Prickly pear inhibited replication by HSV-2 in infected human cervix tissue and inhibited RNA virus replication.[18] Testing included a laboratory strain of influenza A virus, an isolate of the respiratory syncytial virus, and strains of encephalomyocarditis (EMC) virus and HIV-1. The only virus that prickly pear failed to inhibit was the picornavirus EMC. The researchers found prickly pear to be a promising antiviral agent because it combines a breadth of in vitro reactivity with a high index of clinical safety. However, prickly pear pads combined with fresh *Capsicum frutescens* (cayenne) fruit and fresh *Citrus limon* (lemon) did not protect chickens from Newcastle virus.[19]

CICATRIZANT EFFECT

When administered by mouth, dried prickly pear pad *(O. ficus indica)* significantly inhibited hydrochloride-induced, aspirin-induced, and ethanol-induced gastric lesions in rats.[20,21] Prickly pear did not affect gastric juice secretion, acid output, or stomach pH in the rats. Extracts of *O. ficus indica* showed significant wound-healing activity in rats.[22]

Diuretic and Other Renal Effects

Fruit and flower infusions of *O. ficus indica* significantly increased diuresis in rats, and the fruit infusion had an antiuric effect.[14] Prickly pear pads (20 mg/100 g body weight daily for 5 weeks) significantly decreased uric acid levels and increased water intake while only slightly raising urine output in rats.[23] Although the rise in urine flow was slight, the investigators suggested that it could account for the greater excretion of uric acid. *O. megacantha* pads (20 mg/kg daily for 5 weeks) significantly increased urinary sodium output in diabetic rats and normal rats compared with controls.[24] Prickly pear did not alter plasma aldosterone concentrations. In earlier studies, prickly pear extract administered orally (20 mg/100 g body weight) increased creatinine clearance in diabetic rats and raised plasma creatinine and urea levels in all rats.[23,25]

Hypoglycemic Effect

Animal studies showed prickly pear pad had a hypoglycemic effect in streptozotocin-induced diabetes in rats and rabbits, although one study showed no effect if the rabbits' pancreatic β-cells were completely obliterated.[25–28] Prickly pear appears to improve glucose resistance/sensitivity and glucose uptake through a mechanism that involves AMPK/p38 MAPK signaling pathway and GLUT4 translocation from intracellular storage vesicles to the plasma membrane in muscle cells (Fig. 98.2). In one study, prickly pear's hypoglycemic effect was comparable to that of tolbutamide.[26] Prickly pear and insulin equivalently reduced, but did not normalize, glucose and insulin levels in diabetic rats. Prickly pear combined with insulin had a synergistic effect. Diabetic rats given the combination rapidly achieved normal glucose levels, and at 7 weeks, they became hypoglycemic. At that point, prickly pear alone was sufficient to maintain normal glucose levels.[27]

Hypocholesterolemic Effects

Prickly pear pectin was found to have a hypocholesterolemic effect in guinea pigs.[29,30] Prickly pear consistently reduced blood cholesterol levels, reduced low-density lipoprotein (LDL) cholesterol, and increased LDL density.

CLINICAL APPLICATIONS

Alcohol Intoxication

Prickly pear extract administered 5 hours before alcohol consumption reduced symptoms of a hangover. It appeared to act by inhibiting the production of inflammatory mediators.[31] However, a subsequent systematic review found no compelling evidence that prickly pear reduced hangovers.[32]

Diabetes (Adult-Onset Non–Insulin-Dependent)

There are a number of clinical trials on the effect of prickly pear pad in non–insulin-dependent diabetes mellitus (NIDDM).[33–39] A preliminary meta-analysis of the clinical trials on prickly pear's benefit

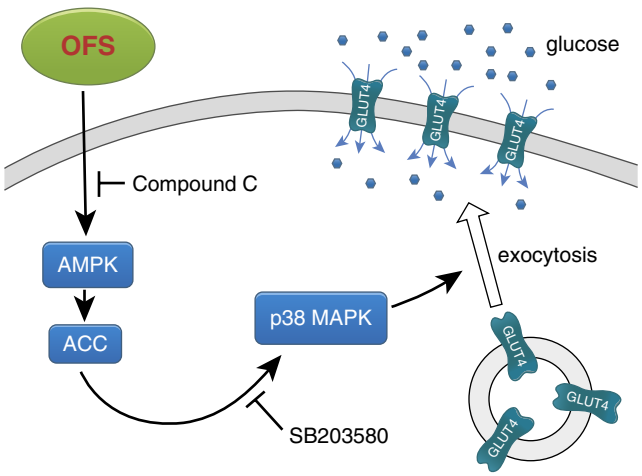

Fig. 98.2 Schematic summary of the possible molecular mechanism by which prickly pear regulates glucose uptake in muscle cell. (From Leem KH, Kim MG, Hahm YT, Kim HK. Hypoglycemic effect of *Opuntia ficus-indica* var. *saboten* is due to enhanced peripheral glucose uptake through activation of AMPK/p38 MAPK pathway. *Nutrients*. 2016;8[12], pii: E800. PubMed PMID: 27941667.)

in NIDDM concluded that the intervention data showed it to lower blood glucose levels by 10 to 30 mg/dL and supported claims that prickly pear had a true metabolic effect in diabetes.[40] Although the control data were insufficient for a full meta-analysis, a statistically significant reduction of blood glucose and, when tracked, in insulin levels was seen consistently when broiled prickly pear was administered. The magnitude of the hypoglycemic effect varied from mild to moderate depending on the dose. For example, a 300-g dose of broiled pad acutely lowered blood glucose levels by 30 mg/dL in eight subjects, whereas 500 g lowered levels by an average of 45 mg/dL in the same subjects. In another open study of 14 subjects with type 2 diabetes, 300 g of steamed pad as part of a high-carbohydrate (HC) or high-soy-protein (HS) breakfast had antihyperglycemic and antihyperinsulinemic effects in both. Prickly pear prevented postprandial blood glucose peaks in the HS breakfast.[41]

Most studies used broiled pads. One that used homogenized prickly pear pad preparation did not find a hypoglycemic effect.[39] However, when the pad was ground in a regular blender rather than ultrahomogenized, it had an effect equivalent to that of broiled pads.[33] Capsules of dried prickly pear did poorly in a small, crossover, single-blind study, in which a single dose of 30 capsules had no hypoglycemic effect.[42] Only a mild effect was seen in volunteers taking 30 capsules per day for 10 days—an impractical dose for most people. In a randomized, placebo-controlled, double-blind, parallel-arm study of 67 individuals with metabolic syndrome, a mixture of dehydrated prickly pear, chia seeds, oats, soy protein, Splenda, and flavoring did not affect blood glucose or insulin levels, although it did reduce the glycemic index after a glucose tolerance test and reduced serum triglycerides.[43]

In contrast, prickly pear has been shown to affect glucose levels mildly or not at all in normal individuals.[34,36,44] In two studies, prickly pear pad did not reduce glucose or insulin levels in healthy volunteers. In a third study, nondiabetic individuals who ate broiled prickly pear pads before meals for 10 days showed a mild but significant reduction in fasting glucose levels, but prickly pear pad had a significant hypoglycemic effect in volunteers in an induced hyperglycemic state.[42–46] In a fourth small study, a proprietary extract of prickly pear pad and fruit skin had an acute blood-glucose–lowering effect.[47]

Hyperlipidemia

Prickly pear pads lowered cholesterol and triglyceride levels and improved cholesterol ratios in a small, non–placebo-controlled trial.[36] Eight healthy patients, 14 obese patients, and 7 patients with NIDDM ate 100 g of broiled prickly pear pads before meals three times a day for 10 days. Each group experienced a significant reduction in total cholesterol levels; triglyceride levels also diminished significantly in obese and diabetic patients (23%–27%). An 8-week pilot study found that prickly pear pulp normalized blood fats as well as other indicators of metabolic syndrome in 24 hypercholesterolemic men.[48] In another 6-week randomized, placebo-controlled, double-blind study of 68 women with metabolic syndrome, an extract of dehydrated prickly pear (NeOpuntia, 4.8 g/day) was reported to significantly increase high-density-lipoprotein (HDL) cholesterol levels.[49] Based on this study, an application was made to the European Food Safety Authority (EFSA) for permission to make a cardiovascular disease reduction claim for NeOpuntia. The application was denied because EFSA found that the evidence failed to demonstrate that NeOpuntia had a significant effect on blood parameters.[50] A meta-analysis found that although prickly pear may have beneficial effects on total cholesterol, the effect sizes are small. It also found that studies are warranted on prickly pear's ability to lower both systolic and diastolic blood pressure.[51]

In 10 patients with familial hypercholesterolemia, prickly pear upregulated LDL binding.[52]

Osteopenia

A 2-year-long, blinded, randomized, quasi-experimental study (n = 181) compared women with normocalciuria taking 2.5 grams/day of prickly pear, women with hypercalciuria also taking 2.5 grams/day, women with hypercalciuria taking 15 grams/day, and untreated women with normal bone density. The high dose of dehydrated, mature prickly pear improved bone density (total hip and lumbar spine regions) and normalized calciuria levels in premenopausal women with low bone density and hypercalciuria.[53]

Prediabetes

In a double-blind, placebo-controlled study, 29 obese prediabetic individuals were given either 400 mg/day of a proprietary product, OpunDia consisting of 75% prickly pear pads and 25% fruit skins, or a placebo for 16 weeks. OpunDia was no more effective than placebo in lowering blood glucose concentrations.[54]

Prostatic Hyperplasia

Dried prickly pear flowers improved the subjective symptomology of prostatic hyperplasia in a preliminary open study.[55] Eighty-eight patients at two centers took two 250-mg capsules of flower extract three times daily for 2 to 6 months. Many patients reported decreases in urgency, emergency urination, and the sensation of fullness in the bladder, but not all patients experienced relief.

Weight Loss

In a small, open-label study, prickly pear pads significantly reduced the body weight of obese and diabetic subjects and showed a trend toward weight loss in normal subjects.[36] Fourteen obese patients, 7 patients with NIDDM, and 8 healthy patients ate 100 g of broiled prickly pear pad before meals three times a day for 10 days. Each group showed a mean reduction in weight of 1.5 kg while maintaining their usual diets. In another double-blind, placebo-controlled, multicenter study, two 500-mg capsules of IQP G-002AS (a prickly pear fiber derivative with added soluble fiber from *Acacia* species) three times daily triggered statistically significant weight loss in the active group (n = 123). Some 75% of those on the active treatment lost at least 3% of their body weight compared with just 28% of the placebo group, a statistically significant difference.[56] Nonetheless, a subsequent meta-analysis did not find that prickly pear supplementation had a statistically significant effect on body weight, although significant reductions in body mass index, percentage body fat, systolic and diastolic blood pressure, and cholesterol levels were observed.[57]

DOSAGE

Studies of the use of this plant have used a variety of forms of prickly pear pad. Most have used broiled or grilled pads, whereas some studies have used juiced slurries. These studies used 100 to 500 g (3–17 oz) of pads three times a day, taken before meals. There is little information on dried preparations, but as mentioned previously, such preparations did not achieve results in some small trials.

TOXICOLOGY

Prickly pear showed a high degree of safety in studies of mice, horses, and humans.[28] It has a long history of use as a food, a factor that also indicates a high level of safety. Most adverse events involving the plant are the result of its glochids (tiny, nearly invisible spines), which can

become embedded in the skin.[58] Sabra dermatitis is an occupational disease among prickly pear fruit handlers, in which the glochids cause a widespread skin eruption resembling scabies, which in chronic cases involves granuloma formation. However, in two animal studies, prickly pear significantly raised blood urea and creatinine levels in rats and increased urinary creatinine clearance rates in diabetic rats only.[23,24] The researchers expressed concern that prickly pear perhaps caused an early stage of kidney dysfunction in rats. However, the same researchers did not report similar results in a subsequent study, and no other studies have reported such effects.[25]

DRUG INTERACTIONS

No human data on drug interactions are available for prickly pear. All herbs rich in complex carbohydrates may affect transit time and thus may alter the absorption of practically any medication.

Many of the diabetes trials of this plant included patients who were taking oral hypoglycemic agents (tolbutamide, glyburide, chlorpropamide), and no adverse interactions were reported.[34–36,38,59] Prickly pear and insulin had a synergistic effect in rats, first normalizing blood sugar levels and then inducing hypoglycemia.[27] The effect of combining prickly pear and insulin in human subjects has not been studied.

Panax ginseng (Korean Ginseng)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

Panax ginseng C.A. Meyer (family: Araliaceae)
Synonym: *Panax schinseng Nees*
Common names: Korean ginseng, Chinese ginseng, Asiatic ginseng, Oriental ginseng

GENERAL DESCRIPTION

Korean or Chinese ginseng is a small perennial plant that originally grew wild in the damp woodlands of northern China, Manchuria, and Korea. Wild ginseng is now extremely rare. However, ginseng is a widely cultivated plant, especially in Korea, but also in Russia, China, and Japan. In addition to *Panax ginseng* C.A. Meyer, four other, closely related species are often used:

- *Panax quinquefolius* (American ginseng)
- *Panax japonicus* C.A. Meyer (Japanese ginseng)
- *Panax pseudoginseng* (Himalayan ginseng)
- *Panax trifolium*
- *P. ginseng* C.A. Meyer is the most widely used and most extensively studied species.[1,2]

Its pharmacology is the major focus of this chapter.

Fully mature, Korean ginseng is an herbaceous plant with a taproot, five-lobed palmate leaves, and greenish-white flowers in an umbel (Fig. 99.1). In its first year, ginseng bears only a single leaf with three leaflets. In the second year, it bears a single leaf with five leaflets, and in its third year, it bears two leaves with five leaflets. It usually starts flowering in its fourth year, while bearing three leaves. The roots of the cultivated plant are 3 to 4 mm in diameter and 10 cm long, and the roots of wild plants may attain 10 cm in diameter and a length of 50 to 60 cm.

Ginseng is often processed in two forms, white and red. White ginseng is the dried root whose peripheral skin is frequently peeled off. Red ginseng is the steamed root, which has a caramel-like color (Fig. 99.2).[2]

There are many types and grades of ginseng and ginseng extracts, which vary according to the source, age, and parts of the root used, where it was grown, the time of harvesting, and the methods of preparation.[1-3] Old, wild, well-formed roots are the most valued, whereas rootlets of cultivated plants are considered the lowest grade. High-quality preparations are usually in the form of extracts of the main root of plants between 4 and 6 years old that have been standardized for ginsenoside content (see later) and ratio to ensure optimum pharmacological effect.

CHEMICAL COMPOSITION

Ginseng contains at least 30 different triterpenoid saponins, collectively known as ginsenosides, which are believed to be the most important active constituents. The usual concentration of ginsenosides is between 2% and 3%. The ginsenosides have been designated R_0, R_{b1}, R_{b2}, R_{b3}, R_c, R_d, R_e, R_f, 20-gluco-R_f, R_{g1}, and R_{g2}. The ginsenosides originate from the following three fundamental aglycones:

- Oleanolic acid (ginsenoside R_0)
- 20-S-protopanaxadiol (ginsenosides R_{b1} to R_d)
- 20-S-protopanaxatriol (ginsenosides R_e to R_{g2})

As can be seen from Fig. 99.3, the ginsenosides differ primarily in their sugar groups.

Ginsenosides R_{b1}, R_{b2}, R_c, R_e, and R_{g1} are present in significant concentrations in Korean ginseng. In contrast, American ginseng (*P. quinquefolius*) contains primarily ginsenosides R_{b1} and R_e and does not contain ginsenosides R_f, R_{b2}, or, in some instances, R_{g1}.[4] These features allow for easy detection of species with high-pressure liquid chromatography.

Other components of ginseng are[1,2]:

- Panacene, a volatile oil
- Free and glucoside-bound sterols (e.g., β-sitosterol and its β-glucoside)

Fig. 99.1 *Panax ginseng.*

Fig. 99.2 Ginseng root preparations.

- Polyacetylene derivatives β-elemene and panaxynol
- 8% to 32% starch
- Low-molecular-weight polysaccharides
- Pectin
- Vitamins (e.g., thiamine, riboflavin, B_{12}, nicotinic acid, pantothenic acid, biotin)
- 0.1% to 0.2% choline
- Minerals (including germanium)[5]
- Simple sugars (glucose, fructose, sucrose, maltose, trisaccharides, etc.)
- Unique proteins (e.g., panaxagin, a protein that possesses antifungal, antiviral, translation-inhibiting, and ribonuclease activities)[5]
- Various flavonoids

Although it was reported that ginseng contains large amounts of germanium (i.e., 300 ppm), a follow-up study using highly sensitive (detection limit of 1 ppb), flameless atomic absorption spectrometry combined with solvent extraction demonstrated that the highest concentration of germanium measured in samples of ginseng purchased in the Osaka market was only 6 ppb.[6] More research is needed to accurately determine the germanium content of botanical medicines, because the reported concentrations vary widely. Such low levels suggest that a connection between the pharmacology of ginseng and its germanium content is unlikely.

HISTORY AND FOLK USE

Perhaps the most famous medicinal plant of China, ginseng has been generally used alone or in combination with other herbs to restore the "Yang" quality. It has also been used as a tonic for its revitalizing properties, especially after a long illness. Conditions for which ginseng is used in folk medicine are shown in Box 99.1. It has been used as an alterative, anodyne, aperitif, aphrodisiac, cardiotonic, carminative, emetic, estrogenic, expectorant, gonadotrophic, nervine, sedative, sialogogue, stimulant, stomachic, and tranquilizer.[1,2] As can be seen, ginseng reflects a broad range of nutritional and medicinal properties.

PHARMACOLOGY AND CLINICAL INDICATIONS

Since the 1950s, significant research has been conducted worldwide to determine whether the therapeutic properties attributed to ginseng are legend or fact. Unfortunately, inconsistent outcomes resulting from different procedures in the preparation of extracts, use of nonofficial parts of the plant, use of adulterants, and lack of quality control in the ginseng used, have made the determination of ginseng's true properties difficult. Nonetheless, research does exist to indicate that ginseng possesses pharmacological activity, especially when high-quality extracts, standardized for active constituents, are used (Fig. 99.4).

Over the years, ginseng has been reported to have numerous pharmacological effects in humans and laboratory animals, including[1,2]:

- General stimulatory effects during stress
- Decrease in sensitivity to stress
- Increase in mental and physical capacity for work
- Improved endocrine system function
- Amelioration of radiation sickness, experimental neurosis, and cancer
- Enhanced protein synthesis and cell reproduction
- Improved glucose control in diabetes
- Modulation of various immune system parameters
- Lowering of serum cholesterol
- Protection of the liver from hepatotoxins

Some of these actions are discussed in greater detail in the following sections.

Adaptogenic and Antistress Activity

Ginseng was originally investigated for its adaptogenic qualities. An adaptogen was defined in 1957 by the Russian pharmacologist I. I. Brekhman[2] as a substance with the following properties:

- It must be innocuous and cause minimal disorders in the physiological functions of an organism.
- It must have a nonspecific action (i.e., it should increase resistance to adverse influences through a wide range of physical, chemical, and biochemical factors).
- It usually has a normalizing action irrespective of the direction of the pathological state.

According to tradition and scientific evidence, ginseng possesses this kind of equilibrating, tonic, antistress action. Thus the term *adaptogen* is quite appropriate to describe its effects.[2]

Fig. 99.3 Ginsenosides. (From Zhang L, Virgous C, Si H. Ginseng and obesity: observations and understanding in cultured cells, animals, and humans. *J Nutr Biochem.* 2017;44:1-10.)

From a clinical perspective, ginseng can be used as a general tonic, especially in debilitated and feeble individuals. This use is consistent with its historic application. It can also be used as an antistress aid because it has been shown to enhance the ability to cope with various stressors, both physical and mental.

Ginseng delays the alarm phase response in Selye's classic model of stress. Animal studies found that adrenal cholesterol levels were many times higher in animals given ginseng than in their matched controls, indicating greater tolerance of stress and delayed alarm phase response.[7-9]

Italian researchers studied the effect of a standardized ginseng extract, the ginsenoside composition of which was accurately determined, on the adrenal functions of rats exposed to cold.[8] The ginseng extract significantly counteracted body temperature decline without affecting blood glucose or cortisone levels. In a group of adrenalectomized rats, the ginseng extract had no significant effects. Administration of hydrocortisone to the adrenalectomized rats did, however, cause body temperature to be maintained when the rats were exposed to cold.

Histological findings in this study were as follows:

- Evidence of hyperfunctioning in the supraoptic and paraventricular nuclei of the hypothalamus in rats fed the ginseng extract
- Remarkable increase in corticotropic basophilic cells (adrenocorticotropic hormone [ACTH] producing) in the pars distalis of the pituitary gland
- Hyperplasia of the adrenal zona fasciculata, indicating that hyperfunctioning of the adrenal was promoted by the administration of the ginseng extract.

Other researchers demonstrated that ginseng saponins significantly increased plasma ACTH and corticosteroids (in a parallel kinetic pattern).[10,11] Because this effect could be blocked by dexamethasone (which acts on the hypothalamus and pituitary to prevent ACTH release), it was concluded that ginsenosides act predominantly on the hypothalamus or pituitary to promote secretion of ACTH. This conclusion was confirmed further by indirect studies. ACTH first stimulates an increase in cyclic adenosine monophosphate (cAMP) in the adrenal and then promotes corticosteroid synthesis. Ginseng administration was shown to increase adrenal cAMP in normal rats but not in hypophysectomized rats.

These investigations indicate that ginseng's antistress action is mediated by the hypothalamic-pituitary-adrenal (HPA) axis, as follows:

- The antistress action of ginseng is greatly reduced by adrenalectomy.
- Ginseng continues to exert its antistress action after hypophysectomy only if ACTH is administered.

BOX 99.1 Conditions for Which Ginseng is Used in Folk Medicine

- Amnesia
- Anemia
- Anorexia
- Asthma
- Atherosclerosis

- Rheumatism
- Rhinitis
- Shortness of breath
- Sores
- Spermatorrhea
- Splenitis
- Swelling
- Vertigo

- Histological and chemical evidence demonstrate a strong link between ginseng and the HPA axis.
- Dexamethasone blocks the effects of ginseng.

ACTH and corticosteroids have been shown to bind directly to brain tissue to increase mental activities during stress. Therefore the release of ACTH and associated pituitary substances (e.g., β-lipoprotein, endorphins, enkephalins) coupled with their end organ effects are likely responsible for many of the antifatigue and antistress actions of ginseng. From a clinical perspective, it is apparent that ginseng has a balancing effect or alterative action on the HPA axis through adjustment of metabolic and functional systems governing hormonal control of homeostasis. Ginseng assists the body's response to the challenge of stress and, therefore, is indicated when there is a disruption in the HPA axis. A double-blind, placebo-controlled, counterbalanced within-group human study investigated the effect on constitutive and stress-induced effects of a Korean ginseng supplement on HPA and antioxidant activity.[12] Ten women and nine men completed three 14-day treatment cycles with different doses (high: 960 mg; low: 160 mg; placebo: 0 mg) separated by a 1-week washout period. Ginseng supplementation produced stress-inducible dose-dependent reductions in circulating cortisol and increased enzymatic and nonspecific antioxidant activity. Twenty-four hours after intense exercise, a high-dose bioactive ginsenoside metabolite (GINST15) significantly reduced muscle damage and HPA responses to physical stress.

Ginseng may be effective in restoration of normal adrenal function and prevention of adrenal atrophy associated with corticosteroid administration. In rats, ginseng was found to inhibit cortisone-induced adrenal and thymic atrophy.[13]

Antifatigue (Mental and Physical) Activity

Some of the first studies of ginseng's adaptogenic activities were performed during the late 1950s and early 1960s by Brekhman and Dardymov[14,15] in the Soviet Union and by Petkov[16-18] in Bulgaria.

In one of Brekhman's experiments, Soviet soldiers given an extract of ginseng ran faster in a 3-km race than those given a placebo. In another, radio operators tested after administration of ginseng extract transmitted text significantly faster and with fewer mistakes than those given placebo. These and similar results reported by European researchers, who demonstrated improvement in human

physical and mental performance after administration of ginseng extracts, prompted researchers to confirm the results in experimental models using mice.[2,14,15,19]

In perhaps the best known of these experiments, mice were subjected to swimming in cold water or running up an apparently endless rope to determine whether ginseng could lengthen the time to exhaustion. A dose-dependent increase in time to exhaustion was noted in mice receiving ginseng, indicating that ginseng possessed significant antifatigue activity.[2,15,20-22] In one study, the time to exhaustion was lengthened by up to 183% in mice given ginseng 30 minutes before exercising, compared with controls.[15]

Experimental animal studies indicated that much of the antifatigue action of ginseng was due to the stimulant effect of ginseng on the central nervous system (CNS). Ginseng has been shown to improve locomotor activity,[23] modify electroencephalographic (EEG) tracings,[17] improve metabolic activity in the CNS,[24] and affect the HPA axis (discussed later), all of which could be responsible for ginseng's antifatigue activity in mental and physical performance. The CNS activity of ginseng is essentially different from that of typical stimulants. Although stimulants are active under most situations, ginseng reveals its stimulatory action only with the challenge of stress.[24]

On the physical level, stress coupled with ginseng ingestion induced alterations in energy metabolism during prolonged exercise. Exercise physiologists established that during prolonged exercise, the development of fatigue is closely related to the depletion of glycogen stores and the buildup of lactic acid, both in skeletal muscle and in the liver. If an adequate supply of oxygen is available to the working muscle, nonesterified fatty acids are the preferential energy substrate, thus sparing use of muscle glycogen, blood glucose, and, consequently, liver glycogen. The greater the ability to conserve body carbohydrate stores through mobilization and oxidizing of fatty acids, the greater the amount of time to exhaustion. Ginseng enhances fatty acid oxidation during prolonged exercise, thereby sparing muscle glycogen stores.[9]

Mental and physical antifatigue activity effects have been demonstrated in animal studies and double-blind clinical trials in humans. In one double-blind clinical study, nurses who switched from day to night duty rated themselves for competence, mood, and general well-being, and were evaluated with an objective test of psychophysical performance, blood cell counts, and blood chemistry analysis. The group administered ginseng demonstrated higher scores in competence, mood parameters, and objective psychophysical performance than those who received a placebo.[25] The antifatigue effects of enzyme-modified ginseng extract (EMGE) were investigated in healthy adults in a randomized, double-blind, placebo-controlled trial. Fifty-two healthy subjects were randomly allocated into one of two groups: EMGE (2000 mg/day) or placebo. EMGE or placebo were administered to each group for 4 weeks.[26] Fatigue scores using the Visual Analog Fatigue Scale (VAFS) and Revised Piper Fatigue Scale (RPFS) were considered as the primary outcome measure. Life-quality scores were investigated using the Short-Form Health Survey (SF-36). A repeated-measures analysis of variance showed that there was a significant difference in the VAFS scores between the treatment and placebo groups after 4 weeks, with the treatment group's score decreasing more than that of the placebo group. Although there was no difference in the RPFS and SF-36 scores between the two groups, EMGE treatment for 4 weeks decreased fatigue severity in a healthy population.

From a clinical standpoint, cancer patients who underwent chemotherapy, patients with chronic obstructive pulmonary disease (COPD), and athletes were all shown to benefit from ginseng use. In one double-blind study, 92 adults with COPD were randomly assigned to receive either ginseng or placebo.[27] Pulmonary function tests, maximum voluntary ventilation, maximum inspiratory pressure, and maximal oxygen consumption were studied before treatment and every 2 weeks throughout the 3-month study. In the ginseng group, but not in the control group, all parameters were significantly higher than baseline and higher than the placebo group. Maximum increases, in comparison with baseline, were forced vital capacity (32.5%), forced expiratory volume$_{1.0}$ (27.0%), maximum voluntary ventilation (40.4%), maximum inspiratory pressure (47.0%), and maximal oxygen consumption (37.5%). No side effects were observed.

Cancer-related fatigue (CRF) is the most common and severe symptom in patients with cancer. In a large double-blind study of 290 cancer patients, subjects were randomized to receive American ginseng in doses of 750, 1000, or 2000 mg/day or placebo given in twice daily dosing over 8 weeks. Over twice as many patients on ginseng perceived a benefit and were satisfied with treatment compared with those on placebo.[28] In another double-blind trial, 53 cancer patients were randomly assigned to receive ginseng (3000 mg/day) or placebo for 12 weeks. Quality of life was assessed using the World Health Organization Quality of Life Assessment-BREF (WHOQOL-BREF) and the General Health Questionnaire-12.[29] After 12 weeks of therapy, the "psychological domain" score of the WHOQOL-BREF was significantly improved in patients randomized to ginseng, compared with those randomized to placebo. There was a tendency for ginseng to improve the "physical health" and "environment" domain scores of the WHOQOL-BREF, compared with placebo. The General Health Questionnaire-12 total score was significantly improved in patients treated with ginseng than in those with placebo.

In a prospective, open-label study, 30 patients with CRF (≥4/10) received high-dose *Panax ginseng* (PG) at 800 mg orally daily for 29 days.[30] Scores on the Functional Assessment of Chronic Illness Therapy-Fatigue (FACIT-F) scale, Edmonton Symptom Assessment System (ESAS), and Hospital Anxiety and Depression Scale (HADS) were assessed at baseline, day 15, and day 29. Global Symptom Evaluation (GSE) was assessed at day 29. Of the 24 evaluable patients, 21 (87%) had an improved (by ≥3 points) FACIT-F score by day 15. The mean ESAS score (standard deviation) for well-being improved from 4.67 (2.04) to 3.50 (2.34) ($P = 0.01374$), and mean score for appetite improved from 4.29 (2.79) to 2.96 (2.46) ($P = 0.0097$). GSE score of PG for fatigue was ≥3 in 15/24 patients (63%) with median improvement of 5. Thus PG is safe and improves CRF fatigue as well as overall quality of life, appetite, and sleep at night.

Cognitive Performance

Standardized extracts of *P. ginseng* alone or in combination with *Ginkgo biloba* (a formula called Gincosan) were shown to improve cognitive performance in animal and clinical studies.[31-41] In university students in Italy (a double-blind, crossover design), ginseng extract alone was compared with placebo in various tests of psychomotor performance.[33]A favorable effect of ginseng relative to baseline performance was observed in attention (cancellation test), mental arithmetic, logical deduction, integrated sensorimotor function (choice reaction time), and auditory reaction time. However, statistically significant superiority of the ginseng group over the placebo group was noted only for mental arithmetic. It was interesting to note that during the trial, the students taking ginseng reported a greater sensation of well-being. Later studies in college-aged students showed similar results with a dose dependence response.[34-36]

The benefits of ginseng on cognitive performance, mood, and quality of life assessment are considerably greater in middle-aged adults than in younger adults. A double-blind, placebo-controlled, balanced, crossover study examined the effect of a ginsenoside-rich extract of American ginseng (*Panax quinquefolius* L.) on working memory and

mood in healthy middle-aged individuals.[37] Fifty-two healthy volunteers (40–60 years old, mean age 51.63) received 200 mg of *P. quinquefolius* or a matching placebo. The Cognitive Drug Research battery and the Computerised Mental Performance Assessment System were used to evaluate cognitive performance at baseline then 1, 3, and 6 hours after treatment. Compared with placebo, *P. quinquefolius* improved cognitive performance on 'Working Memory' factor at 3 hours. Similar effects were observed in one of the two tasks making up this factor: spatial working memory.

Unlike studies in older subjects, no positive effect on mood or quality of life has yet been demonstrated with the administration of ginseng to healthy young adults. In several studies of the administration of ginseng alone or in combination with *G. biloba* extract, significant improvements in tests of cognition and memory were noted, in addition to social functioning and mental health.[38-40] One study demonstrated attenuation of ginseng's effects after 4 weeks of use, indicating that cotherapy with *G. biloba* may be more efficacious or that cycling of the ginseng dosage may be necessary to produce a prolonged effect.[40]

G. biloba and *P. ginseng* have been shown to modulate aspects of cognitive performance, including effects on EEG recordings. One double-blind, placebo-controlled, balanced, crossover experiment of 15 healthy volunteers assessed the effects of single doses of *G. biloba* extract (360 mg), a proprietary *P. ginseng* extract (200 mg G115), and an identical placebo on auditory-evoked potentials, contingent negative variation, and resting power within the δ, θ, α, and β wavebands.[41] The results showed that ginseng use led to a significant shortening of the latency of the P300 component of the evoked potential. Both ginseng and ginkgo also led to significant reductions in frontal "eyes closed" θ and β activity, with additional reduction for ginseng in the α waveband. These findings were the first to demonstrate that *P. ginseng* can directly modulate EEG activity, and that these effects are more pronounced than those that follow ingestion of *G. biloba.* Additional studies with G115 also showed an ability to enhance cognitive function in normal subjects.[42-44]

Results from an open-label study suggest ginseng may improve cognitive performance in Alzheimer's disease (AD).[45] In the study, consecutive AD patients were randomly assigned to the ginseng (n = 58) or the control group (n = 39). The ginseng group was treated with *P. ginseng* powder (4.5 g/day) for 12 weeks. Cognitive performances were monitored using the Mini-Mental State Examination (MMSE) and Alzheimer's disease assessment scale (ADAS) during 12 weeks of the ginseng treatment and for 12 weeks after discontinuing ginseng. MMSE and ADAS scales showed no baseline difference between the groups. After ginseng treatment, the cognitive subscale of ADAS and the MMSE scores began to show improvements and continued up to 12 weeks. After discontinuing ginseng, the improved ADAS and MMSE scores declined to the levels of the control group. These results suggest that *P. ginseng* is clinically effective in the cognitive performance of AD patients.

Ergogenic Aid

The benefits of ginseng on athletic performance are not clear, and results at this time do not support claims that ginseng improves athletic performance. However, other benefits have been noted, such as an ability to protect against muscle injury and inflammation in athletes, reduced exercise-induced oxidative stress, reduced postexercise plasma creatine kinase levels, as well as improved psychomotor performance at rest during a graded exercise test.[46-49]

Diabetes

Ginseng, alone or in combination with other botanicals, has a long folk use in the treatment of diabetes. Hypoglycemic activity was confirmed in both experimental and clinical trials. In one double-blind study in type 2 diabetes, ginseng therapy reduced fasting blood glucose levels, elevated mood, improved psychophysical performance, and lowered body weight and glycosylated hemoglobin.[50] The chief constituents responsible for this effect are[51-55]:

- Five glycans (polysaccharides designated panaxans A to E)
- Adenosine
- A carboxylic acid
- A peptide
- A fraction designated DPG-3-2

The ratio of ginsenosides appears to be an important factor. In one human study, the ratio of protopanaxadiol/protopanaxatriol was the sole predictor of whether a ginseng preparation would exert hypoglycemic effects.[56] It may be important to use crude, standardized extracts having a higher protopanaxadiol/protopanaxatriol ratio, such as those from American ginseng extract, to produce the desired benefit.

Powdered American ginseng root *(P. quinquefolius)* at a dosage of about 3 g before each meal was shown to significantly reduce postprandial blood sugar in patients with type 2 diabetes. It was determined that American ginseng stimulated pancreatic β-cells, with a subsequent increase in insulin secretion. American ginseng also has significant antioxidant properties, improves cognitive function, and possesses nerve protection and regeneration properties. This could prove to be valuable in diabetes considering peripheral and autonomic nerve damage often occurs.[57-59]

It is interesting to note that ginseng raises serum cortisol levels in nondiabetic individuals but reduces serum cortisol levels in patients with diabetes.[60] Because cortisol antagonizes insulin, this is presumably a beneficial effect. This again demonstrates ginseng's nonspecific balancing effect, which is baffling to researchers accustomed to investigating compounds with consistent pharmacological effects.

In a double-blind, randomized, crossover design study of 19 patients with well-controlled type 2 diabetes, each participant received the selected ginseng preparation (rootlets) or placebo at the selected dose (2 g/meal = 6 g/day) and mode of administration (preprandial oral agent [−40 minutes]) for 12 weeks as an adjunct to their usual antidiabetic therapy (diet and/or medications).[61] Although there was no change in glycosylated hemoglobin, ginseng treatment decreased 75 g oral glucose tolerance test plasma glucose (OGTT-PG) indexes by 8% and fasting plasma insulin (PI) and 75 g OGTT-PG indexes by 33%, and increased the fasting insulin sensitivity index and 75 g OGTT-insulin sensitivity index by 33%, compared with placebo.

In another double-blind study, improvements were seen with American ginseng supplementation on fasting blood sugar levels and insulin resistance in type 2 diabetic patients.[62] Proposed mechanisms included effects on insulin release from pancreatic β-cells, insulin-stimulated glucose disposal, and increasing insulin sensitivity related to the peroxisome proliferator-activated receptor.

A systematic review and meta-analysis of randomized clinical trials comparing ginseng supplementation versus control in patients with T2DM or impaired glucose tolerance found no significant difference in Hb A_{1c} levels between the ginseng supplementation and the control groups (pooled standardized difference in means = −0.148, 95% CI: −0.637 to 0.228, P = 0.355).[63] Ginseng supplementation improved fasting glucose, postprandial insulin, and HOMA-IR levels, though no difference in postprandial glucose or fasting insulin was observed among the groups. Similarly, triglycerides, total cholesterol, and low-density lipoprotein levels showed significant difference between the treatment groups, whereas no difference in high-density lipoprotein was seen. In addition, ginseng-related therapy was ineffective in decreasing the fasting glucose levels in patients treated with oral hypoglycemic agents or insulin. The authors concluded that these results

establish the benefit of ginseng supplementation in improving glucose control and insulin sensitivity in patients with type 2 diabetes mellitus or impaired glucose intolerance.

Ginseng appears useful as an adjunctive therapy in the treatment of diabetes, both for its antihyperglycemic effect and for its ability to decrease the atherogenic index. Although the root has received the most attention, animal studies indicate that extracts from the ginseng berry may be more beneficial as a result of a higher concentration of ginsenoside R_e.[60,62,64]

Reproductive Effects

Although ginseng is claimed to be a "sexual rejuvenator" and aphrodisiac, human studies supporting these effects are limited. However, in animal studies, ginseng was shown to[65,66]:

- Promote the growth of the testes and increase spermatogenesis in rabbits
- Accelerate the growth of the ovary and enhance ovulation in frogs
- Stimulate egg-laying in hens
- Facilitate lordotic response in female rats
- Increase gonadal weight in both male and female rats
- Raise testicular nucleic acid content in rats
- Increase sexual activity and mating behavior in male rats

Ginseng was also shown to increase testosterone levels while reducing prostate weight in animals.[67] This suggests that ginseng should have favorable effects in the treatment of benign prostatic hyperplasia. However, no clinical trials have been reported.

Ginsenosides were shown to bind to human myometrial receptor proteins and exert estrogen-like action on the vaginal epithelium significantly enough to prevent the atrophic vaginal changes associated with postmenopause and other menopausal symptoms.[68] Korean red ginseng (KRG) is known to have beneficial effects on women's health as a result of its estrogen-like function. Bisphenol A (BPA) is a significant endocrine disrupting chemical having estrogen-like effects. In a single-blind randomized clinical trial, the efficacy and safety outcomes of KRG against BPA were evaluated, focusing on female quality of life (QOL).[69] Young women (N = 22) consumed 2.7 g of KRG or placebo per day for 2 weeks and completed questionnaires regarding gynecological complaints at four time spots. Urinary levels of total BPA and malondialdehyde (MDA), an oxidative stress biomarker, were also analyzed. KRG consumption decreased urinary BPA and MDA levels and alleviated "menstrual irregularity," "menstrual pain," and "constipation."

Based on historical use and experimental evidence, other clinical indications involving the reproductive system include decreased sperm counts, testicular atrophy or hypofunction, organic causes of male infertility, ovarian atrophy or hypofunction, amenorrhea, and organic causes of female infertility. It should be noted that several reports of mastalgia were reported in women taking ginseng.[70,71]

Many clinical studies involving reproductive effects focused on ginseng's effect on erectile dysfunction (ED). Ginsenosides can facilitate penile erection by directly inducing the vasodilatation and relaxation of penile corpus cavernosum mediated by the release and/or modification of the release of nitric oxide from endothelial cells and perivascular nerves.[72-74]

In one double-blind, crossover study, 45 patients with clinically diagnosed ED showed significantly higher mean International Index of Erectile Function (IIEF) scores with Korean red ginseng than those who received placebo.[74] In response to the global efficacy question, 60% of the patients answered that Korean red ginseng improved erection.

In a double-blind, placebo-controlled trial, a tissue-cultured mountain ginseng extract (TMGE) or placebo was given to 86 male patients with ED.[75] Over the course of 8 weeks, one group took 1000 mg of TMGE twice a day, and the other group took 1000 mg of placebo twice a day. The effects of the TMGE and the placebo were analyzed using the IIEF questionnaire. All 86 patients completed 8 weeks of treatment. The scores on the five domains of the IIEF after medication were significantly higher than the baseline scores in the group treated with TMGE, whereas no significant improvement was observed in the placebo group. Erectile function and overall satisfaction scores after medication were significantly higher in the TMGE group compared with the placebo group.

In another double-blind study, 60 patients presenting with mild or mild to moderate ED were given either *P. ginseng* at a dosage of 1000 mg three times daily or a placebo.[76] The IIEF score after treatment was significantly higher in the ginseng group compared with before the treatment. In contrast, there was no difference before and after the treatment in the placebo group.

Menopause

Ginseng is a popular treatment for menopausal symptoms. However, clinical research is unconvincing. A double-blind study of 384 menopausal women was performed to compare the effects of a standardized ginseng extract with those of a placebo on quality of life, menopausal symptoms, and physiological markers of menopause (follicle-stimulating hormone and estradiol levels, endometrial thickness, maturity index, and vaginal pH).[77] Although the ginseng extract showed no statistically significant effects on the physiological parameters, including vasomotor symptoms (hot flashes), it was associated with statistically significant improvements in mood and well-being. A systematic review of double-blind, randomized, placebo-controlled trials provided positive evidence of ginseng for sexual function and KRG for sexual arousal and total hot flashes score in menopausal women, but the results of KRG or ginseng failed to show specific effects on hot flash frequency, hormones, biomarkers, or endometrial thickness.[78]

Cell-Proliferating, Antioxidant, and Antiaging Effects

Ginseng has a dual effect on cell growth. It stimulates cell division in an adequate nutritional environment but acts cytostatically under adverse conditions. Furthermore, ginseng yielded impressive results in lengthening the life span of cells in culture.[79]

Enhancement of cellular proliferation and function has been shown in a variety of cell types (e.g., epithelial, hepatic, lymphocyte, fibroblast, thymic), especially nerve cells, which may be a result of potentiation of nerve growth factor by ginsenosides.[3,80-82] Clinically, these results indicate a potential use of ginseng in healing damage to virtually all tissue types, particularly the brain.

In animal studies, ginseng was shown to reduce oxidative stress, scavenge free radicals directly, protect endothelial cells from damage, and increase cellular antioxidant enzymes like superoxide dismutase.[83-88]

Immunomodulating Effects

Ginseng enhances the following immune functions[89-96]:

- Antibody plaque-forming cell response
- Circulatory antibody titer against sheep erythrocytes
- Cell-mediated immunity
- Natural killer (NK) cell activity
- The production of interferon
- Lymphocyte mitogenesis
- Reticuloendothelial system proliferative and phagocytic functions

In addition to these immunostimulatory aspects, ginseng components were shown to exert antiallergy and anti-inflammatory effects in experimental models.[97,98] Ginsenosides regulate inflammatory responses primarily through the inhibition of the NF-κβ

signaling pathways. In lipopolysaccharide (LPS)-stimulated macrophages and microglial cells, ginsenosides suppress the production of proinflammatory cytokines such as tumor necrosis factor-α, interleukin-1β, and interleukin-6, as well as inflammatory enzymes such as inducible nitric oxide synthase and cyclooxygenase-2.[99] Furthermore, the biological activities of ginsenoside metabolites have been shown to be effective in ameliorating inflammation associated with several conditions including edema, colitis, atopic dermatitis, and asthma.

The long-term ingestion of ginseng by individuals with mild immunodeficiency may reduce the risk of viral infection. This is consistent with the historic use of ginseng by debilitated individuals. Clinical evidence is also supportive. Extracts of *P. ginseng* were found to stimulate NK function in normal individuals and patients with either chronic fatigue syndrome or AIDS.[100] Ginseng was shown to prevent respiratory viral infections in a nursing home environment (89% relative risk reduction) and potentiate influenza vaccinations.[101,102]

Large doses of ginseng may be contraindicated in acute infections considering its in vitro inhibition of lymphocyte transformation (similar to cortisone) at high (more than 1 mg/mL) but not low concentrations.[103,104] In vitro, ginseng at 1.6 mcg/mL was shown to inhibit phytohemagglutinin-induced transformation of peripheral blood lymphocytes to a greater degree than cortisone at 500 mcg/mL.[103] The greatest level of inhibition was observed when ginseng was used in combination with cortisone. These results demonstrate that ginseng at high doses may be effective against T-cell–mediated inflammatory diseases without producing glucocorticoid-like side effects. It also suggests that a lower dose of cortisone could be used if ginseng were given simultaneously.

When recommending ginseng, the clinician must remember: (1) ginseng's in vitro effect on lymphocyte proliferation is biphasic (i.e., it exerts a strong inhibition at high concentrations and a moderate stimulation at low concentrations); and (2) although ginseng has demonstrated significant inhibition of lymphocyte proliferation in vitro, observed effects in vivo show enhancement of lymphocyte proliferation.[91] These effects may be related to a dose-dependent ginseng-induced elevation of interferon, which inhibits lymphocyte proliferation.

Anticancer Properties

In vivo and in vitro studies have demonstrated the anticancer effect of ginseng in various types of cancer, including breast, lung, liver, colon, and skin cancer. Ginseng increases the mitochondrial accumulation of apoptosis protein and downregulates the expression of antiapoptotic protein, thus reducing the proliferation of cancerous cells and stopping the angiogenesis process (Fig. 99.5).[105] It also aids in the reduction of alopecia, fatigue, and nausea, improves cognitive function, enhances psychomotor performance, and prevents normal cell damage when used with chemotherapeutic drugs. Long-term oral administration of ginseng to newborn mice was shown to reduce the incidence and inhibit the proliferation of tumors induced by various chemical carcinogens, including 7,12-dimethylbenz[*a*]anthracene, urethane, and aflatoxin B_1. In two large population studies, the risk for development of cancer was significantly lower among people who consumed ginseng on a regular basis. Ginseng extract and powder were shown to be more effective than fresh sliced ginseng, ginseng juice, or ginseng tea in reducing cancer risk. A statistically, highly significant dose–response relationship between ginseng intake and cancer risk was observed. These results support the preventive and anticancer effects of ginseng demonstrated in animal and in in vitro studies.[106-108]

The anticancer effects of ginseng can be summarized as[108-112]:

- Ginseng promotes apoptosis.
- The effect is observed only in slow-growing tumors, such as Ehrlich and sarcoma 180 ascites tumor.
- The effect is not observed in rapidly growing tumors, such as l1210, p388, and Walker carcinoma.

