)

levels by roughly 20% after 6 months, whereas in another study of patients with markedly elevated lipoprotein(a) levels, even greater reductions were noted.[111,112]

Insulin sensitivity can be improved with LC supplementation, as shown in a 10-day investigation of newly diabetic men and women. The study consisted of two groups: the control group, which was given a hypocaloric diet to follow (55% carbohydrates, 25% lipids, 20% proteins); and the LC group, which consumed the same hypocaloric diet in addition to 2 g of oral LC twice daily. The LC group had no adverse reactions with 4 g/day for 10 days. Both groups had an improvement in fasting and postprandial serum glucose and decreased body weight. Insulin sensitivity improved significantly in the LC group (plasma insulin: 7.0–4.5 μU/mL; homeostasis model assessment of insulin resistance [HOMA-IR]: 1.9 to 1.1) compared with the control group, which had no change in plasma insulin or HOMA-IR levels.[113]

Neuropathy

Neuropathy can occur for many reasons and may be helped with different therapies that are specific to each individual. L-carnitine or LAC may be particularly beneficial if the patient is infected with HIV (associated with secondary deficiency of LC and also due to antiretroviral drugs), has used chemotherapy drugs (taxanes, platinum drugs and/or vinca alkaloids), or has neuropathy due to diabetes.[114]

In 21 HIV-positive patients with antiretroviral toxic neuropathy characterized as distal symmetrical polyneuropathy, 1500 mg of LAC twice daily was given for 33 months. Skin biopsies were done from the leg for drug-induced neuropathy. The nerve fibers were quantified and analyzed immunohistochemically. The small sensory fibers showed increased staining after 6 months, indicating nerve regrowth. Compared with controls, patients taking oral LAC for 6 months showed 92% epidural, 80% dermal, and 69% sweat gland innervation. The improvement continued at the 12-month biopsy.[115] Another similar study showed improvements in subjective measures such as pain, paresthesias, numbness, and vibration sensation on neurological examination.[116]

A multicenter, randomized, double-blind, placebo-controlled Phase II clinical trial was done on taxoid-induced peripheral neuropathy in 239 patients. The results showed LAC at 1000 mg thrice daily reduced the chemotherapy-induced neurotoxicity in 50.5% of the patients compared with 24.1% in the control group. The improvement was noticed by week 4 but became significant by week 8 with a decrease in grade 3+ neuropathy and an increase in grade 2. There was a significant improvement in the nerve conductive velocity testing with the LAC group versus control.[117]

A multicenter, randomized, double-blind, controlled trial of 204 patients with diabetic peripheral neuropathy compared oral LAC 500 mg or oral methylcobalamin 0.5 mg three times daily for 24 weeks after meals. The results showed that LAC is as effective as methylcobalamin using neuropathy symptom score and disability score. Both scores were reduced significantly at 12 and 24 weeks in both groups. Nerve conduction velocity and amplitude were improved in the LAC group at 24 weeks.[118] Another diabetic neuropathy study using oral 500 mg of LAC thrice daily showed a significant increase in fiber numbers and regenerating clusters. The group taking oral 1000 mg of LAC thrice daily noted improved vibratory parameters as well.[119] Intramuscular injections of 1000 mg of LAC daily for 10 days followed by oral LAC 2000 mg daily for 355 days was used for diabetic neuropathy and showed a mean pain score decrease of 39% at the end of the study, with 67% of those receiving LAC and 23% of placebo.[109]

Because animal studies exist showing benefit in compression neuropathy using LAC, a study of patients with carpal tunnel syndrome and LAC (3000 mg daily for 2 months after surgery) has been done, with results yet to come.[120]

Liver Disease

Carnitine plays an extremely important role in the usage and metabolization of fatty acids in the liver. Some evidence indicates that carnitine deficiency within the liver promotes fatty infiltration (also known as steatosis or liver congestion).[121]

Alcohol ingestion is a common cause of fatty infiltration of the liver. It has been suggested that chronic alcohol consumption results in a functional deficiency of carnitine. Carnitine was shown to significantly inhibit and reverse alcohol-induced fatty liver disease.[122]

Because carnitine normally assists fatty acid transport and oxidation in the mitochondria, a high liver carnitine level may be necessary to handle the increased fatty acid load produced by alcohol consumption or other liver injury.[123] Supplemental carnitine was shown to reduce levels of free fatty acids in patients with liver cirrhosis and to reduce serum TGs and liver enzyme levels while elevating HDL-c in alcohol-induced fatty liver disease.[121–123]

Carnitine has also proven helpful with hepatitis C in relieving the tremendous fatigue associated with interferon-α treatment. In one study, 50 patients with chronic hepatitis treated with interferon-α (3 million IU three times weekly) were given either carnitine (2 g/day) or placebo for 6 months. Patients treated with interferon plus carnitine showed a marked and significant reduction of both mental and physical fatigue levels.[124]

Muscular Dystrophies

Patients with various muscular dystrophies have reduced levels of carnitine in their skeletal muscles.[125–127] Although levels are not as low as those observed in patients with classic myopathic carnitine deficiency, the low carnitine levels are thought to contribute to the muscular weakness experienced by these patients. Unfortunately, it is undetermined whether supplemental carnitine would be of any value in patients with muscular dystrophy.

Low Sperm Counts and Decreased Sperm Motility

Carnitine concentrations are extremely high in the epididymis and spermatozoa, suggesting a role for carnitine in male reproductive function.[1–3] The epididymis derives the majority of its energy requirements from lipids, as do the spermatozoa during transport through the epididymis. After ejaculation, spermatocytes depend on glycolysis of glucose and fructose and on oxidation of lactate and pyruvate. Carnitine (in the form of acetylcarnitine, which is derived from pyruvate) serves as a readily available substrate. The motility of ejaculated sperm correlates positively with acetylcarnitine content.[1,3] In human sperm, high carnitine concentrations are critical to sperm energy metabolism. Several studies showed that the level of free carnitine in seminal fluid was strongly correlated with sperm count and motility.[128,129] The lower the carnitine content, the more likely it is that a man is infertile. A 2011 study measured seminal free LC and found in fertile men (447.6 mole/L), oligoastheno teratospermic men (157.6 mole/L), asthenospermic men (233.3 mole/L), and azoospermic men (46.5 mole/L).[130] Clearly, infertility is associated with decreased LC levels.

Given the known physiological role of carnitine in sperm function and its link to male infertility, a study was designed to assess the therapeutic effect of carnitine in men with low sperm counts and depressed sperm motility.[131] One hundred men selected from infertility clinics participated in the Italian Study Group on Carnitine and Male Infertility. Each subject was given 3000 mg of LC daily for 4 months.

The study results indicated that LC increased sperm counts and sperm motility, in both a qualitative and a quantitative manner:

- The number of ejaculated sperm increased from 142 to 163 billion.
- The percentage of motile sperm increased from 26.9% to 37.7%.

- The percentage of sperm with rapid linear progression increased from 10.8% to 18%.
- The mean sperm velocity increased from 28.4% to 32.5%.

The results were even more impressive when only patients with the poorest sperm motility were studied. This subgroup saw even more significant gains on all parameters. For example, the percentage of motile sperm increased from 19.3% to 40.9%, and the percentage of sperm with rapid linear progression increased from 3.1% to 20.3%.

Androgenetic Alopecia

There are promising in vitro studies on follicular keratinocytes and the effect of a combined natural product including saw palmetto or beta-sitosterol and stigmasterol, carnitine, and thioctic acid.[132–134] Carnitine was chosen for its anti-inflammatory activity and showed significant repression in LPS-activated inflammatory genes.[132] Another study suggested that "LC stimulates human scalp hair growth by upregulation of proliferation and down-regulation of apoptosis in follicular keratinocytes in vitro."[133] The goal of the researchers was to target both 5-alpha-reductase and inflammatory pathways as a new therapeutic approach to androgenetic alopecia.[132–134] One study demonstrated the natural product was more effective than finasteride at suppressing the mRNA expression of 5-alpha-reductase type 1, 2, and 3, DKK-1, FGF-1, 17beta-HSD-3, TGF-beta1, and beta2.[134]

A prospective, double-blind, randomized, placebo-controlled observational study was conducted on 51 healthy volunteers (19 males and 32 females) with clinically diagnosed mild to moderate androgenetic alopecia. The study used a 2% L-carnitine L-tartrate liposomal tonic applied locally twice daily for at least 5 hours each application for 6 months. The results showed a significant increase in the total number of terminal scalp hair shafts (170 hairs/cm^2 before therapy and 197 hairs/cm^2 posttherapy). The number or anagen hair follicles increased by 75%, and the number of telogen hair follicles was significantly downregulated (25%) in volunteers receiving topical 2% solution. In the placebo group, after 6 months, the telogen hair follicles were downregulated by 38%, and the anagen hair follicles increased by 62%.[135]

Chronic Obstructive Pulmonary Disease

Patients with chronic respiratory insufficiency are often severely affected by even the simplest physical activity. Treatment with LC (2 g three times daily) resulted in significant improvements in exercise capability.[136]

Acquired Immunodeficiency Syndrome

Several reports indicated that systemic carnitine deficiency might be a problem in patients with acquired immunodeficiency syndrome (AIDS). Reduced levels of serum carnitine are most often found in AIDS patients. However, more important is the carnitine depletion in peripheral blood mononuclear cells (PBMCs). Even AIDS patients with normal serum carnitine levels demonstrated low levels of carnitine in white blood cells.[137] Increasing the carnitine content of peripheral white blood cells strongly improved lymphocyte function, highlighting the importance of carnitine to immune function.