In addition to a possible role in cancer prevention, some researchers are investigating *P. ginseng* extracts as a possible adjunct in cancer treatment.[113] Exerting some direct and indirect anticancer actions, ginseng may also offer protection against chemotherapy-induced damage to normal cells. In one animal study, *P. ginseng* extract was shown to protect against cisplatin nephrotoxicity.[114] A multicenter, large-sample, randomized, double-blind trial enrolled 414 patients with advanced nonsmall cell lung cancer to examine the efficacy of the combination of chemotherapy and

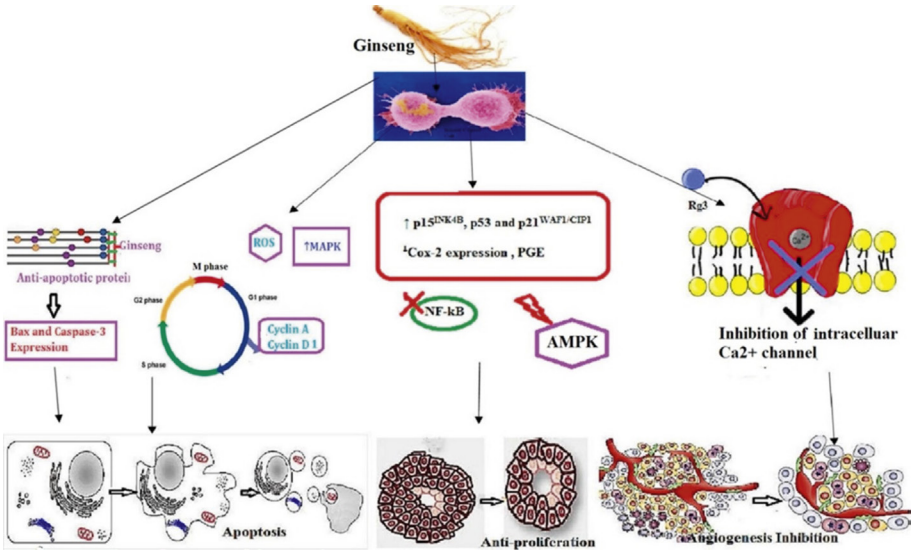

Fig. 99.5 The mechanisms of ginseng in cancer. (From Majeed F, Malik FZ, Ahmed Z, Afreen A, Afzal MN, Khalid N. Ginseng phytochemicals as therapeutics in oncology: recent perspectives. *Biomed Pharmacother.* 2018;100:52-63.)

Ginseng Rg3.[115] One hundred and ninety-nine patients were in the experimental group and treated with the standard first-line chemotherapy combined with Ginseng Rg3, and the 215 patients in the control group were treated with the same chemotherapy combined with placebo. The median overall survival was 12.03 months in the experimental group, which was significantly better than that in the control group (8.46 months). In addition, the combined therapy improved patients' symptoms and reduced chemotherapy-induced myelosuppression.

A randomized, double-blind, placebo-controlled study evaluated the effect of red ginseng on toxicity, health-related quality of life (HRQL), and survival after adjuvant chemotherapy in patients with epithelial ovarian cancer (EOC).[116] A total of 30 patients with EOC were randomly assigned to placebo (n = 15) and red ginseng groups (n = 15). All patients took placebo or red ginseng (3000 mg/day) for 3 months. Changes of genotoxicity, HRQL, and survival were compared between the two groups. In terms of HRQL, red ginseng was associated with improved emotional functioning and decreased symptoms of fatigue, nausea and vomiting, and dyspnea, reduced anxiety and interference affecting life, and improved daytime somnolence. However, there was no effect of red ginseng on prognosis of EOC. There were no differences in adverse events between placebo and red ginseng groups.

Cardiovascular Effects

In vitro and in vivo results show that ginseng has beneficial effects on cardiac and vascular diseases via several mechanisms including antioxidation, control of vasomotor function, modulation of ion channels and signal transduction, improvement of lipid profiles, adjustment of blood pressure, improvement in cardiac function and blood circulation, stimulation of nitric oxide generation, enhancement of vasomotor tone, and reduction in platelet aggregation (Fig. 99.6).[117]

From a clinical perspective, ginseng may offer some protection against atherosclerotic disease, further supporting its use as a general tonic. Its effect on improving arterial endothelial function is especially novel,[118] and may possess a blood pressure–regulating effect via improvement in the endothelial dysfunction underlying many cases of hypertension.[119] A systematic review that included nine randomized, double-blind, placebo-controlled clinical trials of ginseng provides positive evidence for the efficacy of KRG on reducing blood pressure in patients with prehypertension and hypertension in acute and long term.[120]

Ginseng administered to human subjects with hyperlipidemia was shown to reduce total serum cholesterol, triglycerides, and nonesterified fatty acid levels while raising serum high-density lipoprotein cholesterol levels. Platelet adhesiveness was also decreased.[121] These results in humans confirmed earlier studies on rats fed high-cholesterol diets.[122,123] The mechanism of action

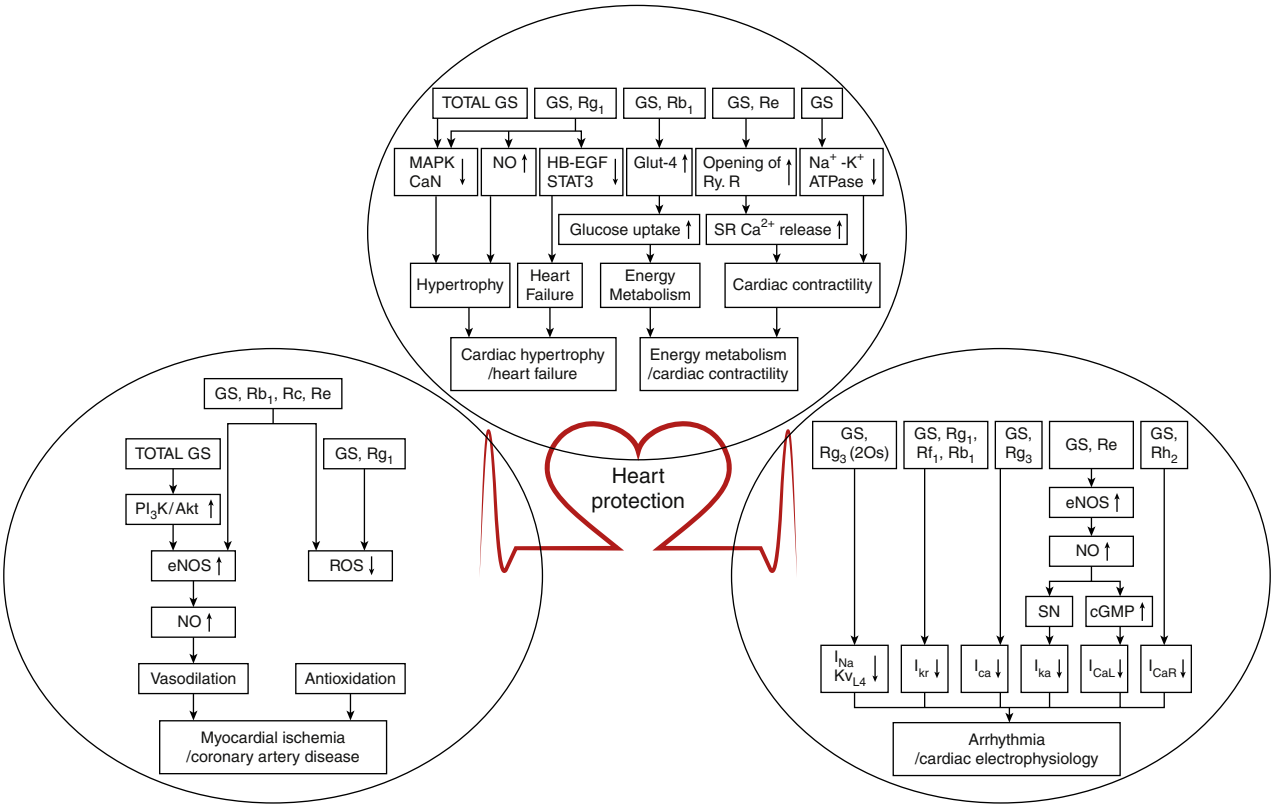

Fig. 99.6 Cardiovascular protection by ginseng and ginsenosides. *eNOS*, Endothelial nitric oxide synthase; *GLUT-4*, glucose transporter-4; *GS*, ginsenoside; *HB-EGF*, heparin-binding EGF-like growth factor; *ICa,L*, L-type calcium channel current; *ICa,R*, R-type calcium channel current; *IKr*, rapidly activating component of delayed rectifier K+ current; *IKs*, slowly activating component of delayed rectifier K+ current; *MAPK*, mitogen-activated protein kinase; *PI3K/Akt*, phosphoinositide 3-kinase/protein kinase B; *ROS*, reactive oxygen species; *RyRs*, ryanodine receptors; *SN*, S-nitrosylation of channel protein; *SR*, sarcoplasmic reticulum; *STAT3*, signal transducer and activator of transcription. appears to be accelerated degradation, conversion, and excretion of cholesterol and triglycerides despite increased lipogenesis and cholesterogenesis. Ginseng was also shown to be effective in inhibiting platelet aggregation and the conversion of fibrinogen to fibrin.[124]

Hepatic Effects

Adaptogenic substances must affect the liver because of this organ's central role in metabolic and detoxification reactions. Ginseng affects the liver in several ways. Several mechanisms of attenuating the damage to hepatocytes have been suggested by experimental and clinical studies of ginseng, including inhibition of cytotoxicity, inhibition of oxidative damage, and anti-inflammatory effects by reducing proinflammatory cytokines.[125] These complicated mechanisms can simultaneously affect the hepatoprotection. Perhaps most important is its ability to produce a marked hyperplasia of the Kupffer cells of the liver and of the folliculi in the spleen and lymph nodes. The hyperplastic folliculi show an increase in the number and volume of light centers, thus demonstrating morphological evidence of increased host defense capacity against a wide variety of external assaults. Because these cells are responsible for filtering out much of the toxins and debris from the portal circulation, increasing their number and activity could have profound effects.

Ginseng was shown to reverse diet-induced fatty liver in animals and to possess significant antihepatotoxic action.[126] In a clinical study that enrolled 26 Egyptian patients with hepatocellular carcinoma (HCC), the therapeutic effect of Korean red ginseng (KRG) was evaluated.[127] Liver function was assessed at 6 weeks and 11 weeks after oral KRG administration (600 mg/day). A significant decrease in the serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were found in patients who received KRG, but not in the control group. In addition, oral administration of KRG resulted in elevated serum albumin levels after 6 weeks of therapy. The same study also revealed KRG administration was associated with a decrease of alpha fetoprotein levels and a decrease in viral loads in patients with hepatitis C compared with control hepatitis C patients. A prospective, randomized clinical trial conducted to evaluate the antifatigue and anti-inflammatory effects of KRG in patients with nonalcoholic fatty liver disease found a significant decrease in the serum levels of alanine aminotransferase, aspartate aminotransferase, gamma-glutamyl transpeptidase, and proinflammatory cytokines in the KRG group compared with placebo.[128] The clinical indications of these hepatic actions of ginseng are quite broad and support its general tonic/adaptogen properties.

Ginseng was also shown to increase nuclear RNA biosynthesis, indicating greater protein synthesis.[3,115] Ginseng increased nuclear RNA synthesis ribosomal and messenger RNA, the amount of rough endoplasmic reticulum, and the activity of RNA polymerase.[3,129-131] These results indicate that ginseng activates virtually every step in protein biosynthesis. Because protein synthesis is often reduced in the elderly, the significance of the effects on enhancement of hepatic protein synthesis could be extremely high. However, results have yet to be confirmed by clinical studies.

Radiation-Protecting Effects

Ginseng was shown to offer some protection against harmful radiation, both in vivo and in vitro, and to hasten recovery from radiation sickness.[132,133] In the presence of ever-increasing environmental radiation contamination, ginseng may be an appropriate prophylactic against radiation exposure.

Antidepressant and Anxiolytic Effects

As a traditional Chinese medicine, *Panax notoginseng* has a long history of clinical value producing effects such as neuronal protection and inhibition of neuronal apoptosis. Research indicates that ginseng may also have antiinsomnia and antidepression effects, alleviate anxiety, and decrease neural network excitation. The main chemical components involved are *Panax notoginseng* saponins (PNS). A thorough review study showed PNS and its components may exert these effects by promoting the release of neurotransmitters (serotonin, dopamine, norepinephrine), modulation of gamma-amino butyric acid neurotransmission, increasing brain-derived neurotrophic factor by regulating multiple upstream neural signal transduction pathways in the CNS, and modulation of the HPA axis.[134] Moreover, PNS exerted antidepressant-like effects and neuronal protection by regulating the release of interleukin-1β, interleukin-6, tumor necrosis factor-α, and anti-inflammatory cytokines interleukin-4 and interleukin-10, leading to the preservation of brain nerves.

In an 8-week prospective study, 35 female outpatients aged 18 to 65 years (45.1 ± 9.5) who were remitted from major depression with residual symptoms were given KRG at doses of 3 g/day to determine the effectiveness and tolerability of KRG as an adjuvant treatment.[135] The Depression Residual Symptom Scale (DRSS) and Montgomery-Åsberg Depression Rating Scale (MADRS) were administrated to evaluate depressive symptoms. The general severity of symptoms was assessed by a clinician using the Clinical Global Impressions Scale for Severity (CGI-S), and the Depression and Somatic Symptom Scale (DSSS) was also used to evaluate somatic symptoms in the subjects. KRG treated individuals reported significant decrease in depressive symptoms on the DRSS, and MADRS decreased significantly over the 8-week period. The scores on the CGI-S, an objective measurement of symptoms, showed significant improvement in the severity of illness. Somatic symptoms on the DSSS also attenuated significantly during the study period. These results suggest that KRG is efficacious as an adjuvant treatment for patients experiencing residual symptoms of major depression.

Antiobesity

In cultured adipocytes, animals, and humans, ginseng and its ginsenosides may prevent/reduce obesity through several effects and mechanisms. Ginseng and ginsenosides may affect appetite, food digestion and absorption, gut microbiota, inhibit fat tissue formation (adipogenesis and angiogenensis), promote fat oxidation, improve leptin resistance, and promote energy expenditure (Fig. 99.7).[136] The adenosine monophosphate (AMP)-activated protein kinase (AMPK) is a key sensor of cellular energy. Once activated, it switches on catabolic pathways generating adenosine triphosphate (ATP) while switching off biosynthetic pathways consuming ATP. Inhibition of peroxisome proliferator-activated receptor-gamma/CCAAT/enhancer-binding protein-alpha (PPAR-γ/C/EBP-α) by ginseng contributes to its antiadipogenic effect, and through the activation of AMPK, metabolism is switched from anabolism to catabolism. Furthermore, peroxisome proliferator-activated receptor-alpha (PPAR-α) is activated downstream by AMPK and stimulates lipid oxidation and energy expenditure.

The antiobesity effect of ginseng may come from both American ginseng and Asian ginseng, but most studies using whole extract/juice in cultured cells, animals, and humans are from Asian ginseng. To investigate the effect of ginseng on gut microbiota, 10 obese middle-aged Korean women took *Panax ginseng* extracts (4 g/tablet, 2 tablets/day) for 8 weeks and assessment of body composition parameters, metabolic biomarkers, and gut microbiota composition was performed at baseline and at 8 weeks.[137] Significant changes were observed in body weight and body mass index; however, slight changes were observed in gut microbiota. The participants were then divided into two groups, the effective and the ineffective

weight loss groups, depending on weight loss effect, to determine whether the antiobesity effect was influenced by the composition of gut microbiota. The composition of gut microbiota was compared between the two groups. Before ginseng intake, significant differences of gut microbiota were observed between both at phyla and genera levels. Results of this study indicate that ginseng exerted a weight loss effect and slight effects on gut microbiota in all participants. In addition, its antiobesity effects differed depending on the composition of gut microbiota before ginseng intake. However, in another double-blind, placebo-controlled, randomized study, KRG powder (6 g/person per day, 12 weeks) did not change the body weight, percent body fat, and insulin sensitivity of overweight and obese adults who did not have diabetes or hypertension.[138]

Interestingly, ginsenosides have a very low bioavailability after oral intake, and only the deglycosylated forms of ginsenosides can be absorbed into the circulatory system. The transformation of ginsenosides is largely dependent on intestinal bacteria, which release various glycosidases to hydrolyze the sugar moieties of ginsenosides. Intestinal microflora varies among individuals, and approximately 20% of people cannot partially or fully transform ginsenosides.[139] This may explain the differing results attained in human-based research. More clinical trials are required to confirm the antiobesity effect of ginseng and individual ginsenosides.

Central Nervous System Effects

Animal models and cell cultures have demonstrated ginseng and its constituents produce beneficial effects on the CNS, including neuroprotection, improved cognition, and memory performance enhancement (Fig. 99.8). In models of neurodegenerative disorders, ginseng and ginsenosides have shown several benefits including[140]:

- Decrease Aβ production and aggregation, increase Aβ clearance, decrease of tau hyperphosphorylation, and improve cholinergic function in Alzheimer's disease
- Protection against neurotoxic damage and inhibition of α-synuclein aggregation in Parkinson's disease
- Protection against neurotoxic damage and inhibition of Ca^{2+} signaling in Huntington disease

TOXICOLOGY

The problem of quality control makes toxicology difficult to address. This is exemplified by a 1979 article in the *Journal of the American Medical Association* titled "Ginseng Abuse Syndrome."[141] In this

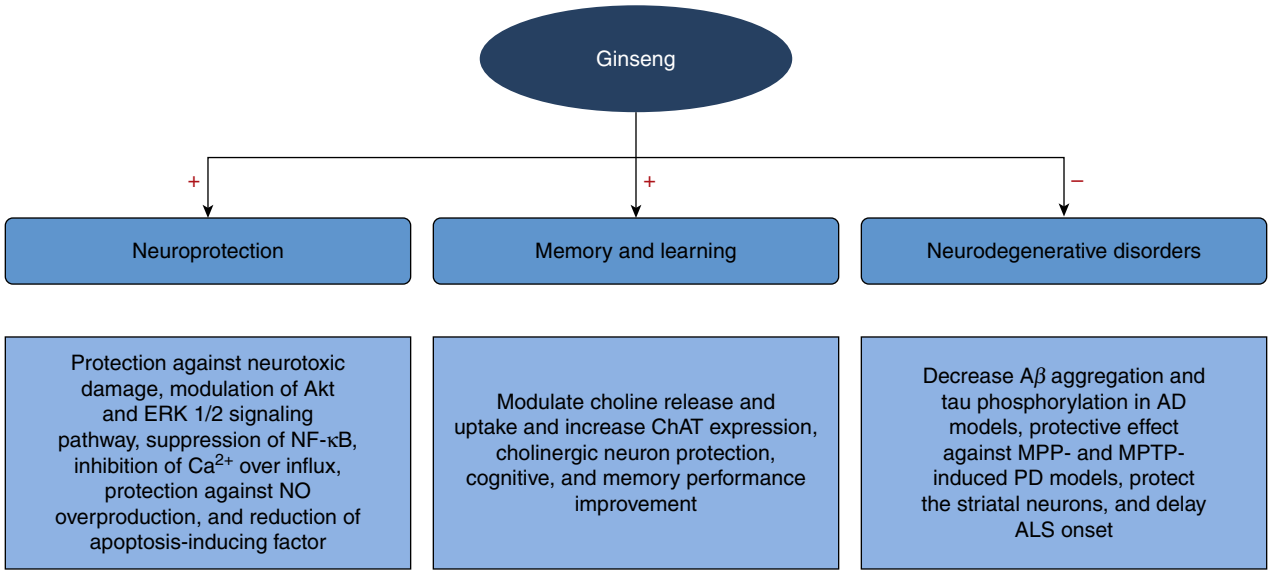

Fig. 99.8 Multiple therapeutic targets of ginseng and its metabolites in the central nervous system. *ERK 1/2*, Extracellular-signal-regulated kinases 1 and 2; *NF-κB*, nuclear factor-kappa B; *NO*, nitric oxide; *ChAT*, choline acetyltransferase; *Aβ*, β-amyloid; *AD*, Alzheimer's disease; *MPTP*, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; *MPP*, 1-methyl-4-phenylpyridium; *PD*, Parkinson's disease; *ALS*, amyotrophic lateral sclerosis. (From Rokot NT, Kairupan TS, Cheng KC, et al. A role of ginseng and its constituents in the treatment of central nervous system disorders. *Evid Based Complement Alternat Med.* 2016;2614742. PubMed PMID: 27630732.)

article, several side effects of commercial preparations of ginseng were reported, including:

- Hypertension
- Euphoria
- Nervousness
- Insomnia
- Skin eruptions
- Morning diarrhea

Given the extreme variation in quality of ginseng in the American marketplace and the use of both nonofficial parts of the plant and adulterants, it is not surprising that side effects were noted. None of the commercial preparations used in the trial were subjected to controlled analysis. Furthermore, the species of ginseng used included *P. ginseng, Panax quinquefolius, Eleutherococcus senticosus,* and *Rumex hymenosepalus* in a variety of different forms—roots, capsules, tablets, teas, extracts, cigarettes, chewing gum, and candies. It is virtually impossible to derive any firm conclusions from the data presented in the *JAMA* article. An important caveat is that these ginseng abuse syndrome effects are neither uniformly negative nor uniformly predictable. Nevertheless, long-term ingestion of large amounts of ginseng should be avoided, as even a panacea can cause problems if abused.

Studies performed on standardized extracts of ginseng demonstrated the absence of side effects and mutagenic or teratogenic effects.[142-144] These studies differed markedly from the trial reported in *JAMA,* in that high-quality extracts were used. An extensive review of the safety of *P. ginseng* concluded, "Data from clinical trials suggest that the incidence of adverse events with ginseng monopreparations is similar to that with placebo."[141] In addition, a systematic review conducted to assess the safety of ginseng in randomized controlled clinical trials concluded that *Panax ginseng* showed a very safe profile with no statistical significance between ginseng and placebo groups on the frequency or symptoms of adverse events, and no serious or severe adverse events reported.[145]

DOSAGE

The dosage of ginseng is inversely proportional to the ginsenoside content; that is, if an extract or ginseng preparation contains high concentrations of ginsenosides (and presumably other active components), a lower dose suffices. The standard dose for ginseng ranges between 4.5 to 6 g/day.

Currently, there is almost a total lack of quality control in ginseng products marketed in the United States. Independent research and published studies clearly documented a tremendous variation in the ginsenoside content of commercial preparations. Many products on the market contain only trace amounts of ginsenosides, and some formulations contain no ginseng at all. This situation has led to several problems, ranging from toxicity reactions to lack of medicinal effect. The widespread disregard for quality control in the health food industry has done much to tarnish the reputation of ginseng as well as other important botanicals.

We recommend the use of standardized ginseng preparations to ensure sufficient ginsenoside content, consistent therapeutic results, and reduced risk of toxicity. Products should be standardized in their ginsenoside content. The typical dose (taken one to three times daily) for general tonic effects should contain a saponin content of at least 5 mg of ginsenosides with a R_{b1}/R_{g1} ratio of 2:1. For example, for a high-quality ginseng root powder containing 5% ginsenosides, the dose would be 100 mg.[144]

Because each individual's response to ginseng is unique, the patient should be monitored for signs of possible ginseng toxicity. It is best to begin at a lower dose and increase it gradually. The Russian approach for long-term administration is to use ginseng cyclically for a period of 15 to 20 days followed by a 2-week interval without any ginseng.

DRUG INTERACTIONS

Taking ginseng preparations may increase the effectiveness of insulin and drugs that lower blood sugar levels such as glyburide (Diabeta, Micronase). It is important to discuss proper monitoring of blood sugar levels with patients who have diabetes before prescribing ginseng. *P. ginseng* may potentiate the monoamine oxidase inhibitor phenelzine (Nardil) to produce manic-like symptoms.[144]

Ginseng may reduce the effectiveness of Coumadin (warfarin). In one double-blind study designed to evaluate the interactions between American ginseng and Coumadin (warfarin), 20 healthy volunteers received warfarin for 3 days during weeks 1 and 4.[146] Beginning in week 2, patients were assigned to receive either American ginseng or placebo. The peak international normalized ratio statistically significantly decreased after 2 weeks of ginseng administration compared with placebo, with the difference between ginseng and placebo being zero. The international normalized ratio area under the curve, peak plasma warfarin level, and warfarin area under the curve were also statistically significantly reduced in the ginseng group compared with the placebo group. These results indicate a potential for ginseng reducing the effectiveness of warfarin. However, in a study in stroke patients, no interaction was noted.[147] Korean ginseng and American ginseng have different ginsenoside profiles, and the heterogeneous composition of compounds among the types of ginseng might have led to different results. Until this interaction is further clarified, ginseng should only be used with careful monitoring, if at all, in patients on Coumadin.

Pancreatic Enzymes[213]

Anthony J. Cichoke Jr., BS, BS, MA, MA, PhD, DC, DACBN

OUTLINE

INTRODUCTION

Pancreatic enzymes produced by the body are well known for the integral role they play in the digestion of the foods we eat. Pancreatic juice contains numerous enzymes, including amylase, lipase, cholesterol esterase, and phospholipase, and the proenzymes trypsinogen, chymotrypsinogen, and procarboxypolypeptidase, which are converted in the small intestine to their active forms trypsin, chymotrypsin, and carboxypeptidase, respectively.[1]

Foods in the human diet are composed primarily of macronutrients, that is, protein, carbohydrates, and fats. Protein leaves the stomach predominantly in the form of proteoses, peptones, and large polypeptides.[1] Upon reaching the small intestine, these are further digested by the proteolytic enzymes trypsin, chymotrypsin, and carboxypolypeptidase. Protein digestion primarily occurs in the duodenum and jejunum. Carbohydrates are digested by α-amylase in the pancreatic juice, which breaks starches (converting them into maltose and other small glucose polymers), whereas pancreatic lipase, cholesterol esterase, and phospholipase digest fats.[1]

Pancreatic enzyme supplements (which include chymotrypsin, trypsin, amylase, lipase, pancreatin, and combinations of one or more) not only aid digestion but also assist in a surprising variety of bodily functions including detoxification, immunity, aging, blood fluidity, and tissue repair. Unfortunately, an inadequate production of, or an excessive requirement for, pancreatic enzymes can occur for a variety of reasons including genetics, illness (including cystic fibrosis, chronic pancreatitis, and pancreatic cancer), surgery (such as after pancreatectomy or gastrointestinal bypass surgery), injury, exercise, aging, and toxins (both endogenous and exogenous). A deficiency of pancreatic enzymes, for whatever reason, may be the cause of numerous illnesses and degenerative conditions. When a deficiency occurs, enzymes from an external source may be necessary.

History

Pancreatic enzymes have a long history of clinical use. In the early 20th century, John Beard, a Scotch embryologist, successfully treated cancer using a pancreatic extract, which he described in his book *The Enzyme Treatment of Cancer and Its Scientific Basis.* Beard injected pancreatic juice (freshly extracted from young animals) into cancer patients and, when possible, directly into their tumors. He found that the pancreatic juice could inhibit the growth of cancer cells.

In 1934, Dr. Ernst Freund, a Viennese physician, studied the blood of people who were free from cancer and discovered a substance that had the ability to dissolve cancer cells. Patients with cancer did not have this material, which Freund called "normal substance." In the early 1930s, Professor Doctor Max Wolf worked with Freund in Vienna and successfully identified "normal substance" as an enzyme that decomposes fatty materials and proteins. For his work in the field of enzymes Wolf is generally considered the father of modern enzyme therapy. The work of Freund and John Beard sparked Wolf's interest in the possibilities of treating malignant diseases with enzymes. He subsequently founded the Biological Institute of New York City and, after studying various enzymes and enzyme combinations, developed what he regarded as an optimal preparation for the treatment of various acute and chronic conditions. His preparation was a combination of a

fractionated hydrolysate of beef pancreas, calf thymus, *Pisum sativum* (common pea), *Lens esculenta* (edible lentil), mannitol, and *Carica papaya* (papaya, a source of the enzyme papain).

In the 1960s, Irving Innerfield conducted landmark research in the area of pancreatic enzymes, primarily relating to the clinical use of trypsin, chymotrypsin, and pancreatin as well as streptokinase (a microbial proteolytic enzyme). Professor Heinrich Wrba, who for many years was head of the Austrian Cancer Research Institute at the University of Vienna, believed that enzyme therapy should be considered a highly effective causal anticancer compound. Dr. Wrba's interest in cancer was piqued when he lost a daughter to leukemia. He devoted his life to educating oncologists in Germany and around the world about enzyme therapy.

It was the late Karl Ransberger, however, who continued and refined Wolf's research, bringing it to doctors, hospitals, and patients throughout the world. Ransberger encouraged and funded research projects in numerous hospitals and universities in Europe, the Americas, and elsewhere. His research, and that of others, validated enzyme therapy's effectiveness in treating numerous conditions, including arthritis,[2,3,4] cancer,[5,6] multiple sclerosis,[5–9] cardiovascular disease,[6,10,11] and human immunodeficiency virus (HIV).[12–14]

PANCREATIC ENZYME SUPPLEMENTS

The pancreatic enzyme supplements commonly used in health care are chymotrypsin, trypsin, pancrelipase, and pancreatin. Chymotrypsin and trypsin are proteolytic enzymes that break proteins into peptides. Chymotrypsin liberates the amino acids L-tyrosine, L-tryptophan, and L-phenylalanine and other molecules, including several synthetic esters and amides.[15] Trypsin hydrolyzes primarily lysyl and arginyl residues. Pancreatin contains amylase (which breaks down starch), lipase (which breaks down fats), and protease (which breaks down proteins). Pancrelipase is similar to pancreatin, but with a higher concentration of lipase.

These enzymes are primarily obtained from hog or ox pancreas, but some (such as lipase) can also be obtained from microbial sources (e.g., *Aspergillus niger* and *Aspergillus oryzae*). Nevertheless, only enzymes isolated from animal pancreatic glands can be considered pancreatic enzymes.

According to the *U.S. Pharmacopeia* (USP), chymotrypsin and trypsin are routinely crystallized from ox pancreas gland extract, and pancreatin from both hog and ox sources, whereas pancrelipase is derived from hog pancreas. [16]Porcine pancreas is especially rich in amylase and lipase and is similar to the human pancreas.[15] Bovine pancreas contains considerable amounts of proteolytic enzymes but substantially lower amounts of lipase and amylase.[15] Germany, Japan, England, India, and other countries use their own pharmacopeia, and foreign companies may use other sources to formulate their enzyme products.

Enzyme concentration and activity levels can vary depending on the age, sex, and species of pork or ox used to produce the supplement. For example, sow glands (from pork) are high in lipase, whereas butcher hogs (young male hogs, up to 90 kg in weight and 6 months of age) are high in protease. Beef cows and bulls have different enzyme levels from those in steers or heifers. Beef, although it provides all three basic enzyme types, does not exhibit the activity levels of pork (which has an activity level one-third to one-half higher). Furthermore, the physiology of hogs is more similar to that of humans than to that of any other animal.

Enzymes extracted from animal sources are sensitive to environmental changes, so manufacturers take particular care during extraction to control pH (usually with buffers), temperature (using precooled solutions and apparatus), substrate, and proteolysis (controlled through the use of inhibitors) to render a product that is enzymatically active.[17]

Enzyme Standardization

In 2010, the U.S. Food and Drug Administration (FDA) began requiring manufacturers of pancreatic enzyme products to test them in clinical trials if those products were prescribed to treat individuals with pancreatic diseases. Until that time, there were frequent inconsistencies in enzyme formulation. For example, a study of six different enzyme preparations found that, in some cases, the actual lipase activity in a product was more than twice that listed on the label.[18] Another study on nine pancreatic enzyme products found that, although within USP limits, the percentage of lipase activity after dissolution was not always equal.[19] These inconsistencies in content and activity level could unexpectedly alter patient enzyme requirements.

The FDA's ruling ensures that pancreatic enzymes are standardized with a consistent activity level. Pancreatic enzymes marketed as dietary supplements, however, do not require testing or approval by the FDA. The requirements regarding activity level apply only to those pancreatic enzyme products prescribed for exocrine pancreatic insufficiency due to cystic fibrosis (CF), chronic pancreatitis, and other conditions.

ABSORPTION OF PROTEINS

In the past, it was believed that the intestinal epithelial mucosa was impermeable to large protein molecules.[20] However, research over the past several decades has shown that the intestinal epithelium can be crossed by macromolecules, including intact proteins such as proteolytic enzymes.[21]

These macromolecules normally penetrate the mucosal surface via the transcellular route because, in healthy mucosa, the tight junctions (zonula occludens) between the enterocytes prohibit paracellular passage.[22] Binding to the luminal membrane of the enterocyte is followed by phagocytosis.[23] Some of the vacuole membrane vesicles formed fuse with lysosomes, and within the resulting phagolysome the peptides and proteins may be hydrolyzed by lysosomal enzymes.[24] Other macromolecules avoid intracellular digestion and are passed from the enterocytes through the basolateral membrane into the interstitial space.[25] In the interstitial space, the macromolecules become available to macrophages and lymphoid cells.[26] Those molecules not taken up by macrophages or lymphatic cells eventually pass from the interstitial space into the blood or lymph.[27]

The exact level of the intestinal absorption of intact molecules or large breakdown products of dietary proteins is not yet totally clear and can vary by individual.[28] Although it is generally assumed that, apart from a very small proportion, all protein is hydrolyzed into amino acids or low-molecular-weight peptides before absorption by the mucosa, some research supports the hypothesis that a considerable proportion of dietary protein is taken up in the form of macromolecules and is only then hydrolyzed intercellularly in the peripheral tissue into amino acids (a process called *distributed digestion*).[29]

Understanding the Absorption of Enzymes

Understanding the intestinal transport of macromolecules is especially important for understanding the functions and absorption of enzymes, specifically. Hydrolases, such as trypsin or elastase, can be transported functionally intact into the bloodstream from the lumen of the gut. These circulating proteinases are bound to antiproteinases, such as $alpha_2$ macroglobulin or $alpha_1$ antiproteinase,[30] and can be resorbed

from the main bloodstream by pancreatic cells (enteropancreatic circulation as an enzyme conservation process).[31] Thus the intestinal absorption of intact enzymes appears to be important for the balance between hydrolases and antiproteinases in the intracellular space[32] and is an important factor for the establishment and maintenance of the internal stability in the body.

Although there are a number of absorption mechanisms, the primary mechanism for the enteral absorption of enzymes and other macromolecules is pinocytotic transfer by the M-cells of the small intestinal epithelium.[33] The enzymes connect to a receptor in the intestinal wall mucosa and are then absorbed into the wall by pinocytosis, guided through the intestinal cells in vesicles, and finally released into the blood by exocytosis.[33]

To clarify the rate of absorption, Steffen et al.[34] investigated the absorption of an enzyme mixture "A" (EMA), which contained 100 mg of pancreatin, 60 mg of papain, 10 mg of lipase, 10 mg of amylase, 24 mg of trypsin, 1 mg of chymotrypsin, 45 mg of bromelain, and 50 mg of the bioflavonoid rutin, in rabbits. Using electrophoresis, these researchers found that entire enzyme molecules were absorbed. Although enzyme particles were also present, the ratio to the entire amount administered was not measured. EMA was found in both the lungs and the liver after 1 to 2 hours. After 1 to 4 hours, approximately twice as much EMA was found in the liver as in the lungs. The absorption maximum in all animals occurred approximately 1 hour after administration. Within 6 hours, the absorption rate of orally ingested EMA was about 20%.[35] After 24 hours, EMA was no longer found in either the lungs or the liver.

FACTORS AFFECTING ENZYME ACTIVITY

Numerous factors, including pH, temperature, substrate (and substrate concentration), cofactors, metal ions, inhibitors, and coating, can affect the activity of supplemental enzymes.

Optimal pH Range

Each enzyme has an optimal pH range, depending on such variables as the temperature and substrate concentration at which the enzymatic catalytic reaction occurs most rapidly. Chymotrypsin has an optimum pH of 8.0, has reversible denaturation at a pH below 3.0, and becomes inactive at a pH above 9.0.[15] Trypsin has an optimum pH between 7.0 and 9.0, is stable at a pH of 3.0 (and at low temperature), and is irreversibly denatured at a pH of 9.0 or higher.[15] The pH of the normal human stomach is 1.5 to 3.0,[36] low enough to denature or inactivate some or all of a pancreatic enzyme supplement if it is not enterically coated or otherwise treated to protect it from a low-pH environment.

The Effects of Temperature

In general, an increase of 18°F (10°C) in the enzymatic environment approximately doubles the rate of the chemical reaction.[37] However, because enzymes are proteins, excessively high temperatures can denature them, thus destroying their activity. The optimum temperature for an enzyme is the temperature at which the catalyzed enzymatic reaction progresses most rapidly without damage to the enzyme. This temperature can vary by enzyme. This is a good rationale for avoiding hot beverages when taking enzyme supplements.

The enzymes in the human body develop high levels of activity at about body temperature, increasing to maximum at about the temperature of a severe fever, that is, 104°F (40°C).[37]

Substrate Concentration

The rate of any reaction is accelerated by raising the substrate concentration until the enzyme is saturated by substrate. At this level, the rate of reaction becomes independent of substrate concentration and is no longer accelerated by the addition of more substrate. This is why it is particularly important to ingest sufficient quantities of supplemental enzymes (which vary according to the condition being treated).

Cofactors

Although all enzymes consist of protein, some are complex proteins; that is, they have a protein component and a *cofactor*. If the cofactor is removed, the protein (no longer active enzymatically) is called the apoenzyme. A cofactor might be a metal (e.g., iron, magnesium, copper, or zinc), a prosthetic group (a moderately sized organic molecule), or a coenzyme (small organic compound). Prosthetic groups and metals can aid in the catalytic function of the enzyme, whereas coenzymes take part in the enzymatic reaction. Many vitamins, trace elements, and minerals essential to human bodily function are part of enzymatic cofactors. Thus the physician must ensure that his or her patients take multivitamins and multiminerals to "feed" their enzymes.

Coenzymes are essential for the activity of many enzymes and serve as a type of substrate in certain reactions. In these reactions, the coenzyme is converted to a form no longer active in catalyzing the reaction.

Metal Ions

Specific metal ions are required for the activity of many enzymes. Some metal ions increase enzyme activity, and others decrease or inhibit it. Calcium, cobalt, copper, iron, magnesium, manganese, molybdenum, potassium, and zinc are the most common enzyme activators in humans. Certain heavy-metal ions inhibit enzyme reactions; they are barium, lead, and mercury, and they combine with the sulfhydryl reactive group (−SH) that is part of the active site of many enzymes.

Inhibitors

Ions, atoms, or molecules that terminate or retard enzyme activity are called inhibitors. They are classified as either noncompetitive or competitive. A noncompetitive inhibitor combines with the enzyme at a location other than the active site. The noncompetitive inhibitor retards the conversion of the substrate by the enzyme, although it does not affect the bonding of the substrate of the enzyme. An inhibitor is classified as competitive if it combines with the active site of the enzyme, preventing the substrate from having access to the active site.

Supplement Coating

The pH of the stomach's hydrochloric acid secretions is about 0.8.[1] This low pH inhibits bacterial growth and activates certain enzymes. This acidic nature, however, can destroy pH-sensitive supplemental enzymes. For this reason, many enzyme products are enterically coated. This coating allows the product to reach the small intestine before disintegrating. Other products are encapsulated in "microspheres," delaying disintegration. For example, pancreatic protease encapsulated with a mixture of cellulose acetate phthalate and maize starch can remain stable in simulated gastric conditions (pH of 3.97) for at least 3 hours.[38] This would theoretically provide enough time for the capsule to pass through each part of the gastrointestinal tract. The capsule then disintegrates rapidly under pH 6.82 and temperature of 39.5°C (as would occur in the small intestine).[38]

Nanotechnology is opening a new field for the delivery of enzymes and other small proteins. Nanotechnology is the study of matter as small as 1 billionth of a meter. According to the National Nanotechnology Initiative, nanoparticles are being used in timed-release drug delivery.[39] Enzymes can be attached to nanoparticles and actually maneuvered to destroy diseased cells. Research on nondegradable nanocapsules showed that proteins can be efficiently transported to individual cells, surviving different pH levels.[40] So, it is no wonder that enzymes (which are proteins) can also be attached to nanoparticles and used to treat disease at the cellular level.

MEASURING ENZYME ACTIVITY

When considering enzymes and enzyme applications, the physician must understand the variables affecting their performance. The selection of an enzyme for therapeutic purposes requires more than knowing whether a given product contains amylase, protease, lipase, or other enzymes. The activity levels of the enzymes are critical.

As mentioned previously, the manufacturers of pancreatic enzymes prescribed to treat specific conditions must clearly disclose content and enzyme activity levels. Unfortunately, the same is not true of enzyme products sold as dietary supplements, whose labels may not indicate enzyme activity levels. In addition, even when the activity is stated, the consumer has no way of knowing which enzyme assay the manufacturer used unless the label also indicates that the product conforms to the guidelines of the USP. This is particularly confusing because activity levels are greatly affected by the conditions under which the assay was performed (including temperature, pH, and substrate).

Adding to the confusion, enzyme manufacturers use diverse assay methodologies, making a direct comparison of competing products difficult, if not impossible. Using a single assay system (such as detailed in the USP) is necessary to directly compare competitive products. Several standardized assay systems are available for enzyme suppliers and are found in the USP (for a definitive assay), the *NFIA Laboratory Methods Compendium,* and the *Food Chemical Codex.*

Incomplete labeling and the inconsistent use of standardized assay methodologies make evaluating competitive products extremely challenging. Price could be the first indication of inequities in assay procedures. For example, if company A is selling a product at 1000 U/g for $30 a bottle, and company B is selling a product at 5000 U/g for $10 a bottle, the units are most likely not the same.

For clinical reliability, one must use only appropriately labeled products or obtain the assay procedures from each of the manufacturers. If possible, competitor products should be compared by means of assays performed in an independent laboratory.

CLINICAL APPLICATIONS

Historically, enzyme therapy has been used in a wide variety of applications, ranging from oral supplementation to treat pancreatic insufficiency to the centuries-old external application of enzymes to treat leg ulcers, topical wounds, wrinkles, blemishes, episiotomies, scars, and so on. Usually administered in capsules or tablets, enzymes are also available as lozenges (dissolved in the mouth) or in powder form. Topical enzyme ointment is currently used to debride necrotic tissue and other wound debris. Enzymes can also be administered by injection (normally in a hospital setting because of the risk of anaphylactic reaction) or rectally, by retention implant.

Enzymes can be used individually but are typically more efficacious when used in combination with other enzymes. An enzyme combination has numerous therapeutic advantages over a preparation with only one or two components. Combining enzymes from different sources—animal, plant, and fungi—results in a wider range of optimal pH, synergism of the combined enzymes, greater absorption, higher level of efficacy, and broader range of application. For example, one German product contains an enzyme extract consisting of proteinases, triacylglycerol lipase, and alpha-glycosidase (amylase); minor amounts of elastase, nuclease, and carboxypeptidase; and calcium ions to boost activity.

Dr. Peter Streichhan, a well-known enzyme researcher, stated that certain enzymatic mixtures have a broader range of action than pancreatin, bromelain, or any other standardized monohydrolytic preparation—this is because certain enzyme mixtures characteristically possess differences in optimal pH and also differences in reactive properties of the proteolytic, lipolytic, and/or amylolytic-acting hydrolases.[41]

BOX 100.1 Clinical Applications of Chymotrypsin

- Debridement, treatment of abscesses and ulcerations, liquefaction of mucous secretions[95]
- Ophthalmic cataract surgeries and therapy of eyeball hematomas and ophthalmorrhagias[95,96]
- Before and after tooth extractions, as well as in operative dentistry[97,98]
- After episiotomy procedures[99]
- As an anthelmintic against enterozoic worms[100]
- Early recognition of tumor cells[101]
- Histologic gastroenterology diagnostics[102]
- Inflammatory conditions (local and systemic) to promote the dispersion of blood extravasates and effusions from fractures[96,103–110]
- Surgical trauma[99,108]
- Sporting injuries[103–117]
- Accidental soft tissue trauma[103–117,110]
- Intervertebral disc lesions[111]
- Uveitis vitreous hemorrhage, diabetic retinopathy, and asthmatic symptoms[112]

BOX 100.2 Clinical Applications of Trypsin

- Debridement of necrotizing wounds, ulcerations, abscesses, empyemas, hematomas, fistulas, and decubitus[113-116]
- To accelerate healing in injuries, inflammations, phlogistic edemas, and traumatic changes[103–110]
- As an auxiliary agent in meningitis therapy[117]
- As an ointment or dressing (wet or dry)[15]
- As a liquid or an aerosol to liquefy sputum in bronchial disorders and in the preparation of sputum for cytological examination[15]
- As an anti-inflammatory agent; oily suspensions are injected intramuscularly[15]
- As an aid in the treatment of intraocular hemorrhage, thrombophlebitis, intestinal obstruction (due to cirrhosis or carcinoma)[118]

BOX 100.3 Clinical Applications of Amylase

- Needs calcium ions for enzymatic activity
- Acts on starch, glycogen, and related poly- and oligosaccharides[119]
- In combination with other enzymes, as a digestant[95,120,121]
- As an anti-inflammatory[120]
- Treatment of deficiencies of exocrine pancreas, amylaceous dyspepsia, and cystic fibrosis[15]

It should be remembered that at the beginning of therapy, an individual's symptoms may occasionally become more severe. This is a sign that a therapeutic reaction is occurring and should be evaluated positively. The medication does not need to be discontinued, although a temporary reduction in dose might be advisable.

Clinical uses of individual enzymes can be found in Boxes 100.1 through 100.5, whereas clinical uses of combinations can be found in Box 100.6. For more information on how enzymes can treat more than 150 conditions, please see the author's book, *The Complete Book of Enzyme Therapy.*

Most conditions treated by enzymes can be assigned to one or more of the following categories:

- Digestive conditions
- Inflammatory conditions
- Cancer

BOX 100.4 Clinical Applications of Lipase

- In pancreatin-containing remedies to increase pancreatic/lipolytic activities (replacement therapy)[122–125]
- When given with pancreatin (in combined preparations), reduces fat level in stools[126–128]
- Synergistically intensifies the activity of lipoprotein lipase in the blood[129] and migration of agranulocytes[130]
- As a digestive aid[128]

BOX 100.5 Clinical Applications of Pancreatin

- In pancreatic insufficiency, inadequate secretion of exocrine pancreas, disturbed digestion, and after gastrectomy[66,123,131-142]
- In chronic pancreatitis[143] and after surgery for chronic pancreatitis[144]
- After pancreatectomy[15,143]
- In ductal obstruction from neoplasm (e.g., of the pancreas or common bile duct)[143]
- To treat severe cases of steatorrhea (as found in cystic fibrosis)[145–150]

BOX 100.6 Clinical Applications of Enzyme Combinations

- Soft tissue injuries[73,151]
- Sprained ankle[73,152,153]
- Tendonitis[47]
- Reabsorption of hematomas[151,154]
- Sports medicine[50,155–162]
- Meniscectomy (pre- and postoperative therapy)[163,164]
- Traumatology[165]
- Fractures[48,49]
- Pancreatitis[166]
- Surgery[151,167]
- Lower extremity bypass surgery[168]
- Operative dentistry[169]
- Proctology[170]
- Sinusitis[2,171–173]
- Acute and chronic bronchitis[6,70,174]
- Cystitis and lower urinary tract infections[2,175,176]
- Prostatitis[2,176,177]
- Pelvic inflammatory disease[178,179]
- Postthrombotic syndrome[3,180–183]
- Pathological venous processes[180,184–188]
- Occlusive arterial disease[189]
- Lymphedema[4,63,190–194]
- Soft tissue rheumatism (nonarticular rheumatoid syndrome)[71,72]
- Rheumatoid arthritis (chronic polyarthritis)[2–4,52,69,70,74–76,195–206]
- Ankylosing spondylitis (Bekhterev's disease)[73–76]
- Degenerative rheumatic joint disease[2,158]
- Monoarticular, activated osteoarthrosis[158,174,207]
- Multiple sclerosis[5–9,79,208,209]
- HIV infections[12–14,210,211]
- Sepsis[83]
- Fibrocystic breast disease[193,212]
- Ulcerative colitis and Crohn's disease[2,6,9,70]
- Autoimmune or immune disorders
- Cardiovascular disorders
- Viral and bacterial disorders
- Other conditions

Digestive Disorders

Supplementing the diet with pancreatic enzymes can improve food digestion and therefore nutrient assimilation. This is especially true if the body's own pancreatic enzyme production and/or supply is deficient, as can occur with age or because of an underlying health condition, such as cystic fibrosis (CF), chronic pancreatitis, pancreatic insufficiency, steatorrhea, biliary tract disease, or celiac disease. Pancreatic enzymes have a long history of use in treating those conditions, as well as indigestion, heartburn, gas, diarrhea, constipation—the list seems endless.

Patients with CF are routinely prescribed pancreatin or pancrelipase capsules containing enterically coated beads. A hereditary disease, CF involves a disorder of the exocrine glands and causes the production of thick mucus, which leads to obstructions in various glands and ducts in the body. When the mucus affects the lungs, it leads to severe coughing and repeated lung infections, including bronchitis and pneumonia. When the mucus obstructs the pancreatic duct, it prevents the enzyme-rich pancreatic juice from reaching the intestine, negatively affecting food digestion and nutrient absorption. This can result in malnutrition, weight loss, steatorrhea (fatty stools), or intestinal obstruction. Poor digestion affects approximately 90% of all CF patients.[42]

Although critical for proper digestion in those with CF, enzyme supplementation can also improve digestion and nutrient absorption in those with chronic pancreatitis, a condition marked by weight loss, steatorrhea, and abdominal pain and swelling. By improving nutrient absorption, enzymes can improve serum albumin levels (low levels reflect protein-calorie malnutrition),[43] improve steatorrhea,[44] and, thereby, increase weight gain[43] in these subjects.

Even healthy individuals can benefit from taking enzymes because enzyme supplementation can improve the digestion of carbohydrates, proteins, and fats. For example, a study on healthy individuals found that ingesting an acid-resistant lipase supplement immediately after eating a high-fat meal (comprising 55% fat) reduced the feeling of stomach fullness that typically follows such a meal.[45]

Inflammatory Diseases and Conditions

The inflammatory process is involved in numerous diseases and conditions, from sports injuries to arthritis to sinusitis to fibrositis. Whenever an injury or infection (regardless of the cause) occurs, a number of repair mechanisms are activated, resulting in microthrombi and fibrin surrounding the traumatized region. The fibrin web cuts off normal circulation, resulting in stasis and inhibiting the repair process (nutrients cannot get into the damaged area, and waste products cannot be removed). This, in turn, leads to increased pressure in the capillaries, causing fluid to be forced out into the surrounding tissue, resulting in swelling and pain. Supplemental enzymes, after absorption, circulate through the bloodstream to the affected area and have been shown to reduce several of the proinflammatory cytokines while increasing anti-inflammatory cytokines.[46] The enzymes attack the microclots and fibrin formation, effectively lysing the fibrin, breaking open the clogged vessels, and reestablishing circulation. The resulting restoration of normal blood flow leads to a faster resolution of postinflammatory pain and edema. Equally important, the essential physiological inflammatory repair process is not blocked or diminished (as with anti-inflammatory agents), but rather is accelerated and reinforced.

In a Canadian study, postal workers with rotator cuff tendonitis were treated with either naturopathic care (NC), which included

dietary counseling, acupuncture, and an enzyme supplement (containing bromelain, trypsin, and rutin), or with physical exercise (PE), which included exercise and placebo.[47] Those participants on the NC therapy saw a decrease in their shoulder pain and disability of over 54% (as measured by Shoulder Pain and Disability Index) compared with 18% in the PE group. The NC group also had significant improvement in range of motion compared with the PE group.[47]

Fractures often require surgery to repair the broken bone. Czech researchers followed the progress of 60 patients after surgery for repair of long-bone fractures. Thirty patients received an enzyme mixture (containing trypsin, bromelain, and rutin), whereas another 30 patients were treated by standard antiedema drugs. Both groups received the same pain medicine. The group that received the enzyme mixture had a significantly faster reduction in posttraumatic and postoperative swelling. In addition, those taking enzymes consumed significantly fewer painkillers.[48]

A similar study in Russia using an enzyme mixture on children with fractured long bones found that swelling and pain subsided twice as fast in the enzyme group as in the group receiving traditional therapy.[49]

Intense exercise can lead to soft tissue injury, inflammation, and muscle soreness. Researchers found that supplementing with protease mixtures could help ease muscle soreness and assist muscle healing after exercise.[50] A similar study[51] conducted a randomized, placebo-controlled clinical trial to determine the effect of systemic enzyme therapy on exercise-induced inflammation.[51] Compared with placebo, the enzyme therapy was superior in reducing biomarkers of inflammation in all study subjects.

Even inflammatory diseases, such as arthritis[52] and herpes zoster,[53] were shown to respond to the systemic application of enzymes. A double-blind, randomized study compared an oral enzyme mixture (containing trypsin, bromelain, and the bioflavonoid, rutin) with diclofenac (a nonsteroidal anti-inflammatory drug frequently prescribed for osteoarthritis and rheumatoid arthritis).[54] Ninety patients received either the enzyme mixture or the diclofenac for a 6-week period. Results indicated that the enzyme mixture was just as effective as diclofenac.

A similar study on 150 patients with moderate to severe knee osteoarthritis compared the effect of an enzyme combination (containing trypsin, bromelain, and rutin) with that of diclofenac.[55] Those patients taking the enzyme combination experienced a significant improvement in joint pain, function, and joint flexibility. According to the researchers, the enzyme treatment was as effective as diclofenac with fewer potential side effects.

Individual enzymes and enzyme combinations (particularly those including trypsin, chymotrypsin, pancreatin, amylase, lipase, papain, and bromelain, with rutin) are effective in treating inflammation because they help limit the injury, aid its rectification, and promote new, healthy tissue formation. Enzymes effectively accelerate the inflammatory process (a necessary component of wound healing). This acceleration means, on the one hand, that the work of damage control, damage repair, and new tissue construction is carried out more actively, and thus completed more swiftly. On the other hand, it means that there can be a temporary increase in the visual and sensory effects produced by the inflammation (i.e., more redness, swelling, heat, and pain).

Despite the supportive research, the administration of enzymes in traumatology and injuries is not widely used in the United States, which is in contrast to Europe, where all types of injuries—sprains, strains, hematomas, dislocations, and even postoperative conditions—are effectively treated with enzymes. Although the inflammatory process is involved in viral and bacterial infections, those disorders are covered in the "Viral and Bacterial Disorders" section within this chapter.

Cancer

Just as Beard researched the effects of enzymes on cancer, so have modern researchers. Dr. William Kelley devised an anticancer program that employed detoxification, pancreatic enzymes (and other nutritional supplements), improved enzyme-rich nutrition, and coffee enemas.[56] He initiated his treatment program in response to his own bout with pancreatic cancer. Building on Kelley's research, Dr. Nicholas Gonzales treated various types of cancer with diet, nutritional supplements, and detoxification methods. Many physicians around the world use systemic enzyme therapy to treat cancer; however, it remains a controversial therapy. Widely accepted, however, is the practice of using enzyme therapy to treat the side effects of cancer and cancer treatment.

Standard cancer therapy can often result in serious side effects. For instance, radiation therapy of the head and neck is often accompanied by acute side effects, including difficulty swallowing, mucous membrane inflammation, and skin redness or soreness. Oral enzyme preparations seem to protect against these acute side effects, reducing their severity and duration.[57]

A study on patients with laryngeal cancer receiving radiation treatment found that those patients receiving an enzyme mixture (containing trypsin, bromelain, and rutin) had no cases of radiomucositis of the second degree and were able to continue on the radiation therapy.[58] Researchers also noted that those on enzyme therapy had a mean weight loss of only 5% compared with 10% in the control group.

In another study, researchers tested an enzyme combination in patients who underwent radiation therapy for cervical cancer.[59] Radiation therapy can cause numerous side effects, including bladder irritation, loose bowels, nausea, vomiting, and vaginal dryness. Results indicated that patients who received the enzyme mixture (which contained trypsin, chymotrypsin, and papain) had a significant reduction in vaginal mucosa reactions, genitourinary symptoms, and subcutaneous changes.[59]

Researchers in another study on patients with lung cancer who underwent chemotherapy found that an enzyme mixture containing papain, trypsin, chymotrypsin, and thymic peptides reduced the incidence of leukopenia, nausea, vomiting, sensory neuropathy, and treatment-related depression.[60]

Breast Cancer

It is estimated that one of every eight women will be diagnosed with breast cancer sometime during her life.[61] Unfortunately, standard treatment (which can include radiation, chemotherapy, and surgery) can cause serious side effects, including gastrointestinal symptoms, headache, pain, skin disorders, and infections. Researchers in Germany evaluated whether treatment with oral enzymes could reduce some of the typical side effects of breast cancer therapy.[62] They found that 74% of the enzyme group experienced a clear reduction in chemotherapy and radiotherapy side effects and that oral enzyme therapy could improve disease signs and symptoms, reduce side effects, and improve quality of life.[62]

Lymphedema

Treatment for breast cancer can sometimes lead to lymphedema (swelling caused by a buildup of lymph). This typically occurs after a lymph node is removed or after radiation treatment and can develop slowly. Symptoms include swelling in the arm, hand, shoulder, chest, or breast and may be accompanied by changes in skin texture, aching, and restricted mobility.

Typical medical therapy for lymphedema includes massage, exercising, special bandaging, manual lymphatic drainage, and the use of diuretic therapy. One clinical trial compared therapy with enzymes

(the product contained pancreatin, papain, bromelain, trypsin, chymotrypsin, and rutosid) with a diuretic.[63] After 7 weeks, significantly more of the patients receiving enzymes were pain-free compared with the patients receiving diuretics.

Pancreatic Cancer

It is estimated that pancreatic cancer will kill more than 43,000 in the United States this year alone.[64] In the past, survival rates for this disease were extremely low because treatment options were limited, and diagnosis usually did not occur until the disease was quite advanced. However, treatment improvements and earlier diagnosis have dramatically improved survival rates.[65] The standard medical treatment for pancreatic cancer involves surgery, radiation therapy, chemotherapy, and immunotherapy (also called biological therapy).

Pancreatic cancer can block the pancreatic duct and prevent enzymes from reaching the small intestine, resulting in malnutrition and weight loss. It is estimated that 80% to 90% of all patients with pancreatic cancer have malabsorption and weight loss.[66] Supplementing with pancreatic enzymes is an important supportive step in treating pancreatic cancer because it can improve digestion and therefore nutrient absorption.[67,44,68]

Autoimmune and Immune Complex–Mediated Diseases

In autoimmune disease, tissue-bound immune complexes activate the complement system. Activation of the enzyme cascade results in an intense protein-destroying inflammatory response, leading to significant local tissue destruction. For instance, when immune complexes collect in the kidneys, complement activation causes inflammation, resulting in glomerulonephritis.

Research showed that some enzymes can inhibit immune complex–mediated diseases, such as glomerulonephritis and rheumatoid arthritis,[2,3,4,52,69] by interrupting the complement cascade. Other disorders with similar mechanisms also respond to supplemental enzymes. Some are conditions such as Crohn's disease,[2,6,9,70] chronic rheumatism,[71,72] and ankylosing spondylitis,[73–76] which do not respond well to conventional medical treatments.

Multiple Sclerosis

According to the Multiple Sclerosis Foundation, there may be as many as 1 million Americans living with multiple sclerosis (MS).[77] Unfortunately, the government does not track MS cases, so the frequency can only be estimated. Although its cause is unknown, it is generally believed to be an autoimmune disease. In MS, antibodies attack the myelin sheath that protects and covers nerve fibers. This leads to inflammation and myelin sheath damage, which in turn interferes with nerve communications.

MS patients typically have higher concentrations of circulating immune complexes (CICs) than healthy individuals. Research showed that enzyme therapy can help reduce those CICs and thereby reduce inflammation.[78]

A Ukrainian study on an enzyme combination containing trypsin, bromelain, and rutin found that patients with MS taking the combination for 1 to 3 years had fewer and less severe complications and longer remissions and also experienced a slowing of their disease progression.[79]

Cardiovascular Disorders

Cardiovascular disorders include diseases of the heart and blood vessels (including strokes). In the United States, heart disease and stroke kill nearly three-quarters of a million people every year and account for nearly one third of all deaths.[80]

In normal circulation, there is a constant dynamic balance between blood clotting and fibrinolysis.[81] If fibrinolysis is impaired, clot formation is abnormal. If fibrinolysis increases, a tendency toward excessive bleeding results. Therefore maintenance of proper equilibrium is extremely important for the circulatory system.

One study examined the effects of various enzyme combinations on fibrinolysis and fibrin formation.[6] The researchers induced fibrin deposition with calcium ions or staphylocoagulase in the plasma of centrifuged, acellular citrated blood from humans or rabbits and treated the clot with various concentrations of enzyme suspensions. They found that the higher the enzyme content of the solution, the more rapidly clots were degraded. Inflammation is considered to play a central role in all atherosclerotic processes. Therefore the use of enzymes is indicated because of their anti-inflammatory effect.

A German study measured the effects of a proteolytic enzyme combination (containing trypsin, bromelain, and rutin) on blood fluidity.[10] Researchers found that even a minimum enzyme concentration resulted in a significant reduction in plasma viscosity and erythrocyte aggregation.

Systemic enzyme therapy appears to be particularly effective in the treatment of phlebitis and thrombophlebitis,[11] as well as chronic venous insufficiency (also called postphlebitic syndrome), which can occur because of phlebitis. In one study, treatment with systemic enzyme therapy led to a decrease in several symptoms, including pain, edema, and trophic ulcers.[82]

Viral and Bacterial Disorders

Enzymes have been used to treat many viral and bacterial conditions, including abscesses, acne, adenoiditis, adnexitis, bladder infection, boils, conjunctivitis, diarrhea, ear infections, empyemas, epididymitis, gingivitis, kidney disorders, laryngitis, pneumonia, rheumatic fever, sinusitis, staphylococcal infection, tonsillitis, and sepsis.

Sepsis is a particularly dangerous systemic response to infection. Researchers in India found that proteolytic enzyme therapy improved recovery time in children with sepsis.[83] Thirty young boys (ages 1 month to 12 years) with sepsis were given proteolytic enzymes. Another group of 30 boys received placebo tablets. Both groups received supportive treatment and the appropriate antibiotics. Fever subsided faster in the enzyme group (3 days) than in the placebo group (4 days), and those in the enzyme group were able to begin oral feeding in 4 days as opposed to 5 days in the placebo group. In addition, hemodynamic support was only needed for 2 days in the enzyme group (as opposed to 3 days in the placebo group), and the modified Glasgow Coma Scale normalized for enzyme participants in 3 days (as opposed to 5.5 days in the placebo group).[83]

As more and more bacteria become resistant to antibiotics, researchers and physicians are investigating supportive treatments, including systemic enzyme therapy. As mentioned previously, enzymes not only reduce inflammation, improve circulation, and stimulate and balance immune system function, but they are also able to enhance the ability of antibiotics when their use is required.[84,83] Enzymes fortify the action of antibiotics, leading to complete healing and preventing the progression of an acute infection into its chronic form. A good example is urogenital chlamydiosis, which is a sexually transmitted disease and a major cause of infertility. According to the Centers for Disease Control and Prevention, there were more than 1 million cases reported in the United States in 2008. By 2016 that number had increased to 1½ million cases.[85] Standard treatment is with antibiotics, including azithromycin or doxycycline. Although antibiotic treatment appears to be highly efficacious, in some individuals the infection becomes persistent and chronic, leading to long-term disorders in females, including pelvic inflammatory disease, ectopic pregnancy, and sterility.[86] A Russian study of 227 patients with urogenital chlamydiosis found

that treatment with antibiotics led to complete recovery in only 61.4% of patients, whereas enzyme therapy in conjunction with antibiotics resulted in over 90% treatment success.[84]

In addition to its use in treating bacterial infections, enzyme therapy can also aid in the treatment of viruses, including HIV, chancre sores, chickenpox, colds and coughs, hepatitis, herpes simplex, herpes zoster, influenza, measles, pneumonia (viral), and warts. The human body defends against these, and other, viruses with the help of macrophages or natural killer (NK) cells. Oral enzyme combinations (e.g., papain, trypsin, and chymotrypsin) synergistically increase the antiviral effects of tumor necrosis factor (TNF), macrophages, and NK cells and the breakdown of CICs.

DOSAGE

Regardless of the condition being treated, a wide range in daily dosage has historically been used for the following reasons:

- There are individual differences in patient health.
- The level of effective absorption in tablet strength can vary.
- There is a wide variety of influencing ranges in pH.
- Enzyme activity levels vary between products.

The dosage of any pancreatic enzyme will depend on the condition being treated, the patient's diet and digestive requirements, and the composition and activity level of the supplement. Dosage can also vary because of the supplement's susceptibility to inactivation in the stomach and duodenum. For best results, follow the label for dosage recommendations.

TOXICOLOGY

In general, the side effects of orally administered enzymes are few, short term, and due primarily to higher dosages or hypersensitivity reactions. According to Wolf and Ransberger, high dosages (70 tablets of 17.5 g each) of a proteolytic enzyme mixture have been given without long-term side effects.[87] Studies and literature searches commissioned by regulatory authorities such as the FDA apparently confirmed that enzyme preparations obtained from suitable sources (e.g., nontoxic, nonpathogenic sources) are safe to consume.[88]

The potential side effects of pancreatic enzyme therapy include diarrhea; intestinal gas; abdominal pain or cramping; and greasy, pale, or pungent stools. Reducing the dose can usually reduce or eliminate these side effects. Hyperuricosuria (excess uric acid in the urine) and hyperuricemia (excess uric acid in the blood) have been associated with extremely high doses. Sneezing, lacrimation, rash, and other hypersensitivity reactions have been reported in sensitive individuals.

Pancreatin preparations held in the mouth or chewed before swallowing can result in stomatitis, or ulcerations and irritation of the mucosa, particularly in infants, in whom pancreatin may also cause perianal soreness.[89] However, some of the capsules containing microencapsulated enzyme beads can be opened and dispensed by the spoonful to infants or mixed into foods such as apple sauce or gelatin.

Prolonged skin contact with proteolytic enzymes (i.e., in ointment form) may cause skin irritation, whereas enzyme enemas can sometimes cause itching or burning in the rectum or anus. Care should be exercised when using powdered enzymes or enzyme capsules to avoid inhaling dust particles, which could irritate the mucous membranes of the throat, nose, and eyes.[88] In addition, inhalation may trigger an asthma attack.[90]

It is not known whether pancreatin or pancrelipase given to pregnant women can harm the fetus because animal reproductive studies have not been conducted. Therefore pancreatin should not be used during pregnancy.[89] Also, it is not known if pancreatin or pancrelipase is distributed into a mother's milk. Therefore caution should be exercised with the use of this substance in nursing women.[89]

Enzymes should not be used by those with hemophilia or those on blood thinners (unless under a physician's care), nor immediately before or after surgical procedures with an increased risk of bleeding. Enzymes should also be avoided by those with pulmonary emphysema or thrombocytopenia. Pancrelipase (and any other enzyme derived from pork sources) is contraindicated in those who are hypersensitive or allergic to pork products.

There is some indication that patients with CF who are undergoing long-term high-dose pancreatic enzyme therapy may demonstrate colonic wall thickening, a condition called fibrosing colonopathy (FCP). It was once believed that the copolymer coating on the tablets might be the culprit,[91] and there have been instances of FCP in CF patients not taking any type of enzyme preparation.[92] However, it is generally believed that FCP occurs because of prolonged treatment with very high doses of pancreatic enzymes.[93] Many of the individuals who were first diagnosed with FCP were taking tens of thousands of units in excess of label recommendations.[94] To reduce the risk of FCP, it is extremely important that patients closely follow their physicians' recommendations regarding dosage.

A note about supplement safety: During the past few decades, there has been increased concern regarding mad cow disease (bovine spongiform encephalopathy [BSE]). Called Creutzfeldt–Jakob disease (CJD) in humans, it can be caused by eating beef that is infected with BSE, but it can also be transmitted through corneal transplant tissue, from hormone extracts (e.g., human growth hormone), and possibly from ingesting contaminated glandular products. Unfortunately, it may take as long as 20 years after infection for the characteristic symptoms of CJD to manifest. Since 1995, the FDA has required that dietary supplement manufacturers ensure that any "high-risk" animal products used in their supplements do not originate in BSE countries, in countries with inadequate surveillance, or in countries with requirements less strict than those that would be acceptable for importation into the United States. The list is constantly updated; for the most current list of BSE countries, refer to the U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service website (https://www.aphis.usda.gov/aphis/ourfocus/animalhealth/animal-and-animal-product-import-information/import-live-animals/ct_bovine_spongiform_encephalopathy). Contact the supplement manufacturer for concerns about pancreatic supplement safety or to see what measures they employ to ensure BSE-free products.

DRUG INTERACTIONS

In addition to lipases and amylases, pancreatic enzymes contain proteases, so they are subject to some of the same drug interaction warnings as is bromelain (see Chapter 59 on bromelain). As with bromelain, caution should be exercised when pancreatic enzymes are used with anticoagulants (blood thinners), as well as over-the-counter nonsteroidal anti-inflammatory drugs, including aspirin and ibuprofen. In addition, certain botanicals, including garlic, gingko biloba, and ginseng, may increase bleeding risk and so should be monitored when used in conjunction with pancreatic enzymes.

Certain diabetes drugs, such as acarbose (brand names Glyset and Precose), function as alpha-glucosidase inhibitors, lowering blood sugar levels by inhibiting the digestion of dietary carbohydrates. This, in turn, limits the rise of blood sugar levels. However, the amylase in pancreatic enzymes has the potential to reduce the effectiveness of alpha-glucosidase inhibitors because amylase improves carbohydrate

digestion. Therefore pancreatic enzymes should not be taken concomitantly with acarbose and other alpha-glucosidase inhibitors.

Similarly, drugs that function as lipase inhibitors (e.g., Orlistat) should be avoided while taking pancreatic enzymes. Orlistat is available in prescription (as Xenical) and nonprescription (as Alli) forms. It functions by inhibiting lipase in both the lumen of the stomach and the small intestine. Although there are no known studies on Orlistat given concomitantly with pancreatic enzymes, it would seem counterproductive to take a drug designed to inhibit lipase activity while also taking a drug containing lipase. In addition, because Orlistat inhibits the activity of lipase, it may interfere with the action of pancreatic enzymes.

Any foods that contain enzyme inhibitors have the potential to decrease the activity of pancreatic enzymes. Heat inactivates enzyme inhibitors (such as those found in potatoes, legumes, and soybeans, which are rarely eaten raw).

CONCLUSION

As we can see, the use of pancreatic enzymes has been found to be extremely effective in treating a wide variety of conditions, from digestive diseases to inflammation, cancer, autoimmune diseases, viral and bacterial conditions, and more. It is my firm belief that future research will not only continue to validate but will also reveal new and exciting applications for systemic enzyme therapy.

This chapter is dedicated to the memory of Dr. Max Wolf, the father of systemic enzyme therapy, as well as Dr. Karl Ransberger, who validated and marketed systemic enzyme therapy, making it a highly accepted worldwide treatment for a wide variety of systemic diseases and injuries.

Phage Therapy: Bacteriophages as Natural, Self-Limiting Antibiotics

Elizabeth Kutter, BS, PhD, Naomi Hoyle, MD, William Eisner, BSc, Sarah Kuhl, MD, PhD, Zemphira Alavidze, PhD, and *Bob G. Blasdel, PhD*

OUTLINE

INTRODUCTION

Phage therapy involves the use of bacteriophages—viruses that only attack bacteria and are very host specific—to kill pathogenic microorganisms. The art was first developed at the Pasteur Institute in Paris in 1917, practiced to some extent in France until the 1980s, and is still fairly extensively used and further developed in such places as Russia and the Republic of Georgia.[1] After the advent of chemical antibiotics in the 1940s, it was largely forgotten in the Western world. Today, however, the increased prevalence of bacteria that are resistant to most or all available antibiotics is precipitating a major health crisis, as is passionately stressed by the World Health Organization and by governments, scientists, and health practitioners worldwide.[2] In particular, extensive research work has been published by the Hirszfeld Institute of Immunology and Experimental Therapy in Wroclaw, Poland's center of phage therapy, complementing the ongoing routine use of phage in the Republic of Georgia.[3] Numerous patients from around the world have been treated in recent years in Phage International's Phage Therapy Center and in the Eliava Phage Therapy Center in Tbilisi, Georgia, long the epicenter of therapeutic phage production and application, as further discussed later in the following section.

Today, the one major western European center carrying out phage therapy is at the LabMCT, which is part of the burn wound center of the Queen Astrid Military Hospital in Brussels, Belgium. The LabMCT provides phage active ingredients to pharmacists who produce preparations for patients in Belgium under the magistral framework (Pirnay et al., 2018).[4] This framework, roughly analogous to the compounding framework in the United States or the Specials framework in the UK, allows the Belgian phage ecosystem to fill prescriptions with phage preparations that are tailor-made to each patient. In Belgium, as at the Hirszfeld Institute, phage cocktails are prepared from phages that have been determined to be active against a patient's clinical isolate through the use of a companion diagnostic method.

In the United States, the Food and Drug Administration (FDA) now also quite routinely approves compassionate use of phage therapy in individual very serious cases where there are no other options. One such case, involving a near-fatal *Acinetobacter* infection of a UC San Diego faculty member and a massive worldwide effort that found the phages that rescued him after 4 months in a coma, is described in some detail later in this chapter. The spectacular success there led the UC San Diego clinic to apply phage therapy in half a dozen cases where organ transplants were being blocked by intransigent infections. The UC San Diego has just made a million-dollar investment in developing a phage therapy center and relevant sources of potential therapeutic phages are springing up.

This chapter was written to put phage therapy into historical and ecological perspective for health practitioners and to explore very interesting early research in France, the United States, and Eastern Europe, as well as growing recent studies worldwide, that provide the

foundation for growing interest today in its possibilities. The hope is that this modality will soon be more readily available for external applications, while physicians and researchers occasionally take advantage of "Compassionate Use" guidelines and deal with the challenges of getting funding for full-scale clinical trials of more invasive approaches. Here, we explore available data that strongly support expedited evaluation of phage therapy to help address the serious menace of antibiotic resistant bacteria.[6-18]

Extensively documented results of early French and Eastern European therapeutic phage applications are very encouraging, but most involved individualized applications to infections recalcitrant to all other available treatments, not double-blind clinical trials. There have been encouraging developments. In 2006 the US FDA and the European Medicines Agency (EMA) both approved phage preparations targeting *Listeria monocytogenes* on ready-to-eat foods. Intralytix (Baltimore, Maryland) in the United States now markets similar products targeting *E. coli* O157, other pathogenic *E. coli*, *Salmonella* (PLSV-1) and *Clostridium perfringens* (INT-401) in poultry, or a wide range of pathogenic *Salmonella* serotypes on food: Typhimurium, Enteritidis, Heidelberg, Newport, Hadar, Kentucky, Thompson, Georgia, Agona, Grampian, Senftenberg, Alachua, Infantis, Reading, and Schwarzengrund. SalmoFresh is specifically designed for treating foods that are at high risk for *Salmonella* contamination. Red meat and poultry can be treated before grinding for significant reductions in *Salmonella* contamination. SalmoFresh received Generally Recognized As Safe (GRAS) recognition from the FDA in 2013 (GRAS Notice No. GRN 000435), for direct applications onto poultry, fish and shellfish, and fresh and processed fruits and vegetables.

Designing and successfully carrying out successful double-blind trials has been very challenging; safety has been established, but difficulties involving design have made proof of efficacy unavailable. For example, the Nestlé corporation carried out an extensive project in Dhaka, Bangladesh, to study the safety and efficacy of phage therapy in treating infant diarrhea believed to have been caused by *E. coli*.[19] Either a novel cocktail of T4-like phages used in earlier safety trials, a commercially available Russian anti-*E. coli* phage cocktail (Microgen), or a placebo were added in blinded fashion to standard oral rehydration solution. The phages being used for the main experimental arm of the trial had been isolated from the stools of pediatric diarrhea patients in Bangladesh, with the broad-spectrum ones applicable for phage therapy all turning out to be members of the highly studied T4 family of phages, described in the following section.[20] They also reported the details of their very extensive genomic, mouse, and human safety studies of representative phages from their set.[21] The trial very effectively established safety. However, for several technical reasons that are now much clearer, despite the enormous expense, it was unable to establish efficacy. Apparently, the true culprits were, at least partly, a pair of previously unknown streptococci. Also, as our laboratory established at about that time, T4-infected stationary-phase *E. coli* goes into a sort of hibernation-mode state, killing the bacteria but not completing the cycle, and releasing a large burst of phages until glucose and amino acids are added, as much as 48 hours later (Bryan et al., 2016).[5]

PROPERTIES OF BACTERIOPHAGES

Bacteriophages, like other viral particles, are like spaceships that can transfer their genomes into susceptible cells where they can reproduce. In the case of bacteriophages, the targets are bacterial cells, specific to varying degrees for each phage; they cannot infect the cells of eukaryotic organisms. Each virion consists of DNA or RNA, containing the information that determines the properties of the virus, which is encased in a protein coat (Fig. 101.1). Unlike eukaryotic viruses, most

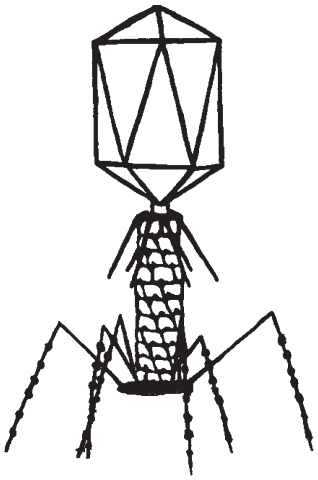

Fig. 101.1 Phage diagram (bacteriophage T4).

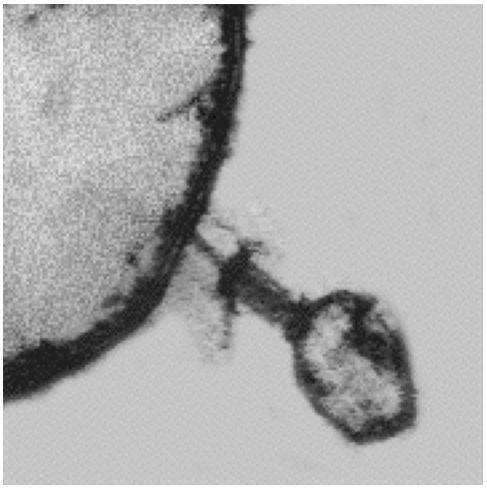

Fig. 101.2 Electron micrograph of phage infecting a bacterium.

DNA phages have tails, the tips of which can bind to specific molecules on the surfaces of their target bacteria (Fig. 101.2). Many have 4 to 6 tail fibers that initiate the bacterial recognition process and help the virion position itself in a manner facilitating the injection of its DNA into the cell. Once in the cell, the DNA is replicated, creating numerous copies of the entire virion. At human body temperature, many phages produce more than 100 virions per cell in about half an hour while for phages targeting oceanic bacteria, for example, that process may take 24 hours.

Each strain of bacteria has characteristic protein, carbohydrate, and lipopolysaccharide molecules present in very large quantities on its surface. These molecules are involved in forming pores, conferring motility, and binding of the bacteria to particular surfaces. Each such molecule can act as a receptor for particular phages. Development of resistance to a particular phage generally reflects mutational alteration or loss of its specific receptor; this loss frequently has negative effects on the bacterium, often making such mutants less virulent, and does not confer protection against the many other phages that use different receptors. Each kind of bacterium has its own phages, which can generally be isolated wherever that bacterium grows: from sewage, feces, soil, and even ocean depths or hot springs. However, finding phages suitable for therapeutic applications is much easier for some species than for others; this relates significantly to the ability to grow the host bacterium in the laboratory. The process of isolation is straightforward for

phages targeting many of the best-studied pathogens. An environmental sample is combined with an appropriate nutrient-fortified solution and one or more kinds of targeted bacteria, incubated overnight, and lysed with chloroform. A series of tenfold dilutions is made and 10 μL of each dilution is spotted on a nutrient-agar plate prepared with a single strain of target bacteria. The next day, a dense bacterial lawn is seen, hopefully with cleared spots at each dilution, until small, clear individual plaques are seen. Each plaque contains over a million phages, all of them progeny of a single initial phage. An individual plaque is plucked from that furthest dilution and put through a redilution to a concentration giving about 10 to 30 plaques. Finally, one plaque is picked and grown up in an appropriate host to give a stock of a phage whose host range, purity, and other properties can then be studied.

One major source of confusion in the early phage work was that each laboratory isolated its own new phages, often infecting different bacteria, so there was little continuity or basis for comparison. Key technical developments in the 1930s to 1940s that helped clarify the general nature and properties of bacteriophages were (1) the concentration and purification of a few large phages using the newly available high-speed centrifugation and the demonstration that they contained roughly equal amounts of DNA and protein; and (2) visualization of phages by the newly developed electron microscopes (EM).[22,23] Phages specific for virtually every well-studied bacterial species have now been isolated and studied in substantial detail in laboratories all over the world. Many are becoming well classified.

The early EM work helped resolve the major disputed question as to whether the lytic principle termed "bacteriophage" simply reflected an inherent property of the specific bacteria, as strongly proposed by eminent immunologist Jules Bordet, 1919 winner of a Nobel Prize, or required regular reinfection by an external agent, as indicated by d'Hérelle's research (see "Historical Context of Phage Therapy"). During the 1930s and 1940s, it gradually became clear that in some senses both were true—that there were two quite fundamentally different groups of bacteriophages. Obligatorily lytic phages always have to infect from outside, reprogram the host cell, and release a burst of phage through breaking open or lysing the cell after a relatively short fixed interval. Temperate phages, in contrast, have another option; they can actually integrate their DNA into the host DNA, much as HIV can integrate the DNA copy of its RNA. For several reasons, such temperate phages are not appropriate for therapeutic applications. They generally make the host resistant to related phages, blocking treatment efficacy, and may carry genes that actually increase the pathogenicity of the host; very specific prophages are a key factor in such diseases as cholera and diphtheria.

Using the EM, each phage family was found to have its own specific shape and size, from "lunar lander"–style complexity with a contractile tail and long tail fibers attached to a baseplate, to globular heads with long or short tails, to the small filamentous phages that looked much like bacterial pili (Fig. 101.3). With recent advances in DNA sequencing techniques, our understanding of various phages is exploding in powerful and important ways; the genomes of several hundred phages, infecting a variety of organisms, have now been sequenced, revealing a remarkable variety of types and properties that can be very important when considering potential therapeutic applications. In general appearance, 95% of the studied phages belong to one of the three-tailed morphotypes: the short-tailed podoviridae, the siphoviridae with long, often flexible tails, and the myoviridae, with tails composed of an inner tube and an outer contractile sheath attached to a complex baseplate. There are both obligatorily lytic and temperate phage families with each of these three general morphotypes, so other kinds of data are also needed to determine whether a newly isolated phage is temperate or lytic.

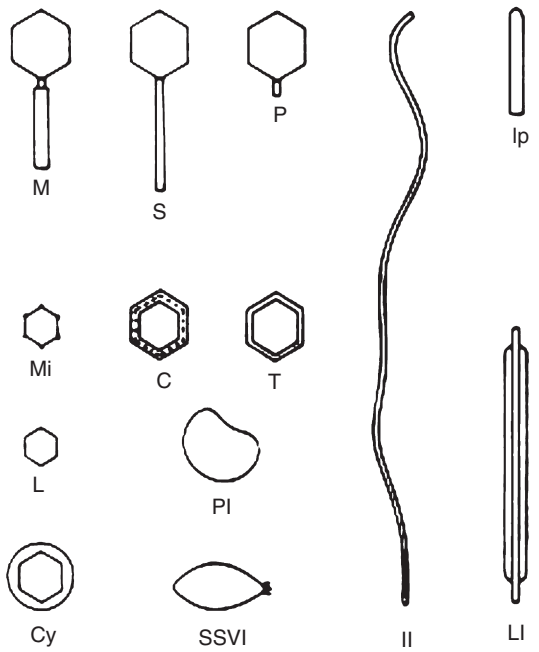

Fig. 101.3 Various phages.

Obligatorily Lytic Phages and the Development of Molecular Biology

A much better understanding of the interactions between the lytic life cycle of phages and bacteria began with one-step growth curve experiments. These demonstrated an eclipse period, during which the DNA began replicating and there were no free phages in the cell; a latent period of accumulation of intracellular phages; and a precisely timed lysis process that released the phage to go in search of new hosts. This phage infection cycle is illustrated in Fig. 101.4 for coliphage T4, which does a particularly effective job of shutting off all host functions and whose family is very widespread in nature and in therapeutic phage preparations for enteric bacteria.

In 1943 an event occurred that had a major effect on the orientation of phage research in the United States and much of western Europe, strongly shifting the emphasis from practical applications to basic science. Physicist-turned–phage biologist Max Delbruck met with Alfred Hershey and Salvador Luria to form a "Phage Group" and establish a long-lasting annual phage course and meeting at Cold Spring Harbor, Long Island. A major element of the success of phages as model systems for working out fundamental biological principles at the molecular level was that Delbruck persuaded most US phage biologists to focus on one bacterial host (*E. coli* B) and seven of its highly lytic phages, arbitrarily named types T1 through T7. Fortuitously, T2, T4, and T6 are quite similar to one another, defining a family of myoviridae now called the T-even phages, which were key in demonstrating that DNA is the genetic material, that viruses can encode enzymes, that gene expression is mediated through special "messenger RNA," that the genetic code is triplet in nature, and other fundamental concepts. The negative side of this focus on a few phages growing on one host under rich laboratory conditions was that there was very little study or awareness of the ranges, roles, and properties of bacteriophages in the natural environment or of potential applications. On the positive side, most of the strongly lytic phages selected for therapeutic applications targeting enteric phages have turned out to belong to one or another of these three very well-studied families of phages (as confirmed by sequencing data as well as morphological details), which is very useful as we work to ensure their safety and to understand the physiological properties involved.

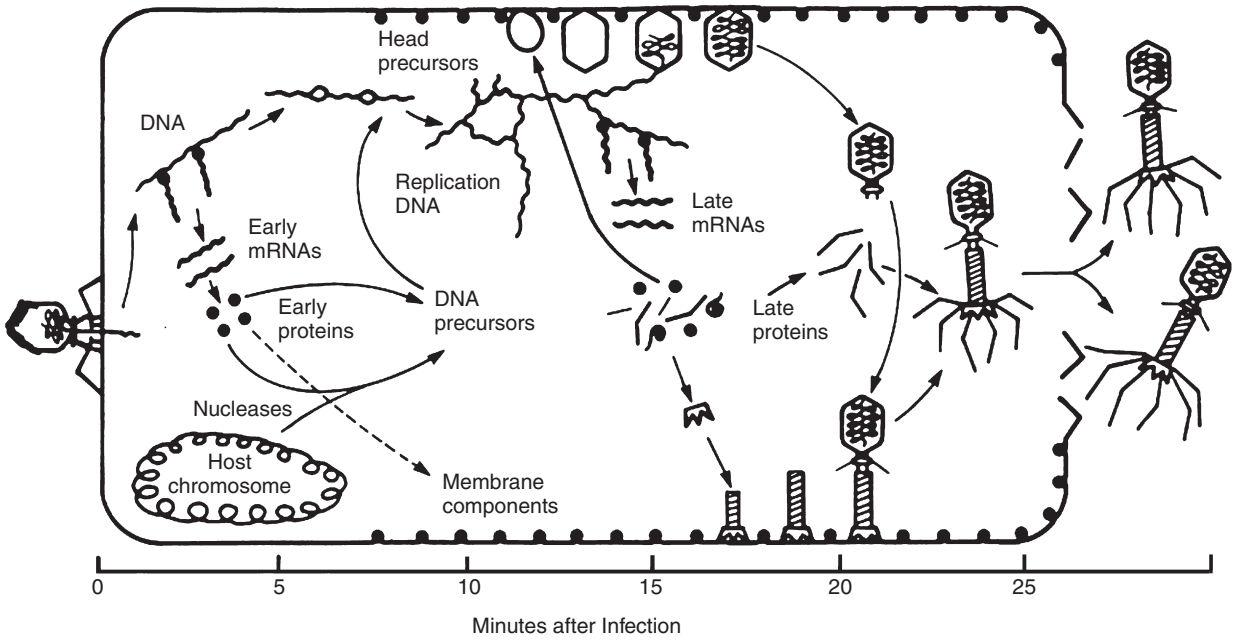

Fig. 101.4 Bacteriophage intracellular growth cycle. Noteworthy features: both nucleolytic action on host chromosome and new phage enzymes furnish DNA precursors; replicating DNA is much longer than virion DNA; a number of phage-coded proteins become associated with the host membrane to alter host functions and to facilitate phage assembly and maturation.

The temperate phages generally encode repressors to turn off most of their own genes when they are in the temperate prophage state, integrases to let them insert themselves into the DNA of their hosts, and excision enzymes to cut their DNA back out to enter a lytic cycle. Obligately lytic phages generally have much more extensive mechanisms for shutting off the host, often involving nucleases and transcription factors and a variety of small host-lethal "monkey-wrench" proteins made under the control of strong promoters very early in infection to redirect cellular metabolism; T4, for example, encodes at least 50 such proteins (Miller et al., 2003).[105]

HISTORICAL CONTEXT OF PHAGE THERAPY

Edward Twort and Félix d'Hérelle independently reported the isolation of filterable entities capable of lysing bacterial cultures. When diluted sufficiently, they made small round cleared areas d'Herelle called "plaques" on plates of bacterial cultures, implying that discrete particles were involved. It was d'Hérelle, a Canadian working at the Pasteur Institute in Paris, who gave the name *bacteriophage* to these entities, which he discovered in the stools of soldiers recovering from dysentery—using the suffix *phage* "not in its strict sense of *to eat*, but in that of *developing at the expense of*."[24] He soon also isolated phages targeting avian typhosis and tested their application during an outbreak in French chickens, showing that three-quarters of the untreated chickens died, whereas all of the phage-treated infected chickens survived. He then accepted an urgent request to treat several children battling dysentery at the Paris Hôpital des Enfantes Malades; the day before treating the first child, he and several assistants swallowed far more phages than they would be administering, thus carrying out the first known Phase I clinical trial. The treatment of the children was fully successful, but d'Hérelle turned to intense study of the nature of bacterial infection by phages before publishing the results or carrying out further therapeutic applications. In a 300-page 1922 book, *The Bacteriophage: Its Role in Immunity*,[24] d'Hérelle wrote the original, classic descriptions of bacteriophage formation of "plaques" (clear round holes in lawns of susceptible bacteria), isolation of phages from various sources, the lysis process, host specificity of adsorption and multiplication, the dependence of phage production on the precise state of the host, and the factors controlling stability of the free phage. He quickly became fascinated with the apparent role of phages in the natural control of microbial infections and discussed the frequent specificities of the phages isolated from recuperating patients for the disease organisms infecting them, as well as the rather rapid variations over time of their phage populations. Throughout his life, he worked to develop the therapeutic potential of properly selected phages against the most devastating health problems of the day, traveling to many parts of the world, then teaching at Yale from 1928 to 1933 while establishing his own Laboratoire du Bactériophage in Paris, where they produced the first commercial phage cocktails such as Bacté-Intesti-Phage and Bacté-Pyo-Phage, which form the basis for today's complex cocktails in Eastern Europe.