LC was shown to prevent the toxicity of the drug azidothymidine (AZT) on the mitochondria of the muscle cells.[138] AZT poisons the mitochondria of the muscle, leading to abnormal energy production within the muscle, which manifests clinically as muscle fatigue and pain. If LC can prevent this negative effect of AZT in human patients with AIDS, it would be a major improvement in the clinical management of AIDS.

Preliminary studies indicated that LC supplementation could improve immune function and reduce the level of human immunodeficiency virus-induced immune suppression. When AIDS patients treated with AZT were given 6 g/day of LC, it led to significantly increased PBMC proliferation and reduced blood levels of TGs and circulating tumor necrosis factor.[139] Given the suspected systemic carnitine deficiency, along with the tremendous safety of use, carnitine supplementation appears to be warranted in treating AIDS.

Inborn Errors of Amino Acid Metabolism

The use of carnitine to treat inborn errors of metabolism involving the urea acid cycle appears to be well justified. Preliminary studies showed impressive therapeutic response to LC supplementation in cases of glutaric aciduria, isovaleric acidemia, propionic acidemia, and methylmalonic aciduria.[140–143]

Protection Against Drug Toxicity

Carnitine was shown to protect against the damaging effects on the heart produced by the chemotherapy drug adriamycin.[144] Carnitine was also shown to improve the symptoms attributed to anticonvulsant medications, such as valproic acid (trade names: Depa, Depakene, Depakote, and Deproic) and carbamazepine (trade names: Epitol and Tegretol).[145,146] However, a subsequent study challenged the need to administer carnitine prophylactically because no significant differences were noted in well-being scores between the carnitine group and the placebo group.[147]

Attention Deficit Hyperactivity Disorder

Preliminary evidence indicated that carnitine might be beneficial in attention deficit hyperactivity disorder (ADHD). In one double-blind, placebo-controlled, double-crossover trial, 13 of 24 boys receiving carnitine demonstrated a significant positive response in school and home behavior.[148] However, researchers found no significant improvement in ADHD symptoms with LAC (500–1500 mg twice a day, weight dependent) in a U.S. multicenter, placebo-controlled trial of children 5 to 12 years old.[149]

In a double-blind, placebo-controlled trial on boys with fragile X syndrome ages 6 to 13 years with symptoms of ADHD, LAC (20–50 mg/kg per day) produced a reduction in hyperactivity and improved social behavior compared with placebo counterparts. These improvements were measured by Conners's Parent Global Index Scale and the Vineland Adaptive Behavior Scale.[150]

Miscellaneous Conditions

Beta-Thalassemia Major: A small study ($n = 30$) was done on children with beta-thalassemia major and short stature and the effect of supplemental LC (50 mg/kg/day divided into 3 doses) over 6 months. The growth hormone and IGF-1 values were significantly increased after LC therapy.[151]

Wound Healing: Wound healing improved significantly compared with placebo in a rat study with LPC at different dosages. The LPC-treated animals (100 mg/kg/day in drinking water) showed faster blood flow recovery of skin flap wound and improved viability. Also, the necrotic skin area was less than that of placebo-treated rats. Also, another part of the same study showed that the LPC group had dose-dependent (30, 60, 120 mg/kg/day) faster reepithelialization compared with the control group.[152]

Muscle Cramping: LC was studied in specific conditions to help lessen or resolve muscle cramping. In a small study of 42 patients with hepatic cirrhosis and painful muscle cramps, LC was given (300 mg three or four times daily) for 8 weeks. The muscle cramp frequency significantly decreased in all patients, with 29% having complete resolution. The visual analog scale score decreased in 27 patients (87%) and increased in 3 patients (10%) after treatment. The response was dose dependent, with better response in the 1200-mg

daily group.[153] In another study on patients with dialysis complications of muscle cramping and hypotension, LC (500 mg/day) was combined with vitamin E (200 IU/day) for 45 days and led to a significant improvement in both complications.[104]