Unfortunately, most of the English-language literature reviews of phage therapy ignored the successful application of phage therapy in France using these phage preparations, which were very carefully produced and tested by d'Hérelle's laboratory or by the Bacteriophage Service of the Lyon and Paris branches of the Institut Pasteur. Effectively complementing other antimicrobials, some of this French use continued until the early 1990s, when the AIDS scare led the French Parliament to ban the inclusion of any sort of viruses in any kind of medications.

Key to d'Hérelle's many successes was that he focused intensely on first understanding phage biology and on applying that knowledge in his production and application of phages, including careful ongoing quality control and close work with physicians. The depth of his insights became more accessible via publication of a translation of this book's appendix.[24]

Through much of the early developmental time, he worked closely with George Eliava, director of the Georgian Institute of Microbiology. Over the years, the two developed plans for an Institute of Bacteriophage Research in Tbilisi as a world center of phage therapy.

In 1926 the current large campus on the river Mtkvari was allotted for the project, and d'Hérelle sent supplies, equipment, and library materials. In 1934 to 1935 he visited Tbilisi for 6 months, set up his laboratory, and wrote a book, *The Bacteriophage and the Phenomenon of Recovery*.[25] He intended to move to Georgia, but Eliava was arrested in 1937 as a "people's enemy" by Beria, and was executed, sharing the tragic fate of many Georgian and Russian progressive intellectuals of the time, and d'Hérelle, disillusioned, never returned to Georgia. However, their Bacteriophage Institute survived under the leadership of a group of Institute women well trained by Eliava and d'Hérelle. The Institute was transferred to the All-Union Ministry of Health in 1951, and hundreds of thousands of pathogenic bacterial samples were sent to the Institute from throughout the Soviet Union to isolate more effective phage strains and better characterize their usefulness. A new five-story building on the Eliava grounds provided facilities for making up to 2 tons of phage products twice a week, with 80% of the preparations going to the Soviet military. Products included tablets against dysentery, a serious problem among soldiers, pyophage cocktails targeting wound and other purulent infections, and Intestiphage, still used today for a wide range of enteric pathogens. Research laboratories continually isolated new phages, upgraded therapeutic cocktails, and collaborated closely with physicians to test the phage preparations and ways of administering them. In 1988 an official Scientific Industrial Union "Bacteriophage" was formed, centered in Tbilisi with branches in Ufa, Perm, and Gorki (now called Nizhny Novgorod). After the 1991 breakup of the Soviet Union, the three Russian sites were pulled into the developing pharmaceutical giant, Microgen (eng.microgen.ru), which produces an even wider range of phage preparations.

What is now the Eliava Institute lost most of its markets and funding and struggled for survival as the factory portions were privatized. Lead research scientists switched to preparing their two most important phage cocktails for Georgian use in 30-L batches in their own laboratories, packaged them by hand in 5-mL ampules, and sold them in the Eliava diagnostic clinic, where laboratory leaders continued to do the actual patient testing and diagnosis, supporting the laboratories while continuing to acquire new pathogenic strains for research and production purposes. By 1996 help became available from the International Science and Technology Centers and the NATO Civilian Research and Development Fund, the PhageBiotics Foundation, and other sources, and the institute is again thriving at its original site.

Initial Western Explorations

Phage therapy was explored extensively in Europe and the United States in the 1920s through 1940s, with early successes being reported for a variety of diseases, including dysentery, typhoid and paratyphoid fevers, staphylococcal, pyogenic and urinary tract infections, and cholera.[8] Phages have been given orally, through colon infusion, as injections and aerosols, or infused directly into lesions. The early strong interest in phage therapy is reflected in some 800 papers published on the topic between 1917 and 1956. The reported results were quite variable. Unfortunately, many of the physicians, entrepreneurs, and pharmaceutical firms who initially became very excited by the potential clinical implications, especially in the preantibiotic era, jumped into application efforts with very little understanding of phages, microbiology in general, or the basic scientific process. Thus many of the early studies were anecdotal and/or poorly controlled; many of the failures were predictable; and some of the reported successes did not make sense in light of current knowledge. Too often, uncharacterized phages at unknown concentrations were given to patients without previous specific bacteriologic diagnosis, and there is no mention of follow-up, controls, or placebos. Much of the understanding being gained by d'Hérelle was ignored in this early work, and inappropriate methods of preparation, "preservatives," and storage procedures were often used. On one occasion, d'Hérelle reported testing 20 preparations from various companies and finding that not one of them contained active phages! In general, little of the essential quality control was carried out except in a few research centers, mainly in France, the Soviet Union, and the United States.

Specific Problems of Early Phage Therapy Work

Some still believe (erroneously) that phage therapy was proven not to work during that period; however, it simply was never adequately researched for a variety of reasons, and the work that was done well is not widely enough known. It is thus important to carefully consider the reasons for the early problems and for the questioning of efficacy:

- Total lack of understanding of the heterogeneity and ecology of the phages and the bacteria involved
- Lack of availability or reliability of bacterial laboratories for carefully identifying the pathogens involved (important considering the relative specificity of phage therapy)
- Use of too few of the needed different phages in infections that involved mixtures of different bacterial species and strains
- Failure to select obligatorily lytic phages against the target bacteria before using them in patients
- Emergence of phage-resistant bacterial strains, through selection of resistant mutants, or through lysogenization (in cases where temperate phages were used, as discussed in "Properties of Bacteriophages")
- Failure to appropriately characterize or titer phage preparations, many of which, even from major companies, were shown to be totally inactive[26,27]
- Failure to neutralize gastric pH before oral phage administration
- Inactivation of phages by both specific and nonspecific factors in bodily fluids

All of these factors need to be taken into consideration as we now work to formally document phage efficacy and integrate phages into medical practice worldwide.

PHAGE INTERACTIONS IN THE BODY

A number of early experiments involving phage injection into animals led to widespread belief that phage therapy could not succeed because the phages were too rapidly cleared by the immune system. Early experiments in rabbits, rats, and mice indeed showed rapid disappearance of phage from the blood and organs but long-term survival in the spleen.[28,29] However, these experiments were done in the absence of host bacteria in which the phage could multiply and were often carried out by the unnatural mode of intravenous injection, exposing the phage almost immediately to the reticuloendothelial system. Many later studies made it clear that phages are seen in the mammalian circulatory system for prolonged periods when they are entering it from some sort of reservoir in other tissues and the host is dealing with infection by a bacterium in which they can replicate—precisely the sort of situation usually seen in phage therapy as currently practiced.

This pattern is demonstrated particularly well in research published in 1943 by noted Harvard bacteriologist René Dubos[30] (Fig. 101.5). Dubos et al.[30] injected mice *intracerebrally* with a dose of a smooth *Shigella dysenteriae* strain that was sufficient to kill more than 95% of the mice in 2 to 5 days and then treated them with *intraperitoneal* injection of a mixture of phages that had been isolated from New York City sewage, grown in the same bacteria, and purified only by sterile filtration. With no treatment, or when treated with filtrates of bacterial cultures or with *heat-killed* phage, only three of 84 mice (3.6%) survived; in contrast, 46 of 64 (72%) of the mice given 10^7 to 10^9 of

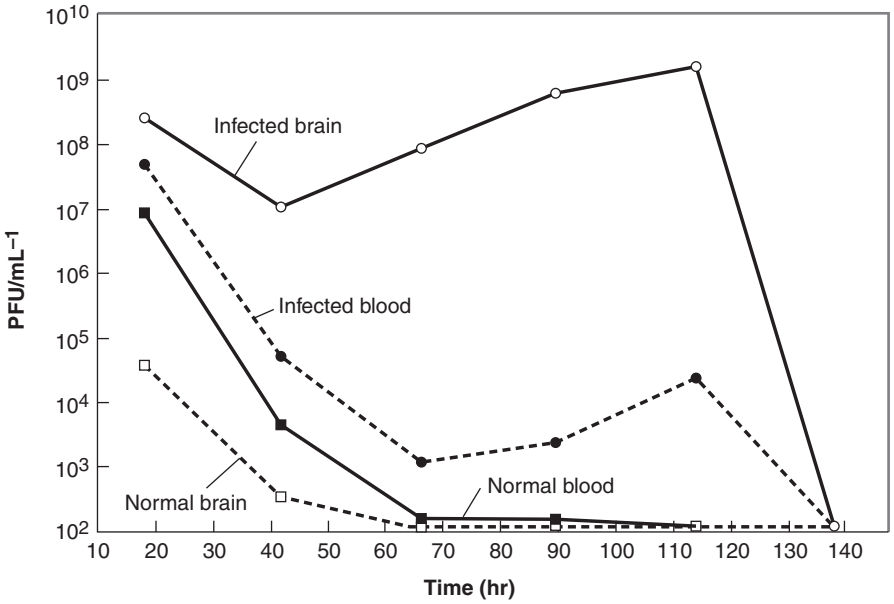

Fig. 101.5 This figure, based on the data in the 1943 mouse studies of Dubos et al.,[30] provides significant insight into why phage therapy works well even in treating infections that antibiotics cannot treat. When the mice were injected intraperitoneally with 10^9 phage, they quickly appeared in the bloodstream and some even crossed the blood–brain barrier, but they were rapidly cleared. However, when the mice were also injected intracerebrally with *Shigella dysenteriae*, the host for these phages, 46 of 64 of the mice survived (compared with 3 of 84 in the absence of appropriate viable phage), and the brain level of phage climbed to over 10^9/g. Once the bacteria cleared, the level of phage dropped below detection limits.

the appropriate phages survived. Pharmacokinetic studies showed that when phages were given to *uninfected* mice, they appeared in the bloodstream almost immediately, but the levels started to drop within hours and very few were seen in the brain, as shown in Fig. 101.5. However, in the *infected* animals, brain levels of the viable phage appropriate to those bacteria soon far exceeded blood levels; around 10^7 to 10^9 phages/g were often seen between 8 and 114 hours after administration, with the level dropping between 75 and 138 hours after phage addition. After the first 18 hours, blood levels were far lower than brain levels, but phages were still present in blood at 10^4 to 10^5 phages/mL in those animals in which the brain levels were still high.

Equally well-controlled experiments performed by Henry Morton and Enrique Perez-Otero from 1943 to 1945 at the University of Pennsylvania supported those of Dubos et al.[30] and further showed the lack of any protection when phages with inappropriate host specificities were used. These results clearly established that (1) the phages themselves were responsible, not something in the lysate that just stimulated normal immune mechanisms; (2) phages could rapidly find and multiply in foci of infection anywhere in the body, including crossing the blood–brain barrier; and (3) phages could be maintained in the circulation as long as there was a privileged reservoir of infection where phages were continually being produced. A final review authorized by the Council on Pharmacy and Chemistry discussed the major advantages of phages, such as their ability to replicate into problem areas and treat localized infections that are relatively inaccessible via the circulatory system, and the fact that their high specificity greatly aided in reducing later resistance problems.[31] The review also emphasized that most of the earlier phage research had been so poorly conceived and/or carried out that it offered no proof either for or against the promise of phages as antibiotics; therefore the negative conclusions of the earlier American Medical Association reviews were neither unexpected nor very relevant to the potential for eventual success.

The context of these studies sheds enlightening insights into the historical course of phage therapy in the United States.[32] In 1942 both *The Lancet* and the *British Medical Journal* published editorials about the apparently successful use of anti-dysentery phages by the Soviet military in the Middle and Far East. By November 1942 the US National Research Council Committee on Medical Research began supporting research possibilities offered by anti-dysenteric phages for dealing with this perpetual scourge of armies (including the previous studies) in top US bacteriology laboratories new to phage work, initially requiring them to keep the results secret. This promising work ended in 1944, when the end of World War II made penicillin generally available. The military secrecy, the end of the war emergency funding, the rapid rise in antibiotic availability and their broad-spectra "wonder-drug" status, and Max Delbruck's success in persuading the phage community to strongly shift its focus to basic molecular research involving a few model systems all contributed to the fact that there was little US follow-up to these very interesting and successful results. Although the results were published in major journals, few people even knew about them, or about any of the highly successful ongoing human applications, until they were recently rediscovered in medical journals by Thomas Häusler during an intensive search at major libraries around the world, such as those at the National Institutes of Health and the Pasteur Institute.[6]

Penicillin works only against gram-positive bacteria, so it cannot treat typhoid fever, and early phage efforts against typhoid had very mixed success. It was then found that the major pathogenic strains of *Salmonella typhi* all carried one particular antigen, named Vi (for "virulence"). In 1936 a pair of Canadians identified a number of phages specific against the Vi antigen; these are still used as "typing phages" in rapidly identifying and following outbreaks. In the late 1930s and early 1940s, physicians at the Los Angeles County Hospital used phage treatments to help deal with repeated serious outbreaks of typhoid that were killing one in five of those afflicted.[33] Walter Ward tested the

Vi-specific phages against mouse typhus and found that the death rate fell to 6% versus 93% in controls.[33] When these phages were then used to treat patients with typhoid, only three of 56 treated patients died compared with the 20% mortality for the other treatments available at the time.[34] Most impressively, this study reported that the patients who received phage therapy rapidly changed from being largely comatose to full of vigor, with renewed appetite, in 24 to 48 hours. In 1948 and 1949 near Montreal, Desranleau treated nearly 100 patients with dysentery by giving them a cocktail of six different Vi-specific phages, and the death rate dropped from 20% to 2%.[35] By then, however, chloramphenicol had been shown to work well against typhoid, and it was much easier for pharmaceutical companies to deal with, so that seems to have been the end of phage clinical trials in the western hemisphere.

The high specificity of phages still plays a strong role in the phage typing sets used for detecting and following problem strains of such bacteria as *Shigella, Salmonella,* and *E. coli,* but phage therapy itself is only beginning to stage a comeback.

CLINICAL APPLICATION

The growing understanding of phage biology had the potential to facilitate more rational thinking about the therapeutic process and the selection of therapeutic phages. However, there was generally little interaction between those who were so effectively using phages as tools to understand molecular biology and those working on phage ecology and therapeutic applications. Many in the latter group were spurred on by a concern about the rising incidence of nosocomial infections and of bacterial resistance against most or all known antibiotics, as well as by the fact that phages are far more effective than antibiotics in areas of the body where circulation is poor and does not disrupt normal flora, such as in treating foot infections in diabetics. This strong sense of the potential importance of phages was particularly seen in Poland, France, Switzerland, and the former Soviet Union, where use of therapeutic phages never died out and where there has been ongoing research and clinical experience, if not the double-blind experiments that are now the gold standard. In France, Dr. Jean-François Vieu led the therapeutic phage efforts until 1997. He worked in the Service des Entérobactéries of the Pasteur Institute in Paris and, for example, prepared *Pseudomonas* phages on a case-by-case basis for patients. His experience there is discussed in two articles.[36,37] In Vevey, Switzerland, the small pharmaceutical firm Saphal made "Coliphagine," "Intestiphagine," "Pyophagine," and "Staphagine" in drinkable and injectable forms, salves, and sprays into the 1960s.[32] The owner, Harrmann Glauser, had been encouraged and trained by d'Hérelle's old colleague Paul Hauduroy, who had become a professor of microbiology at the University of Lausanne during World War II. These phage preparations were officially approved and were paid for by insurance.

Phage therapy was used extensively in many parts of eastern Europe as a regular part of clinical practice, and companies in Russia now make phages for this purpose. However, most of the research and much of the phage preparation came under the direction of key centers in Tbilisi, Georgia, and Wroclaw, Poland. In both cases, the close interactions between research scientists and physicians played an important role in the high degree of success obtained, just as was the case for d'Hérelle's early work.

Clinical Research at the Institute of Immunology and Experimental Medicine, Polish Academy of Sciences

The most detailed publications documenting phage therapy are from the Polish group originally led by Director Stefan Slopek at the Wroclaw Institute of Immunology and Experimental Medicine. Slopek's initial series of papers described work completed in 1981 to 1986 with 550 patients in 10 regional Polish medical centers, under the careful supervision of the physicians there and with access to new phages from the Institute as needed.[38-40] The patients ranged in age from 1 week to 86 years, and venues included the Wroclaw Medical Academy Institute of Surgery's Cardiosurgery Clinic, Children's Surgery Clinic and Orthopedic Clinic, the Institute of Internal Diseases Nephrology Clinic, and the Clinic of Pulmonary Diseases. In 518 cases, phage use followed unsuccessful treatment with all then-available methods, including antibiotics. The major categories of infections included long-persisting suppurative fistulas and abscesses, septicemia, respiratory tract suppurative infections, pneumonia, and purulent peritonitis. In a final summary article, the results were carefully analyzed with regard to such factors as nature and severity of the infection and mono infection versus infection with multiple bacteria.[40] Rates of success under these ideal conditions ranged from 75% to 100% (92% overall), as measured by marked improvement in relevant physical condition, wound healing, and disappearance of titratable bacteria; 84% of subjects demonstrated full elimination of the suppurative process and healing of local wounds. Infants and children did particularly well. Not surprisingly, the poorest results occurred in elderly patients and those in the final stages of extended serious illnesses.

In the first study alone, 259 of their phages were tested (116 targeting *Staphylococcus*, 42 for *Klebsiella*, 11 for *Proteus*, 39 for *Escherichia*, 30 for *Shigella*, 20 for *Pseudomonas*, and one for *Salmonella*); 40% were selected to be used for therapy. All treatments were conducted in research mode, with the phage prepared at the Institute and tested for sterility. Treatment generally involved 10 mL of sterile phage lysate given orally half an hour before each meal, with gastric juices neutralized by ingesting (basic) Vichy water, baking soda, or gelatin. Phage-soaked compresses were generally applied three times a day where dictated by localized infection. Treatment ran for 1.5 to 14 weeks (mean, 5.3 weeks). For intestinal problems, short treatment usually sufficed, whereas months-long use was necessary for such problems as pneumonia with pleural fistula and pyogenic arthritis. Bacterial levels and phage sensitivity were continually monitored, and the phage(s) were changed if the bacteria lost their sensitivity. Therapy was generally continued for 2 weeks beyond the last positive test result for the bacteria. Few side effects were observed; those that were seen seemed to be directly associated with the therapeutic process.[38]

Various methods of administration were successfully used, including oral, aerosols, and infusion, either rectally or into surgical wounds. Intravenous administration was not recommended for fear of possible toxic shock from bacterial debris in the lysates.[38] However, it was clear that the phages readily entered the body from the digestive tract or wounds and multiplied internally wherever appropriate bacteria were present, as measured by their presence in blood and urine and by therapeutic effects.[41] This interesting and rather unexpected finding has been replicated in many studies and systems.[42-45] The final evaluating therapist filled out a special inquiry form that was also sent to the Polish Academy of Science research team. The Computer Center at Wroclaw Technical University carried out extensive analyses of the data, using the categories established in the World Health Organization's (1977) *International Classification of Diseases*. They also looked at the effects of age, severity of initial condition, type(s) of bacteria involved, length of treatment, and other concomitant treatments. After Slopek's retirement, his prime assistant Dr. Beatta Weber-Dabrowska carried on with his phage therapy work with patients in regional hospitals, publishing a summary in English of the results for the next 1600 patients.[46] In 1998 immunologist A. Górski took over as Institute director and revived a strong focus on phage work, with special emphasis on the immunological consequences of phage treatment. These researchers have been

working with the basic phage group of Dr. Malgorzata Lobocka in Warsaw to sequence and further characterize their key phages since I introduced them to each other during my first visit to the Institute in 2001.

Clinical Research at the Bacteriophage Institute, Tbilisi

Particularly extensive efforts for phage therapy were carried out over many decades by scientists at the Bacteriophage Institute in Tbilisi, Georgia, working closely with local physicians. Phage therapy is an accepted component of the general standard of care in Georgia, and was used extensively in pediatric, burn, and surgical hospital settings. Phage preparation was carried out on an enormous scale before the breakup of the Soviet Union, employing 700 people in the factory and several hundred more in the research arm of the Institute, often making 2 tons of phage products weekly to ship throughout the former Soviet Union. They were available both over the counter and through physicians; 80% went to the military for wound and burn infections and, largely as tablets, for preventing debilitating gastrointestinal epidemics. In hospitals, they were used to treat both primary and nosocomial infections, alone or in conjunction with other antimicrobials. The International Science and Technology Centers program, set up jointly by the United States, Europe, and Japan to give constructive opportunities to scientists formerly working with Soviet military projects, became one of the strongest supporters of basic and applied research in this area in Tbilisi.

From the Bacteriophage Institute's inception, the industrial part was run on a self-supporting basis, whereas its scientific branch was government supported. The Institute carried out the extensive studies needed for approval by the Ministry of Health in Moscow of each new strain, therapeutic cocktail, and means of delivery. This careful study of the host range, lytic spectrum, cross-resistance, and other fundamental properties of the phages being used was a major factor in the reported successes of their phage therapy work, as were their methods for selecting highly virulent phages from among the many available against any given host. Where necessary, new cocktails were prepared with broader host ranges. The depth and extent of the work involved are impressive. For example, in 1983 to 1985, the Institute's Laboratory of Morphology and Biology of Bacteriophages carried out studies of growth, biochemical features, and phage sensitivity on 2038 strains of *Staphylococcus,* 1128 of *Streptococcus,* 328 of *Proteus,* 373 of *P. aeruginosa,* and 622 of *Clostridium* received from clinics and hospitals in towns across the former Soviet Union. New broader acting phage strains were isolated and were included in a reformulation of their extensively used Pyophage preparation. A good deal of work went into developing the documentation for Ministry of Health approval of specialized new delivery systems, such as a spray for use in respiratory tract infections, in treating the incision area before surgery, and in sanitation of hospital problem areas. An enteric-coated pill was also developed, using phage strains that could survive the drying process, and accounted for the bulk of the shipments to other parts of the former Soviet Union. Much work focused on combating nosocomial infections, in which multidrug-resistant organisms have become a particularly lethal problem.

Staphylococcus aureus Infections, Whether or Not Methicillin-Resistant

Methicillin-resistant *S. aureus* (MRSA) is a particular concern given its reduced susceptibility to antibiotic treatment, wide prevalence in hospital-acquired infections and in the community, and potentially lethal and otherwise serious consequences. These pathogens are targeted by the anti-*S. aureus* activity of phage preparations such as Pyophage (which include potent anti-*Staphylococcus* phages of the broad-spectrum Sb1-staph phage K family). Here as elsewhere, there is no cross-resistance between phages and antibiotics. Furthermore, very little development of resistance to this family of phages has been observed, presumably implying that the still unidentified primary receptor is a molecule of significant importance to the bacteria. Thus as far as phages are concerned, MRSA is simply another strain of *Staphylococcus aureus.* Treatment of MRSA using phages can be accomplished by local application for local infections or, if necessary, with substantially more caution, more systemic dosing such as intraperitoneally for systemic infections.[47] The use of phage treatment for local infections, including particularly those resulting from *S. aureus*, has the distinction of being one of only two phage therapy strategies that were deemed to be convincingly efficacious by the Eaton and Bayne-Jones report in 1934,[48-50] and an otherwise phage therapy skeptical publication.[51]

The first human phage therapy publication reported on treatment of *S. aureus* skin infections.[10,52,53] The first publication on successful phage treatment in the United States in about 40 years also involved phage targeting *S. aureus*, in this case in diabetic toe ulcers.[54] The Eliava commercial staph phage Sb1 was used to treat a series of 11 patients where antibiotics had failed and whose only other option was amputation, and all of them healed in a matter of weeks; details for six of the cases are reported here, and further information on both this work and diabetic foot phage work in Novosibirsk is provided in Fish et al.[55] and Morozova et al.[56] A follow-up 2 years later for one of Fish's patients with osteoporosis showed that there was also significant bone regeneration.[54] In France, the Pherecydes corporation now has a clinical trial underway, approval for which by their board was based on this successful work, they have told us[57] (Fig. 101.6).

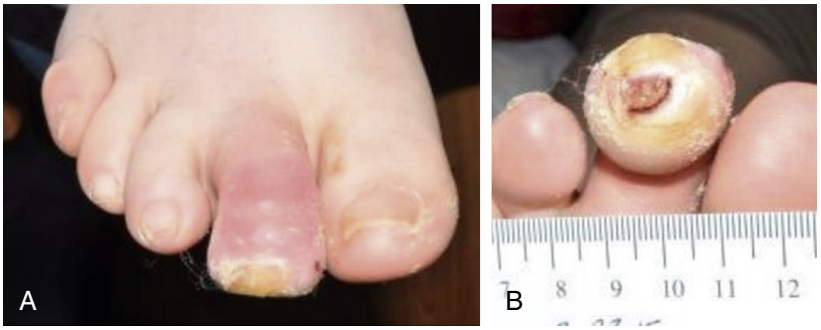

Fig. 101.6 Diabetic toe ulcer healed with phage. Images of the patient's ulcer on presentation. (A) Top view of foot. (B) View of ulcer at the distal tip. (From https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6316425/figure/antibiotics-07-00087-f001.)

Leszczynski et al.[58] described the use of oral phage therapy for targeting MRSA in a nurse who was a carrier. This individual had MRSA colonized in her GI tract and also had a urinary tract infection. The result was complete elimination of culturable MRSA. The same group argued that MRSA treatment using phages could be economically preferable to MRSA treatment using antibiotics.[59] Jikia et al.[60] described phage treatment of MRSA infecting radiation burns. Slopek et al.[40] reported 92.4% positive cases for phage treatment of 550 single and mixed-etiology infections involving *S. aureus*. Slopek et al.[39] specifically used phage treatment for suppurative staphylococcal infections, with a reported 93% "effective" rate "based on case history and data contained in a special questionnaire," while also using this treatment of various kinds of *Staphylococcus* infections in children (95.5% positive results for the 90 children treated). Working in New York, MacNeal and Frisbee[47] described their relatively successful treatment of staphylococcal bacteremia in 100 patients. MacNeal et al. subsequently reported very positive results in the cumulative treatment of 500 patients with staphylococcal bacteremia, using cocktails of phages that were lytic in vitro.[61]

Urogenital Tract Infections

Phages have been applied to treat various infections of the urogenital systems either systemically, via direct injection into the bladder, or via topical application. Phage treatment of urogenital tract infections could potentially be complimented by current naturopathic protocols involving alkalinization of the urine with citrates and minerals. Eaton and Bayne-Jones[48-50] in their otherwise-critical 1934 report were convinced of the efficacious use of phage therapy against cystitis. Letwiewicz et al.[62] described phage application rectally to target *Enterococcus faecalis* infection of the prostate, with substantial success in eliminating the target bacteria. In this case, the phages were presumed to be taken up through the rectal wall. Letarov et al.[63] noted that rectal phage suppositories are available on the Russian market. Slopek et al.[40] reported 92.9% positive results for phage treatment of 42 "diseases of the genitourinary tract." Chanishvili and Sharp's[64] book has chapters on "Phage Therapy in Urology" and "Phage Therapy in Gynecology." They summarize the results there as follows: "In cases of acute cystitis a therapeutic effect was observed within 4 to 5 hours of the first administration and resulted in relief of pain, a decrease in the frequency of urination and a normalization of the composition of the urine. Full recovery was achieved within 1 to 3 days in all 13 cases (100%), but treatment of chronic forms of cystitis was less successful, with only a moderate improvement observed."[64] Supported by a 3-year grant from the International Science and Technology Centers, the Eliava Institute developed a new phage cocktail specifically targeted against a large pool of bacteria from prostatitis and urinary tract infections. At the 2009 Evergreen International Phage Biology Meeting, Alavidze reported on its production and on very successful preliminary trials involving more than 100 patients. A collaborative Western-style double-blind, placebo-controlled trial involving addition of this phage to the standard treatment at one of the major urology hospitals in Tbilisi is currently underway, supported by Swiss funding of a collaborative research project.[65]

Gastrointestinal Infections

From the beginning, acute diarrheal infections were a major and very successful part of phage therapy practice, and in both Russia and the Republic of Georgia. However, most GI problems, such as irritable bowel syndrome, diverticulitis, and Crohn's disease, typically involve factors other than bacteria, and may include long-term chronic infections and immune system challenges. Although there is no body of older literature to build on from work in Tbilisi or Poland on the latter application, this would appear to be an area well worth exploration. Intestinal phage communities change in patients with inflammatory bowel disease (IBD) and other gut-related diseases.[66] There are some reports of disease specific alterations that could potentially contribute to high trend inflammation.[67] Other reports indicate specific targeting of pathogenic bacteria in IBD patients may be beneficial. The use of phage as treatment for IBD is an area that requires further study. Some research indicates the potential for targeting invasive *E. coli* strains implicated in Crohn's disease,[68] while some authors have observed an abnormal enteric virome in patients with IBD.[69] As we begin to better understand the depth of the human microbiome through metagenomic analysis, we also recognize the importance of the virome, and its role in maintaining normal function.[70] Extensive clinical experience using phage cocktails such as Intestiphage to treat functional gastrointestinal disorders has shown a positive effect in a large portion of patients being treated in the Republic of Georgia (unpublished data), with the idea of targeting the overgrowth of pathobionts that produce by-products and that are a potential trigger for visceral pain.[71] As work towards making fecal transplant a standard of care, the idea that phage preparations may contain those essential elements for restoration of normal function is an important one to consider.[72] A recent American controlled clinical study used phage as a prebiotic with the intent to modify gut microbiota. Its general conclusions were that phage was both safe and tolerable for consumption.[73] Much additional highly relevant gastrointestinal-related work has just been published.[74-78]

Respiratory Tract Infections

Respiratory infections can be differentiated into numerous types; however, phage therapy is limited in efficacy to those with a bacterial etiology. Weber-Dabrowska et al.[79] reported successful treatment of pneumonia in 6 cancer patients. Similarly, Slopek et al.[80] reported 86.7% positive results for phage treatment in 180 "diseases of the respiratory system" (see also Slopek et al.[38]). The first case studies of phages used to treat people for chronic lung infections of *S. aureus* and *P. aeruginosa* in Tbilisi used Pyophage and their fully sequenced *S. aureus* phage, phage Sb-1, which is now sold commercially, delivered by standard cystic fibrosis (CF) nebulizers.[81,82] The latter study included a detailed description of the successful treatment of *P. aeruginosa* infection in the lungs of a 7-year-old patient (using Pyophage) along with treatment of an *S. aureus* coinfection in the same patient using phage Sb-1. Success in treating infections in animal models of CF associated infection was also reported by Debarbieux et al.[83] and Carmody et al.,[84] in addition to the exploration of using nebulization as a phage delivery strategy. Work with CF patients has continued at the Eliava Phage Therapy Center, with more than 20 CF patients being treated over a 5-year period. Clinical improvement and a reduction in hospitalization has been seen consistently in most patients.[85] Although complete eradication of pathogens from the CF lung is not expected as a result of the well-established and complex microbiota of the CF lung, they have observed several cases of eradication of particularly problematic bacterial infections such as the *Achromobacter* infection in a 17-year-old girl using a specially prepared phage preparation. In addition to general clinical improvement, lung function also significantly improved. Treatment of these infections via nebulizer is generally tolerable, although some patients do observe increased sputum production and cough or dyspnea, and all patients should be closely monitored during treatment.

Phage treatments of lung infections can also be used effectively from systemic circulation, in at least some circumstances, as animal models have also shown.[84]

Ear Infections

Chronic otitis externa, known less formally as swimmer's ear, is often caused by a *P. aeruginosa* ear infection that resists antibiotic treatment. Otitis media is often caused by *Streptococcus pneumoniae* and is the leading cause of physician visits from children. The British company Biocontrol (now part of AmpliPhi Biosciences) developed anti-*P. aeruginosa* phages targeting otitis externa, after publishing similar studies on dogs.[86,87] In 2009 they published the results of their double-blinded Phase 1/2a (safety and small-number efficacy) trial in human patients with this condition.[88] Increases in phage numbers in situ, microbiological improvements (reductions in bacterial presence), and reduction in disease symptoms in the phage-treated cohort, but not the phage-negative controls, were observed. No side effects were seen. Complete bacterial eradication was not observed, but the extent of success was particularly notable considering that only a single phage dose was administered. Weber-Dabrowska et al.[79] also reported phage therapy success in treated purulent otitis media, and Slopek et al.[80] reported 93.8% positive results for phage treatment of 16 cases of conjunctivitis, blepharoconjunctivitis, and otitis media.

TOXICOLOGY

From a clinical standpoint, all indications are that phages are very safe. This feature is not surprising, given that humans are exposed to a very wide variety of phages from birth. Bergh et al.[89] reported that nonpolluted water contains about 10^8 phages/mL. Phages are normally found in the GI tract, skin, urine, and mouth, where they are harbored in saliva and dental plaque.[90-92] They have also been shown to be unintentional contaminants of sera and therefore of commercially available vaccines,[93-96] which were given dispensation to be sold despite this discovery, because of the general consensus that phages are safe for humans.

Extensive preclinical animal testing was required for approving new phage formulations in the former Soviet Union, but only a few of these studies were published. For example, Bogovazova et al.[97,98] evaluated the safety and efficacy of *Klebsiella* phages produced by the Russian company Immunopreparat. Pharmacokinetic and toxicologic studies using intramuscular, intraperitoneal, or intravenous administration of phages were carried out in mice and guinea pigs. The researchers found no signs of acute toxicity or histologic changes, even using a dose 3500-fold higher than the projected human dose. They then evaluated the safety and efficacy of the phages in treating 109 patients. The phage preparation was reported to be nontoxic to humans and to be effective in treating *Klebsiella* infections, as manifested by marked clinical improvements and bacterial clearance in the phage-treated patients.

Occasional mild side effects such as liver pain and fever reported in the early days of Western phage therapy may have been caused least in part by bacterial byproducts in preparations used intravenously.[99-101] Concerned about this possibility, the Polish phage therapy group does not administer their phages intravenously. The same is true for almost all of the therapeutic work carried out in Tbilisi and may help explain the apparent lack of any significant problems in both places; their many years of experience, careful attention to detail, and supportive infrastructure are presumably also important factors. Because phages readily enter the bloodstream after infusion in or near wounds and other sites of localized infection and travel to sites of infection throughout the body,[102] there seems to be no reason for undergoing the extra risks of intravenous administration in most cases.

Drug Interactions

No negative effects on the efficacy or safety of other drugs have been reported anywhere as a result of phage administration. No systematic studies have been carried out in this regard, but phages are so specific in their actions that it is hard to determine where such interactions might occur. In contrast, at least some antibiotics can interfere with phage treatment of localized infections by killing off the most accessible of the bacteria in which the phages could multiply as they work their way deeper into the site of infection; this would be a particular problem in cases in which the phages still attach and infect but cannot complete their replication cycle. Georgian physicians generally believe that antibiotics should never be used topically for wounds and deep-seated infections, because the decrease in antibiotic concentration below the surface provides a strong selection for antibiotic resistance; this problem does not occur with phages.

DOSING STRATEGY

Phage cocktails can be designed in two distinctly different ways. The major style currently used in Georgia, Russia, and Poland, termed "active treatment," uses a low concentration of phages and relies on in situ phage replication to achieve a therapeutically relevant concentration at all sites of infection by that pathogen encountered by progeny phage in the body. Titers of the many individual phages in each commercial cocktail are typically about 10^5 to 10^6 PFU/mL and in general 5 to 10 mL is used per dose. This approach is preferred when antibiotics fail because of poor circulation or surgical inaccessibility. "Passive treatment" ignores the self-replicating nature of phages when the infected area is directly accessible and enough phage particles are applied to treat the infection in a single dose.[103]

CONCLUSION

Phages have many potential advantages:

- They are self-replicating but also self-limiting, because they multiply only in the presence of susceptible bacteria.
- They can be targeted much more specifically than most antibiotics to the problem bacteria, causing far less of the bacterial imbalance or "dysbiosis" that are major problems with antibiotics, which often lead to serious secondary infections involving relatively resistant bacteria that can increase hospitalization time, expense, and mortality. Particular resultant problems involve *Pseudomonads*, which are especially difficult to treat, and *Clostridium difficile*, the cause of serious diarrhea and membranous colitis[104]; though no therapeutic phage cocktails directly targeting the anaerobe *C. difficile* are currently available, Intestiphage can help, presumably through rebalancing of the gastrointestinal flora.
- Phages can often be targeted to receptors on the bacterial surface that are involved in pathogenesis, so any resistant mutants are less problematic.
- No serious side effects have been reported for phage therapy.
- Phage therapy is particularly useful for people with allergies to antibiotics.
- Appropriately selected phages can easily be used prophylactically to help prevent bacterial disease at times of exposure or to sanitize hospitals and help protect against hospital-acquired (nosocomial) infections.
- At least for external applications, useful phages can potentially be prepared for administration fairly inexpensively and locally, facilitating their applications to underserved populations.
- Phages can be used either independently or in conjunction with other antimicrobials to help reduce the development of bacterial resistance.

The time has come to look more carefully at the potential of phage therapy for future practice, both by strongly supporting new research

and by scrutinizing the research already available, such as the very interesting human anti-typhoid phage research carried out in the United States in the 1940s,[34] as well as the extensive earlier work in France, the United States, Georgia, Poland, and Russia.[8,9]

With the enormous possibilities and decreasing costs of genomic analysis, it is now possible to sequence the phages included in cocktails to ascertain more about the phage families involved and be sure that phages from temperate families are excluded, which is generally necessary or at least highly desirable because they may carry or acquire genes related to pathogenicity or toxin production. Sequencing is now standard procedure for therapeutic phages being developed in the West. Such modern techniques are also beginning to be applied to some of the Georgian phage preparations with help from grants from the International Science and Technology Centers and Civilian Research and Development Foundation programs, both of which were set up to support civilian applications of science formerly funded by the Soviet military, and we are also doing some cocktail sequencing and detailed analysis here at Evergreen. This is an important step in considering the importation of such phages for use in the Western world.

The attitude toward phage therapies and its potential are at last beginning to change in both the United States and Europe, with more and more people now becoming aware of its existence and potential applications. The 2016 case discussed in the introduction in which a UC San Diego faculty member was cured with US Navy phage of a life-threatening *Acinetobacter* infection obtained while visiting Egypt has been key in creating far more US attention to the efficacy of phage as a medicine. It has had wide publicity, and the many articles, mass-media releases and recent book about the experience have led to an explosion of interest in phage therapy and in expediting its compassionate use.

That successful treatment was made possible by the ability of the practitioners to send patient samples to several groups working with *Acinetobacter* and their ability to very rapidly identify and obtain multiple phages against the very unusual infective strain. Due to the recent strong interest in *Acinetobacter* as a result of its frequent appearance in wounds from the conflicts in Iraq and the ways the Navy and others were isolating and handling relevant phages, it was possible to very quickly test them, identify several effective phages, grow them up and purify them sufficiently with the help of phage labs in Texas and San Diego, and use them sequentially to eradicate this infection. Building libraries with several iterations of phages targeting particularly threatening pathogens, as some have begun to do across the world, is facilitating a very rapid potential response and collaborative preparation of cocktails for treatment of such cases.

The professor and his wife have developed a new phage therapy center at UC San Diego, taking advantage of their experience and the subsequent treatment there of six candidates for organ transplants, which were being seriously delayed by infectious complications. This is the first actual phage therapy center in the Americas, and is already collaborating with Ampliphi and the new Adaptive Phage Therapeutics company, set up in D.C. to work with the Navy and others to very rapidly identify and prepare appropriate phages for emergency compassionate use cases.

In the U.S. any newly developed medicine attempting to make its way to market must go through the FDA, which is now accepting the concept and potential importance of phage therapy and working to adapt to its very unique aspects. The three phases of FDA clinical trials are designed to prove safety, efficacy, and marketability in respect to other approved treatments. To date, there have been just three completed Phase II clinical phage trials. The first took place in 2009 in England and dealt with very long-term chronic *Pseudomonas* osteitis, including a total of 12 patients; it was deemed successful in demonstrating safety and efficacy of the phage preparation used. Nestlé funded a 2016 trial of phage for acute infant diarrhea patients, developed over 15 years of selecting and intensively studying phages targeting infant diarrheal *E. coli* strains from the central hospital in Bangladesh and testing them in adults and older children in Switzerland and Bangladesh, as well as in the laboratory. The French firm Pherecydes led the Phagoburn trial for topical treatment of severe *Pseudomonas* infections in burn victims at 14 hospitals in France, Belgium, and Switzerland. Both of the latter trials confirmed safety but were deemed unsuccessful in proving efficacy, largely due to various design complications that became apparent.

Although it seems premature to broadly introduce injectable phage preparations in the West without further extensive research, their successful use in the extreme San Diego cases has helped stimulate FDA approval for very serious cases. More broadly, the carefully implemented use of phage in external applications and for a variety of agricultural purposes should help reduce the emergence of antibiotic-resistant strains and deal with problems with which we have serious difficulty handling today. Compassionate use of appropriate phages seems now warranted and increasingly widely accepted in cases in which bacteria resistant to all available antibiotics are causing life-threatening illness. Phages are especially useful in dealing with recalcitrant nosocomial infections, in which large numbers of particularly vulnerable people are being exposed to the same strains of bacteria in a closed hospital setting. In these cases especially, the environment as well as the patients can be effectively treated with phage preparations.

Acknowledgments

Special thanks to Drs. Guram Gvasalia, Ramaz Katsarava, Mzia Kutateladze, Rezo Adamia, Teona Danelia, and their colleagues in Tbilisi, and to Beata Weber-Dabrowski and Andre Gorski in Wroclaw for their hospitality, hard work on phage therapy, and efforts through the years to help us understand the extensive therapeutic work carried out there. We express our thanks to the many phage biologists, companies and health care personnel around the world who are now working hard to bring phage therapy back into the Western world. Special thanks also to the Phagebiotics Research Foundation and to The Evergreen State College for their long-time support of phage therapy research (since 1997) and of our bacteriophage research here at The Evergreen State College since 1972, respectively.

Phosphatidylserine (PS)

Parris M. Kidd, BSc, PhD

OUTLINE

INTRODUCTION

Phosphatidylserine (PS) is a phospholipid nutrient that occurs naturally in all cells; it is an orthomolecule ("orthodox to the body") according to Linus Pauling's definition.[1] In humans, PS is most highly concentrated in the brain, and as a dietary supplement its clinical benefits are most apparent for memory, attention, and other higher brain-related functions, such as mood and coping with stress.[2-6]

PS is fundamentally important for all known life forms. PS is an essential building block for cell membranes, which occur in all known cells and are the sites of most of the cell's functional activity.[7] Cell membranes are thin, continuous structures composed mainly of a double molecular layer of phospholipids (the "lipid bilayer"), into which are inserted diverse arrays of enzymes and other catalytic proteins. The presence of PS makes essential contributions to the physical and chemical *milieu* required for the optimal functioning of numerous membrane proteins.[2,7]

The PS molecule has a characteristic layout (Fig. 102.1)—featuring a head piece, a middle piece, and two tail pieces ("tails").[2,7] The head piece contains serine attached to a phosphoryl chemical group, has a net negative charge, and is positioned on the membrane's inner (cytoplasmic) surface.[7] The middle piece is a three-carbon glyceryl sequence. The two tail pieces are constructed from fatty acids, extend deep into the membrane, and help create a water-free, oily, semifluid membrane interior that is crucial for membrane protein catalytic activity.[2]

Biochemically, PS is not a single molecule but a family of molecules.[2,8] The head and middle pieces are standard, but each of the two tail pieces can be constructed from many different fatty acids. Thus there are as many PS molecules as there are fatty acid permutations. Further, all cells carry enzymes ("acylases") that can detach fatty acid tails and substitute them with others, thereby modifying the membrane's fluidity or other biochemical characteristics.[8] In the brain's highly active gray matter, the PS molecules carry more of the highly fluidizing ω-3 fatty acids, consistent with high membrane metabolic activity. In the less active white matter, by contrast, the PS molecules carry less ω-3 and more saturated and monounsaturated (ω-9) fatty acid tails, which are less fluidizing and support lower membrane metabolic activity.[8]

PHYSIOLOGICAL ROLES

The physiological activity of PS seemingly is based exclusively in cell membranes. In the membrane systems of nerve cells, for example, PS enables energy generation, electrical conduction activity, and neurotransmission across synaptic junctions.[2,7–11] PS is also intrinsic to the blood coagulation cascade, again as a constituent of cell membranes, and is central to physiological disposal of dying and dead cells.[2,7] At the cell membrane level, activities specifically linked to PS include[8,9,12–14]:

- Membrane/cell stabilization: PS binds with structural proteins to stabilize the cell's outer membrane and overall cell shape.[9]
- Energetics: Mitochondrial production of adenosine triphosphate (ATP) requires the membrane phospholipid phosphatidylethanolamine (PE), which local enzymes derive almost exclusively from membrane PS.[8]
- Ion pumping: The sodium, potassium ATPase enzyme, which moves sodium in and potassium out of our cells, uses some 25% of all the body's energy. It requires PS for its activity.[7]
- Signal transduction: The conversion of external signals to internal cell transformations, which often requires G-protein coupled receptors (GPCR) and protein kinase C enzymes (PKC), protein families both likely dependent on PS for optimal activity.[10]
- Electrical signal transmission: The fusion of nerve cells' synaptic vesicles with the outer cell membrane to release neurotransmitters requires the presence of PS.[11]
- The "eat me" message: In all tissues, as cells lose function and become moribund, PS becomes relocated to the outer half of their outer membrane. This serves to "tag" such cells for disposal by circulating immune cells. Immune phagocytes have PS receptor proteins that interpret the PS "tag" as an "eat me" message.[12]

PHARMACOLOGY

The pharmacology of PS is consonant with its diverse actions in cell membranes.[2,10,11] Through its presence in synaptic membranes, PS fundamentally enables the brain's diverse neurotransmitter systems.[10] PS facilitates stress management by enhancing hypothalamic-pituitary-adrenal axis (HPAA) function.[11,15]

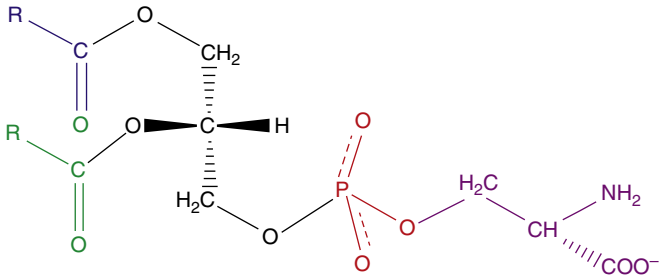

Fig. 102.1 Phosphatidylserine.