Narcolepsy: A case report discussed the use of oral LC as a treatment for narcolepsy during pregnancy. A 32-year-old woman was titrated up to 500 mg twice daily. She had a progressive improvement in daytime somnolence and showed a regular night-time sleep schedule. She also reported a decrease in diurnal time for dozing off and the number of diurnal naps.[154]

DOSAGE

The daily dosage of LC in all of its forms has typically been between 1500 and 4000 mg in divided doses; however, a few studies have used up to 6000 mg daily. According to the Council for Responsible Nutrition, the "observed safety level" of LC for long-term supplementation is 2000 mg/day. However, it also stated that "much higher levels have been tested without adverse effects and may be safe."[155]

TOXICOLOGY

LC is extremely safe, with potential side effects being gastrointestinally related, such as nausea and diarrhea. Again, only LC should be used. The D form, the mirror image of the L form, has side effects, indicating that it interferes with the natural L form of carnitine. Patients undergoing hemodialysis given a mixture containing D,L-carnitine for 45 days experienced muscle pain and loss of muscle function, presumably due to lack of energy.[156] The symptoms disappeared on cessation of D,L-carnitine supplementation. Subsequent studies showed that D-carnitine produced an LC deficiency in cardiac and skeletal muscle.[157] Although LC resulted in significant improvement in exercise tolerance in patients with angina, D,L-carnitine actually dangerously reduced exercise tolerance in these patients.[158]

DRUG INTERACTIONS

There are two case reports of L-carnitine at 1000 mg/d potentiating the effect of the anticoagulant medication acenocoumarol.[159,160] Because acenocoumarol is similar to warfarin, it is advised to also avoid or use caution with carnitine and warfarin.

Carnitine and coenzyme Q_{10} appear to work synergistically when combined.[161] The same is true for pantethine.[162]

Perhaps the most important interaction is with choline. In young adult women, daily choline supplementation (20 mg/kg body weight) resulted in a 75% lower urinary carnitine excretion than in controls, without significantly altering plasma carnitine concentrations. Studies in guinea pigs demonstrated that choline supplementation resulted in a significantly lower urinary excretion and higher skeletal muscle carnitine concentrations. These studies indicate that choline supplementation results in a conservation of carnitine and might increase intracellular carnitine levels.[163]

Centella asiatica (Gotu Kola)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

Centella asiatica (family: *Umbelliferae* or *Apiaceae*)
Synonym: *Hydrocotyle asiatica* L.
Common names: gotu kola, Indian pennywort, South African pennywort, mandukaparni

GENERAL DESCRIPTION

Centella asiatica is an herbaceous perennial plant native to India, China, Indonesia, Australia, the South Pacific, Madagascar, and southern and middle Africa. This slender, creeping plant flourishes in and around water. Although it grows best in damp, swampy areas, centella is often observed growing along stone walls or other rocky, sunny areas at elevations of approximately 2000 feet in India and Sri Lanka.[1]

Depending on the environment, the form and shape of centella can change dramatically. In shallow water, centella forms floating leaves, whereas in dry locations, the leaves are small and thin, and numerous roots are formed.[1]

Typically, the constantly growing roots give rise to reddish stolons. The round-to-reniform, smooth-surfaced leaves, found on furrowed petioles, can reach a width of 1 inch and a length of 6 inches. The leaf margin may be smooth, crenate, or slightly lobed (Fig. 64.1). Usually three to six red flowers arise in a sessile manner or on short pedicels in axillary umbels at the end of 0.08- to 0.3-inch long peduncles. The fruit, formed throughout the growing season, is approximately 0.2 inches long, with seven to nine ribs and a curved, strongly thickened pericarp.[1]

Historically, the entire plant was used medicinally, with harvesting occurring any time during the year.[1]

CHEMICAL COMPOSITION

Although the primary pharmacologically active constituents of *C. asiatica* are known to be triterpenoid compounds,[2] its exact chemical profile is difficult to determine because of duplicate names and contradictory findings. In addition, centella samples from India, Sri Lanka, and Madagascar apparently do not contain the same constituents. In India, three (and possibly more) chemically different subspecies of *C. asiatica* have been found.