Other animal findings indicate PS has an overall trophic (restorative) effect in the brain. Feeding PS to aging rats significantly slowed the usual age-related decline of forebrain cholinergic synapses[16] and of nerve cell dendritic densities in the hippocampus.[17,18] Also in aging rats, PS given by mouth significantly slowed the age-associated decline of receptors for nerve growth factor, a protein factor that stimulates brain circuit maintenance and renewal.[18]

Consistent with its importance for mitochondrial function, PS has enhanced human brain energetics. A positron emission tomography (PET) imaging study of dementia patients found that orally administered PS improved energy production and utilization by an average 14% across the brain.[19]

CLINICAL APPLICATIONS

Memory Decline

The primary clinical application of PS is to improve memory and other cognitive functioning in the middle-aged and elderly. In multiple randomized, double-blind, placebo-controlled trials, PS as a dietary supplement consistently improved memory, learning, word recall, and other cognitive functions.[2–5,20–28] In one such trial conducted with healthy subjects at an early measurable stage of cognitive decline (age-associated memory impairment), PS partially reversed the decline in the subgroup that was worst afflicted at the outset. The researchers estimated PS may have reversed approximately 12 years of decline and stated, "the magnitude of effect may be considered significant by many patients and clinicians."[3]

For patients with full-blown dementia, PS has shown mild benefits for memory and concentration, along with improvement in sociability and sometimes also in activities of daily living.[2,4,5,20,21,23] In the largest controlled dementia trial, a total of 425 elderly patients (aged 65–93 years) received either PS (300 mg/day) or a placebo for 6 months.[5] The PS group showed improvements in verbal learning and memory as well as in withdrawal/apathy that were highly statistically significant (P <0.01) compared with the placebo group. These patients were maintained on a variety of drugs, and no clinically meaningful adverse interactions with PS were observed.

In May 2003 PS acquired landmark regulatory status as a brain nutrient. The U.S. Food and Drug Administration granted two "qualified health claims" that PS may: (1) reduce the risk of dementia in the elderly; and (2) reduce the risk of cognitive dysfunction in the elderly.[29]

There have been indications PS also can improve mood and anxiety, but the trials conducted to date have been very small and poorly designed.[30–32] Larger and better designed clinical trials are needed to clarify the mood benefits of PS.

Stress

There is better evidence that PS can improve coping with stress, even in young, healthy men. British male undergraduate students were randomized to receive PS (300 mg/day) or a placebo for 30 days, then subjected to a challenging timed mental arithmetic test.[33] The PS group reported feeling less stressed after the test, compared with the placebo group. On visual analog mood scales, the PS group also surpassed placebo for feeling clear-headed, composed, and confident. Among subgroups with higher neuroticism scores, the PS subgroup reported significantly better mood after taking the test and were less stressed.

Regarding stress imposed by physical challenge, a low dose of PS (200 mg/day for 42 days) was found to significantly improve golfers' driving accuracy compared with placebo.[34] High daily doses of PS (750–800 mg/day) may also improve physical performance in cycling, running, and weight training.[35] Physical challenge can raise blood cortisol, and in two small trials with healthy men subjected to cycling stress, PS may have blunted this cortisol response.[6,36] High doses were needed: 600 mg/day[6] or 800 mg/day[36] for 10 days. However, both these trials had a crossover design that may not be optimal for PS. Because PS is a cell membrane nutrient, it may require a longer "washout" time to depart the membranes than the 10 or 14 days these trials allowed. Further, well-designed trials are needed to refine the utility of PS for countering mental or physical stress.

Other clinical trials suggest PS may work better against stress when combined with phosphatidic acid (PA), a phospholipid known to have cell membrane and cell-to-cell messenger functions in humans. In a randomized, double-blind trial, three groups of healthy men received two different doses of PS+PA (called PAS, in a ratio of 1:1 PS:PA by weight), or a placebo, for 42 days.[37] Then they were subjected to acute stress from the Trier Social Stress Test: make an unrehearsed job application speech THEN perform a complex mental arithmetic task. This increased their salivary and serum cortisol and adrenocorticotropic hormone (ACTH) levels. The high PAS dose (400 mg PS + 400 mg PA) maintained their ACTH level (but not cortisol) significantly lower, versus either the low PAS (200 mg PS + 200 mg PA) or the placebo. However, a subgroup with higher stress response to the Trier Test did also display both cortisol and ACTH blunting on the high PAS dose.

Evolution of PS Sourcing

PS as a dietary ingredient has evolved. PS used in early clinical trials came from cow brain as bovine cortex PS (BC-PS), produced by a laborious and costly process. By the 1990s the advent of prion-related "mad cow disease" made this source no longer guaranteed safe. Soy became the new source. Skeptics suggested this plant-source PS would not work because its tail fatty acid profiles differed from BC-PS. BC-PS had a small content of omega-3 docosahexaenoic acid (DHA) in its tails (well below 10%), whereas soy has none.[38] However, soy PS preparations have since produced clinical benefits in at least 16 double-blind trials.[38] Sunflower PS was also developed to avoid the perceived allergenicity of soy PS.

Advances with enzyme technology have resulted in commercial PS preparations with omega-3 DHA and eicosapentaenoic acid (EPA) contained in the molecules' tail pieces. In a 2008 double-blind trial, a group of children with attention deficit hyperactivity disorder (ADHD) showed improved visual sustained attention after 3 months on a "PL-Omega3" that provided 300 mg PS and 168 mg other phospholipids that altogether carried 156 mg EPA and 95 mg DHA.[39] This group's improvement surpassed the other groups that received fish oil (triglyceride) EPA+DHA or placebo. Subsequently a larger ADHD trial was conducted with a "PS-Omega3" that provided 300 mg PS carrying 80 mg EPA and 40 mg DHA per day for 15 weeks. Then all the children were continued on half that dose for another 15 weeks.[40] Restlessness and impulsivity improved significantly more in the PS-Omega3 group, as did a measure termed "Parent Impact-emotional." During the extension phase, those children switched from placebo to PS improved significantly on oppositional and hyperactivity scores.

Another omega-3, PS-DHA, was tried on nondemented elderly subjects with memory complaints.[41] After 15 weeks, this preparation (300 mg PS, carrying about 59 mg DHA and about 20 mg EPA per day) had improved verbal immediate recall superior to a placebo. The trial was then extended for another 15 weeks,[42] during which all the subjects received one third of the previous PS-DHA dose (100 mg PS, about 20 mg DHA, about 6 mg EPA) each day. Those subjects who were continuers on the PS-DHA maintained their improvement, whereas those who switched to PS-DHA from placebo attained significant improvement in attention and memory.

These technologically advanced omega-3 PS preparations all proved safe and well tolerated.[39–42] But their positive trial outcomes are tempered by findings that soy PS seemingly can perform just as well without omega-3 fatty acids attached. Thus in a double-blind trial with elderly subjects, soy PS at either 100 or 300 mg/day taken for 6 months significantly improved delayed word recall compared with placebo.[43] Also, in a double-blind trial with ADHD children, soy PS at 200 mg/day for 2 months displayed significant improvements in their overall ADHD symptoms, attention, and auditory memory, versus a placebo group.[44] The researchers commented that the children who received soy PS were noticeably better behaved at school and more tidy at home. Animal research had previously indicated that the head piece of the PS molecule is the key to its cell biology and clinical benefits.[2]

DOSAGE

The standard dosage recommendation for PS is 100 mg taken with meals one to three times daily. For optimal memory results, daily doses of 300 mg are more predictably beneficial.

TOXICOLOGY AND DRUG INTERACTIONS

After more than 3 decades' use as a dietary supplement, PS has shown no evidence of toxic effects or adverse drug interactions at dosages up to 800 mg/day.[2,5,21,39–44] The superb benefit-risk profile of this cell membrane nutrient makes it a premier option for anyone desiring to rescue, upgrade, or optimize their memory and overall brain wellness.

Common name: kava

GENERAL DESCRIPTION

Kava is a hardy, slow-growing perennial that generally resembles other members of the pepper family. It is an attractive shrub and can attain heights of more than 9 ft. The plant does not have many leaves, but those it does have are thin, single, heart-shaped, alternate, petiolate, 4 to 10 in. long, and sometimes wider than they are long. Although *Piper methysticum* does flower, it is incapable of self-reproduction; its propagation is vegetative and now caused solely by human effort.[1,2]

For medicinal purposes, it is the rootstock that is used. The rootstock is knotty, thick, and sometimes tuberous with holes or cracks created by partial destruction of the parenchyma. In other words, the rootstock is often somewhat pithy (Fig. 103.1). From the main rootstock, there are extensions of lateral roots up to 9 ft long.[1,2]

CHEMICAL COMPOSITION

Analysis of the composition of the dried kava rootstock indicates that it contains approximately 43% starch, 12% water, 3.2% simple sugars, 3.6% proteins, 3.2% minerals (primarily potassium), and 15% kavalactones (Table 103.1).[1,2]

Based on detailed analysis of the active ingredients of kava, a laborious process over the past 120 years, many experts now believe that the pharmacological activities of kava are caused mostly, if not entirely, by the presence of compounds known as kavalactones (also referred to as kava α-pyrones). Although the kavalactones are the primary active components, other components appear to contribute to the sedative and anxiolytic activities of kava, as one study found the sedative activity of a crude preparation to be more effective than the isolated kavalactones (Fig. 103.2).[3] The kavalactone content of the root can vary between 3% and 20%.

HISTORY AND FOLK USE

Oceania, the Pacific island communities of Micronesia, Melanesia, and Polynesia, is one of the few geographic areas of the world that did not have alcoholic beverages before European contact in the 18th century. However, these islanders did possess a "magical" drink used in ceremonies and celebrations because of its calming effect and ability to promote sociability. The drink, kava, is still used today in this region of the world, where the people are often referred to as the happiest and friendliest in the world.

The origins of kava use are not known, as it predates written history in Oceania.[1,2] It was first described for the Western world by Captain James Cook in the account of his voyage to the South Seas in 1768.

Many myths and legends surround the early use of kava. The plant itself probably originated in the New Guinea/Indonesia area and was spread along with other plants from island to island by early Polynesian explorers in canoes. Each culture has its own story on the origins of kava. For example, in Samoa, a story is told about the origins of kava and sugar cane. The story involves a Samoan girl who went to Fiji, where she married a great chief. After some time, she returned to Samoa, but before doing so, she noticed two plants growing on a hill. She saw a rat chewing on one of the plants and noticed that the rat seemed to go to sleep. She concluded that the plant was a comforting food. She decided she would take this plant, sugar cane, back to Samoa, but then she noticed that the rat awoke and began to chew the root of another plant, kava. The animal that had been weak and shy became bold, strong, and more energetic. She decided that she would take both plants back with her to plant in Samoa. The plants grew very well in Samoa, and soon a chief from a neighboring island exchanged two laying hens for roots of the two plants. Hence, the Samoans take credit for the spread of both sugar cane and kava.

In Tonga, a legend is told about a great chief named Loau who lived on the island of Euaiki. He went to visit his servant Feva'anga, who wanted to give a feast in honor of the chief, but it was a time of

great famine. In desperation, he and his wife killed and cooked their only daughter to be served to the chief. However, Loau recognized the human flesh in the food when it was served and would not eat it. He instructed Feva'anga to plant the food in the ground and to bring him the plant that would spring forth. On receiving the mature plant, Loau instructed that a drink be prepared from it and consumed with due ceremony.

The Kava Ceremony

Regardless of exactly how kava originated, it has been used in ceremonies by the Oceanic people for thousands of years. There are three basic kava ceremonies: the full ceremonial enacted on every formal occasion; the one performed at the meeting of village elders, chiefs, and nobles and for visiting chiefs and dignitaries; and the less formal kava circle common on social occasions.[1,2]

The first step of any kava ceremony was the preparation of the beverage. The following description of the classic process was written in 1777 by Georg Forster, a young naturalist on James Cook's second Pacific voyage:

> *[Kava] is made in the most disgustful manner that can be imagined, from the juice contained in the roots of a species of pepper-tree. This root is cut small, and the pieces chewed by several people, who spit the macerated mass into a bowl, where some water (milk) of coconuts is poured upon it. They then strain it through a quantity of fibres of coconuts, squeezing the chips, till all their juices mix with the coconut-milk; and the whole liquor is decanted into another bowl. They swallow this nauseous stuff as fast as possible; and some old topers value themselves on being able to empty a great number of bowls.*

As this traditional method of preparation became frowned upon or made illegal by colonial governments and missionaries, more sanitary methods of preparation, involving grinding or grating, took its place in many parts of Oceania.

The full kava ceremony, reserved for very highly honored guests, involves leading all the guests to a platform. The ceremony begins with the arrival of a group of young men dressed in ceremonial attire and carrying a bowl of the kava drink and necessary utensils. The bowl is placed between the kava preparers and the visitors. The kava is poured in a cup by a specially selected individual who then turns and faces the visitor and delivers the beverage to the chief guest. The guest is instructed to hold the cup with both hands and drink from it. If the whole cup is drained without stopping, everyone says "a maca" (pronounced "a matha," meaning "it is empty") and claps three times with cupped hands. The cupbearer then returns to the kava bowl and proceeds to serve the person next in rank or importance.

Important people who visit Fiji and other islands of Oceania still participate in the kava ceremonies. For example, during a 1992 presidential campaign visit to Hawaii, Hillary Clinton participated in a kava ceremony conducted by the Samoan community on O'ahu.

The Effects of Drinking Kava

Kava drinkers relate a pleasant sense of tranquility and sociability upon consumption. Subjective reports given by scientists who have sampled kava themselves are relatively abundant. One of the first scientific studies of kava was performed by the noted pharmacologist Louis Lewin in 1886. A later description written in 1927 is as follows[1]:

> *When the mixture is not too strong, the subject attains a state of happy unconcern, well-being and contentment, free of physical or psychological excitement. At the beginning, conversation comes in a gentle, easy flow and hearing and sight are honed, becoming able to perceive subtle shades of sound and vision. Kava soothes temperaments. The drinker never becomes angry, unpleasant, quarrelsome or noisy, as happens with alcohol. Both natives and whites consider kava as a means of easing moral discomfort. The drinker remains master of his consciousness and his reason. When consumption is excessive, however, the limbs become tired, the muscles seem no longer to respond to the orders and control of the mind, walking becomes slow and unsteady and the drinker looks partially inebriated. He feels the need to lie down. He is overcome by somnolence and finally drifts off to sleep.*

A later description was provided by researcher R.J. Gregory, who wrote the following from his own experience[1]:

> *Kava seizes one's mind. This is not a literal seizure, but something does change in the processes by which information enters, is retrieved, or leads to actions as a result. Thinking is certainly affected by the kava experience, but not in the same ways as are found from caffeine, nicotine, alcohol, or marijuana. I would personally characterize the changes I experienced as going from lineal processing of information to a greater sense of "being" and contentment with being. Memory seemed to be enhanced, whereas restriction of data inputs was strongly desired, especially with regard to disturbances of light, movements, noise and so on. Peace and quiet were very important to maintain the inner sense of serenity. My senses seemed to be unusually sharpened, so that even whispers seemed to be loud while loud noises were extremely unpleasant.*

Drinking about half a coconut shell (100–150 mL) of certain varieties of kava is enough to put most people into a deep, dreamless sleep within 30 minutes. Unlike alcohol and other sedatives, kava does not produce a morning hangover. The kava drinker awakens having fully recovered normal physical and mental capacities.

PHARMACOLOGY

Many of the first comprehensive studies on the activities of kavalactones were conducted by a team of scientists from the Freiburg University Institute of Pharmacology in Germany, led by Hans J. Meyer, during the 1950s and 1960s.[3] This research determined that kavalactones exhibit sedative, analgesic, anticonvulsant, and muscle-relaxing effects in laboratory animals. These studies seemed to confirm earlier empirical and subjective observations. Later studies used better-defined kava extracts.

Isolated Kavalactones Compared With Crude Extracts

Some evidence suggests that the whole complex of kavalactones and other compounds naturally found in kava produce greater pharmacological activity. In addition, studies showed that kavalactones are more rapidly absorbed when given orally as an extract of the root rather than as the isolated kavalactones. The bioavailability of lactones, as measured by peak plasma concentrations, is three to five times higher from the extract than when given as isolated substances.[3] Further evidence that kava root extracts are superior to isolated kavalactones was offered by an animal study demonstrating that although isolated kavalactones were well absorbed by the brain, crude kava preparations produced brain concentrations of lactones 2 to 20 times higher.[4] This evidence suggests that crude extracts standardized for kavalactone content may offer the greatest therapeutic benefit.

Several clinical trials featured a kava extract standardized to contain 70% kavalactones. However, this high percentage of kavalactones might be sacrificing some of the other constituents that may contribute

to the pharmacology of kava. More important than the actual percentage of kavalactones is the total dosage of the kavalactones and the assurance that the full range of kavalactones and other important constituents are present.

Sedative Effects

Numerous studies confirmed and/or elaborated on the sedative effects of kava. Most notable were studies that demonstrating that kavalactones exert many of their effects through nontraditional mechanisms. For example, most sedative drugs, including the benzodiazepines (e.g., diazepam, triazolam, clorazepate dipotassium), work by binding to specific receptors (benzodiazepine or γ-aminobutyric acid [GABA] receptors) in the brain, leading to the neurochemical changes (potentiation of GABA effects) that promote sedation. Studies in animals showed that the kavalactones do not bind to benzodiazepine or GABA receptors.[5] Instead, the kavalactones are thought to somehow modify receptor domains rather than interact specifically with receptor-binding sites. In addition, other studies indicated that the kavalactones appear to act primarily on the limbic system, the ancient part of the brain that affects all other brain activities and is the principal seat of the emotions.[6] It is thought that kava may also promote sleep by altering the way in which the limbic system modulates emotional processes. It appears that many of the laboratory models of identifying how a substance works to promote a calming effect are simply not sophisticated enough to evaluate the physiological effects of kava.

Analgesic Effects

In another example of the unusual pharmacological qualities of kava, a study designed to evaluate its pain-relieving effects could not demonstrate any binding to opiate receptors.[7] The significance of this finding was that the study used experimental models in which nonopiate analgesics like aspirin and other nonsteroidal anti-inflammatory drugs were ineffective. In addition, it was determined that the sedative or muscle-relaxing effects were not responsible for the pain-relieving effects. These findings indicate that kava reduces pain in a manner unlike morphine, aspirin, or any other pain reliever.

Anxiolytic Effects

An interesting difference of kava from other anxiolytics is that kava does not lose effectiveness with time. Kavalactones, even when administered in large doses, demonstrated no loss of effectiveness in animal studies.[8] This is another example of the unusual qualities of kava. Despite the long history of kava consumption and the wealth of clinical evidence in favor of the efficacy of kavalactones in treating anxiety, there is a severe gap in our understanding of the molecular target(s) and the mechanism(s) of action of these psychoactive compounds.

Anti-Ischemia Effects

Another important pharmacological activity of kava is its ability to protect against brain damage resulting from ischemia.[9] This effect was demonstrated in two animal models of focal cerebral ischemia. The effectiveness of the kavalactones was a result of their ability to limit the infarct area and to provide a mild anticonvulsant effect. Kava extract may prove useful in the recovery from a stroke.

Anti-Inflammatory Effects

In animal studies, the compounds extracted from *Piper methysticum* show promise in the prevention and treatment of inflammatory conditions. Kava-241, an optimized kavain derived compound, significantly reduced epithelial downgrowth and alveolar bone loss in a model of periodontitis.[10] Kava-241 treatment also significantly decreased tumor necrosis factor-α in serum from mice, emphasizing the novel properties of Kava-241 in the management of tumor necrosis factor-α–related diseases such as infective rheumatoid arthritis.[11]

CLINICAL APPLICATIONS

The primary clinical application of kava is in the treatment of anxiety. This application is well supported by clinical research.[12] However, the medicinal use of kava is shrouded in uncertainty as a result of reports of hepatoxicity (discussed in the "Toxicology" section).

Anxiety

Early clinical trials used D,L-kavain, a purified kavalactone, at a dosage of 400 mg/day. For example, in one double-blind, placebo-controlled study of 84 patients with anxiety symptoms, kavain was shown to improve vigilance, memory, and reaction time.[13] In another double-blind study, kavain was compared with oxazepam (a drug similar to diazepam [Valium]) in 38 patients.[14] Both substances caused progressive improvements in two different anxiety scores (Anxiety Status Inventory and the Self-rating Anxiety Scale) over a 4-week period. However, whereas oxazepam and similar drugs are addictive and cause side effects, kavain appeared to be free of these complications.

In one of the early studies with kava extracts, a 70% kavalactone extract was shown to exhibit significant therapeutic benefit in patients with anxiety.[15] The study was double-blind, and 29 patients were assigned to receive 100 mg of the kava extract three times a day whereas 29 other patients received a placebo. Therapeutic effectiveness was assessed using several standard psychological assessments, including the Hamilton Anxiety Scale (HAMA). The results of this 4-week study indicated that individuals taking the kava extract had a statistically significant reduction in symptoms of anxiety, including feelings of nervousness, and somatic complaints, such as heart palpitations, chest pains, headache, dizziness, and feelings of gastric irritation. No side effects were reported with the kava extract.

Studies also compared the effects of a kava extract standardized to contain 30% kavalactones with buspirone and opipramol. In the double-blind study, 129 patients with generalized anxiety disorder (GAD) were given either 400 mg kava (30% kavalactones), 10 mg buspirone, or 100 mg opipramol daily for 8 weeks.[16] Detailed analysis showed that no significant differences were observed regarding all efficacy and safety measures. About 75% of patients were classified as responders (50% reduction of the HAMA score) in each treatment group, and about 60% achieved full remission.

Kava was also shown to be particularly effective in relieving anxiety in perimenopausal and postmenopausal women.[17–19] In one double-blind study, two groups of 20 women with menopause-related symptoms were treated for 8 weeks with the 70% kavalactone extract (100 mg three times daily) or placebo.[20] The measured variable was once again the HAMA. The group receiving the kava extract demonstrated significant improvement at the end of the very first week of treatment. Scores continued to improve over the course of the 8-week study. In addition to symptoms of stress and anxiety, a number of other symptoms also improved. Most notably there was an overall improvement in subjective well-being, mood, and general symptoms of menopause, including hot flashes. As with previous studies, no side effects were noted.

Additional studies showed that unlike benzodiazepines, alcohol, and other drugs, kava extract was not associated with depressed mental function or impairment in driving or the operation of heavy equipment.[21,22] In one of these studies, 12 healthy volunteers were tested

in a double-blind crossover manner to assess the effects of oxazepam (placebo on days 1–3, 15 mg on the day before testing, 75 mg on the morning of the experiment), the extract of kava standardized at 70% kavalactones (200 mg three times daily for 5 days), and a placebo on behavior and event-related potentials (ERP) in electroencephalographic readings on a recognition memory task. The subjects' task was to identify within a list of visually presented words those that were shown for the first time and those that were being repeated. Consistent with other benzodiazepines, oxazepam inhibited the recognition of both new and old words as noted by ERP. In contrast, kava allowed a slightly greater recognition rate and a larger ERP difference between old and new words. The results of this study once again demonstrated the unusual effects of kava. In this case it improved anxiety, but unlike standard anxiolytics, kava actually improved mental function and, at the recommended levels, did not promote sedation. Another study indicated that kava helped improve reflex vagal control of heart rate in GAD patients.[23]

In 2009 the first documented human clinical trial assessing the anxiolytic and antidepressant efficacy of an aqueous extract of kava was published.[24] The World Health Organization suggested the investigation of aqueous kava extracts as a way to reduce the risk of hepatotoxicity with kava preparations. The Kava Anxiety Depression Spectrum Study was a 3-week, placebo-controlled, double-blind crossover trial that recruited 60 adult participants with 1 month or more of elevated generalized anxiety. The kava preparation produced significant anxiolytic and antidepressant activity and raised no hepatoxicity or safety concerns at the dose and duration studied. Specifically, kava reduced participants' HAMA scores in the first controlled phase by −9.9 versus −0.8 for placebo and in the second controlled phase by −10.3 versus +3.3. Pooled analyses also revealed highly significant relative reductions in anxiety and depression scale scores. In a subsequent 6-week, parallel, double-blind, randomized, controlled trial involving 75 participants with GAD (58 randomized to 120 mg daily kavalactones titrated to 240 mg for nonresponse), results revealed a significant reduction in HAMA scores in favor of kava over placebo.[25] For participants with moderate-to-severe level of anxiety, the treatment effect was more pronounced. As part of this trial, five GABA transporter polymorphisms were examined as potential pharmacogenetic markers of kava response. Within the kava group, GABA transporter polymorphisms rs2601126 and rs2697153 were associated with significant reductions in HAMA scores, suggesting specific GABA transporter polymorphisms may potentially modify anxiolytic response to kava.

DOSAGE

In clinical studies using pure kavalactones or kava extracts standardized for kavalactones, the dosage was based on the level of kavalactones. Because the kavalactone content of the root varies between 3% and 20%, preparations standardized for kavalactone content are preferred to crude preparations. A standard bowl of traditionally prepared kava drink contains approximately 250 mg of kavalactones, and in Oceania, several bowls may be consumed at one sitting. Dosages vary according to the desired therapeutic effect.

- Anxiolytic dosage: 45 to 80 mg of kavalactones three times a day
- Sedative dosage: 180 to 250 mg of kavalactones 1 hour before retiring

SIDE EFFECTS AND TOXICOLOGY

In November 2001 German health authorities announced that 24 cases of liver disease (including hepatitis, liver failure, and cirrhosis) associated with the use of kava had been reported. Of the affected persons, one died and three required a liver transplant. As a result, in December 2001, the US Food and Drug Administration began advising consumers of the potential risk of severe liver injury associated with the use of kava-containing dietary supplements. Kava was subsequently withdrawn from the market in the European Union, United Kingdom, and Canada. In 2007 Germany reevaluated the data, and the ban imposed on kava was overturned in 2014 after the decisions of two administrative German courts.[26] In the initial report, the true nature of kava-induced liver damage was clouded by the fact that in 18 of the cases, conventional prescription or over-the-counter pharmaceutical drugs with known or potential liver toxicity were also being used. Proponents of kava quickly argued that it was entirely possible that the use of kava by these individuals was a coincidence rather than the cause of the liver problems, resulting from excessive dosage or some other factor. As of 2007, of the approximately 100 cases of hepatotoxicity that were reported worldwide, causality deemed to be "probable" occurred in only 14 cases.[27] Two drug-monitoring studies, including a total of 7078 patients taking 120 to 150 mg kava extract per day, did not find a single case of kava-induced hepatotoxicity. A thorough review concluded that kava-induced hepatotoxicity would be extremely rare, highlighting the fact that even if all the cases of reported toxicity were causally linked to kava intake, as drug-induced hepatotoxicity frequency ranges from 1 to 10 per 100,000 exposed individuals, kava would be under 1 per 100,000.[28]

The existing data are complex, but it appears that the major factor in any kava-induced hepatotoxicity was the use of aerial parts, such as stems and leaves as well as stem peelings.[29] Once the demand for kava skyrocketed, there was not enough kava root to fill the demand. Suppliers then knowingly or unknowingly purchased the leaves and peelings of kava. The only parts of the kava plant that were traditionally used throughout its 3000-year history were the roots, never the peelings or the leaves. According to a World Health Organization report, German pharmaceutical industries preferred to buy kava stem peelings to extract kavalactones to make kava drugs; kava stem peelings were sold at almost one tenth of the price of kava roots.[30] In addition, dosage might also have been a factor in some of the cases of hepatotoxicity. A survey of 400 German medical practices showed that 78% of the kava prescriptions that were written before 2001 significantly exceeded the recommended intake.[31] Nonetheless, there were reports of hepatitis in patients using kava at dosages equal to or only slightly higher than recommended levels, indicating other factors beyond dosage.[32] Flavokawain B, a chalcone from kava root, was identified as a potent hepatocellular toxin.[33]

Measures suggested to address the hepatotoxicity issue include: (1) use of a noble kava cultivar such as Borogu, which is at least 5 years old at time of harvest; (2) use of peeled and dried rhizomes and roots; (3) dosage recommendation of less than or equal to 250 mg kavalactones per day (for medicinal use); and (4) a Pan Pacific quality control system enforced by strict policing.[29] Another important step may be determination of flavokawain B. It should be mentioned that although it has been suggested that traditional aqueous extracts should be used over ethanolic or acetonic extracts, the toxicity is linked to the kava plant itself, with a possibly low quality of the used kava cultivar or kava plant part rather than the method of extraction or solvent.[34]

High daily dosages of kava consumed over a prolonged period (a few months to a year) are associated with a number of side effects beyond liver damage, including the development of "kava dermopathy," a condition of the skin characterized by a peculiar generalized scaly eruption known as kani.[35] The skin becomes dry and covered with scales, especially the palms of the hands, soles of

the feet, forearms, the back, and shins. It was thought at one time that kava dermopathy might be caused by interference with niacin. However, in a double-blind, placebo-controlled study, niacinamide (100 mg/day) demonstrated no therapeutic effect.[36] It appears that the only effective treatment for kava dermopathy is reduction or cessation of kava consumption. No cases of kava dermopathy have been reported in persons taking standardized kava extracts at recommended levels.

Other reported adverse effects of extremely high doses of kava (e.g., more than 310 g/week) for prolonged periods are[37]:

- Biochemical abnormalities (low levels of serum albumin, protein, urea, and bilirubin)
- Elevated liver enzymes
- Presence of blood in the urine
- Increased red blood cell volume
- Decreased platelet and lymphocyte counts
- Shortness of breath

At this time, kava is not recommended for use by anyone who has any liver problems or who is a regular consumer of alcohol. Use of kava for more than 4 weeks requires close monitoring of liver enzymes (once every 4–6 weeks). Patients should be instructed to discontinue use of kava if symptoms of jaundice (e.g., dark urine, yellowing of the eyes) occur. Nonspecific symptoms of liver disease include nausea, vomiting, light-colored stools, unusual tiredness, weakness, stomach or abdominal pain, and loss of appetite.

Kava is not recommended for use by pregnant or breastfeeding women.

DRUG INTERACTIONS

Kava may potentiate the effects of benzodiazepines, barbiturates, and prescription sedatives. Kava also inhibits a number of the cytochrome P450 enzymes that play a role in the breakdown of many medications.[38] Therefore it has the potential to interact with a wide range of medications. There is evidence that kava interferes with dopamine or other drugs used in the treatment of Parkinson's disease; therefore until this issue is resolved, kava extract should not be used by patients with Parkinson's disease.[35]

Prebiotics, Synbiotics, and Colonic Foods

Jason A. Hawrelak, ND, BNat(Hons), PhD

OUTLINE

INTRODUCTION

Two of the main tools commonly used to beneficially modify the gastrointestinal tract (GIT) microbiota are probiotics and prebiotics. The focus of this chapter is to review the beneficial actions and safety profile of the latter. A *prebiotic* is defined as "*a substrate that is selectively utilized by host microorganisms conferring a health benefit.*"[113] Prebiotics are typically prescribed to modify the GIT microbiota; however, they are also now being used to modify the vaginal ecosystem and, in the future, will undoubtedly be used to modify the microbiota of other body sites, such as the skin, nose, and oral cavity.

Gastrointestinal prebiotics must meet several criteria:

1. Neither be digested nor absorbed in the stomach or small intestine[1]
2. Act as a selective food source for one or a limited number of potentially beneficial native bacterial species in the intestines[1]
3. Change the microbiota ecosystem toward a healthier composition[1]
4. Induce luminal or systemic changes that improve the health of the host[2]

Most emphasis at this stage has been on finding and studying food sources that are used by lactic acid-producing bacteria. This is a result of the health-promoting properties of these organisms.[1] The best-known lactic acid-producing bacteria belong to the genera *Lactobacillus* and *Bifidobacterium.* However, more recently, there has also been an expansion of focus onto substrates that enhance the growth of other beneficial bacterial groups, such as *Faecalibacterium prausnitzii, Akkermansia muciniphila,* and butyrate-producing species, such as *Anaerostipes* spp., *Eubacterium* spp., and *Roseburia* spp.[113]

Not all food ingredients that make it to the colon undigested will be prebiotics. Only compounds that are selectively consumed by species generally considered to be beneficial members of the microbiota, while being unused by potentially pathogenic ones, can truly be termed prebiotics. When prebiotics reach the colon (or distal small bowel), they are preferentially used by those organisms that have the capacity to hydrolyze their bonds. The metabolism of the prebiotic results in the increased growth and activity of the beneficial organism(s), often at the expense of other components of the microbiota.[3] Fig. 104.1 illustrates the prebiotic concept using two types of FOS as examples. Food ingredients that make it to the colon undigested but lack the selectivity of fermentation are best termed "colonic foods" and are discussed in more depth at the end of this chapter.

There are numerous compounds with the potential to be termed gastrointestinal prebiotics (Fig. 104.2). Table 104.1 lists these compounds and the type of microorganisms whose growth they promote. However, the best-researched prebiotics are fructooligosaccharides (FOS), galactooligosaccharides (GOS), and lactulose.

FRUCTOOLIGOSACCHARIDES

Description

FOS are linear or branched chains of fructose and glucose molecules.[8] The number of fructose units contained in the compound determines the name of the FOS. Oligofructose is generally composed of between 2 and 7 units, whereas inulin is composed of up to 60.[9] FOS are found in varying percentages in foods and have been discovered in more than 36,000 plant species, where they function primarily as storage carbohydrates.[10] FOS are found in many common vegetables, including asparagus, onion, leek, garlic, artichoke, Jerusalem artichoke, and chicory

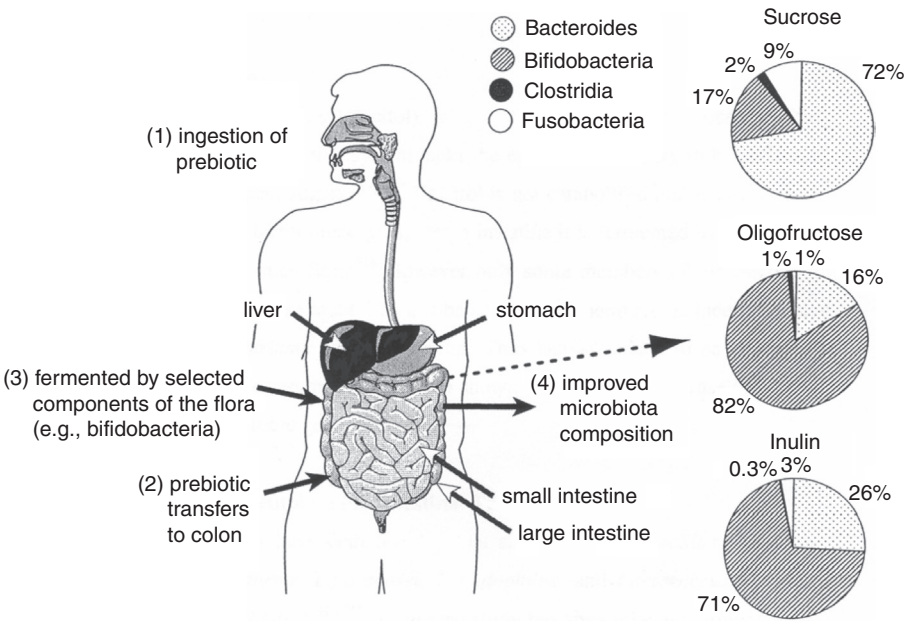

Fig. 104.1 The prebiotic concept: the effects of sucrose (placebo), oligofructose, and inulin on the intestinal ecosystem. Pie diagrams illustrate how the microbiota can develop during the feeding of sucrose and the prebiotics, oligofructose and inulin. (From Gibson GR. Dietary modulation of the human gut microflora using prebiotics. *Br J Nutr.* 1998;80[suppl 2]:S209-S212, used with permission.)

root. However, it is from the chicory root (*Cichorium intybus*) that most of the commercially produced inulin and oligofructose is manufactured. Short-chain fructans, such as oligofructose, are produced from inulin through a process of partial enzymatic hydrolysis.[8]

Commercial Forms

There are two ways in which FOS can be consumed, in supplements and in foods.

Fructooligosaccharide Supplements

The most commonly employed method to purify and concentrate FOS for supplement use is via a hot water extraction of fresh chicory roots. This process results in inulin (a large-chain FOS) as the end-product. Some manufacturers use enzymatic hydrolysis to produce oligofructose (a medium-chain FOS) from inulin,[9] although other manufacturers synthesize FOS from sucrose using the fungal enzyme fructosyltransferase (from *Aspergillus niger*). This latter process involves chemical synthesis of a new compound (called Neosugar or Actilight, a short-chain FOS) from two other natural compounds (fructose and glucose). The finished compound is similar to naturally obtained FOS, only smaller in size.[8]

FOS are resistant to digestion in the upper GIT because of the β-configuration of the bonds between the fructose units. Human digestive enzymes are specific in requiring α-linkages; thus, FOS are classified as nondigestible oligosaccharides.[8]

Food Sources of Fructooligosaccharides

As previously mentioned, FOS are common food ingredients. Individuals consuming the standard Western diet consume an average of 5.1 g/day of FOS.[11] However, this can easily be increased if foods rich in FOS are consumed daily. Foods containing FOS are outlined in Table 104.2.

There is no advantage to the consumption of FOS in supplements compared with FOS-rich foods. If the amount of FOS consumed in a food is similar to that used in clinical studies, it will promote similar effects, as all FOS consumed reach the colon intact, whether ingested in whole foods or in supplements.

Clinical Applications

The health benefits claimed for FOS mainly stem from their ability to increase numbers of beneficial organisms in the colon, to reduce numbers of potentially pathogenic microorganisms, and to stimulate short-chain fatty acid (SCFA) production. These health benefits include:

- Enhanced resistance to enteric pathogens due to colonization resistance provided by the increased growth of lactic acid bacteria[12]
- Increased resistance to infections due to the nonspecific stimulation of the immune system[12]
- Modification of carcinogen metabolism[12]
- Enhanced absorption of minerals[12]
- Improved serum lipid parameters[12]
- Improved satiety[13]
- Improved metabolic health[114]
- Treatment of atopic eczema and prevention of atopy development[14]
- Increased intestinal mucin production and trophic effects on the colonic epithelium, secondary to the increased production of SCFAs[15]

This review focuses primarily on the ability of FOS to improve the microbiota composition, enhance the immune response, improve mineral absorption, treat and prevent atopic diseases, improve satiety, and improve metabolic health.

Microbiota Composition

A number of trials have now verified the capacity of FOS to beneficially modify the microbiota-increasing levels of beneficial bacterial species while simultaneously decreasing levels of pathobionts. Table 104.3 contains an overview of some of these trials showing the effects observed at different dosage points.

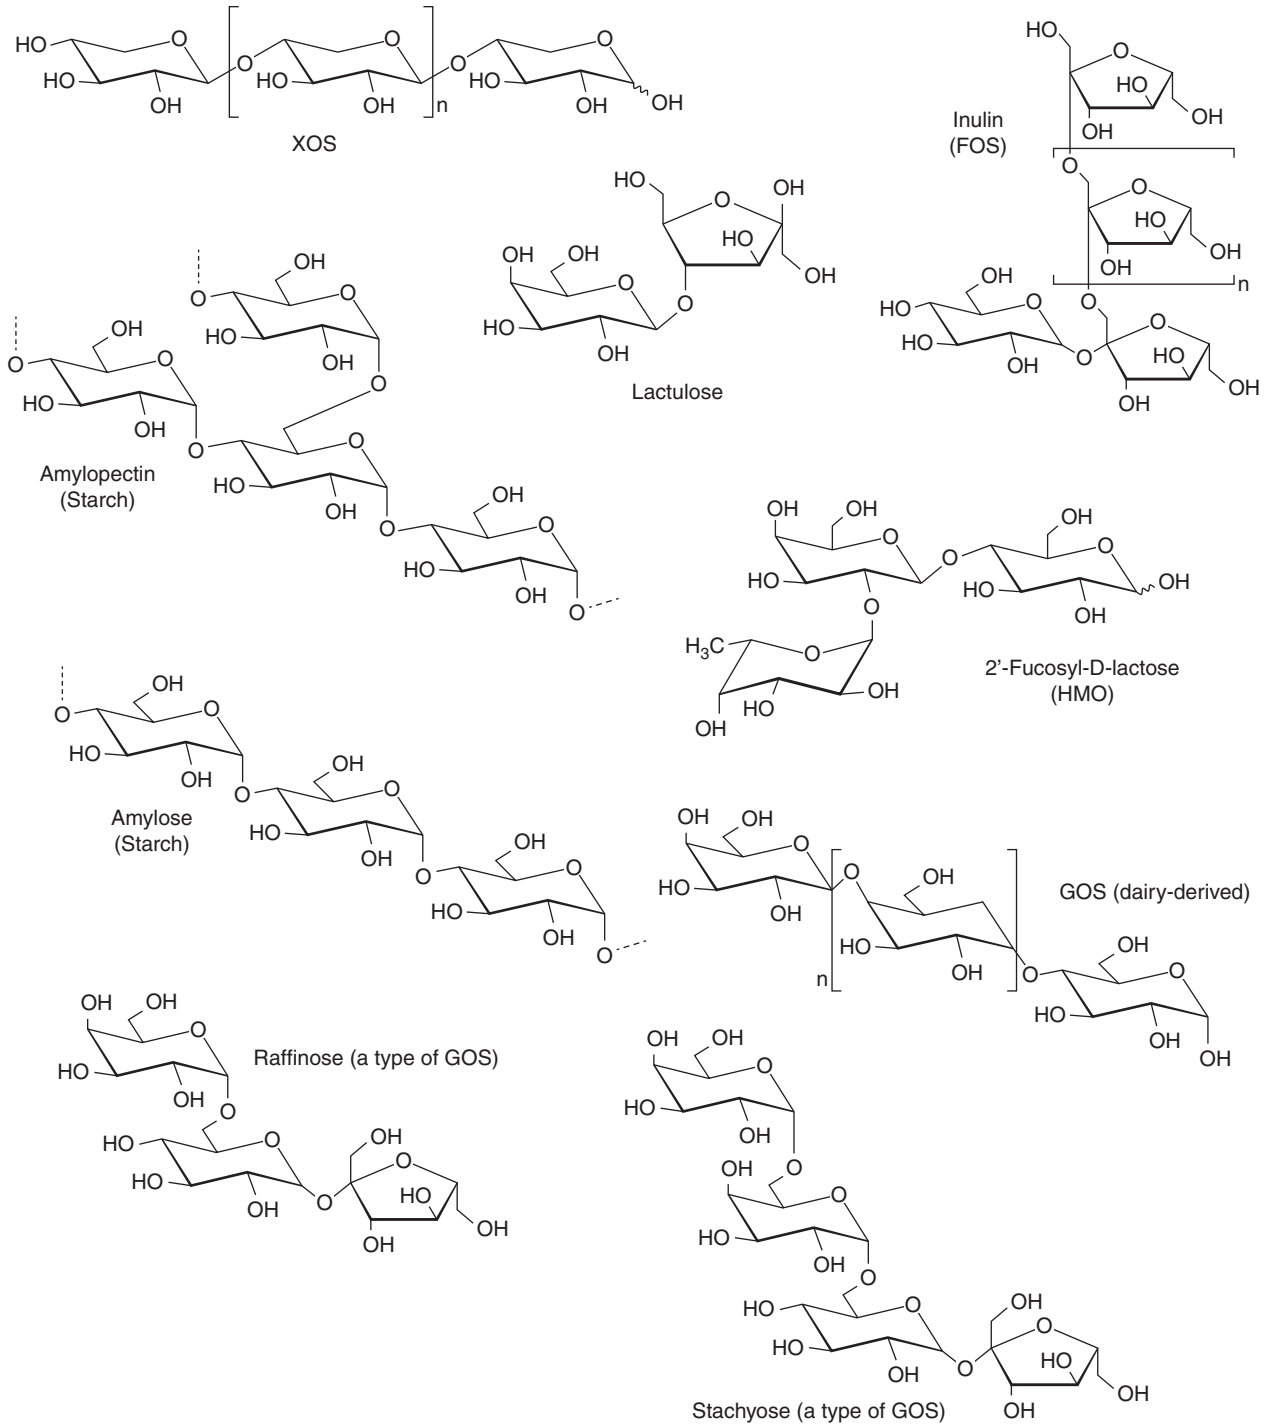

Fig. 104.2 Chemical structures of some of the main prebiotics and resistant starch. (From Healthy effects of prebiotics and their metabolites against intestinal diseases and colorectal cancer - Scientific Figure on ResearchGate. Available from: https://www.researchgate.net/Chemical-structures-of-the-different-prebiotics-families-FOS-fructo-oligosaccharides_fig1_292963145 [accessed Aug 27, 2018].)

In an attempt to determine the optimal dose of FOS, in terms of maximizing bifidobacteria numbers and minimizing side effects, Bouhnik et al.[16] designed a trial that used five different dosage levels. The dosages used were 20, 10, 5, and 2.5 g/day of oligofructose and 0 g/day as the placebo. The trial lasted 7 days. The data indicated that bifidobacteria counts did not change in subjects who received 0 or 2.5 g/day of oligofructose, but that concentrations in those subjects who ingested 5, 10, and 20 g/day were significantly greater ($P < 0.05$) at day 8 than at baseline. A significant correlation between the ingested dose of oligofructose and fecal bifidobacterial counts was observed at day 8 ($P < 0.01$). In terms of side effects, all groups, including the placebo group, experienced mild abdominal symptoms, such as bloating, excess flatus, borborygmi, or mild abdominal pain. In general, the higher the dose of oligofructose, the more side effects experienced.

TABLE 104.1 Potential Prebiotics and Their Target Organisms

Prebiotic Compound	Food Source	Targeted Microorganisms
Acacia gum	Gum Arabic (*Acacia senegal*)	*Bifidobacterium* spp.
Fructooligosaccharides	See Table 104.2	*Bifidobacterium* spp.
Galactooligosaccharides	See Table 104.4	*Bifidobacterium* spp.
Glucomannan	Konjac root (*Amorphophallus konjac*)	*Lactobacillus* spp.
Human milk Oligosaccharides	Human milk	*Bifidobacterium* spp.
Lactitol	None known	*Lactobacillus* spp.; *Bifidobacterium* spp.
Lactulose	UHT milk	*Lactobacillus* spp.; *Bifidobacterium* spp.
Larch arabinogalactans	Western larch (*Larix occidentalis*)	*Lactobacillus* spp.
Partially hydrolyzed guar gum	Guar bean (*Cyamopsis tetragonoloba*)	*Bifidobacterium* spp.; Butyrate-producing species
Polydextrose	None known	*Lactobacillus* spp.; *Bifidobacterium* spp.
Xylooligosaccharides	Oats	*Bifidobacterium* spp.

UHT, Ultrahigh-temperature. Potential prebiotic substances and the organisms whose growth they promote.[162-167,5-8]

TABLE 104.2 Fructooligosaccharide-Containing Foods

Foodstuff	Form	Average percentage of FOS Fresh Weight	Typical Serving Size	Approximate Dose of FOS per Serving
Asparagus	raw	2.5%	½ bunch (~250 g)	6.3 g
	boiled	1.7%	½ bunch (~250 g)	4.3 g
Banana	raw	0.5%	Medium sized banana	0.6 g
Barley	cooked kernels	0.15%	1 cup	0.2 g
Burdock (gobo)	root (raw)	14.5%	1 cup chopped	18.0 g
Chicory	roasted (as 'coffee')	41.7%	1 teaspoon powder	1.3 g
Dandelion	leaves (raw)	13.5%	½ cup chopped	2.0 g
	root (raw)	7.9%	1 cup chopped	8.0 g
Garlic	raw	12.9%	1 medium-sized clove	0.4 g
Globe artichoke	boiled	4.4%	1 medium-sized bud (assuming 45% edible portion)	3.0 g
Jerusalem artichoke	tubers (raw)	18.0%	Medium tuber	9.0 g
Leek	raw	3.0%	1 cup chopped	2.7 g
Onion	raw	4.3%	½ cup chopped	3.5 g
	cooked	3.1%	½ medium-sized onion	3.0 g
Rye	flour (raw)	0.7%	1 cup	0.9 g
Salsify	root (raw)	4.2%	1 cup chopped	4.3 g
Wheat	flour (baked)	2.4%	1 cup	2.9 g
Yacon	root (raw)	11.0%	1 cup chopped	13.2 g

The richest food sources of FOS.[151,152]

Bouhnik et al.[16] concluded that 10 g/day was well tolerated and that this dose was probably the optimal dose of oligofructose because it led to a significant increase in colonic bifidobacteria with minimal side effects in most participants.

Immune Response

Prebiotics, like FOS, have long been suggested to have immune enhancing effects.[18,19] It is, however, only recently that human clinical trials with hard outcomes have been completed. One of the first of these trials investigated the effects of a prebiotic mixture (containing a combination of FOS and GOS) in protecting against infections during the first 6 months of life in formula-fed infants. In this randomized, double-blind, placebo-controlled trial, infants allocated to the prebiotic group experienced significantly fewer episodes of all types of infections combined ($P = 0.01$) compared with those in the placebo group. There was also a trend for fewer episodes of upper respiratory tract infection ($P = 0.07$) and fewer infections requiring antibiotic treatment ($P = 0.10$) in the prebiotic group. Additionally, the cumulative incidence of recurring infection and recurring respiratory tract infection was 3.9% and 2.9% in the prebiotic group versus 13.5% and 9.6% in the placebo group, respectively ($P < 0.05$).[20]

This same infant cohort was followed up over the next 1.5 years. Those infants that received the prebiotic-enhanced formula for the first 6 months of life experienced significantly fewer episodes of

TABLE 104.3 The Effects of Various Doses of FOS on the Microbiota

Dose of FOS	Effects of FOS on the GIT Microbiota
4 g/day	Increase in bifidobacteria; decrease in β-glucuronidase activity[153]
8 g/day	Increase in bifidobacteria; decrease in enterobacteria populations[154]
10 g/day	Increase in bifidobacteria and *Faecalibacterium prausnitzii* populations[155]
12 g/day	Increase in bifidobacteria and the butyrate-producing species *Anaerostipes;* decrease in *Bilophila* abundance (an H_2S producer)
15 g/day	Increase in bifidobacteria; decrease in fecal bacteroides, clostridia, and fusobacteria concentrations[156]
15.4 g/day	Increase in bifidobacteria; decrease in fecal concentrations of Bacteroides/Prevotella and clostridia[157]
40 g/day	Increase in bifidobacteria; decrease in fecal concentrations of enterococci and enterobacteria[158]

physician-diagnosed respiratory tract infections ($P < 0.01$), fever episodes ($P < 0.00001$), and fewer antibiotic prescriptions ($P < 0.05$) compared with those in the placebo group.[21]

In a randomized, placebo-controlled, open-label study, Bruzzese et al.[22] also investigated the efficacy of a prebiotic-enhanced infant formula (a combination of GOS and FOS) on infection incidence in infants. The prebiotic-enhanced formula or a standard infant formula was consumed over the initial 12 months of life. During this period, the incidence of gastroenteritis was 59% lower in the prebiotic group ($P = 0.015$). Additionally, the number of children with recurrent upper respiratory tract infections tended to be lower in the prebiotic group (28% vs. 45%; $P = 0.06$), and the number of children prescribed multiple antibiotic courses per year was also lower (40% vs. 66%; $P = 0.004$).[22]

In a randomized, double-blind, placebo-controlled trial looking at older children (aged 7–19 months) attending daycare centers, short-term administration (21 days) of FOS was found to significantly reduce the number of infectious diseases requiring antibiotic treatment ($P < 0.001$), episodes of diarrhea and vomiting ($P < 0.001$), and episodes of fever ($P < 0.05$) compared with controls.[23]

In another randomized, controlled trial investigating the effects of FOS in toddlers (4–24 month olds) attending daycare, FOS administration was found to significantly reduce antibiotic use (32% reduction; $P = 0.001$) and daycare absenteeism (61% decrease; $P = 0.025$) compared with those in the control group. There was also a 34% reduction in episodes of fever in combination with any cold symptoms ($P = 0.001$) and a 61% decrease in episodes of fever in association with diarrhea ($P < 0.05$) in the FOS-supplemented group.[24]

Mineral Absorption

Studies using animal models have demonstrated that microbiota degradation of FOS significantly increases calcium and magnesium absorption.[25-27] Human studies have also shown that FOS consumption improves calcium absorption.[28-30] The proposed mechanism by which mineral absorption is enhanced by FOS is via the action of the protonated SCFA. Protonated SCFAs are absorbed across the apical membrane of colonocytes by direct diffusion. Due to the low pK_a values of the SCFA in relation to the intracellular pH, the SCFA dissociates once it enters the cell. This results in the release of a hydrogen ion. The hydrogen ion is subsequently secreted from the cell in return for a cation, which may be a magnesium or calcium ion. The hydrogen ion is then available to protonate another SCFA and enable it to diffuse into the cell.[28] However, other mechanisms may also be involved, such as the decrease in colonic pH, which results in increased solubility of calcium, increased colonic venous blood flow, enlarged colonic villi, and enhanced expression of calbindin-D9k (the active calcium transport route).[31] These effects are more pronounced in the colon, some of which are calcium-specific, explaining why calcium absorption is increased, whereas there is very little effect on the absorption of other minerals (e.g., iron and zinc).[32]

Bioavailability of Phytoestrogens

An interesting animal (rat) study recently found that concurrent consumption of FOS and the soy isoflavones genistein and daidzein significantly improved the bioavailability of these compounds. The relative absorption of genistein was approximately 20% higher in FOS-fed rats than in controls. In addition, the presence of both phytoestrogens in serum was maintained longer in FOS-fed rats than in controls, suggesting that FOS enhanced colonic absorption of these compounds.[33]

This result may be especially relevant to women after antibiotic therapy, when the metabolism and subsequent absorption of phytoestrogens appears to be impaired.[34] Bifidobacteria were demonstrated to possess β-glucosidase activity, and FOS administration resulted in enhanced β-glucosidase activity in animal models[35] and improved phytoestrogen bioavailability.[36] Therefore FOS consumption not only aids in the reestablishment of a healthy gut microbiota, but its consumption also increases colonic β-glucosidase activity, resulting in enhanced deglycosylation and, thus, increased colonic concentrations of the medicinally active aglycones.

Atopic Eczema and Prevention of Atopy Development

A number of studies found an aberrant composition of the GIT microflora in infants who later developed food allergies and atopic eczema.[37-39] More specifically, the development of atopic eczema was correlated with increased colonic concentrations of *Bacteroides* spp., *Clostridia* spp., and *Escherichia coli,* with a decreased concentration of bifidobacteria. This change in microbial composition was theorized to deprive the developing immune system from counterregulatory signals against T-helper 2 (Th2) mediated responses, and therefore promote Th2-type immunity.[39] Infantile atopic eczema is characterized by a Th2-dominated immune response, as well as excessive intestinal inflammation and aberrant macromolecular absorption across the intestinal mucosa.[40-42] These latter characteristics may also be caused by the dysbiotic condition. Bacteroides, clostridia, and *E. coli* all have the potential to trigger inflammatory responses in the gut and can release toxins that can impair intestinal permeability, leading to increased exposure to potential antigens.[39] Supplementation with FOS was demonstrated to decrease colonic concentrations of both bacteroides and clostridia, as well as promoting a bifidobacteria-dominated colonic flora.[17] FOS use may thus bring the aberrant intestinal flora back into balance and improve gut barrier function. The promotion of an intestinal flora dominated by gram-positive bacteria may also promote a shift toward Th1 immunity via enhanced production of interleukin-12 and interferon-γ.[43]

No trials appear to have assessed FOS in isolation in the treatment or prevention of atopic eczema. One trial was conducted, however, which assessed the efficacy of a FOS and GOS combination in the prevention of atopic dermatitis in infants.

In a randomized, double-blind, placebo-controlled trial, Moro et al.[44] evaluated the effects of a prebiotic-enhanced infant formula

on the incidence of atopic dermatitis during the first 6 months of life in formula-fed infants at high risk of atopy development. Atopic dermatitis developed in 23% of infants in the control group compared with 10% in the prebiotic group ($P = 0.014$) over the 6-month intervention period.[44] Subjects in the prebiotic group were also found to have significantly reduced plasma levels of total immunoglobulin (IgE) ($P = 0.007$), IgG2 ($P = 0.029$), and IgG3 ($P = 0.0343$), as well as cow's milk protein-specific IgG1 ($P = 0.015$), suggesting that FOS and GOS supplementation induced an antiallergic antibody profile.[45]

These same infants were followed up over the next 18 months. Those infants that received the prebiotic-enhanced formula for the first 6 months of life were at reduced risk of developing atopic disease over the follow-up period. Infants in the control group experienced a significantly higher rate of atopic disease, such as atopic dermatitis (27.9% vs. 13.6%), recurrent wheezing (20.6% vs. 7.6%), and allergic urticaria (10.3% vs. 1.5%), compared with infants in the prebiotic group (all $P < 0.05$).[21]

The capacity of prebiotics (as a class of agents) to prevent allergic diseases was assessed in a recent systematic review and meta-analysis. Prebiotic supplementation to formula-fed infants significantly reduced the risk of developing eczema (RR = 0.68, 95% CI: 0.40–1.15), wheezing/asthma (RR = 0.37; 95% CI: 0.17–0.80), and food allergy (RR = 0.28, 95% CI: 0.08–1.00). Nineteen of the 22 studies included in the review evaluated the effects of a FOS-GOS combination (like that previously mentioned) typically added to formula.[115]

Satiety

In the wake of some interesting preliminary animal research,[46] a single-blind, crossover, placebo-controlled trial was performed to assess the effects of FOS on satiety and energy intake in humans. Subjects ingested either 8 g of FOS twice daily (with breakfast and dinner) or a placebo. FOS supplementation was found to significantly increase satiety at breakfast and dinner (both $P = 0.04$), but not lunch. At dinner, FOS supplementation was also found to reduce hunger ($P = 0.04$) and prospective food consumption ($P = 0.05$). Energy intake at breakfast ($P = 0.01$) and lunch ($P = 0.03$) were also found to be significantly reduced after FOS supplementation, resulting in a 5% decrease in total energy intake per day.[13]

A randomized, double-blind, placebo-controlled trial investigated the effects of FOS supplementation in overweight and obese subjects. Over a 12-week period, subjects consumed either a placebo or 21 g/day of FOS. Subjects in the FOS group experienced a mean reduction of 1.03 kg body weight compared with a 0.45 kg increase in weight in the control group ($P = 0.01$). FOS consumption was also associated with a lower area under the curve for ghrelin ($P = 0.004$) and a higher area under the curve for peptide YY ($P = 0.03$), suggesting an upregulation of satiety hormone secretion. These changes coincided with a reduction in self-reported caloric intake ($P \leq 0.05$). Serum glucose concentrations and insulin levels also significantly improved in the FOS group compared with baseline measures (both $P \leq 0.05$).[47]

Metabolic Health and Type 2 Diabetes

Inulin and Jerusalem artichokes have a long history of use in the treatment of diabetes, with the first recommendations of their use in the medical literature dating back to 1925.[116] More recently, there have been a number of animal and human trials that have substantiated this use.

A systematic review and meta-analysis of animal models that evaluated the effect of FOS supplementation on glucose homeostasis found the consumption of FOS to consistently decrease fasting blood glycemia levels, irrespective of the animal's metabolic status (e.g., in healthy, obese, or diabetic animals) and diet (low-fat or high-fat). A global reduction of 18% in fasting glycemia was observed in the FOS-treated animals compared with controls. There was a clear dose-dependent effect. FOS supplementation also increased fasting and postprandial glucagon-like peptide 1 concentrations, as well as peptide YY concentrations.[117]

A number of recent randomized controlled trials have shown FOS supplementation to aid in the management of type 2 diabetes. In one of the first of these trials, 10 g daily FOS supplementation over a period of 2 months to women with type 2 diabetes resulted in significant decreases in fasting plasma glucose levels of 8.5%, glycosylated hemoglobin levels of 10.4%, and malondialdehyde levels of 37.2% (all $P < 0.05$). Additionally, there were significant increases in total antioxidant capacity (18.8%) and superoxide dismutase activity (4.4%) in the FOS group compared with controls (both $P < 0.05$). However, changes in fasting insulin, homeostasis model assessment of insulin resistance, and catalase activity were not significant compared with the placebo group.[118]

In a follow-up study, the same dose of FOS given over 8 weeks to women with type 2 diabetes resulted in significant decreases in fasting blood sugar (8.5%), hemoglobin A1c (10.4%), fasting insulin (34.3%), homeostasis model assessment of insulin resistance (39.5%), high-sensitivity C-reactive protein (35.6%), tumor necrosis factor (TNF)-α (23.1%), and plasma lipopolysaccharide (27.9%) compared with the placebo group (all $P < 0.05$). The authors concluded that FOS supplementation improved blood sugar regulation, modulated inflammation, and decreased metabolic endotoxemia in diabetic women.[119]

In another similarly designed trial, 10 g FOS/day given to overweight women with type 2 diabetes for 8 weeks resulted in significant decreases in levels of fasting plasma glucose of 9.5%, glycosylated hemoglobin of 8.4%, interleukin-6 of 8.2%, TNF-α of 19.8%, and plasma lipopolysaccharide of 22.0% compared with placebo controls (all $P < 0.05$). Decreases in levels of interferon-γ and high-sensitivity C-reactive protein and increases in the level of interleukin-10 were not significant in the FOS group compared with controls.[114]

A further study in a similar population of overweight diabetic patients evaluating the anti-inflammatory effect of FOS found 10 g/day over 45 days to significantly decrease TNF-α mRNA expression, in addition to decreasing high-sensitivity CRP levels and diastolic blood pressure (all $P < 0.05$ vs. placebo). Gastrointestinal populations of the beneficial microbe *Akkermansia muciniphila* significantly increased with FOS supplementation.[120]

Dosage

Studies showed a bifidogenic effect in dosages of 4 to 40 g/day of FOS. The optimum dosage in adults, in terms of side effect profile and increases in bifidobacteria, is considered to be 10 g/day.[16] However, it may be a good idea to start off with a lower dose (e.g., 3 g/day) and slowly increase it to reduce chances of adverse GIT reactions. Dosages of less than 3 g/day in adults are unlikely to cause significant alterations in the GIT microecology. Studies in infants and toddlers generally administered between 1 and 3 g/day of FOS.

Toxicity

FOSs are components of many common foods. There are no genotoxic, carcinogenic, mutagenic, teratogenic, or toxicological effects associated with the ingestion of any FOS.[12,48] Oligofructose and inulin are officially recognized as natural food ingredients in most European countries and have a self-affirmed "Generally Regarded as Safe" status in the United States.[8]

Recently a published case study described an instance of anaphylaxis attributed to inulin found in vegetables and processed foods. This

TABLE 104.4 Galactooligosaccharide-Containing Foods

Foodstuff	Form	Average Percentage of GOS Fresh Weight	Typical Serving Size	Dose of GOS per Serving
Beetroot	tuber (raw)	0.14%	1 cup grated	0.20 g
Borlotti beans	canned	1.00%	½ cup	0.91 g
Broccoli	raw	0.13%	½ cup chopped	0.05 g
Chick peas	boiled	1.25%	½ cup	1.08 g
Fennel	Bulb (raw)	0.10%	1 cup sliced	0.09 g
Haricot beans	boiled	1.09%	½ cup	1.09 g
Lentils - green	boiled	0.46%	½ cup	0.43 g
Lentils - red	boiled	0.46%	½ cup	0.43 g

The richest food sources of GOS.[159,160]

was later confirmed with skin-prick testing and blinded food-provocation testing.[49] This allergy does appear to be extremely rare, however, considering the widespread consumption of FOS-containing foods.

The only side effects noted with administration are mild digestive symptoms, such as flatulence, borborygmi, abdominal bloating, and abdominal discomfort. However, these effects are dose-dependent and occur less regularly in smaller doses. Over time, these symptoms will diminish as the intestinal flora adjusts to the greater amount of substrate available.[50] However, some individuals may continue to experience mild abdominal bloating and discomfort even with continued use.

There have been some concerns in the literature regarding the ability of *Klebsiella pneumoniae* to use FOS as a growth substrate.[51,52] FOS was shown to stimulate the growth of *K. pneumoniae* in Petri dishes. However, this occurred only when *Klebsiella* was grown in isolation, with no other competing organisms present. In mixed culture experiments, where *Klebsiella* was grown in the presence of many other human GIT microorganisms, this did not occur.[9] In these situations, which more closely resemble the environment of the human GIT (where more than 500 species of bacteria compete for available growth substrates),[53] FOS did not stimulate the growth of *Klebsiella*.[8] In addition, no human or animal experiment has ever reported an increase in the *Klebsiella* concentration in the GIT after FOS consumption.

Given the efficacy of a diet low in oligosaccharides (e.g., the low fermentable oligosaccharide, disaccharide, monosaccharide and polyol [FODMAP] diet) in the management of irritable bowel syndrome (IBS),[121] it would be prudent to be cautious with FOS supplementation in patients with IBS. Not all patients react negatively to FOS supplementation, however.[122] Additionally, some research has found FOS supplementation in IBS patients to decrease rectal hypersensitivity and reduce anxiety levels; thus providing benefit to these patients.[123] Therefore in IBS patients where FOS supplementation is warranted, it may be a case of starting low and slowly increasing the dose over a few weeks to achieve the therapeutic dose.

GALACTOOLIGOSACCHARIDES

Description

Galactooligosaccharides (GOS) are chains of galactose molecules, typically containing between three and eight units, with a glucose molecule at the reducing terminus. Galactose-containing oligosaccharides are found in all mammalian milks.[54] Commercially, they are produced synthetically from lactose, typically using the bacterially derived enzyme β-galactosidase.[55] Like all prebiotics, GOS are neither broken down nor absorbed in the upper GIT.

Commercial Forms

GOS are available in two main forms: syrup and powder. As galactose-containing oligosaccharides are abundant in human breastmilk, GOS have recently been added to some artificial infant formulas in efforts to more closely approximate breastmilk.[56,57] Foods naturally rich in GOS are outlined in Table 104.4.

Clinical Applications

GOSs have a number of clinical applications, including:

- Promotion of bifidobacterial growth
- Treatment of constipation
- Prevention of atopic disease
- Treatment of irritable bowel syndrome
- Increased resistance to infections
- Prevention of gastrointestinal infections
- Improved absorption of calcium
- Promoting skin health
- Modulating mood and the stress response

Bifidobacterial Growth

A number of studies have now shown the ability of GOS to beneficially modify the gastrointestinal microbiota—both increasing levels of beneficial bacterial species while simultaneously decreasing levels of

TABLE 104.5 The Effects of Various Doses of GOS on the Microbiota

Dose of GOS	Effects of GOS on the GIT Microbiota
2.5 g/day	Increase in bifidobacteria ($P < 0.05$); decreased fecal concentrations of protein putrefactive byproducts (indoles and isovaleric acid)[161]
2.6 g/day	Fecal bifidobacteria counts increased significantly, as did fecal levels of *Lactobacillus-Enterococcus* spp. (both $P < 0.001$ compared with placebo); concentrations of *Bacteroides* spp., the *Clostridium histolyticum* group, *E. coli,* and *Desulfovibrio* spp. decreased compared with placebo treatment (all $P < 0.001$)[162]
5 g/day	Increase in bifidobacteria and *Faecalibacterium prausnitzii* (both $P < 0.05$); decrease in *Bacteroides* spp. ($P < 0.01$)[163]
10 g/day	Increase in bifidobacteria ($P = 0.007$)[129]

pathobionts. Table 104.5 contains an overview of some of these trials showing the effects observed at different dosage points.

A randomized, double-blind, placebo-controlled trial attempted to determine the optimal dose of GOS by investigating the effects of four different doses: 2.5, 5, 7.5, and 10 g/day. After 7 days of consumption of 10 g/day, fecal bifidobacteria levels increased 0.4 log units ($P = 0.007$ compared with placebo). In the dose–response phase of the trial, there were no significant differences found between the different GOS doses in their capacity to increase bifidobacteria numbers (i.e., there was a lack of dose response).[58]

Treatment of Constipation

A number of studies were conducted to evaluate the effects of GOS administration on bowel function. Consuming 9 g/day of GOS was found to increase defecation frequency (from 5.9–7.1 movements per week) in elderly subjects over a 2-week treatment period. There was also a trend for easier defecation ($P = 0.07$) during the GOS phase of the trial.[59]

Randomized controlled trials evaluated the laxative effects of GOS in healthy adult subjects with a tendency to constipation. At a daily dose of 5 and 10 g, there were significant improvements in defecation frequency, from 0.92 to 1.07 movements daily ($P < 0.05$) and from 0.85 to 0.97 times per day ($P < 0.05$), respectively.[60]

Atopic Disease

No trials appear to have assessed GOS in isolation for the treatment or prevention of atopic eczema. One trial was conducted, however, assessing the efficacy of a GOS and FOS combination in the prevention of atopic dermatitis in infants. This trial is discussed in the FOS section under "Treatment of Atopic Eczema and Prevention of Atopy Development."

Irritable Bowel Syndrome

In a randomized, single-blind, placebo-controlled, crossover trial, supplementation of 3.5 g/day of GOS to subjects with IBS was found to significantly improve stool consistency, flatulence scores, bloating scores, and overall IBS symptom scores compared with placebo (all $P < 0.05$) over a 4-week treatment period. Supplementation of 7 g/day resulted in significant improvements in overall IBS symptom scores and a reduction in anxiety levels compared with placebo (both $P < 0.05$). However, there was also a significant increase in bloating scores relative to baseline when subjects were taking the higher dosage ($P < 0.05$).[61]

Immune Function

No human studies appear to have assessed GOS on their own for the improvement of immune function. A number of trials were conducted assessing the efficacy of FOS and GOS combinations, however. These trials are discussed in the FOS section.

Gastrointestinal Infections

Animal and in vitro models suggested that GOS supplementation might have a protective effect against a range of gastrointestinal pathogens. GOS was demonstrated to reduce adherence of pathogenic strains of *E. coli* to gastrointestinal cells,[62] inhibit binding of *Vibrio cholerae* toxin to its receptor in the human GIT,[63] and reduce colonization and pathology associated with *Salmonella typhimurium* infection in a murine model.[64]

These preliminary results inspired a recent randomized, double-blind, placebo-controlled trial evaluating the potential of GOS administration to prevent travelers' diarrhea. Subjects ingested 2.6 g GOS once daily, starting 7 days before reaching their holiday destination and continued taking it daily throughout their holiday. Compared with the placebo group, subjects in the GOS group experienced a 40% decrease in the incidence ($P < 0.05$) and a 48% reduction in duration of travelers' diarrhea ($P < 0.05$). Additionally, they had less abdominal pain ($P < 0.05$) and experienced improved quality of life ($P < 0.05$).[65]

Calcium Absorption

Research found supplemental GOS significantly increased calcium absorption in a randomized, double-blind, crossover trial in postmenopausal women. Administration of 20 g/day was found to increase true calcium absorption from 16% during placebo administration to 24% during GOS treatment ($P = 0.04$). This increase in absorption was not accompanied by increases in urinary calcium excretion.[66]

Skin Health

In a randomized, double-blind, placebo-controlled trial, investigators examined the effects of GOS ingestion (2 g/day) on the condition of the skin. After 12 weeks of supplementation, the increase in corneometer values from baseline to week 12 was significantly greater in the GOS group than in the placebo group (6.9 vs. 2.9 arbitrary units, $P < 0.05$). A corneometer uses the high dielectric constant of water to analyze the water-related changes in the electrical capacitance of the skin. An increase in corneometer values is interpreted as improved skin hydration. The transepidermal water loss in the GOS group was also significantly reduced after 12 weeks of GOS treatment (20.1 g/h/m^2 at baseline vs. 17.5 g/h/m^2 at week 12; $P < 0.05$). Additionally, GOS treatment significantly reduced total wrinkle area and the percentage of wrinkle area compared with baseline ($P < 0.05$), whereas both these values increased slightly in the placebo group.[124]

A further randomized, double-blind, placebo-controlled trial evaluated the effects of a prebiotic combination (GOS + lactulose; 4.5 g/day total) on skin health. At the end of the 8-week trial, subjects in the prebiotic group showed a reduction in mean wrinkle length and depth as measured via a quantitative skin evaluation, whereas the placebo group showed slight increases in these parameters ($P < 0.001$). The wrinkle severity rating scale significantly improved in the prebiotic group, versus a worsening in the placebo group ($P < 0.001$). The global esthetic improvement scale was also significantly higher for the prebiotic group ($P < 0.001$). The mechanisms by which orally ingested prebiotics improve skin condition and hydration are not currently known.[125]

Mood and Stress Response

As detailed in the previously mentioned IBS GOS trial, the 7 g/day dose was found to significantly reduce anxiety scores in IBS patients.[126] This

finding has stimulated other researchers to examine the potential of prebiotics, and GOS treatment in particular, to modify mood.

Using a mouse model of chronic stress, investigators found GOS or a GOS-FOS combination to attenuate acute stress-induced corticosterone release and reduce the number of stress-induced bowel movements. The combination also significantly increased hippocampal brain-derived neurotrophic factor gene expression, GABA receptor gene expression, and serotonin levels in the prefrontal cortex. Additionally, the GOS-FOS combination reduced stress-induced depression-like and anxiety-like behavior in the mice.[127]

In a double-blind, placebo-controlled trial, healthy volunteers were randomized to receive either FOS (5.5 g/day), GOS (5.5 g/day), or placebo for 3 weeks. At the end of the 3 weeks, salivary morning cortisol was significantly lower only in the GOS group ($P < 0.05$). This group also experienced increased processing of positive versus negative attentional vigilance. The results suggest the capacity of GOS to beneficially modify neuroendocrine stress responses in humans.[128]

Dosage

A bifidogenic effect was observed in doses of 2.5 to 15 g/day. With no apparent dose response, there appears to be little benefit in dosing higher than the minimum required dose (i.e., 2.5 g/day) for this purpose. For the treatment of IBS, 3.5 g/day seems to be the optimal dose. For anxiety management and to modify the stress response, 5.5 to 7.0 g/day appears efficacious, whereas for the prevention of travelers' diarrhea 2.6 g/day has been shown to be effective. To enhance calcium absorption, higher doses may be required (e.g., 20 g/day).

The Golden Rule of prebiotic dosing is to start low and slowly increase the dose over a period of weeks to achieve the therapeutic or optimal dose. Most individuals tolerate a starting dose of 2.5 g/day with few issues—only minor digestive discomfort (if any). However, if a patient is very prone to bloating and distension, one can start at one-quarter to one-half this dose. It is worth noting, however, that GOS supplements have been found to decrease bloating, distension, and abdominal pain scores in patients with irritable bowel syndrome,[126] and some research has found GOS to actually decrease intestinal gas (hydrogen) production.[129]

Toxicity

Galactose-containing oligosaccharides are found in all mammalian milks. Animal research has consistently demonstrated a lack of genotoxic, mutagenic, or toxicologic effects with GOS ingestion.[67] The nontoxic dose level of GOS was found to be over 2000 mg/kg body weight per day in murine models.[68] Therapeutic use of GOS is considered very safe and GOS themselves are components of many commonly consumed foods. Clinical trials have generally found GOS to be very well tolerated (in infants, adolescents, adults, the elderly, and during pregnancy),[126,130-133] with GIT side effects (e.g., bloating) only noted with higher doses in most research.[126] Supplemental GOS is generally very well tolerated, even in individuals who react to other prebiotics (e.g., FOS and lactulose) and even in those patients who react to food sources of GOS (i.e., legumes).

LACTULOSE

Introduction

Lactulose is a semisynthetic disaccharide composed of the monosaccharides fructose and galactose. It was first synthesized from lactose in 1929 by Montgomery and Hudson.[69] The human digestive system lacks the ability to break down lactulose into its component hexose and pentose moieties. Hence, lactulose is neither catabolized nor absorbed in the small intestine.

Once lactulose reaches the large intestine, it is fermented by the normal intestinal microflora. Fermentation is the process through which the normal intestinal microflora catabolizes carbohydrates to obtain energy for growth and maintenance of cellular functions. The end products of lactulose fermentation include SCFA, lactic acid, hydrogen, and carbon dioxide.[70] In vitro experiments demonstrated that overall SCFA production is increased two- to threefold by the addition of lactulose, whereas acetate synthesis is increased four- to sixfold.[71]

Within the large intestine, these SCFAs are avidly absorbed by colonocytes and used as a source of energy, either locally or systemically. The production of SCFA also results in the acidification of the colonic contents.[70] Bown et al.[72] demonstrated that a daily dose of 30 to 40 g of lactulose decreased the pH of the proximal colon from 6.0 to 4.85.

Commercial Forms

Lactulose is available in two forms: syrup and crystalline powder. Lactulose syrup generally contains between 5% and 67% lactulose (in addition to some lactose and galactose), whereas the crystalline powder is composed of 99% lactulose. The only food source of lactulose thus far identified is ultraheat treated milk; however, lactulose is present only in insignificant amounts.[4]

Clinical Applications

Lactulose has a wide variety of clinical applications, including:

- Promotion of lactobacilli and bifidobacteria growth
- Decreasing growth of intestinal pathogens
- Constipation
- Prevention of colon cancer
- Liver disease
- Endotoxemia
- Prevention of urinary tract infections (UTIs)
- Enhancing calcium and magnesium absorption

Lactobacilli and Bifidobacterial Growth

In one of the original studies using lactulose to change the GI microbiota, MacGillivray et al.[73] assessed the effects of lactulose feeding on infants. All infants were formula-fed and under 4 months old. After a short feeding period of 2 days, the lactulose-containing formula feed produced a preponderance of *Lactobacillus bifidus* (now known as *Bifidobacterium bifidum*) in the stools of 88% of infants. In 66% of the infants, *B. bifidum* dominated the microbiota in concentrations of greater than 90%. None of these infants had a bifidobacteria-dominated flora at baseline.[73]

Terada et al.[74] reported that 3 g/day of lactulose taken over a 2-week period altered intestinal microbiota and fecal bacterial metabolism in adults. The study was conducted in eight healthy volunteers. During the intake of lactulose, the number of bifidobacteria increased significantly ($P < 0.001$), as did the lactobacilli population ($P < 0.05$), whereas the number of Bacteroidaceae and clostridia decreased ($P < 0.05$) compared with baseline. Bifidobacteria became the numerically dominant microorganism in the fecal flora after 14-day administration. The fecal metabolites skatole, indole, and phenols were also significantly decreased with lactulose intake ($P < 0.05$). Fecal β-glucuronidase, azoreductase, and nitroreductase activities also decreased significantly ($P < 0.05$) after 14 days of treatment. These latter results indicated decreased metabolism of putrefactive (protein fermenting) organisms of the microbiota. The mean fecal pH also decreased from 7.0 to 6.4.[74]

Ballongue et al.[75] conducted a double-blind, randomized, placebo-controlled study, assessing the effects of a daily dose of 20 g of lactulose (10 g bid) on the gastrointestinal microbiota. After a 4-week treatment period, populations of *Bacteroides, Clostridium,*

and coliforms decreased by 4.1, 2.3, and 1.8 log units, respectively. *Bifidobacterium* and *Lactobacillus* populations increased by 3.0 and 1.9 log units (both $P < 0.01$ compared with placebo), respectively. The fecal pH also decreased from a baseline of 6.9 to 5.8 by the end of the treatment period ($P < 0.01$). Acetic acid production was increased by 33% and lactic acid production by 30% ($P < 0.01$) via lactulose administration. Gastrointestinal production of putrefactive by-products, cresol, indole, phenol, and skatol were all significantly reduced by lactulose administration (all $P < 0.05$), as were the production of the bacterial enzymes, azoreductase, 7α-dehydroxylase, β-glucuronidase, nitroreductase, and urease (all $P < 0.05$).[75]

Inhibition of Potentially Pathogenic Microorganisms

Research suggests that lactulose not only enhances the growth of beneficial members of the GIT microbiota, but also inhibits the growth of potential intestinal pathogens. Studies demonstrated that lactulose consumption can decrease colonic concentrations of clostridia, *Bacteroides* spp., and coliforms,[75] as well as eradicating carrier states of *Salmonella* spp.[76] Some preliminary evidence also suggests a possible role for lactulose therapy in the treatment of small intestinal bacterial overgrowth.[77]

The ability of lactulose to increase numbers of lactobacilli and bifidobacteria and to decrease numbers of gram-negative bacteria is believed to be a result of two mechanisms. The first is lactulose's ability to act directly as a food source for lactobacilli and bifidobacteria organisms, while being only weakly metabolized by gram-negative organisms.[78] The second mechanism is the change in colonic pH caused by the end products of lactulose metabolism—lactic acid and SCFAs. The coupled effect of production of SCFAs and pH decrease has been shown to inhibit the growth of gram-negative bacteria. The decreased pH resulting from lactulose administration was shown to increase the total concentration of the undissociated forms of SCFA.[75] These lipophilic acids can penetrate the microbial cell membrane, and at the higher intracellular pH, dissociate to produce hydrogen ions. The hydrogen ions interfere with essential metabolic functions, such as substrate translocation and oxidative phosphorylation, and hence inhibit the growth of gram-negative microbes.[79]

In vitro experiments also demonstrated the ability of lactulose to inhibit the growth of *Candida albicans.* A continuous flow culture was used as a model of the human GIT ecosystem. Within 24 hours of the input of 0.25% lactulose, *C. albicans* numbers were reduced by 97%. The reduction in *Candida* numbers was believed to be caused by the increase in the growth of beneficial lactic acid bacteria and the overall decrease in pH.[80]

Constipation

Lactulose is used in conventional medicine mainly for its laxative effects. It works primarily as an osmotic laxative, but the increased production of SCFAs may also play a role.[70,81] Ingestion of lactulose was found to cause statistically significant increases in the frequency, weight, volume, and water content of stools and to produce stools of softer consistency compared with both baseline and placebo.[82]

Colon Cancer Prevention

Lactulose may protect against the development of colon cancer via a number of different mechanisms. Firstly, lactulose administration was found to decrease the production of secondary bile acids in the intestinal tract (secondary bile acids have been postulated to be promoters of colonic carcinogenesis). This effect was thought to be mediated by the reduction in luminal pH caused by lactulose fermentation.[83]

Secondly, lactulose also has the ability to decrease the metabolism of PPMs. This action appears to be directly related to lactulose's ability to decrease the colonic pH. The low pH suppresses overall metabolism of these organisms, which can be indirectly measured by the decrease in fecal enzymatic activity by these microorganisms. In a human trial, Ballongue et al.[75] demonstrated a statistically significant decrease in the specific activity of a number of bacterial enzymes that are believed to be involved in the genesis of colon cancer. Azoreductase activity was lowered by 45%, 7-α-dehydroxylase by 40%, β-glucuronidase by 38%, nitroreductase by 36%, and urease by 27% (all $P < 0.01$). Facultative anaerobes like coliforms and anaerobes like *Clostridium* and *Bacteroides* normally produce β-glucuronidase, 7-α-dehydroxylase, and nitroreductase. The decreased activity of these enzymes correlated with the decreased numbers of bacteroides, clostridia, and coliforms found in this clinical trial after administration of lactulose.[75]

Thirdly, lactulose appears to inhibit the formation of ammonia within the intestinal tract.[84] Ammonia was shown to alter the morphology and intermediary metabolism of intestinal cells, as well as increasing DNA synthesis in, and reducing the life span of mucosal cells.[85] It is also considered to be more toxic to healthy mucosal cells than transformed cells and, thus, it may potentially select for neoplastic growth.[86] Thus any inhibition of ammonia production should be of benefit in the prevention of colon tumorigenesis.

Additionally, a randomized clinical trial conducted by Roncucci et al.[87] demonstrated the ability of lactulose to prevent the growth of resected colorectal polyps. Lactulose administration (20 g/day) reduced the recurrence rates of colonic polyps by 66% ($P < 0.02$) compared with controls.[87]

Hepatic Encephalopathy

Hepatic encephalopathy is often found as a complication of liver cirrhosis. It is considered the totality of nervous system manifestations of liver failure. Symptoms include tremors, mental confusion, memory loss, and personality changes. The exact cause of hepatic encephalopathy is not known. However, it is commonly believed that an accumulation of neurotoxins (particularly ammonia) in the cerebral circulation is the main causative factor.[88] A number of studies have found lactulose to be effective in the management of this condition[89-91] and in its prevention.[92]

Endotoxemia

Endotoxins (also known as lipopolysaccharides) are constituents of the outer membranes of gram-negative bacteria. Gram-negative bacteria continuously shed components of their outer cell membranes, particularly as they die. Gram-negative bacteria can comprise a significant portion of the intestinal microbiota (e.g., members of the Bacteroidetes and Proteobacteria phyla can make up more than 50% of the microbiota in some individuals)[134]; thus, this membrane shedding results in significant quantities of endotoxins being released into the intestinal lumen. In healthy individuals, with good intestinal integrity, luminal endotoxin causes minimal systemic effects. However, in individuals with a compromised intestinal barrier or suboptimal liver function, this intestinal endotoxin can have pathological consequences.[94]

In fact, a number of diseases are now being linked to excessive absorption of GI-derived endotoxins, which has a negative effect on the systemic inflammatory milieu, including: alcoholic liver disease,[135] Alzheimer's disease,[136] atherosclerosis,[137] congestive cardiac failure,[138] chronic fatigue syndrome,[139] depression,[140] metabolic syndrome,[141] nonalcoholic fatty liver disease,[142] obesity,[143] and type 2 diabetes.[144] Hence, there is a great need for agents capable of both decreasing endotoxin load in the lumen, as well as having other antiendotoxin effects.

Research by Liehr et al.[95] has demonstrated that lactulose possesses antiendotoxin activity. When rats were fed lactulose over 4 or 8 days before intravenous administration of galactosamine, the liver damage

that normally develops was prevented. Because galactosamine-induced liver necrosis and inflammation is mediated by systemic endotoxemia of intestinal origin, the prevention of liver inflammation and necrosis after lactulose consumption suggests an antiendotoxin effect. This effect was most likely mediated by an alteration of the intestinal microecology, which indirectly diminished the intestinal pool of endotoxin. However, the authors also suggested a direct antiendotoxin effect, as intravenous administration of lactulose also prevented galactosamine-induced hepatitis.[95]

This work was followed by a prospective, controlled trial assessing the use of lactulose in endotoxemia secondary to obstructive jaundice. Oral lactulose (30 mL/6 h) was given to 12 patients for 3 days before surgery, whereas another 12 patients served as controls. Lactulose administration significantly reduced the incidence of endotoxemia in the portal blood during the operation and in the systemic blood postoperatively (both $P < 0.05$). Interestingly, lactulose appeared to both decrease the luminal pool of endotoxin and directly prevent endotoxin absorption.[96]

Urinary Tract Infections

Two human studies demonstrated the efficacy of lactulose therapy in the prevention of UTIs. McCutcheon and Fulton[97] conducted a retrospective study using 45 elderly, long-term hospital patients as subjects. The study found that daily lactulose therapy for 6 months (30 mL lactulose syrup) resulted in a significant reduction in UTIs compared with controls ($P < 0.025$). Sixteen of the 17 lactulose-treated patients (94%) remained infection free over the 6 months compared with 16 of the 28 control patients (57%) ($P < 0.005$). In addition, there was a significant reduction in the number of antibiotic prescriptions ($P < 0.05$) and in the number of patients who received antibiotics ($P < 0.005$) in the lactulose group.[97]

In the second study, Mack et al. enrolled 75 elderly, hospitalized patients in a randomized, placebo-controlled trial. Thirty-eight patients received the placebo and 58 received lactulose therapy. Twelve percent of the lactulose group developed UTIs during follow-up compared with 32% in the control group ($P < 0.01$). Thus lactulose consumption demonstrated significant protection against the development of UTIs.[98]

The intestinal microbiota appears to act as a reservoir for urinary tract pathogens. Microorganisms such as *E. coli, Enterococcus faecalis, E. faecium,* and *K. pneumoniae* are all frequent urinary tract pathogens, and these organisms are also commonly found in the GIT. These organisms can escape the confines of the large bowel, and in susceptible individuals colonize the vagina, periurethral area, and distal urethra. From these areas they can ascend into the bladder. Thus interventions that can inhibit the growth of these organisms in the GIT should result in decreased numbers of these organisms colonizing the genitourinary tract.[93] This is likely to be the mechanism by which lactulose therapy prevents UTIs. Ingestion of lactulose acidifies the large bowel and significantly increases the production of SCFAs.[72,75] At a low pH, these SCFAs (particularly butyrate) inhibit the growth and metabolism of enterococci and *E. coli,* substantially reducing their overall populations in the large bowel,[93] and thus decreasing the intestinal reservoir of urinary tract pathogens.

Calcium and Magnesium Absorption

In a randomized, controlled trial, low-dose lactulose consumption (2 g/day) was found to significantly improve magnesium absorption, and high dose (4 g/day) administration significantly improved both calcium and magnesium absorption in adult males (all $P < 0.01$ compared with placebo). There appeared to be a clear dose-dependent effect, with the higher lactulose dose being more effective than the lower for both magnesium and calcium.[99]

Dosage

Doses as low as 3 g/day (equivalent to about 5 mL of the syrup) have been shown to cause beneficial alterations in the intestinal microbiota.[74] However, higher doses (e.g., 10 g twice a day) appeared to produce more substantial positive changes.[75] As with FOS and GOS, therapy should commence with a lower dose and slowly increase over time. For the treatment of constipation, the recommended dose is from 15 to 40 g/day.[82,100] Higher dosages are usually used (~35 g/day) for the management of liver disease.[101]

Toxicity

Therapeutic use of lactulose is considered to be extremely safe, with adverse reactions generally being mild and few. Side effects consist of vomiting, nausea, diarrhea, and abdominal cramping.[102] However, these reactions tend to occur only in single doses of more than 60 g. This appears to be the maximum load of lactulose that the intestinal flora is able to metabolize to SCFAs at one time. When the bacterial fermentation capacity is exceeded, osmotic diarrhea, abdominal cramping, and nausea may result. These symptoms are most likely caused by the interference with net fluid absorption in the colon as a result of the osmotic effect of malabsorbed and intact sugars.[70] Nonetheless, flatulence, abdominal bloating, and discomfort are common symptoms when lactulose therapy is commenced. Gastrointestinal symptoms, however, diminish as the colonic microbiota adapt to the greater amount of fermentable substrate.[103]

SYNBIOTICS

Synbiotics are products that contain both probiotic and prebiotic agents.[104] The combination is supposed to enhance the survival of the probiotic bacteria through the upper GIT, improve implantation of the probiotic in the colon, and have a stimulating effect on the growth and/or activities of both the exogenously provided probiotic strain(s) and the endogenous inhabitants of the bowel.[105] Over the past 10 years, research in this area has been steadily growing.

When considering the therapeutic potential of a product claimed to be a synbiotic, a number of factors should be assessed:

1. Does the product use well-characterized and researched probiotic strains? (See Chapter 105 on Probiotics.)
2. Does the "prebiotic" substance meet the requirements to be truly considered a prebiotic?
3. Has the "prebiotic" been demonstrated to enhance the growth of the exact probiotic strain(s) contained in the product?
4. Are both agents included in therapeutic doses?

Ideally, a synbiotic product should meet all four of these criteria. Unfortunately, many currently on the market do not.

Strain-Specific Synbiotic Combinations

Individual probiotic strains (see Chapter 105 on Probiotics) have variable capacities to use different prebiotic substrates. For example, *Bifidobacterium lactis* Bb12 can use GOS, lactulose, and FOS, but is unable to use lactitol.[106] *Lactobacillus rhamnosus* GG is unable to use lactulose, lactitol, or FOS.[107,108] Both *L. acidophilus* NCFM and *L. acidophilus* DDS-1 can use FOS as a growth substrate.[108] Sadly, there is currently a paucity of research in this area to guide decision-making.