The concentration of triterpenes in centella can vary between 1.1% and 8%, with most samples yielding a concentration between 2.2% and 3.4%.[3] Fig. 64.2 illustrates the major triterpenoid components of *C. asiatica.*

The Madagascar variety is most commonly used to produce standardized extracts. It yields triterpene concentrations of asiatic acid (29%–30%), madecassic acid (29%–30%), asiaticoside (40%), and madecassoside (1%–2%).[2]

Centella also contains a green, volatile oil composed of an unidentified terpene acetate (which accounts for 36% of the total oil), camphor, cineole, and other essential oils. Centella oil also contains glycerides of

Fig. 64.2 The triterpene compounds of *Centella asiatica*.

fatty acids, various plant sterols (e.g., campesterol, stigmasterol, and sitosterol), and various polyacetylene compounds.[1,2]

Other notable compounds isolated from centella include the flavonoids kaempferol, quercetin, and their glycosides; myoinositol; sugars; a bitter substance (vellarin); amino acids; and resins.[1,2]

HISTORY AND FOLK USE

Centella has been used as a medicine in India since prehistoric times and is thought to be identical to the plant mandukaparni, listed in the *Susruta Samhita* (one of the valuable treatises in Ayurveda). Centella was also used extensively as a medicine, both internally and externally, by the people of Java and other islands of Indonesia. The medicinal use of centella in India and Indonesia centered around its ability to heal wounds and relieve leprosy, although it was also considered to be one of the "Rasayana" (rejuvenator) herbal medicines and was used to enhance memory and prolong life.[1,2]

In the 19th century, centella and its extracts were incorporated into the Indian pharmacopeia. In addition to being recommended for wound healing, it was recommended for the treatment of skin conditions such as leprosy, lupus, varicose ulcers, eczema, and psoriasis. It was also used to treat diarrhea, fever, amenorrhea, and diseases of the female genitourinary tract.[1]

In China, the leaves are prescribed for turbid leukorrhea and toxic fevers, whereas the shoots are used for boils and fevers. The plant is also used in the treatment of fractures, contusions, strains, and snakebites.[1] Centella was also used in China to delay senescence. One of the reported "miracle elixirs of life," centella's reputation as a promoter of longevity stems from the report of Chinese herbalist LiChing Yun, who reportedly lived 256 years. LiChing Yun's longevity was supposedly a result of his regular use of an herbal mixture chiefly composed of centella.[4]

C. asiatica was first accepted as a drug in France in the 1880s. Since then, centella extracts have been used to treat many of the previously listed conditions, along with those described in the section "Clinical Applications."

Centella, or gotu kola, has aroused much curiosity in American consumers. Many confuse gotu kola with kola nuts and assume gotu kola's rejuvenating activity is nothing more than the stimulant effect of caffeine. However, gotu kola is not related to the kola nut (*Cola nitida* or *Cola acuminata*), nor does it contain any caffeine.

BOX 64.1 Physiological Effects of *Centella asiatica* on Connective Tissue

- Stimulates hair and nail growth[1,4,6]
- Increases vascularization of connective tissue[1,4,6]
- Increases the formation of mucin and structural glycosaminoglycans, such as hyaluronic acid and chondroitin sulfate[1,4,6]
- Increases the tensile integrity of the dermis[1,4,6]
- Increases keratinization of epidermis through stimulation of the stratum germinativum[1,5,6]
- Possesses a eutrophic or balancing effect on connective tissue[1,6]

PHARMACOLOGY

The majority of pharmacological investigations on *C. asiatica* focused on the triterpene's wound-healing and venotonic activity.[1,2] Although the exact mechanism of action has not yet been fully determined, a number of interesting observations have been made:

- In one of the early pharmacological investigations of centella, Boiteau and Ratsimamanga[5] demonstrated that asiaticoside substantially hastened the healing of experimentally induced wounds. These authors concluded that asiaticoside worked selectively in stimulating the rapid and healthy activity of the reticuloendothelial system.
- Additional studies on the mechanisms of action of centella to enhance wound healing showed that asiaticoside, given orally, by intramuscular injection, or by implantation to rats, mice, guinea pigs, and rabbits, produced a wide range of effects (Box 64.1).
- The efficacy of centella in stimulating collagen synthesis was demonstrated in human tissue cultures.[3] Interestingly, this research demonstrated an additional benefit when vitamin C was added to the experimental cultures.
- The outcome of centella's complex actions is a balanced multiphasic effect on cells and tissues participating in the process of healing, particularly in connective tissues. Enhanced development of the normal connective tissue matrix is perhaps the prime therapeutic action of *C. asiatica.*
- Centella was shown to enhance the connective tissue structure of the perivascular sheath, reduce sclerosis, and improve blood flow through the affected veins.[1,6]

Research has also demonstrated positive effects of centella on the central nervous system, cognitive function, stress, and anxiety.[2] The major effects are an enhancement of cholinergic mechanisms and a significant antioxidant action via increasing glutathione levels.[7,8] Presumably, these mechanisms are responsible for the improvements in mental function noted in both animal and clinical trials. Excellent results in improving cognitive function and memory were seen in animal models of Alzheimer's disease.[9]

Ethanolic and methanolic extracts of *C. asiatica* have shown significant protection and lowered blood glucose to normal levels in glucose tolerance tests carried out in alloxan-induced diabetic rats.[10] Water extract has a chemopreventive effect on colon tumorigenesis,[11] and asiaticoside might be useful in cancer chemotherapy because it induces apoptosis and enhances the antitumor activity of vincristine in

cancer cells.[12] Animal studies also demonstrate cardioprotective activity against cardiomyopathy in rats, and results strongly suggest the cardioprotective activity of the plant in limiting ischemia-reperfusion-induced myocardial injury through preservation and restoration of the antioxidant defense system.[13] Centella was also shown to possess other diverse pharmacological effects in experimental models, including antiulcer, antimicrobial, immunomodulatory, and spasmolytic activity.[2]

CLINICAL APPLICATIONS

Centella is a valuable agent for the healing of wounds and the treatment of venous insufficiency and may also prove useful in improving mental function. Table 64.1 provides an abridged list of documented clinical applications of *C. asiatica*. Details on some of the more popular uses of centella are discussed in the following sections.

Burns

The standardized extract from *C. asiatica* has been used effectively in the treatment of patients with second- and third-degree burns caused by boiling water, electrical current, or gas explosion. Daily local application, intramuscular injections of the extract, or both, resulted in excellent results when treatment was started immediately after the accident.[14] The extract prevented or limited the shrinking and swelling of the skin caused by skin infection, and it inhibited scar formation, increased healing, and decreased fibrosis. A randomized controlled study compared the efficacy of silver sulfadiazine versus Centiderm (an ointment made from an ethanol extract of fresh *C. asiatica* leaves) in patients with partial-thickness burns from October 2014 to February 2015 in Iran.[15] Burn wounds were treated once daily, and patients followed up daily with a burn specialist until the wounds were completely healed, with subjective and objective variables recorded on days 3, 7, and 14. The use of Centiderm ointment not only improved the objective and subjective findings in less than 3 days but also improved the reepithelialization and complete healing times (about 7 days sooner compared with placebo).

Cellulite and Striae Gravidarum

Cellulite, known as liposclerosis, is a noninflammatory change within the subcutaneous adipose tissue caused by an increase in the volume of fat cells or by the increased division of connective tissue, which causes constriction of small blood vessels. Treatments for cellulite involve preparations that affect the adipose and connective tissue and improve microcirculation; they can be used topically, internally, and/or transdermally.

The effect of centella in the treatment of cellulite appears to be related to its ability to enhance connective tissue structure and reduce sclerosis by acting directly on fibroblasts. Madecassoside, an extract from *C. asiatica,* is known to induce collagen expression and/or modulate inflammatory mediators.[16] Triterpenes of *C. asiatica* increase the metabolism of lysine and proline, the amino acids that build collagen, and increase the synthesis of tropocollagen and mucopolysaccharide in the connective tissues, thus improving the nutrition of tissues and providing connective vascular stimulation.[17]

In several clinical studies, standardized extracts of *C. asiatica* demonstrated good results in the treatment of cellulite and the prevention of stretch marks during pregnancy. In the treatment of cellulite, Bourguignon observed the action of the extract on several types of cellulite in 65 patients who underwent other therapies without success.[18] Over a period of 3 months, good results were produced in 58% of the patients and satisfactory results in 20%. A study of 60 people with cellulite evaluated the influence of Madecassol® applied four times a day for 4 months.[19] Results clearly showed a beneficial effect of the gotu kola extract on inhibiting the progression of cellulite and a significant improvement in the skin condition in 85% of the experiment participants.

A randomized, double-blind, placebo-controlled trial of the cream Trofolastin®, containing an extract of *C. asiatica,* α-tocopherol, hydrolyzed collagen, and elastin, was carried out on 100 pregnant women.[20] The cohort was split evenly between the treatment group and the placebo group. After 30 months of treatment, striae occurred in 56% of the placebo group compared with 34% of the treated group; this difference was statistically significant. In women with a history of striae during puberty, the active cream induced a significant absolute prevention in 89% of the cases, whereas in the placebo group, all the women developed striae.