COLONIC FOODS

Introduction

Colonic foods are defined as "foods entering the colon and serving as substrates for the endogenous colonic bacteria, thus indirectly providing the host with energy, metabolic substrates and essential micronutrients."[2] By definition, colonic foods escape digestion and absorption in

TABLE 104.6 Other Foods and Food Constituents That Have Been Shown to Cause Beneficial Shifts in the GIT Microbiota

Food (dose)	Effects on the GIT Microbiota
Almonds (roasted with skins; 56 g/day = ~1/3 cup)	Increased fecal concentrations of bifidobacteria and lactobacilli; decreased fecal β-glucuronidase, nitroreductase and azoreductase activities[164]
Apples (2 medium apples/day)	Increased fecal concentrations of bifidobacteria; trend for increased concentrations of lactobacilli; decrease in fecal clostridia; decreased fecal sulfide concentrations[165]
Black currants (4 capsules/day black currant powdered extract)	Increased fecal concentrations of bifidobacteria and lactobacilli; decreased counts of *Bacteroides* spp., and *Clostridium* spp.; decrease in fecal pH; decreased fecal β-glucuronidase activity; increased β-glucosidase activity[166]
Blueberries (wild) (25 g of powdered wild blueberries in water/day)	Increased fecal concentrations of bifidobacteria[167]
Brown rice (~550 g/day = 4 cups cooked)	Increased numbers of bifidobacteria; decreased counts of *Bacteroides* spp., *Collinsella aerofaciens, Escherichia coli,* and *Clostridium* spp.[168]
Cocoa powder (~14 g dark cocoa powder/day)	Increased fecal concentrations of bifidobacteria and lactobacilli; decrease in fecal clostridia[169]
Green tea (300 mg catechins/day; equivalent to ~5–6 cups/day)	Increased fecal concentrations of bifidobacteria and lactobacilli; decreased concentrations of bacteroides, clostridia, and enterobacteria; decrease in fecal pH; decrease in fecal concentrations of potentially toxic protein putrefactive byproducts ammonia, sulfide, skatol, indole, and cresol; increased production of short-chain fatty acids (SCFAs)[170]
Resistant starch (30g/day; from potato tubers; 70% type 2 resistant starch)	Increased fecal concentrations of bifidobacteria; decrease in fecal Proteobacteria populations[171]

the upper GIT to reach the colon intact. Here members of the colonic microbiota ferment them to produce SCFAs, hydrogen, methane, and carbon dioxide. Through the production of SCFAs, the ingestion of colonic foods plays a pivotal role in the health of the host.[81]

Colonic foods lack the specificity of fermentation that prebiotics possess. Thus their ingestion promotes the growth and/or metabolic activity of a number of different bacterial species within the large bowel, including species that are considered potentially harmful. Colonic foods include plant cell wall polysaccharides (e.g., cellulose), hemicelluloses, pectins, and many gums.[2]

Commonly used fibers, such as slippery elm, pectin, psyllium husks, and guar gum should all be considered colonic foods, not prebiotics, because they are used by a number of different bacterial species in the bowel. For example, guar gum is metabolized by *Bacteroides* spp. and *Ruminococcus* spp.[109]; pectin is fermented by *Bacteroides* spp., *Bifidobacterium* spp., *Eubacterium* spp., and *Clostridium* spp.[110]; and psyllium husks are fermented primarily by *Bacteroides* spp.[109]

Some foods, however, have demonstrated the ability to selectively promote the growth of beneficial species of bacteria. Foods and food constituents that have shown this selective fermentation capacity are listed in Table 104.6.

Drug Interactions

FOSs and GOSs do not appear to interact with any pharmaceuticals. When used in prebiotic dosages, lactulose is also unlikely to elicit any drug interactions. When administered in larger doses for use as a laxative over prolonged periods of time, however, there is a theoretical risk of increased electrolyte loss, which could affect electrolyte balance. These electrolyte alterations could potentiate the risk of more severe electrolyte imbalances, such as hypokalemia, which has been associated with the use of some medications (e.g., corticosteroids, diuretics, and drugs that prolong the QT interval). However, lactulose is less likely to elicit electrolyte disturbances with long-term use than other laxatives because of the capacity of the colonic microflora to adapt to lactulose ingestion, with long-term ingestion resulting in a reduction in lactulose-induced gastrointestinal symptoms and diarrhea.[103,111]

When used in laxative dosages, lactulose was found to significantly increase the relative risk of over anticoagulation in patients taking coumarin anticoagulants, presumably via decreased intestinal absorption.[112]

Probiotics

Jason A. Hawrelak, ND, BNat(Hons), PhD

OUTLINE

INTRODUCTION

The term *probiotic* (from the Greek *for life*) has had a number of different meanings over recent history. First coined by Lilley and Stillwell, they used the term to describe substances secreted by one microorganism that stimulated the growth of another.[1] In 1974 this definition was modified by Parker to mean "…*organisms and substances which contribute to intestinal microbial balance,*" which more closely approximates the contemporary use of the term.[2] The current definition comes from the International Scientific Association for Probiotics and Prebiotics.[3] They define probiotics as "*live microorganisms that, when administered in adequate amounts, confer a health benefit to the host.*"

The current definition of probiotics includes preparations that contain viable, microbial agents that have been demonstrated to improve health. Typically, these products will contain freeze-dried (lyophilized) or live bacteria or yeasts, most commonly from the genera *Lactobacillus* and *Bifidobacterium.*[4]

The original definitions of probiotics were inclusive of traditional fermented foods such as yogurt (nonmedicinal varieties), sauerkraut, and kefir, but the most recent interpretation of the definition has, somewhat controversially, excluded these traditional ferments. These are now considered food sources of "*live and active cultures*" but not probiotics.[3] The reasoning behind this decision is that these foods may contain a diverse community of microbes that are not well defined in terms of strain composition or stability, both of which can also differ from batch to batch. Additionally, the strains contained in these foods may also lack specific therapeutic qualities (e.g., they may not confer any health benefit on the host, beyond the enhanced nutritional profile of the fermented food). It is for these reasons that traditional fermented foods (wild ferments) cannot be relied upon for specific therapeutic effects in the same way that probiotic preparations containing well-defined strains, with well-characterized clinical effects, in precise doses can.

Currently, there is an explosion of interest in the fields of fermented foods and probiotics. This interest has been stimulated by the ongoing expansion of research in these areas. This chapter focuses on the health benefits and therapeutic uses of probiotics.

DESCRIPTION

At the turn of the century, Metchnikoff[5] asserted that yogurt was the elixir of life. He theorized that putrefactive bacteria in the large intestine produce toxins that cause disease and shorten life. He believed that eating yogurt would cause lactobacilli to become dominant in the colon and displace the putrefactive bacteria. For years, these claims

of healthful effects from fermented foods were considered unscientific folklore. However, a substantial and growing body of scientific evidence has now demonstrated that lactobacilli, bifidobacteria, and, more broadly, fermented foods, can play a significant role in promoting human health and treating disease.

The bulk of probiotic research to date has focused on strains from two genera—*Lactobacillus* and *Bifidobacterium*. The genus *Lactobacillus* is characterized by considerable heterogeneity. They are gram-positive, nonsporing, and rod-shaped bacteria that produce lactic acid as the major end product of carbohydrate fermentation. Lactobacilli appear to be fairly unique, in that they have been isolated from a number of diverse environments, such as fermented vegetables and dairy foods, as well as the human gastrointestinal tract (GIT) and vagina.[6]

In contrast, bifidobacteria are not found in natural fermentative processes but are native to the GIT.[7] Bifidobacteria are also gram-positive, nonsporing bacteria; however, they are Y-shaped instead of rod-shaped, and their major fermentative end product is acetic acid.[8]

Research is currently underway on the isolation and commercialization of next-generation probiotics, using novel strains isolated from important gastrointestinal species, such as *Akkermansia muciniphila* and *Faecalibacterium prausnitzii*.[6,9] Other research has evaluated microbiologically complex "probiotic" products derived from human fecal specimens.[6,7] A number of so-called "soil-based probiotics" are now also commercially available and have a growing research base,[8] so expect the marketplace to expand dramatically in the variety of probiotic products over the coming decade.

PROPOSED MECHANISMS OF ACTION

The exact mechanisms by which probiotics accomplish their myriad beneficial actions have become clearer over the past two decades and we now know of several mechanisms that explain many of their favorable effects.

Immune Modulation

A growing body of evidence indicates that some probiotic strains are capable of modulating the immune system at both the systemic and the mucosal levels, affecting many cell types (e.g., dendritic cells, epithelial cells, natural killer cells, etc.). This immune response may take the form of increased secretion of immunoglobulin A via interaction with mesenteric lymph nodes,[10,11] enhanced phagocytic activity of macrophages, or elevated numbers of natural killer cells.[12] Recent research has demonstrated that dendritic cells in the lamina propria can extend their appendices between epithelial cells, and, via toll-like receptors on their surface, sample probiotic-bacterial molecular patterns. This interaction leads to the maturation of the dendritic cells and to the release of cytokines, which orchestrate the conversion of naive T-helper cells (Th0) into a mature, balanced response of T-helper cells (Th1, Th2, and Th3/Tr1).[11]

Anti-Inflammatory Activity

Probiotic strains have been shown to have anti-inflammatory effects via a number of different mechanisms. Some can secrete metabolites with anti-inflammatory properties (e.g., antitumor necrosis factor [TNF]-α effects),[13] some can interact with toll-like receptors,[14] others down-regulate the transcription of a number of genes encoding proinflammatory effectors,[15] and others upregulate production of anti-inflammatory cytokines.[16]

GIT Transit Time Modification

Some probiotic strains can modify GIT transit. Two strains of bifidobacteria have been found to significantly speed colonic transit time,[17,18] and a strain of propionibacteria has been shown to slow descending colon transit.[19] The mechanisms by which probiotics alter GIT transit time have not yet been fully elucidated; however, it is postulated that a bacterial metabolite may affect sigmoid tone and alter colonic motility.[20]

Induction of Oral Tolerance

The GIT microbiota has been shown to play a crucial role in generating an adequate population of Th2 cells that are capable of oral tolerance induction.[21] In the presence of intestinal dysbiosis, some probiotic strains can also help induce oral tolerance and help protect against the development of food allergies.[22] Other strains have been shown to induce oral tolerance even in the presence of anaphylactic reactions.[23]

Decrease Visceral Hypersensitivity

Animal research has suggested that some probiotic strains are capable of decreasing visceral hypersensitivity, believed to be one of the main contributing factors to irritable bowel syndrome (IBS) and other functional gastrointestinal disorders.[24-26] The exact mechanisms are unknown, but another lactobacilli strain has been shown to decrease visceral hypersensitivity by inducing cannabinoid and opioid receptor expression in the colonic epithelium.[27]

Competition for GI Adhesion Sites

Many pathogenic organisms must associate with the GIT epithelium to colonize effectively. However, some strains of bifidobacteria and lactobacilli can adhere to the epithelium and act as "colonization barriers" by preventing pathogens from adhering to the mucosa.[28] This effect has been demonstrated with *Lactobacillus rhamnosus* GG and *L. plantarum* 299v. Both of these organisms have shown the ability to inhibit attachment of *Escherichia coli* to human colon cells.[29]

Antagonism Against Potentially Pathogenic Microorganisms (PPMs) and Viruses

One of the mechanisms by which probiotics exert their beneficial effects is via inducing changes to the GIT microbiota, specifically by inhibiting the growth of potentially pathogenic organisms. Some probiotic strains are capable of producing inhibitory substances such as bacteriocins, lactic acid, and oxygen metabolites, such as hydrogen peroxide.[30,31] A number of probiotic strains have demonstrated in vitro inhibitory activity against a range of potentially pathogenic microorganisms, such as *Helicobacter pylori, Clostridium difficile, E. coli, Candida albicans, Salmonella enteric, Shigella sonnei,* and *Vibrio cholerae*.[32-35] Some probiotic strains (*L. rhamnosus* GG and *Bifidobacterium lactis* Bb12) can also bind to viruses, such as rotaviruses, helping prevent mucosa-associated viral infections.[36] Several probiotic strains have also demonstrated the ability to bind or remove toxins, such as aflatoxins and cyanotoxins,[36] as well as inhibit the effects of bacterial toxins, such as *C. difficile* toxins A and B.[37] Specific strains have also been found to reduce the expression of virulence factors via inhibition of pathogen gene encoding.[38]

Selective GI Antimicrobial Activity

Ingestion of selected probiotic strains has been found to significantly increase GI populations of beneficial bacteria (i.e., lactobacilli or bifidobacteria) while simultaneously decreasing populations of less health-promoting genera.[39-41]

Production of Beneficial Compounds

The production of short-chain fatty acids (SCFAs) as metabolic byproducts is a characteristic that almost all probiotic strains share. These SCFAs help create a healthier colonic milieu by decreasing the

luminal pH, and some (e.g., butyrate) are used as energy sources by colonocytes.[42,43] Other probiotic strains can help restore normal small intestinal architecture and upregulate intestinal brush border enzyme expression via the luminal release of polyamines.[44-46] These strains will have clinical utility in situations of small intestinal damage and decreased brush border enzyme activity, such as celiac disease, Crohn's disease, or after small intestinal infections.

Strengthen the Intestinal Barrier

A number of probiotic strains have been found to increase mucin production in the gut via increases in mucin gene expression, which provides a protective coating between the lumen and intestinal epithelial cells.[47,48] Probiotics are also capable of directly strengthening the intestinal barrier. A strain of *L. plantarum* (WCSF1) has been found to decrease paracellular intestinal permeability by increasing the relocation of occludin and zonulin into the tight junction between duodenal epithelial cells.[49] Other strains appear to enhance barrier function via the preservation of enterocyte cytoskeleton architecture and enhancement of tight junctional protein structures.[43] Such strains should prove useful in the treatment and prevention of intestinal permeability.

PROBIOTIC CHARACTERISTICS

Probiotic organisms require certain characteristics to enable them to exert maximum therapeutic effects. These qualities are summarized in Table 105.1.

Of these characteristics, there are some that are considered almost a prerequisite for a probiotic strain to have therapeutic effects. These are: (1) gastric acid and bile salt stability; (2) an ability to adhere to the intestinal mucosa; and (3) an ability to temporarily colonize the intestinal tract.[34] Unfortunately, many commercially available probiotic supplements and yogurts contain strains that do not exhibit these vital characteristics. If a probiotic strain does not exhibit these characteristics, then it will have only a limited capacity to interact with host cells.

Probiotics in Use

There are many different microorganisms currently used as probiotics. Table 105.2 lists commonly used probiotic species.

To better understand how bacteria are named and classified, the following discussion may be helpful. Genus is the first name of a bacterium (e.g., *Lactobacillus*). It is somewhat general and refers to a grouping of organisms based on similarity of qualities, such as physical characteristics, metabolic needs, and metabolic end products. Species is a bacterium's second name (e.g., *acidophilus*). It is a much more narrow classification based on shared common characteristics that distinguish them from other species. Strain is an even more specific classification that divides members of the same species into subgroups based on several properties that these bacteria have in common that are distinct from other members of the species (e.g., strain LA5).[37]

Issues in Probiotic Nomenclature

There are some changes in nomenclature, some more recent and some fairly antiquated, that should be noted to make better sense of probiotic literature.

- The species *Lactobacillus bulgaricus* is now referred to as *Lactobacillus delbrueckii* ssp. *bulgaricus*.[38]

TABLE 105.1 The Desirable Characteristics of Effective Probiotic Strains

Characteristics	Functional Benefit
Human origin	Human origin should translate to ability to survive conditions in the human GIT, as well as the possibility of species-specific health effects
Gastric acid and bile salt stability	Survival through stomach and small intestine
Adherence to intestinal mucosa	Believed to be essential for immune cell modulation and competitive inhibition of pathogens
Temporary colonization of intestinal tract	Multiplication in the intestines suggests that daily ingestion may not be needed; immune cell modulation
Safety in food and documented clinical safety	Adverse effects absent or minimal; accurate identification (genus, species, strain)
Production of antimicrobial compounds	Normalization of the GIT ecosystem; suppressed growth of pathogens
Antagonism against pathogenic organisms	Prevention of adhesion and toxin production by pathogens
Clinically documented and validated health effects	Clinicians can be confident of therapeutic effects; dose–response data for minimum effective dosage in different formulations is known

GIT, Gastrointestinal tract.

TABLE 105.2 Common Probiotic Microorganisms

Lactobacillus spp.	*Bifidobacterium* spp.	*Bacillus* spp.	*Streptococcus* spp.	*Enterococcus* spp.	*Saccharomyces* spp.
acidophilus	*adolescentis*	*clausii*	*salivarius*	*faecium*	*cerevisiae*
brevis	*animalis*	*coagulans*	*thermophilus*		
casei	*bifidum*	*subtilis*			
crispatus	*breve*				
delbrueckii	*infantis*				
fermentum	*lactis*				
gasseri	*longum*				
johnsonii	*thermophilum*				
lactis					
paracasei					
plantarum					
reuteri					
rhamnosus					

The most common species currently used as probiotics.[33,35,36,153-156]

- *Lactobacillus bifidus* (also known as "bifidus") was renamed *Bifidobacterium bifidum* more than 30 years ago, yet the improper nomenclature is still sometimes used.[38]
- Many strains of bacteria that were once classified as *Lactobacillus casei* have been reclassified as strains of *Lactobacillus rhamnosus* (e.g., *L. rhamnosus* GG) or *Lactobacillus paracasei.*[50]
- Strains of *Lactobacillus sporogenes* have been renamed *Bacillus coagulans* (they are not true lactobacilli because they form spores).[40]
- Bacterial strains that were once classified as *Lactobacillus acidophilus* (often referred to as "acidophilus") have now been divided into six species: *L. acidophilus*, *L. gasseri*, *L. amylovorus*, *L. gallinarum*, *L. johnsonii*, and *L. crispatus.*[39]
- Strains of *Saccharomyces boulardii* are now definitively regarded as a distinct group within the species *Saccharomyces cerevisiae* should be referred to as *Saccharomyces cerevisiae* var. *boulardii.*[41,42] The improper nomenclature of *S. boulardii* is still widely used.

Importance of Strain

Within each species of bacteria there is a multitude of strains. Some probiotic strains are resilient and strong, with a demonstrated capacity to survive passage through the upper GIT and have therapeutic actions, whereas others cannot even survive transit through the stomach.[51] It is vital to note that just because one strain of bacteria in a given species has a proven action or characteristic, it does not mean that another strain will, too, even if they are closely related.

Strains of bacteria within the same species can have significantly different actions, properties, and characteristics, as these are all essentially strain-specific qualities.[52,53] For example, *L. plantarum* strain 299v has been shown to effectively reduce IBS symptoms,[54] whereas administration of *L. plantarum* strain MF1298 actually worsens IBS symptoms.[55] In another study, two strains of *L. rhamnosus* were used in a trial assessing their efficacy in the treatment of viral gastroenteritis. One strain was *L. rhamnosus* strain GG (LGG); the other was a strain found in a supplemental product (Lactophilus). LGG accelerated recovery from diarrhea, whereas the closely related strain did not.[44] Thus to achieve the desired therapeutic result, it is imperative to prescribe the precise probiotic strains that have demonstrated therapeutic and clinical efficacy in the condition in question.

Additionally, strains that work in one condition will not necessarily be effective in other conditions. For example, the multistrain preparation commonly referred to as Lab4 (containing *L. acidophilus* strains CUL21 and CUL60, *B. bifidum* CUL20, and *B. lactis* CUL34) appears effective in the management of IBS[56] but is ineffective in the prevention of antibiotic-associated side effects.[57] As another example, *L. rhamnosus* GG appears to be effective in the prevention of antibiotic-associated side effects[58] but not of any demonstrable benefit in urinary tract infections.[59]

Unfortunately, this strain specificity is not well known, leading to inaccurate extrapolations from the literature. For example, some supplement manufacturers will quote a study that used *L. rhamnosus* strain GG and then say that their probiotic supplement containing a strain of *L. acidophilus* or another strain of *L. rhamnosus* will do the same. This is quite incorrect. Unless proven, one cannot assume that a given strain of *L. acidophilus*, *B. bifidum*, or any other species of lactic acid bacteria will survive transit through the upper GIT, let alone colonize the intestines or have specific therapeutic actions. They might, but, unless proven, it is impossible to know.

Thus clinicians are urged to use well-researched probiotic strains whenever possible. By choosing well-researched strains, one can be assured of getting probiotics that have documented gastric acid and bile tolerance, can adhere to the intestinal mucosa, and can temporarily colonize the intestinal tract, as well as having proven therapeutic actions. This latter point is particularly important in improving the probability of achieving good clinical outcomes.

TABLE 105.3 The Pros and Cons of Different Probiotic Delivery Systems

Delivery System	Pros	Cons
Fermented dairy	Affordability and easy availability Ease of incorporation into daily patterns Additional nutritional benefits Enhanced bacterial survival through upper GIT (100 times less bacteria can be given per dose)[66] Effective in the upper GIT	Contains dairy proteins and lactose Taste can be issue Not suitable when traveling Not suitable for vegans
Capsules	Ease of administration Contain no binders	Not therapeutic in upper GIT (unless opened or chewed) May contain allergenic excipients Higher cost
Tablets	Ease of administration Effective in the upper GIT	May contain allergenic or otherwise problematic binders and excipients (e.g., gluten) Higher cost Chewable tablets may contain potentially problematic sweeteners
Oils	Ease of administration Effective in the upper GIT Dosages can be easily adjusted Can be incorporated into foods or drinks Contain no binders	
Powders	Effective in the upper GIT Dosages can be easily adjusted Can be incorporated into foods or drinks Contain no binders	

GIT, Gastrointestinal tract.

COMMERCIAL FORMS

Probiotic organisms can be incorporated into supplements (powders, capsules, tablets, oils, wafers) and foods (milk drinks, medicinal yogurts, fruit juices, confectionery bars, ice cream). All of these mediums essentially work as carriers for the probiotic organisms. Common probiotic delivery systems are compared in Table 105.3. Regardless of the form in which the microorganisms are consumed, for clinical efficacy, products containing probiotic organisms must provide live organisms in sufficient numbers to exert therapeutic effects.

The quality of probiotic preparations depends on two main factors: (1) the characteristics of the strains contained in the supplement; and (2) adequate viability, so that sufficient numbers of bacteria are viable at the point of consumption. Bacterial strains used in probiotic preparations should ideally demonstrate all the characteristics outlined in Table 105.1 and have evidence of efficacy in treating the clinical condition in question (see "Clinical Applications" section later).

Viability at consumption depends on a number of factors, such as proper manufacturing and the "hardiness" of the strain and packaging and storing the product in the right amount of moisture and at the correct temperature. Some strains of lactobacilli and bifidobacteria do not respond well to freeze-drying (lyophilization), spray drying, or conventional frozen storage, and excessive temperature during packaging or storage can dramatically reduce viability. Typically, unless the product has been shown to be stable, refrigeration is necessary during storage and ideally during transport. Some products may not have to be refrigerated until after the bottle has been opened, however, and others not at all.

Some manufacturers use enteric coatings on their tablets and capsules to improve survival through the acidic medium of the stomach. Research suggests that this practice does enhance survival through the upper GIT,[60] although enteric coatings are not necessary if the strain has demonstrated satisfactory tolerance to gastric acid.

Although there are a number of companies providing high-quality probiotic products, it can be difficult to sort through all of the manufacturers' claims of superiority. Additionally, market-basket surveys found that some supplements contain potentially pathogenic contaminants,[61] whereas others fail to contain the species and quantity of bacteria listed on the label.[62]

Clearly, the clinician needs documentation of strain designation, strain characteristics, product viability, microbiological content, and strain-specific research before prescribing to his or her patients.

CLINICAL APPLICATIONS

The clinical applications of probiotics have grown myriad in the past decade—from solely gastrointestinal conditions to a wide range of diseases and conditions affecting other body systems. Although they can still be used to promote optimal digestive health, they are more often being used to treat specific disease conditions.

Antibiotic Use

Antibiotic use frequently results in significant perturbations in the GIT microbiota and GI adverse events, such as diarrhea.[63] It was once believed that taking probiotics concurrently with antibiotics would be a waste of time and money, as the antibiotic would likely destroy all the administered probiotic bacteria. However, research conducted over the past 20 years clearly shows that concurrent administration of specific probiotic strains alongside antibiotics significantly decreases the incidence of antibiotic-related side effects. A number of meta-analyses have now shown conclusively that probiotics are an effective class of tools to decrease antibiotic-associated side effects.[64-67] Table 105.4 highlights the research examining the effect of specific probiotic strains and strain combinations on antibiotic-related GI adverse events, primarily antibiotic-associated diarrhea (AAD). Not all probiotic preparations have been found to be effective, however. For example, the multistrain preparation commonly referred to as Lab4 (containing *L. acidophilus* strains CUL21 and CUL60, *B. bifidum* CUL20, and *B. lactis* CUL34) has been found to be ineffective in the prevention of antibiotic-associated side effects.[57]

Abdominal Pain (Functional)

A meta-analysis of trials evaluating *L. rhamnosus* GG (LGG) in the treatment of functional abdominal pain in children found LGG effective. LGG supplementation was associated with a significantly higher rate of treatment responders (defined as no pain or a decrease in pain intensity) in the overall population of children with abdominal pain-related functional gastrointestinal disorders (three trials; $n = 290$; relative risk [RR] 1.31, 95% CI 1.08–1.59) and in the IBS subgroup (three randomized controlled trials [RCTs], $n = 167$; RR 1.70, 95% CI 1.27–2.27, NNT 4, 95% CI 3–8). There was also a significant decrease in the perception of pain intensity in children with functional abdominal pain.[62]

Other probiotic strains, such as *B. infantis* 35624 and the combination of *B. lactis* Bi-07 and *L. acidophilus* NCFM, have been found to be ineffective in reducing functional abdominal pain, although the latter combination did improve abdominal bloating scores.[68,69]

Atopic Eczema

The intestinal microbiota plays a major protective role against the development of allergy through its ability to reduce antigen transport through the intestinal mucosa and induce oral tolerance.[70] Consequently, probiotics have been theorized to have a protective role in the prevention and/or management of atopic dermatitis (AD) and eczema.[71] A number of clinical trials have investigated probiotic therapy to prevent atopic eczema development, and some have evaluated the efficacy of probiotic therapy in the treatment of atopic eczema.

Prevention of Atopic Eczema

The initial ground-breaking research detailing the efficacy of probiotics in the prevention of atopic eczema used the probiotic strain *L. rhamnosus* GG (LGG).[72] This initial positive result led to a number of follow-up trials—some using the same strain and others evaluating other probiotic strains. A 2015 meta-analysis found that probiotics, as a class of agents, are effective in reducing the risk of atopic eczema. Meta-analysis found a reduced risk of eczema when used by women during the last trimester of pregnancy (RR = 0.71; 95% CI 0.60–0.84), when probiotics were used by breastfeeding mothers (RR = 0.57; 95% CI 0.47–0.69), or when given directly to infants (RR = 0.80; 95% CI 0.68–0.94).[73] The conclusions of this review have been criticized, however, because the authors combined the data from a number of different probiotic strains into a single analysis—a process that does not provide meaningful guidance to consumers or practitioners about which probiotic strain should be used in this clinical scenario. In fact, a meta-analysis by strain on the only probiotic preparation with more than one RCT for this application (LGG) found a nonsignificant decreased relative risk of eczema at 12 to 24 months (RR = 0.68; 95% CI 0.42–1.10).[74]

A number of other probiotic strains have been evaluated for their effectiveness in the prevention of atopic eczema with differing results. In a randomized, double-blind, placebo-controlled trial, Taylor et al. administered *L. acidophilus* strain LAVRI-A1 (3×10^9 CFU/day) to infants at high risk of allergic disease for the first 6 months of life. At both 6 and 12 months, the incidence of atopic dermatitis was similar in both the probiotic and placebo groups. However, the proportion of children with a positive skin prick test and atopic eczema was significantly higher in the probiotic group ($P = 0.045$) at 12 months, as was the rate of allergen sensitization ($P = 0.030$). Hence, this strain was not only ineffective in decreasing the incidence of atopic dermatitis development, it appears to have actually increased allergen sensitization, despite promising preliminary in vitro results.[75]

Abrahamsson et al. conducted a double-blind, randomized, placebo-controlled trial investigating the role of *L. reuteri* strain BioGaia in the prevention of atopic dermatitis development ($n = 232$). The mothers received *L reuteri* BioGaia (1×10^8 CFU) daily from gestational week 36 until delivery. Their babies then continued with the same product from birth until 12 months of age. The incidence of eczema was found to be similar in both groups at 2 years of age. Infants in the probiotic group did, however, have less immunoglobulin E-associated eczema (8 vs. 20%; $P = 0.02$) and in infants with allergic mothers, less skin-prick test reactivity (14 vs. 31%; $P = 0.02$).[76]

Wickens et al. performed a randomized, double-blind, placebo-controlled trial to assess the effect of two different probiotic strains

TABLE 105.4 Effect of Probiotics on Antibiotic-Related GI Adverse Events

Trial Methodology	Strain(s) Used	Results
Meta-analysis 5 studies *n* = 445 subjects of all ages	*Lactobacillus rhamnosus* GG	Pooled data from randomized, controlled trials found this strain reduced the risk of AAD in children from 23%–9.6% (RR = 0.48; 95% CI 0.26–0.89) and in a subset of adult patients receiving antibiotics as part of *Helicobacter pylori* eradication therapy (RR = 0.26; 95% CI 0.11–0.59).[67]
Meta-analysis 5 studies *n* = 1076 subjects of all ages	*Saccharomyces cerevisiae* var. *boulardii* Biocodex	Supplementation reduced the risk of AAD from 17.2% in controls to 6.7% (RR = 0.43; 95% CI 0.23–0.78).[160]
R, DB, PC *n* = 162 adult subjects receiving antibiotic treatment for *H. pylori* infection	*L. acidophilus* strains CUL-60 and CUL-21, *Bifidobacterium lactis* CUL-34, and *B. bifidum* CUL-20 (Lab4)	Coadministration of the probiotic combination with antibiotics prevented the increase in fecal *Candida albicans* populations immediately after antibiotic therapy ($P = 0.049$).[161]
R, DB, PC *n* = 239	*L. plantarum* 299v	Thirty-one percent reduced risk of developing loose or watery stools (95% CI 0.52–0.92; $P = 0.012$); 49% reduced risk of experiencing nausea (95% CI 0.30–0.85; $P = 0.0097$).[162]
R, DB, PC *n* = 40 pediatric subjects	*L. reuteri* DSM 17938	Reduced incidence of a number of GI symptoms relative to placebo in triple therapy-treated children—epigastric pain (15% vs. 45%; $P < 0.04$), abdominal distension (0% vs. 25%; $P < 0.04$), disorders of defecation (15% vs. 45%; $P < 0.04$), and halitosis (5% vs. 35%; $P < 0.04$).[163]
R, DB, PC *n* = 87	*L. rhamnosus* GG, *L. acidophilus* LA5, and *B. lactis* Bb12	Seventy-nine percent reduced risk of developing AAD ($P = 0.035$).[164]
R, DB, PC *n* = 72 pediatric subjects	*L. rhamnosus* GG, *L. acidophilus* LA5, and *B. lactis* Bb12	Concurrent ingestion of these three strains in a yogurt base resulted in a reduced risk of AAD in children. Severe diarrhea occurred in 17% of controls versus 0% of the probiotic group ($P = 0.025$). Minor diarrhea occurred in 58% of controls compared with 3% of the probiotic-treated children ($P < 0.001$).[138]
R, DB, PC *n* = 135 hospital inpatients	*L. casei* DN-114 001	Patients treated with *L. casei* DN-114 001 had a decreased risk of developing AAD compared with placebo (12% vs. 34%; $P = 0.007$). There was zero incidence of *Clostridium difficile*-associated diarrhea in the probiotic group versus 17% in placebo group ($P = 0.001$).[60]
R, DB, PC *n* = 437	*L. acidophilus* CL 1285 and *L. casei* LBC80R	Patients receiving antibiotic therapy had reduced incidence ($P = 0.037$) and duration ($P = 0.045$) of AAD compared with placebo-controls.[61]

AAD, Antibiotic-associated diarrhea; *DB,* double-blind; *GI,* gastrointestinal; *PC,* placebo-controlled; *R,* randomized.

on the development of atopic eczema. Pregnant women with an atopic family history were randomized to take *L. rhamnosus* HN001 or *B. lactis* strain HN019 or placebo daily from 35 weeks' gestation until 6 months if breastfeeding, and their infants were randomized to receive the same treatment from birth to 2 years ($n = 474$). Infants in the *L. rhamnosus* HN001 group had a 49% reduced risk of eczema development at 2 years of age (95% CI 0.30–0.85; $P = 0.01$). On the other hand, there was no reduction in eczema risk in infants receiving *B. lactis* strain HN019.[77]

In another randomized, placebo-controlled, double-blind trial, the efficacy of *L. paracasei* F-19 was evaluated. In this trial, the probiotic was administered to the infant ($n = 179$) directly at the time of weaning (mixed into food). Infants consumed the probiotic agent (1×10^8 CFU/day) from 4 to 13 months of age. Probiotic supplementation resulted in a significantly reduced cumulative incidence of eczema at 13 months of age (11 vs. 22%; $P < 0.05$) and an improved Th1/Th2 ratio.[78]

In a further double-blind trial, women ($n = 415$) were randomized to receive either placebo or a probiotic milk (containing *L. rhamnosus* GG, *L. acidophilus* La5, and *B. lactis* Bb12) from 36 weeks' gestation to 3 months postnatally during breastfeeding. At 2 years old, the odds ratio (OR) for the cumulative incidence of atopic eczema was 0.51 in the probiotic group compared with the placebo (95% CI 0.30–0.87; $P = 0.013$). There were no significant effects on rates of asthma or atopic sensitization.[79]

Treatment of Atopic Eczema

To determine whether probiotics, as a class of agents, are efficacious in treating atopic eczema (AE), Kim et al. performed a meta-analysis of randomized, controlled trials. Twenty-five eligible studies were located, including 1599 subjects. Significant differences in eczema severity (SCORAD values) favoring probiotics over placebo were observed for the total population (mean −4.51; 95% CI −6.78 to −2.24), in children aged 1 to 18 years old (mean −5.74; 95% CI −7.27 to −4.20), and in adults (mean −8.26; 95% CI −13.28 to −3.25). However, the effectiveness of probiotics as a whole in infants (< 1 year old) was not demonstrated.[80] Individual probiotic preparations that have been evaluated in the treatment of atopic eczema are highlighted in the following section.

A randomized, double-blind study of 56 young children (aged 6–18 months) with moderate or severe atopic AE found that treatment with *L. fermentum* VRI-003 PCC (1×10^9 CFU; twice daily) produced a significant reduction in the SCORAD index. At week 16, 92% of children receiving the probiotic had a SCORAD index that was significantly better than baseline compared with 63% in the placebo group ($P = 0.01$).[81]

A randomized, controlled trial conducted by Sistek et al. found that a combination of two probiotic strains (*L. rhamnosus* HN001 and *B. lactis* HN019) given to children with established AE effectively reduced the SCORAD index among the food-sensitized children ($P = 0.047$) but not in the group as a whole. Children in this study received 2×10^{10} CFU/day of the probiotic combination or placebo.[82]

Gastrointestinal Infections

Probiotics have a role in the management of various gastrointestinal infections, such as bacterial and viral-induced diarrhea, *H. pylori,* travelers' diarrhea prevention, and recurrent *C. difficile*-associated disease.

Diarrhea

Various probiotic strains have been subjected to clinical trials to evaluate their efficacy in diarrhea of different origins.

Viral Gastroenteritis—Prevention

In a randomized, double-blind, placebo-controlled trial, infants admitted to a chronic medical hospital (average duration of stay 80 days) ingested formula that was supplemented with either placebo or a combination probiotic. The probiotic contained *B. lactis* Bb12 (1.9×10^8 CFU/g powdered formula) and the TH-4 strain of *Streptococcus thermophilus* (0.14×10^8 CFU/g powdered formula). Probiotic supplementation was found to significantly reduce diarrhea incidence (7 vs. 31%; $P = 0.035$) and rotavirus shedding (10 vs. 39%; $P = 0.025$).[83]

Another randomized, controlled trial found the administration of *L. rhamnosus* GG to hospitalized children to reduce the risk of rotavirus gastroenteritis by 87% ($P = 0.02$).[84]

Viral Gastroenteritis—Treatment

A meta-analysis of eight RCTs ($n = 988$) by Szajewska et al. found that supplementation of *L. rhamnosus* GG significantly reduced duration of rotavirus diarrhea by 2.1 days in children ($P = 0.006$), and the risk of diarrhea lasting > 7 days was reduced by 75% ($P = 0.01$). The authors did caution, however, that the heterogeneity and methodological considerations of the studies limited the strength of the conclusions.[85]

To determine the dose-dependent effect of *L. rhamnosus* Lcr35 (Lcr35) on fecal rotavirus shedding, Fang et al. conducted an open-label randomized study. Twenty-three children with rotavirus gastroenteritis were treated for 3 days with either a placebo, a low dose of Lcr35 (2×10^8 CFU/day), or a high dose (6×10^8 CFU/day). Only the high-dose group experienced a significant reduction of rotavirus levels in stool samples (an 86% decrease after 3 days).[86]

A randomized, placebo-controlled trial comparing the efficacy of two different doses of *L. reuteri* DSM 17938 (1×10^{10} CFU/day or 1×10^7 CFU/day) with placebo in children with rotavirus-associated diarrhea ($n = 66$) found that probiotic treatment reduced the duration of viral gastroenteritis-induced diarrhea from 2.5 days in the placebo group to 1.9 days in the low-dose group and 1.5 days in high dose group ($P = 0.01$). By the second day of treatment, watery diarrhea persisted in 80% of the placebo, 70% of the low-dose group, and 48% of the large-dose group ($P = 0.04$, large dosage vs. placebo).[87]

Another double-blind, randomized, placebo-controlled study evaluated the efficacy of the multistrain probiotic preparation (VSL#3) in the treatment of rotavirus diarrhea in children. Two hundred and thirty children were enrolled in the trial. By day 2, a lower mean stool frequency and improved stool consistency was noted in the VSL#3 group (both $P \leq 0.05$). On day 4 of treatment, 89% of VSL#3-treated children were recovered versus 40% of controls ($P < 0.001$).[88]

Travelers' Diarrhea

Travelers' diarrhea (TD) is the most common health problem in those visiting developing countries, affecting between 20% and 50% of tourists. Although it is usually short-lived and self-limiting, travelers' diarrhea represents a considerable socioeconomic burden for both the traveler and the host country. The most common enteropathogen is *E. coli,* but a number of other microorganisms are also implicated.[89] Recent research has highlighted the causative role of TD in the development of postinfectious irritable bowel syndrome.[90] Thus agents capable of preventing the development of TD are much needed.

Clinical trials with probiotics have thus far produced mixed results. In an attempt to clarify the role of probiotics in the prevention of TD, McFarland conducted a systematic review and meta-analysis on the area. Combining the data from the 12 included RCTs indicated that probiotics (as a class of agents) appear to significantly prevent the development of TD, with a pooled relative risk of 0.85 (95% CI 0.79–0.91; $P < 0.001$). Although the data for probiotics as a whole were positive, there were a number of preparations found ineffective—*L. fermentum* VRI-003,[91] Lactinex (unspecified strains of *L. acidophilus* and *L. helveticus* in combination),[92] and an unspecified strain of *L. acidophilus* (Antibiophilus-Kapseln).[93] Only strains with proven efficacy in TD should be used clinically (see later).

In a randomized, double-blind, placebo-controlled trial by Black et al., the combination of *L. acidophilus* La5 and *B. lactis* Bb12 was evaluated for the prevention of TD. Ninety-five Danish travelers touring Egypt took part in the trial and consumed either placebo or a probiotic preparation containing 1.8×10^{10} CFU/day of a combination of *L. acidophilus* La5, *B. lactis* Bb12, *L. delbrueckii* ssp. *bulgaricus,* and *S. thermophilus* starting 2 days before travel. The first two strains constituted 90% of the mixture. The number of tourists developing diarrhea was significantly reduced in the probiotic group—from 71% in controls to 43% ($P = 0.019$). This equated to a protection rate of 39.4%.[94]

In another randomized, placebo-controlled trial investigating the efficacy of LGG (2×10^9 CFU/day) in the prophylaxis of TD, 245 subjects traveling from Finland to developing nations were enrolled. The risk of TD development for subjects taking LGG was reduced by 47% compared with the placebo-treated controls ($P = 0.05$).[95]

Using a randomized, placebo-controlled, double-blind trial design, Kollaritsch et al. investigated the efficacy of two different doses of *S. cerevisiae* var. *boulardii* strain Biocodex (250 mg/day and 500 mg/day) in the prevention of TD. Four hundred and six Austrian subjects traveling to tropical locales were enrolled. The rate of TD in the placebo group was 42.6%, versus 33.6% in the low-dose group and 31.8% in the high-dose group. This equates to a 21% reduction in incidence in the 250 mg/day group ($P < 0.007$) and 25% reduction with 500 mg/day ($P < 0.002$) compared with placebo.[93]

In another placebo-controlled double-blind study, two doses (250 and 1000 mg) of *S. cerevisiae* var. *boulardii* strain Biocodex (ScB) were administered prophylactically to 3000 Austrian travelers. A significant reduction in the incidence of diarrhea was observed, with success depending directly on the rigorous use of the preparation. A tendency was noted for ScB to have a regional effect, which was particularly marked in North Africa and in Turkey. The effect was also dose-dependent, with participants taking the higher dose of probiotics experiencing the lowest incidence of travelers' diarrhea (29%); little difference was observed between low-dose supplementation (34%) and placebo (39%). The treatment was well tolerated.[96]

Clostridium-difficile-Associated Diarrhea (CDAD)

Clostridium difficile is a common cause of diarrhea associated with treatment with antimicrobial and/or antibiotic medication and can potentially progress to colitis, pseudomembranous colitis, toxic megacolon, and death. Despite antimicrobial therapy, recurrence is common, and increasingly, probiotic supplementation has been investigated as a potential treatment for CDAD.

A meta-analysis by Johnston et al. assessed 20 RCTs ($n = 3818$ patients) that used probiotic preparations in the management of CDAD. Pooling the data on all the probiotic preparations found a 66% reduced incidence of CDAD (RR = 0.34; 95% CI 0.24–0.49) in patients taking probiotics concurrently with antibiotics. However, not all probiotic preparations were found to be effective.

Probiotic preparations that have demonstrated efficacy in randomized, controlled trials for the prevention or treatment of CDAD include *S. cerevisiae* var. *boulardii* Biocodex,[98] *L. plantarum* 299v,[99] *L. casei* DN-114 001,[100] and the combination of *L. acidophilus* CL 1285, *L. casei* LBC80R, and *L. rhamnosus* CLR2.[101]

Vancomycin-Resistant Enterococci

Over the past 15 to 20 years, there has been a rapid increase in the prevalence of vancomycin-resistant enterococci (VRE). This has been associated with the widespread use of broad-spectrum antibiotics. VRE can be involved in the pathogenesis of persistent, nosocomial infections that often have poor outcomes. Additionally, they have the capacity to transfer their antibiotic resistance genes to other organisms. Nonantibiotic control measures of VRE are thus much needed.

This randomized, double-blind, placebo-controlled trial was performed to assess the efficacy of a medicinal yogurt containing *L. rhamnosus* GG (LGG), *L. acidophilus* La5, and *B. lactis* Bb12 in the eradication of VRE. Twenty-seven VRE-positive hospital inpatients were randomly allocated to consume either a yogurt containing LGG (100 g daily for 4 weeks) or an equivalent amount of pasteurized yogurt. All subjects who received the probiotic yogurt were cleared of VRE compared with only 8% of controls ($P < 0.001$).[102] On the other hand, two trials investigating the capacity of LGG on its own to decrease VRE colonization found this strain in isolation unable to clear or reduce VRE colonization.[103,104]

Chemotherapy-Induced Diarrhea

In an open-label trial, subjects ($n = 150$) undergoing 5-fluorouracil-based chemotherapy for colorectal cancer were randomly assigned to receive supplementation with *L. rhamnosus* GG ($1–2 \times 10^{10}$ CFU/day). *L. rhamnosus* GG supplementation was associated with a 41% reduced frequency of severe diarrhea ($P = 0.027$), an 83% reduction in abdominal discomfort scores ($P = 0.025$), and 55% decreased frequency in bowel toxicity-induced dose reductions ($P = 0.0008$) compared with untreated controls.[105]

AIDS-Related Diarrhea

In a small double-blind, placebo-controlled study, 24 women with AIDS/HIV, aged 18 to 44 years, who were not being treated with antiretrovirals and had moderate diarrhea, were given either a yogurt supplemented with the probiotic strains *L. rhamnosus* GR-1 and *L. reuteri* RC-14 or an unsupplemented yogurt for 15 days. Women receiving the supplemented probiotic–yogurt experienced less diarrhea, flatulence, and nausea than those receiving the control yogurt. All probiotic-treated subjects were free of diarrhea after 15 days' treatment versus 9% of controls. Additionally, there was an increase in CD4 counts observed in probiotic-treated subjects compared with a decrease in controls ($P < 0.02$).[106]

In an open-label trial, 17 HIV-positive patients with chronic diarrhea were given *S. cerevisiae* var. *boulardii* Biocodex strain (3 g/day) for 15 days. The mean number of stools per day decreased from 9.0 on enrollment to 2.1 on day 15. Patients gained a mean of 3.6 kg during the trial.[107]

Constipation

Constipation affects a significant proportion of the population. Probiotics have long been touted as useful for the treatment of constipation, and recent meta-analyses of randomized controlled trials have demonstrated efficacy for some probiotic strains. In a systematic review of randomized controlled trials (14 trials, including 1182 subjects), combining the data from all of the different probiotic strains found a significant reduction in whole-gut transit time (12.4 h reduction; 95% CI: −22.3 to −2.5 h) and increased stool frequency by an extra 1.3 bowel movements/week (95% CI: 0.7–1.9 bowel movements/week). Stool consistency was also significantly improved.[108]

Strains that have shown consistent efficacy in trials to date include *B. lactis* DN-173 010,[109] *E. coli* Nissle 1917,[110] *B. lactis* Bb12,[111] *L. reuteri* DSM 17938,[112] and the combination of *B. breve* PXN 25, *B. longum* PXN 30, *L. acidophilus* PXN 35, *L. casei* PXN 37, *L. rhamnosus* PXN 54, and *S. thermophilus* PXN 66.[113]

Another systematic review evaluating the capacity of probiotics to specifically speed intestinal transit time found that probiotics, as a whole, could significantly reduce intestinal transit time ($P < 0.0001$). Large effect sizes were seen in particular with two probiotic strains—*B. lactis* HN019 and *B. lactis* DN-173 010.[114]

Immune Enhancement

The potential role of probiotics in the enhancement of immune function has been under investigation over the past few decades. The process started with in vitro and animal research, followed by studies evaluating the effects of probiotic administration on immune cell function in human subjects. More recently, well-conducted, human trials with hard outcomes have finally been published. In a recent Cochrane review, Hao et al. assessed the data from randomized controlled trials (12 trials; $n = 3720$) that had investigated the role of probiotics for the prevention and treatment of acute upper respiratory tract infections (URTIs). Probiotics were found to be better than placebo in reducing the number of participants experiencing episodes of acute URTIs ([OR] of at least one URTI = 0.53; 95% CI 0.37 to 0.76; $P < 0.001$) and in reducing the mean duration of an acute URTI episode (mean difference [MD] = −1.89 days; 95% CI −2.03 to −1.75 days; $P < 0.001$). Antibiotic prescription rates for acute URTIs was also significantly reduced (OR = 0.65; 95% CI 0.45–0.94), as was the incidence of cold-related school absence (OR = 0.10; 95% CI 0.02–0.47).[115]

Data suggest, however, that some, but not all, probiotic preparations will demonstrate the capacity to enhance immune function and decrease risk and duration of respiratory tract infections. A number of probiotic strains that have demonstrated the capacity to reduce the incidence of infections and/or shorten their duration are detailed in Table 105.5.