Cirrhosis of the Liver

Darnis et al. reported on the therapeutic use of an extract of *C. asiatica* in alcohol-induced cirrhosis (six patients), cirrhosis of unknown etiology (two patients), and chronic hepatitis.[21] In the cirrhosis patients, improvement in the histological findings and regression of inflammatory infiltration were observed. No effect was observed in the patients with chronic hepatitis. Other reports supported the use of centella in fibrotic conditions of the liver.[22]

Keloids

Keloids and hypertrophic scars are characterized by a prolonged inflammatory phase that may go on for months or even years without progressing to the maturation phase. The inflammatory phase is characterized histologically by large numbers of immature, swollen collagen bundles intermingled with inflammatory debris, whereas the maturation phase is characterized by mature fibrocytes, normal collagen fibers, and few inflammatory cell elements.

The standardized extract of *C. asiatica* demonstrated impressive clinical results in the treatment of keloids and hypertrophic scars.[23–25]

The mechanism of action appears to be multifaceted but is primarily the result of reducing the inflammatory phase of scar formation while simultaneously enhancing the maturation phase of scar formation. Asiaticoside has been shown to downregulate the expression of TGF-β1 mRNA and tissue inhibitors of metalloproteinases-1 and upregulate TGF-β3 mRNA expression, resulting in the ability to decompose the products of type I collagen and reduce hypertrophic scars.[26] It has been further proposed that asiaticoside interferes with scar formation by increasing the synthesis of acidic mucopolysaccharides and increasing the activity of myofibroblasts. In one study, 227 patients with keloids or hypertrophic scars were treated by oral administration with a standardized centella extract (effective dosage 60–90 mg). The centella extract was used alone in 139 patients (the curative group), and 88 used the extract along with surgical scar revision (preventive group).[24] In the curative group, 116 patients (82%) were found to have benefited from the extract after 2 to 18 months, either by relief of their symptoms or by the disappearance of the inflammatory phase. In a double-blind substudy of 46 of the 139 patients, 22 of 27 receiving the extract improved, whereas only 9 of 19 given a placebo improved. In the preventive group, the centella extract also demonstrated a significant positive effect. The therapeutic course in these patients began a few weeks before surgery. If a positive response was observed, the patient was brought to surgery and kept on the centella extract for 3 months. (This method of preselection allowed the researchers to offer other forms of therapy to unresponsive patients.) Clinical improvement was observed in 72 of the 88 patients (79%).

Kidney Disease

Traditional Chinese medicine has used gotu kola to treat kidney diseases for centuries. Its direct benefits for the kidneys have only been shown in animals but are encouraging. In rats, gotu kola showed a protective effect from Adriamycin-induced nephropathy, resulting in dramatically improved kidney function.[27] Another study combined gotu kola in conjunction with naringenin and showed decreased fibrosis formation in the kidneys.[28]

Leprosy

Several investigators reported impressive clinical results using *C. asiatica* and its extracts (oral, intramuscular, or topical) in the treatment of leprosy in both uncontrolled and controlled studies.[29,30] The therapeutic response was comparable to that of dapsone, the standard allopathic drug used in the treatment of leprosy.

In addition to its wound-healing activity, it appears that oxyasiaticoside, an oxidized form of asiaticoside, inhibited the growth of the tubercle bacillus in vitro and in vivo by dissolving the waxy coating of *Mycobacterium leprae*.[5]

Improving Mental Function and Quality of Life

The neuropharmacological properties of *C. asiatica* have been extensively studied. Mechanisms of action for its efficacy in memory disorders involve antioxidant, free radical scavenging, and cholinergic modulatory activities. Although long used to promote improved mental function, the first clinical investigation involving centella significantly increased the mental abilities of 30 developmentally disabled children.[31] After a 12-week period, the children were more attentive and better able to concentrate on assigned tasks.

Based on historical use and clinical studies, centella may also help improve mental function and quality of life in the elderly. Eighty elderly subjects participated in a double-blind study and were randomly assigned to receive placebo or standardized extract of *C. asiatica* at doses of 250, 500, and 750 mg once daily for 90 days.[32] The subjects were evaluated to establish baseline data of physical performance using the 30-second chair-stand test, hand-grip test, and 6-minute walk test. The health-related quality of life was assessed using a standard questionnaire. These assessments were repeated every month throughout the 3-month experimental period using the aforementioned parameters. Moreover, 1 month after the cessation of *C. asiatica* treatment, all subjects were also evaluated using these parameters again. The results showed that after 2 months of treatment, *C. asiatica* at doses of 500 and 750 mg/day increased lower extremity strength assessed via the 30-second chair-stand test. In addition, the higher doses of *C. asiatica* improved the life satisfaction subscale within the physical function subscale. Therefore the results from this study appear to support the traditional reputation of *C. asiatica* on strength improvement, especially in the lower extremities of the elderly. *C. asiatica* also possesses the potential to be a natural resource for increasing vigor and strength in healthy elderly persons.

Asiatic acid exerts a significant neuroprotective effect on cultured cortical cells by potentiation of the cellular oxidative defense mechanism, which may prove efficacious in protecting neurons from the oxidative damage caused by exposure to excessive glutamate.[33] The plant accelerates nerve regeneration and contains multiple active fractions that increase neurite elongation in vitro, suggesting that components in centella may be useful for accelerating repair of damaged neurons.[34]

Centella is also being investigated for its potential in Alzheimer's disease as an inhibitor of β-amyloid (Aβ) formation.[35,36] Water extracts of *C. asiatica* inhibit phospholipase A2 (PLA2) enzymes, particularly cPLA2 and sPLA2, which play key roles in Aβ-induced neurotoxicity.[37] Further studies on the water extract found that caffeoylquinic acids act as the active substances preventing Aβ-induced cell death by enhancing mitochondrial biogenesis in conjunction with activating antioxidant response genes and normalizing calcium homeostasis.[38]

Relieving Anxiety

Centella is viewed as an anxiolytic on the basis of in vitro models and emerging clinical evidence. An early study was conducted in humans to measure the effect of centella on reducing the acoustic startle response. After a single administration of centella, subjects experienced a significantly reduced acoustic startle response compared with the placebo—a clear indication of significant antianxiety action.[39] In an open clinical study in patients with generalized anxiety disorder, a 70% hydroethanolic extract of *C. asiatica* (500 mg/capsule, twice daily, after meal) was shown to significantly ($P < 0.01$) attenuate anxiety-related disorders and reduce the stress phenomenon and depression.[40]

Scleroderma

A standardized extract of *C. asiatica* was tested in several trials in the treatment of scleroderma (including systemic sclerosis).[41–44] In addition to decreasing skin induration, patients noticed a lessening of arthralgia and improved finger motility. Presumably, the positive therapeutic response was a result of centella's eutrophic effect on connective tissue, thereby preventing the excessive collagen synthesis observed in scleroderma.

Venous and Microcirculatory Disorders

The most well-documented clinical utility for a standardized extract of *C. asiatica* is in the treatment of chronic venous insufficiency, venous hypertension, and microcirculatory disorders.[45–51] The effect of *Centella* in venous insufficiency and varicose veins appears to be related to its ability to enhance connective tissue structure, reduce sclerosis, and improve blood flow through the affected limbs. Asiaticoside has been shown to improve microcirculation and reverse fibrosis in humans with varicose veins. 3, 5-Di-O-caffeoylquinic acid, a constituent of gotu kola, has been found to display an antithrombotic and

inhibitory effect on dynamic coagulation.[52] This is significant when one considers that fibrin clots play a pivotal role in cardiovascular conditions.

In the treatment of chronic venous insufficiency, significant improvement in symptomatology (e.g., feelings of heaviness in the lower legs, paresthesias, nocturnal cramps), physical findings (e.g., edema, telangiectasias, trophic ulcers, vein distensibility), and functional capacity (improved venous flow) was observed in approximately 80% of patients in the clinical trials.[1,45–51]

In studies of patients with venous hypertension (ambulatory venous pressure >42 mm Hg), detailed evaluations using laser Doppler flowmetry, transcutaneous oxygen, and carbon dioxide tension measurements and the determination of capillary filtration rate, ankle circumference, and ankle edema, along with detailed symptom evaluation, clearly demonstrated that centella extracts were clinically effective in dealing with this disorder.[45–47]

The standardized extract of *C. asiatica* also showed an ability to improve diabetic microangiopathy, it prevented the edema and microcirculation alterations seen during medium- to long-distance flights, and it normalized the echographic character of carotid arteries with significant plaque.[49–51]

Wound Healing

Standardized extracts of *C. asiatica* were shown in many clinical studies to greatly aid wound repair.[53,54] The types of wounds healed include the following:

- Surgical wounds, such as episiotomies and ear, nose, and throat surgeries
- Skin ulcers caused by arterial or venous insufficiency
- Traumatic injuries to the skin
- Gangrene
- Skin grafts
- Schistosomiasis lesions
- Perineal lesions produced during childbirth

DOSAGE

The majority of clinical studies on *C. asiatica* used proprietary formulas available in Europe (e.g., Madecassol, TECA, Centelase). These standardized extracts contain asiaticoside (40%), asiatic acid (29%–30%), madecassic acid (29%–30%), and madecassoside (1%–2%).