Infantile Colic

Infantile colic is defined as excessive crying or fussing in infants without apparent cause. Probiotics have been suggested as potential strategies to treat this common clinical scenario. In a systematic review and meta-analysis, Bird et al. evaluated the effect of probiotics on the symptoms of infantile colic. Five trials ($n = 317$) were included in this systematic review. Only two probiotic strains were evaluated—*L. reuteri* DSM 17938 and its nearly identical parent strain *L. reuteri* ATCC 55730. Analysis of response rates showed that infants receiving the *L. reuteri* strains had a 2.3-fold greater chance of having a 50% or greater decrease in crying/fussing time compared with controls ($P = 0.01$).[116]

Irritable Bowel Syndrome

Although the etiology of IBS is still debated, there is growing evidence that there is a persistent, mild inflammatory state with changes in mucosal function or structure and an associated imbalance in the gastrointestinal microbiota.[117] Dysbiosis has long been theorized to play a role in the pathophysiology of IBS, and the first trial conducted investigating the efficacy of probiotics in IBS was published in 1955.[118] Many trials have been conducted since this time, as have a number of systematic reviews.

Didari et al. performed a systematic review and meta-analysis of randomized controlled trials that investigated the efficacy of probiotics in the treatment of IBS. Twenty-four RCTs were included in the review, but only 15 of these ($n = 1793$) had data that could be combined into a meta-analysis. Subjects taking probiotics were nearly twice as likely to respond with a reduction in abdominal pain as those taking placebo (RR = 1.96; 95% CI 1.14–3.36; $P = 0.001$) and more than twice as likely to have an improvement in their global IBS symptom score (RR = 2.43; 95% CI 1.13–5.21; $P = 0.02$). They were also twice as likely to report adequate relief of their IBS symptoms (RR = 2.14; 95% CI 1.08–4.26; $P = 0.03$).[119]

Once again, not all probiotic strains have been shown to be effective, with studies using *L. rhamnosus* GG (in isolation),[120] *L. salivarius* UCC4331,[121] and *L. acidophilus* NCFM[122] failing to demonstrate

TABLE 105.5 Probiotics in the Prevention of Infections

Trial Methodology	Strain(s) Used	Results
R, DB, PC *n* = 201; infants 4–10 months old	*Bifidobacterium lactis* Bb12	Over a 3-month period, there was a reduction in fever episodes by 34% ($P < 0.001$), diarrhea episodes by 58% ($P < 0.001$), and duration of diarrhea episodes by 37% ($P < 0.001$).[166]
R, DB, PC *n* = 326; children 3–5 years of age	*Lactobacillus acidophilus* NCFM	Over a 6-month period, fever incidence was reduced by 53% ($P = 0.0085$) and coughing incidence by 41% ($P = 0.027$); use of antibiotics reduced by 68% ($P = 0.0002$); 32% reduction in days absent from childcare ($P = 0.002$).[167]
R, DB, PC *n* = 326; children 3–5 years of age	*L. acidophilus* NCFM and *B. lactis* Bi07	Over a 6-month period, fever incidence was reduced by 73% ($P = 0.0009$), coughing incidence by 62% ($P = 0.005$), and rhinorrhea incidence by 59% ($P = 0.03$); use of antibiotics was reduced by 84% ($P < 0.0001$); 28% reduction in days absent from childcare ($P < 0.001$).[167]
R, DB, PC *n* = 215 infants 6–12 months old	*L. fermentum* CECT5716	Over a 6-month period, there was a 46% reduced incidence of gastrointestinal infections ($P = 0.032$), a 26% reduction in respiratory tract infections ($P = 0.022$), and a 30% reduction in the total number of infections ($P = 0.003$); the incidence of recurrent respiratory tract infections was reduced by 72%.[168]
R, DB, PC, CO *n* = 20; elite, male distance runners	*L. fermentum* VRI-003	Over a 4-month winter period, distance runners taking the probiotic reported less than half the number of days of respiratory symptoms (30 vs. 72; $P = 0.00006$) compared with placebo; illness severity was also decreased ($P = 0.06$).[169]
R, DB, PC *n* = 201; infants 4–10 months old	*L. reuteri* DSM 17938	Over a 3-month period, fever episodes were reduced by 73% ($P < 0.001$), diarrhea episodes by 94% ($P < 0.001$), duration of diarrhea by 75% ($P < 0.001$), and childcare absences by 67% ($P = 0.015$) in infants.[166]
R, DB, PC *n* = 262; healthy adults	*L. reuteri* DSM 17938	Over the 80-day trial period, there was a 58% reduction in number of subjects reporting sick days in the DSM 17938 group compared with placebo ($P < 0.01$); among shift workers, 33% of those in the placebo group reported sick over the study period vs. none in the DSM 17938 group ($P < 0.005$).[170]
R, DB, PC *n* = 571; children aged 1–6 years	*L. rhamnosus* GG	Over the 7-month winter period, there were 16% fewer days absent from daycare in children in the LGG group ($P = 0.03$) and a 19% reduction in antibiotic use for respiratory tract infections ($P = 0.03$).[171]
R, DB, PC *n* = 281 day-care-aged children	*L. rhamnosus* GG	Over the 3-month intervention period, there was a 34% reduced risk of upper respiratory tract infections in toddlers in the LGG group, a 43% reduced risk of respiratory tract infections lasting longer than 3 days, and significantly fewer number of days with respiratory tract symptoms (all $P < 0.001$). There was a trend for reduced number of days with gastrointestinal symptoms ($P = 0.06$).[172]
R, DB, PC *n* = 81 infants < 2 months old	*L. rhamnosus* GG and *B. lactis* Bb12	Over the 10-month period, there was a 56% reduced risk of otitis media in infants ($P = 0.014$), a 48% reduced risk of antibiotic prescription ($P = 0.015$), and a 49% reduced risk of recurrent respiratory tract infection ($P = 0.022$).[173]

CO, Crossover; *DB,* double-blind; *PC,* placebo-controlled; *R,* randomized.

positive results. Probiotic preparations that have shown efficacy in the treatment of IBS are detailed in Table 105.6.

Inflammatory Bowel Disease

Probiotics are also being used as adjunctive therapy for the two main inflammatory bowel diseases—Crohn's disease (CD) and ulcerative colitis (UC). Overall, current research indicates a limited role for probiotics in CD, whereas the results for UC are more promising.

Crohn's Disease

Derwa et al. in their systematic review and meta-analysis of RCTs found no benefit of probiotics (as a whole) in inducing remission of active CD, in preventing relapse of quiescent CD, or in preventing relapse of CD after surgically induced remission.[123]

However, there is some preliminary supportive evidence for one probiotic strain. In an open-label study, Guslandi et al. compared *S. cerevisiae* var. *boulardii* Biocodex plus mesalazine versus mesalazine alone and found that adjunctive probiotic treatment resulted in fewer relapses (6% vs. 38%; $P = 0.04$).

Given this promising preliminary research on *S. cerevisiae* var. *boulardii* Biocodex (ScB) in CD, the strain was evaluated using a more rigorous randomized, double-blind, placebo-controlled trial design. One hundred and sixty-five subjects with CD that was currently in remission after treatment with steroids or salicylates were randomly allocated to receive either placebo or probiotic (1 g/day) for 12 months. Over the 12 months, the relapse rates were 47.5% in the probiotic group and 53.2% in the placebo group (a nonsignificant difference). The median time to relapse did not differ significantly between patients given probiotics (40.7 weeks) versus placebo (39.0 weeks). There were also no significant differences between groups in mean Crohn's disease activity index scores or erythrocyte sedimentation rates or in median levels of C-reactive protein. A post-hoc analysis did reveal, however, that nonsmokers given ScB were less likely to experience a relapse of CD than nonsmokers given placebo (OR 0.22, 95% CI 0.07–0.70; $P = 0.01$).[124] The latter result requires confirmation in future research to ensure it was not a random finding, but in the meantime, a trial of this probiotic strain would be warranted in nonsmoking CD patients.

Ulcerative Colitis

A recent meta-analysis of randomized, controlled trials assessed the effect of probiotics on remission induction and maintenance in UC. Thirteen RCTs were included in the analysis. Seven reports evaluated remission rates ($n = 399$). When combined (8 studies; $n = 709$), the adjunct use of probiotics alongside standard care did not significantly alter remission rates. There was, however, marked heterogeneity in the results. Compared with the placebo group, the use of probiotics was found to significantly reduce the UC recurrence rate (recurrence rate: 0.69, 95% CI 0.47–1.01;

TABLE 105.6 Probiotics in the Treatment of Irritable Bowel Syndrome

Trial Methodology	Strain(s) Used	Results
R, DB, PC *n* = 34 female subjects with C-IBS	*Bifidobacterium lactis* DN-173 010	After a 4-week treatment period, there was a significant reduction in abdominal distension ($P = 0.02$), an acceleration of gut transit time ($P = 0.049$), and a reduction in overall IBS symptom severity ($P = 0.032$). There were also reductions in abdominal pain/discomfort ($P = 0.044$), bloating ($P = 0.059$), and flatulence scores ($P = 0.092$).[174]
R, DB, PC *n* = 362 female subjects with IBS	*B. infantis* 35624	After a 4-week treatment phase, there were significant reductions in abdominal pain/discomfort ($P = 0.023$), bloating/distension ($P = 0.046$), feeling of incomplete evacuation ($P < 0.04$), sense of straining at stool ($P < 0.02$), passage of gas ($P < 0.04$), and composite IBS symptom scores ($P = 0.013$) compared with controls. There was also a significant improvement in bowel habit satisfaction ($P < 0.02$).[147]
R, DB, PC *n* = 52 subjects with IBS	*Lactobacillus acidophilus* strains CUL-60 and CUL-21, *B. lactis* CUL-34, and *B. bifidum* CUL-20 (Lab4)	After an 8-week treatment period, there were significant reductions in composite IBS symptom scores ($P = 0.0217$) and improvements in quality-of-life scores ($P = 0.0068$) compared with controls.[175]
R, DB, PC *n* = 214 subjects with IBS	*L. plantarum* 299V	After a 4-week treatment phase, the frequency and severity of abdominal pain, bloating, and feeling of incomplete evacuation scores were significantly reduced in the 299V group compared with controls (all $P < 0.05$). Stool frequency was significantly reduced in the 299V group ($P < 0.05$), and 78% of subjects in the 299V group scored the symptomatic effect as excellent or good versus 8% of controls ($P < 0.01$).[54]
R, DB, PC *n* = 48 subjects with IBS and bloating	VSL#3	After either a 4- or 8-week treatment phase, there was a significant reduction in flatulence scores ($P = 0.011$). There were no significant changes in other IBS symptoms or bowel function, although colonic transit time was retarded in the VSL#3 group.[176]

C-IBS, Constipation-predominant irritable bowl syndrome; *CO,* crossover; *DB,* double-blind; *IBS,* irritable bowel syndrome; *PC,* placebo-controlled; *R,* randomized.

$P = 0.05$). Heterogeneity was again observed. The results suggest that concurrent us of probiotics provides little additional benefit in inducing remission in a UC flare but that probiotic auxiliary therapy is much better than nonprobiotics therapy for maintenance of remission.[125] The significant heterogeneity observed in this study, which should have precluded the conduction of a meta-analysis, was most likely caused by the all-too-common error of combining research conducted on different probiotic strains, as each strain must be viewed as a separate therapeutic agent. Probiotic strains and specific preparations that have shown efficacy in the management of UC are detailed in Tables 105.7 and 105.8.

Nonalcoholic Fatty Liver Disease (NAFLD)

Nonalcoholic fatty liver disease comprises a spectrum of diseases ranging from simple steatosis to nonalcoholic steatohepatitis, fibrosis, and cirrhosis. Probiotics have been proposed as a treatment option because of their modulating effect on the gut flora that could influence the gut-liver axis, and there are now considerable data from animal models in support of this idea and some promising human data.

In a randomized, double-blind, placebo-controlled trial, supplementation of obese children ($n = 20$; mean age 10.7 years) with persisting hypertransaminasemia and ultrasonographic changes suggestive of NAFLD, with *L. rhamnosus* GG (1.2×10^{10} CFU/day) for 8 weeks resulted in a decrease in alanine aminotransferase concentration ($P = 0.03$) and in antipeptidoglycan-polysaccharide antibody levels ($P = 0.03$). Alanine aminotransferase levels normalized in 80% of LGG-treated subjects.[126]

Colon Cancer

In vitro and animal data have supported the potential use of probiotics, as a general class of agents, to prevent colorectal cancer—mainly via their antimicrobial effects against carcinogen-producing microorganisms, direct antimutagenic properties, and via alteration of tumor differentiation processes.[127]

One strain with supportive human data is *L. casei* Shirota. A randomized, controlled trial evaluated the efficacy of this probiotic strain in the prevention of colorectal cancer in patients ($n = 398$) who had had at least two colorectal tumors removed previously. Daily consumption of the probiotic over a 4-year period resulted in a significant reduction in the occurrence of colorectal tumors with moderate or severe atypia compared with the dietary instruction–only group ($P < 0.05$).[128]

Mastitis

Mastitis is an inflammatory condition of the breast that may, or may not, be associated with infection. It is, however, a common reason for premature cessation of breastfeeding.[129] Recent research has found some probiotic strains to be of benefit in the treatment of mastitis and the prophylaxis of recurrent mastitis.

In a randomized, double-blind, placebo-controlled trial, 352 women with lactational mastitis were allocated into one of three groups—antibiotics, *L. fermentum* CECT5716, or *L. salivarius* CECT (both at 1.0×10^9 CFU/day). After 3 weeks' treatment, both probiotic strains were found to be superior to antibiotics in decreasing levels of pathogenic bacteria in breast milk, increasing lactobacilli counts in breast milk, and decreasing breast pain scores (all $P < 0.001$). They also significantly reduced the rate of recurrence compared with antibiotics—10.5% in the *L. fermentum* CECT5716 group and 7.1% in the *L. salivarius* CECT5713 group versus 30.7% in the antibiotic group (both $P < 0.001$).[130]

In another randomized, placebo-controlled trial, women ($n = 20$) with antibiotic-resistant mastitis were allocated to receive either placebo or a probiotic preparation (*L. salivarius* CECT5713 and *L. gasseri* CECT5714; 2.0×10^{10} CFU/day) for 14 days. All mastitis signs were eliminated by day 14 in the probiotic group, whereas mastitis persisted in all women in the control group. There was also an ~100-fold decrease in milk staphylococcal counts in the probiotic group.[131]

Postpartum Obesity

Another novel area of research is using probiotics to prevent postpartum obesity. Ilmonen et al. investigated the use of a probiotic combination product (containing *L. rhamnosus* GG and *B. lactis* Bb12) in the prophylaxis of

TABLE 105.7 Probiotics in the Treatment of Ulcerative Colitis (UC)—Induction of Remission

Trial Methodology	Strain(s) Used	Results
R, DB, C *n* = 116 patients with active UC	*Escherichia coli* Nissle 1917	Over a 12-month treatment period, *E. coli* Nissle 1917 supplementation in conjunction with standard IBD therapy (corticosteroids) was equivalent to mesalazine in terms of remission rate ($P = 0.05$) and time to remission ($P = 0.009$). The duration of remission was also equivalent ($P = 0.017$).[177]
R, DB, PC *n* = 90 patients with moderately active distal UC	*Escherichia coli* Nissle 1917	Intrarectal administration (via enema) of three different doses of *E. coli* Nissle 1917 (40, 20, or 10 mL) daily for 2 weeks did not significantly affect rates of remission in ITT analysis. There was a large number of protocol violations, however, and a per protocol analysis demonstrated a significant dose-dependent effect ($P = 0.0446$). Remission rates in the 40 mL group were 53%, 44% in the 20 mL group, and 27% in the 10 mL group compared with 18% in the placebo group.[178]
R, DB, PC *n* = 147 subjects with mild-to-moderate active UC	VSL#3	At 6 weeks, 33% of VSL#3-treated subjects achieved a > 50% in the UC disease activity index versus 10% of controls ($P = 0.001$). At week 12, 43% of subjects in the VSL#3 group were in remission versus 16% of controls ($P < 0.001$).[179]
R, DB, PC *n* = 29 children with active UC	VSL#3	In conjunction with standard UC therapy (steroids and mesalamine), remission was achieved in 93% of VSL#3-treated children versus 36% of controls ($P < 0.001$). Twenty-one percent of VSL#3 treated subjects relapsed within 1 year versus 73% of controls ($P = 0.014$).[180]

DB, Double-blind; *IBD,* irritable bowel disease; *ITT,* intention to treat; *PC,* placebo-controlled; *R,* randomized.

TABLE 105.8 Probiotics in the Treatment of Ulcerative Colitis (UC)—Maintenance of Remission

Trial Methodology	Strain(s) Used	Results
R, DB, C *n* = 327 UC patients in remission	*Escherichia coli* Nissle 1917	Over the 12-month trial period, *E. coli* Nissle 1917 treatment was found to be equally effective as mesalazine in preventing relapse (36.4% relapse vs. 33.9%; $P = 0.003$).[181]
R, DB, C *n* = 120 UC patients in remission	*E. coli* Nissle 1917	Over a 12-week period, relapse rates were 11.3% under mesalazine and 16.0% under *E. coli* Nissle 1917 (not significantly different). The mean relapse-free time was 103 ± 4 days for mesalazine and 106 ± 5 days for *E. coli* Nissle 1917 (not significantly different).[182]
OL *n* = 34 UC patients in remission aged 11–18 years	*E. coli* Nissle 1917	Over the 12-month treatment period, the relapse rate was 25% in probiotic-treated subjects versus 30% in the mesalazine group.[183]
R, OL *n* = 187 UC patients in remission	*Lactobacillus rhamnosus* GG	Subjects were randomized to receive either *L. rhamnosus* GG (LGG) alone or in combination with mesalazine, or mesalazine alone. Over the 12-month trial period, there was no difference in relapse rates between the three groups. LGG supplementation was as equally effective as mesalazine in maintaining clinical remission but significantly more effective than mesalazine in prolonging the relapse-free time ($P < 0.05$).[184]
OL *n* = 20 UC patients in remission	VSL#3	After 12 months, 15 of the 20 participants remained in remission, which compares favorably with rates of remission observed during long-term mesalazine therapy.[185]

C, Controlled; *DB,* double-blind; *OL,* open-label; *PC,* placebo-controlled; *R,* randomized.

postpartum obesity. In the first trimester of pregnancy, 256 women were randomly assigned to receive no dietary counseling or nutritional counseling (low-fat and high-fiber diet) plus probiotics (LGG and Bb12; 2.0×10^{10} CFU/day) or counseling plus placebo. Interventions lasted until the end of exclusive breastfeeding for up to 6 months. At 6 months' postpartum, the risk of central adiposity (defined as waist circumference 80 cm or more) was lowered in women in the diet/probiotics group compared with the control/placebo group (OR 0.30, 95% CI 0.11–0.85; $P = 0.023$ adjusted for baseline body mass index), whereas the diet/placebo group did not differ from the controls (OR 1.00, 95% CI 0.38–2.68; $P = 0.994$). The number needed to treat with diet/probiotics to prevent one woman from developing a waist circumference of 80 cm or more was four.[132] At 12 months postpartum, central obesity occurred in 25% of diet/probiotic subjects versus 43% in the diet/placebo group. The proportion of body fat was also 3.5% lower in the diet/probiotic group ($P = 0.018$).[133]

Urogenital Infections

Probiotics are widely used in the treatment and prevention of urogenital infections. They can be administered both orally and locally, with multiple trials supporting their use. There are additional criteria needed for probiotic strains to be efficacious in urogenital applications. Strains must demonstrate the capacity to adhere to uroepithelial and vaginal cells, temporarily colonize the vagina, inhibit urogenital pathogen growth and/or attachment, and ideally should produce hydrogen peroxide and lactic acid. Strains that will be administered orally must also have sufficient tolerance to gastric acid and bile salts and the verified capacity to colonize the vagina after oral intake.[134] Probiotic strains that do not exhibit these characteristics are unlikely to be therapeutic for urogenital applications.

The mechanisms by which some *Lactobacillus* strains reduce bacterial vaginosis, vaginal candidiasis, and UTIs appear to involve a combination of antiadhesion factors, byproducts such as hydrogen peroxide, bacteriocins, and lactic acid (both D- and L-forms), and destruction of urogenital pathogen biofilms, as well as immune modulation or modification of vaginal epithelial cell cytokine production.[30,135-137]

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most prevalent vaginal infection worldwide and is characterized by an altered vaginal ecosystem (i.e.,

TABLE 105.9 Probiotics in the Treatment of Bacterial Vaginosis (BV)

Trial Methodology	Strain(s) Used	Results
R, DB, PC *n* = 64 women	*Lactobacillus rhamnosus* GR-1 and *L. reuteri* RC-14	After a single dose of tinidazole and 4 weeks of oral probiotic treatment, subjects in the probiotic group had a higher rate of BV cure (88% vs. 50%; *P* = 0.001) and vaginal flora normalized in 75% of probiotic-treated subjects versus 34% of controls (*P* = 0.011).[186]
R, DB, PC *n* = 40 women	*L. rhamnosus* GR-1 and *L. reuteri* RC-14	Intravaginal application of probiotics nightly for 5 days resulted in a 90% cure rate by day 30; follow-up at day 6, 15, and 30 showed cure of BV in significantly more probiotic-treated subjects (16, 17, and 18/20, respectively) compared with metronidazole gel treatment (9, 9, and 11/20, respectively; *P* = 0.016 at day 6, *P* = 0.002 at day 15, and *P* = 0.056 at day 30).[187]
R, DB, PC *n* = 106 women	*L. rhamnosus* GR-1 and *L. reuteri* RC-14	Women receiving an antibiotic prescription for BV (metronidazole 500 mg twice daily for 7 days) who were given concurrent probiotics (*L. rhamnosus* GR-1 and *L. reuteri* RC-14) for 30 days had an eradication rate of 88% versus 40% in the antibiotic/placebo group (*P* < 0.001).[188]
R, DB, PC *n* = 80 women	*Bifidobacterium breve* PXN 25, *B. longum* PXN 30, *L. acidophilus* PXN 35, *L. casei* PXN 37, *L.* delbrueckii ssp. *bulgaricus* PXN 39, *L. rhamnosus* PXN 54, and *Streptococcus thermophilus* PXN 66	In women receiving oral metronidazole, oral supplementation with this probiotic combination resulted in an 87.5% treatment success rate compared with 67.5% treatment success in placebo group (*P* = 0.032).[189]

CO, Crossover; *DB,* double-blind; *OL,* open-label; *PC,* placebo-controlled; *R,* randomized.

dysbiosis)—specifically a depletion of the indigenous lactobacilli population. Administration of exogenous lactobacilli strains has thus been an area of research interest.[138]

A Cochrane systematic review conducted in 2009 included four RCTs that examined probiotic agents in the treatment of BV. Analysis suggested that probiotics were effective in enhancing microbiological cure rates with the oral metronidazole/probiotic (*L. rhamnosus* GR-1 and *L. reuteri* RC-14) regimen (OR 0.09, 95% CI 0.03–0.26) and the probiotic (unspecified strain of *L. acidophilus*)/estriol preparation (OR 0.02, 95% CI 0.00–0.47) showing effectiveness. The authors cautioned, however, that larger, well-designed trials were needed before any firm conclusions could be made.[139] Research on specific strains that have demonstrated efficacy are highlighted later in Table 105.9.

Urinary Tract Infections

Grin et al. performed this systematic review and meta-analysis to review the data on the potential effectiveness of lactobacilli in the prevention of recurrent urinary tract infections in women. Five randomized, controlled trials were included in the analysis. Combining the data from all the trials (294 patients) found no preventative effect of lactobacilli supplementation (RR = 0.85, 95% CI 0.58–1.25; *P* = 0.41). However, a sensitivity analysis was performed, excluding studies using ineffective strains and studies testing for safety only. Data from 127 patients in two trials were included. A statistically significant decrease in recurrent UTI was found in patients given lactobacilli, denoted by the pooled risk ratio of 0.51 (95% CI 0.26–0.99; *P* = 0.05).[140]

A significant reduction in UTI recurrence rate was reported in a randomized double-blind study involving 55 premenopausal women. The study investigated the effectiveness of treatment for 1 year with a weekly suppository containing either a combination of *L. rhamnosus* GR-1 and *L. fermentum* B-54 or a *Lactobacillus* growth factor (skim milk). Treatment resulted in the UTI rate decreasing by 73% and 79%, respectively, with no adverse effects reported.[141]

A recent, randomized, double-blind, noninferiority trial compared the efficacy of 12 months of prophylaxis with antibiotics (trimethoprim-sulfamethoxazole; 480 mg/day) or oral probiotics (2×10^9 CFU/day of a combination of *L. rhamnosus* GR-1 and *L. reuteri* RC-14) in the prevention of UTIs in postmenopausal women with recurrent cystitis (*n* = 252). The number of symptomatic UTIs over the 12-month treatment period was 2.9 in the antibiotic group and 3.3 in the lactobacilli group—a between-treatment difference of 0.4 episodes (95% CI −0.4–1.5) or 13.8%. In the year preceding the trial, the subjects experienced a mean of 6.9 UTIs. The percentage of patients with at least one UTI at 12 months was 69.3% in the trimethoprim-sulfamethoxazole group and 79.1% in the lactobacilli group. The median times to first recurrence were 6 and 3 months, respectively. After 12 months of trimethoprim-sulfamethoxazole prophylaxis, all urinary *E. coli* isolates of asymptomatic women were resistant to trimethoprim-sulfamethoxazole and trimethoprim. Probiotic use, however, was not associated with increased antibiotic resistance. The authors stated that this lactobacilli combination may be an acceptable alternative for the prevention of UTIs, especially in women who dislike taking antibiotics.[142] Although probiotic therapy appeared slightly less effective than antibiotic prophylaxis in postmenopausal women with recurrent UTIs, their use does not damage the GIT microbiota or create antibiotic resistant organisms.[143]

Vaginal Candidiasis

In theory, supplying specific lactobacilli strains to the vagina in women with vaginal candidiasis (VC) or at risk of VC should help manage or prevent the infection. Lactobacilli can impair the growth of *C. albicans* via the production of lactic acid, which creates a low-pH environment resulting in suppressed fungal growth. Cocultures of some lactobacilli strains with *C. albicans* has revealed inhibitory effects. Transcriptome analyses showed increased expression of stress-related genes and lower expression of genes involved in antifungal resistance.[136] Research to date, however, has produced mixed results.

Some probiotic preparations have been shown to be clearly ineffective in the treatment of VC. For example, a combination of *L. rhamnosus* HN001 and *B. longum* Bl-05 and a propriety preparation, Femilac (unspecified strains of *L. rhamnosus, L. delbrueckii* ssp *bulgaricus, L. acidophilus*, and *S. thermophilus*).[144] Other preparations have shown some degree of efficacy, however. Those preparations that have shown efficacy in the treatment of VC are detailed in Table 105.10, although it should be noted that most of these trials were small in size.

TABLE 105.10 Probiotics in the Treatment of Vulvovaginal Candidiasis (VC)

Trial Methodology	Strain(s) Used	Results
R, DB, PC *n* = 27 women with a history of recurrent VC	*Lactobacillus acidophilus* NAS as a vaginal suppository in isolation or with *L acidophilus* NAS strain; *Bifidobacterium bifidum* Malyoth strain, and *L. bulgaricus* LB-51 strain taken orally	In women who used the *L. acidophilus* NAS vaginal suppository, the incidence of recurrent VC was significantly reduced compared with controls ($P = 0.005$). Subjects who took both the suppository and oral probiotic supplement also had a significant reduction in the number of infections compared with controls ($P = 0.011$). There was, however, no extra benefit seen from taking the oral probiotic preparation.[189]
R, DB, PC *n* = 55 women with VC	*L. rhamnosus* GR-1 and *L. reuteri* RC-14	After a single dose of fluconazole and 4 weeks of oral treatment with either probiotic or placebo, subjects in the probiotic group had reduced *Candida* colonization (10% vs. 39%; $P = 0.014$) and decreased vaginal discharge (10% vs. 35%; $P = 0.03$).[190]
R, PC, CO *n* = 33 women with a history of recurrent VC	*L. acidophilus* LA5	The mean number of infections per 6 months decreased while in the probiotic phase compared with the control phase of the trial (0.38 vs. 2.54; $P = 0.001$). The incidence of *Candida* colonization also decreased during probiotic treatment (0.84 vs. 3.23 per 6 months; $P = 0.001$).[191]
OL *n* = 28 women with a history of recurrent VC	*L. rhamnosus* GG	Twice-daily intravaginal application of LGG resulted in decreased symptoms of VC, as well as less erythema and discharge; 4/5 women who were positive for *Candida* at baseline had negative cultures at the end of 7 days.[178]

CO, Crossover; *DB*, double-blind; *OL*, open-label; *PC*, placebo-controlled; *R*, randomized.

Toxin Reduction

Some *Lactobacillus* strains are able to break down aldehydes in the body through enhancement of the enzyme aldehyde dehydrogenase.[145] In addition, some probiotic strains can bind to aflatoxin B_1 in the intestine, preventing the toxin from causing damage to the liver and other organs.[146]

DOSAGE

The dosage of probiotic foods and supplements is based solely upon the number of live organisms present in the product. Successful results have been attained in clinical trials using between 10^7 and 10^{11} CFU per day.[147-149] Interestingly, it appears that 100 times fewer viable bacteria need to be given in a dairy medium than in a freeze-dried supplement to achieve similar numbers of live bacteria in the lower bowel.[63] Dairy appears to work as an ideal transport medium for the bacteria, enhancing their survival through the upper GIT.[50]

Supplements

Supplements are best consumed with meals to take advantage of the increased alkalinity of the gastric environment (which equates to greater bacterial survival).[150] A dosage of 10^8 bacteria per sitting is often mentioned in the probiotic literature as the minimum quantity of bacteria needed to produce therapeutic effects.[50,150] Additionally, there have been a handful of studies that demonstrated therapeutic effects using 10^7 to 10^8 viable bacteria per dose.[147,148,151] However, most of the successful probiotic research used greater than or equal to 10^9 CFU per dose.

The minimum concentration of probiotic bacteria needed to achieve therapeutic effects appears to be strain dependent, in that for some strains (e.g., *L. reuteri* DSM 17938) 10^7 bacteria is a sufficient quantity to produce beneficial effects,[148] whereas for other strains, 10^9 viable bacteria is needed (e.g., *L. rhamnosus* GG).[63] This situation, unfortunately, makes it hard to give firm dosage recommendations, as the minimum effective dosage appears to differ by strain. Thus it is best practice to ensure that supplements contain bacteria in concentrations greater than or equal to 10^9 CFU per dose, unless research has demonstrated that the specific strain contained in the supplement is effective in smaller amounts.

Therefore the dosage of viable bacteria given in supplemental forms should generally be 10^9 to 10^{11} bacteria per dose. If a formulation contains multiple strains, each strain must be present in amounts greater than or equal to 10^9, because dosages of less than 10^9 CFU may not produce therapeutic effects.

Studies evaluating a potential dose-response have to date been extremely limited. Results do suggest, however, that at least for the areas of acute viral diarrhea and antibiotic-associated diarrhea, there is a probable dose-dependent effect—with doses of $> 10^{10}$ CFU/day generally more effective. Perhaps not surprisingly, fecal concentrations also correlated well with oral dosing regimens for most probiotic strains, with higher oral dosing equating to higher fecal concentrations.[152]

Dosage in Dairy Mediums

The minimum dosage of viable bacteria needed in a dairy medium is 10^8 CFU of each strain per dose. Therapeutic yogurts contain greater than or equal to 10^6 viable bacteria per milliliter, thus a 100 g serving (approximately 1/2 cup) will provide sufficient probiotic bacteria for therapeutic effects.[150] Unfortunately, many so-called "acidophilus" and/or "bifidus" yogurts do not contain this minimum level.[153] Only yogurt brands that are guaranteed to contain this level of viable bacteria or those that have done so in market-basket surveys should be used. A serving of yogurt containing less than 10^8 viable bacteria is unlikely to have any medicinal effects beyond its inherent nutritional content.

A 100 g serving of yogurt contains only 3.1 to 3.5 g of lactose,[154] which is well below the threshold level in individuals with lactose intolerance. Hence, lactose-intolerant individuals should be able to consume the minimum amount of yogurt without ill effects.[155]

TOXICITY

Lactobacilli have been consumed in large numbers throughout recorded history. The fermentation of foodstuffs is one of the oldest known uses of biotechnology, and even today, fermented foods and beverages constitute 20% to 40% of the human food supply worldwide. Thus lactobacilli have a long history of safe ingestion.[5]

In a recent review done to assess the safety of probiotics, Hempel et al. evaluated the adverse event profiles of 622 human trials that used probiotics from the genera *Lactobacillus, Bifidobacterium, Saccharomyces, Streptococcus, Enterococcus* and *Bacillus.* Combining the data from those studies that reported adverse events, no increased risk of adverse events was observed in those subjects receiving probiotics

versus those taking a placebo (RR = 1.00; 95% CI 0.93–1.07). Nor was there an increase in gastrointestinal side effects, infections, or serious adverse events in probiotic-consuming subjects (RR = 1.06; 95% CI 0.97–1.16).[149]

Another systematic review looking specifically at probiotic safety in children evaluated the data from 74 clinical trials. Studies included healthy, immune-compromised, and obese subjects, as well as subjects with intestinal disorders, infections, and inflammatory disorders. Probiotics were found to be well-tolerated, with adverse events occurring more frequently in the placebo arm compared with those taking probiotics. The authors caution, however, that there was inadequate reporting and classification of adverse events in many of the trials.[150]

Serious adverse events (such as bacteremia and fungemia) occur very rarely with probiotic use. Most cases have been associated with an immune-compromised state, impaired intestinal barrier function (such as in multiorgan failure), and the use of a central venous catheter. As these conditions are often present in critically ill patients, probiotic treatment is contraindicated in this population.[151]

Despite a substantial increased use of probiotic supplements worldwide, epidemiological evidence suggests there has been no corresponding increase in cases of bacteremia or fungemia as a consequence—further supporting their excellent safety profile.[156]

DRUG INTERACTIONS

Lactobacilli and bifidobacteria are negatively affected by alcohol and antibiotics.[157,158] Although there is no evidence that the organism interferes with the activity of most antibiotics, the metabolism of sulfasalazine, chloramphenicol palmitate, and phthalylsulfathiazole may be affected by some strains of *L. acidophilus.*[159]

Procyanidolic Oligomers

Michael T. Murray, ND

OUTLINE

GENERAL DESCRIPTION

The proanthocyanidins (also referred to as "procyanidins") are one of the most beneficial groups of plant flavonoids. The most active proanthocyanidins are those bound to other proanthocyanidins. Collectively, mixtures of proanthocyanidin dimers, trimers, tetramers, and larger molecules are referred to as procyanidolic oligomers (PCOs) or oligomeric proanthocyanidins (OPCs).[1,2] Although PCOs exist in many plants as well as red wine, commercially available sources of PCOs include extracts from grape seed skin *(Vitex vinifera)* and the bark of the maritime (Landes) pine.[1,2] This chapter reviews the benefits of PCOs from grape seeds and pine bark interchangeably because of their similar chemical composition and pharmacological profiles.

CHEMICAL COMPOSITION

Grape seed and pine bark PCO extracts are well defined chemically. Grape seed extracts are available that contain 92% to 95% PCOs, whereas the PCO content of pine bark extracts varies from 80% to 85% (Fig. 106.1).

HISTORY AND FOLK USE

In 1534, French explorer Jacques Cartier led an expedition up the Saint Lawrence River in what would become North America. Trapped by ice, Cartier and his crew were forced to survive on a ration of salted meat and biscuits. Cartier's crew began to exhibit signs and symptoms of scurvy, the cause of which was unknown at that time. Fortunately for Cartier and the surviving members of his crew, they met a Native American who advised them to make a tea from the bark and needles of pine trees. As a result, Cartier and his men survived.

More than 400 years later, Professor Jacques Masquelier of the University of Bordeaux, France, read the book Cartier wrote detailing his expedition. Intrigued by Cartier's story, Masquelier and others concluded that pine bark must contain some vitamin C as well as bioflavonoids, which can exert vitamin C–like effects.

Masquelier termed the active components of the pine bark *pycnogenols.*[1,3] This term was used to describe an entire complex of proanthocyanidin complexes found in a variety of plants, including pine bark, grape seeds, lemon tree bark, peanuts, cranberries, and citrus peels. The term *pycnogenol* has been replaced in the scientific community by the terms *proanthocyanidins, OPC,* and *PCO.* In the United States, Pycnogenol is a registered trademark of Horphag Ltd of Guernsey, United Kingdom, and refers to the PCO extracted from the bark of the French maritime pine.

Masquelier patented the method of extracting PCOs from pine bark in France in 1951 and from grape seeds in 1970. The two PCO sources have volleyed back and forth in popularity, based largely on which one is receiving research focus and marketing support.

PHARMACOLOGY

Extracts of PCOs demonstrate a wide range of activity, as listed in Box 106.1. Pharmacokinetic studies showed that proanthocyanidins and other breakdown products of PCOs from either grape seed extract or maritime pine are detectable in the serum after oral intake.[4,5] Pharmacokinetic studies in humans and animals given C^{14}-labeled PCOs also showed efficient oral absorption.[6,7]

Antioxidant and Free-Radical-Scavenging Activity

Perhaps the most celebrated effects of PCOs in the United States are their potent antioxidant and free-radical-scavenging activities. The

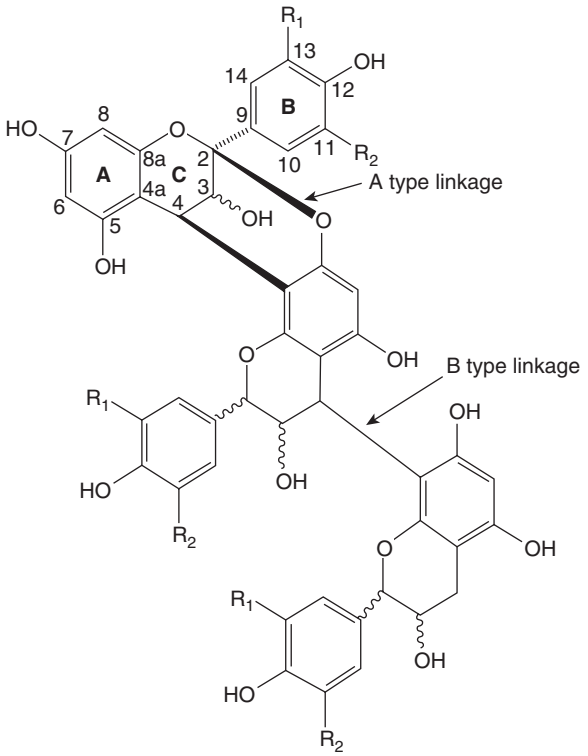

Fig. 106.1 General structure of proanthocyanidins. (R1, R2 = H, propelargonidin; R1 = OH, R2 = H, procyanidin; R1, R2 = OH, prodelphinidin). (From Ly Q, Luo F, Zhao X, Liu Y, Hu G, Sun C, Li X, Chen K. Identification of proanthocyanidins from litchi *[Litchi chinensis Sonn.]* pulp by LC-ESI-Q-TOF-MS and their antioxidant activity. *PLoS One.* 2015;10[3]:e0120480. PubMed PMID: 25793378.)

BOX 106.1 Basic Pharmacological Activity of Proanthocyanidins

- Increase intracellular vitamin C levels
- Decrease capillary permeability and fragility
- Scavenge oxidants and free radicals
- Inhibit destruction of collagen
- Reduce inflammation

Data from Rohdewald P. A review of the French maritime pine bark extract (Pycnogenol), a herbal medication with a diverse clinical pharmacology. *Int J Clin Pharmacol Ther.* 2002;40:158–168; and Schwitters B, Masquelier J. *OPC in practice: biflavanols and their application.* Rome: Alfa Omega; 1993.

antioxidant and free-radical-scavenging effects of PCOs were discovered by Masquelier in 1986.[1]

One study evaluated the free-radical-scavenging activity of PCOs and determined their inhibitory effects on xanthine oxidase (a primary generator of oxygen-derived free radicals) and the lysosomal enzyme system (which governs the release of enzymes that can damage the connective tissue framework acting as a protective sheath around capillary walls).[8] This research, summarized in Box 106.2, provides a detailed explanation of the vascular protective action of PCOs and a strong rationale for their use in vascular disease.

In experimental models, the antioxidant activity of PCOs is much greater (approximately 50 times) than that of vitamin C and vitamin E. PCOs reduce lipid peroxidation[9] and oxidation of low-density lipoprotein (LDL),[10] increase basal levels of α-tocopherol in endothelial cells,

BOX 106.2 Antioxidant and Free-Radical-Scavenging Activities of Procyanidolic Oligomers

- Trap hydroxyl free radicals
- Trap lipid peroxides and free radicals
- Markedly delay the onset of lipid peroxidation
- Chelate free iron molecules, thereby preventing iron-induced lipid peroxidation
- Inhibit production of free radicals by noncompetitively inhibiting xanthine oxidase
- Inhibit the damaging effects of the enzymes (e.g., hyaluronidase, elastase, collagenase) that can degrade connective tissue structures

protect endothelium from oxidative stress induced by reactive nitrogen species,[11,12] and protect endothelial cells from activated macrophage-induced glutathione depletion.[13] From a cellular perspective, one of the most advantageous features of PCOs' free-radical-scavenging activity is that, because of their chemical structure, they are incorporated into cell membranes. This physical characteristic, along with their ability to protect against both water- and fat-soluble free radicals, provides significant cellular protection against damage by free radicals.[8]

Ant-Iinflammatory Activity

PCOs affect the activity or expression of many inflammatory mediators. In particular, PCOs suppress the nuclear factor (NF)-κB pathway and activate the Nrf2 pathway. NF-κB is a transcription factor activated by cell stress and in turn regulates the expression of many genes involved in the inflammatory response, such as immune receptors (interferon-gamma [IFN-γ] receptor, major histocompatibility complex [MHC], interleukin [IL]-2 receptor), cytokines (tumor necrosis factor-alpha [TNF-α], IL-6, IL-1), adhesion molecules (vascular cell adhesion molecule-1 [VCAM-1], intercellular adhesion molecule-1 [ICAM-1]), prooxidant enzymes (cyclooxygenase-2 [COX-2], inducible nitric oxide synthase [iNOS]), and chemokines (monocyte chemoattractant protein [MCP]-1, MIP-1α, IL-8). PCOs reduce oxidative stress and inflammation by suppressing NF-κB and the mRNA expression of proinflammatory cytokines like TNF-α and IL-1β as well as the inflammatory prostaglandin products of COX-2. All of these effects support an anti-inflammatory and cancer preventive action for PCOs. Further supporting this action is that PCOs also activate Nrf2, a crucial transcriptional regulator needed to manufacture cytoprotective compounds in response to oxidative stress and inflammation.

In vitro and in vivo studies also show that PCOs significantly directly inhibit COX-1 and COX-2 enzymes as well as the formation of proinflammatory cytokines, IL-1β, and TNF-β, as well as histamine release from mast cells.[14–17] When 10 volunteers received a single dose of 300 mg Pycnogenol, within 30 minutes, serum samples showed statistically significant inhibition of both COX-1 and COX-2 ($P < 0.002$). Blood samples before and after 5 days of administration of 200 mg Pycnogenol to five healthy humans showed similar inhibition.

Anticancer Activity

PCOs also prevent oxidative-induced DNA damage and promote DNA repair through direct antioxidant protection of DNA and prevention of the formation of highly mutagenic cyclobutane pyrimidine dimers (CPDs), enhancing the functions of DNA and CPD repair enzymes, promoting nucleotide excision repair mechanisms, and inhibiting DNA hypomethylation.[18] PCOs exert a number of anticancer effects beyond their general antioxidant actions. PCOs were shown to selectively induce apoptosis in human breast cancer cells, inhibit cell

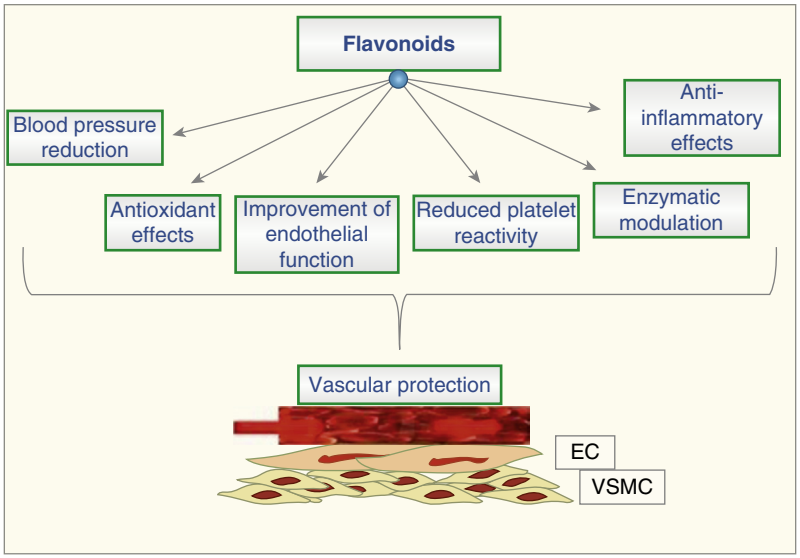

Fig. 106.2 Potential effects of flavonoids on cardiovascular protection. (From Grassi D, Desideri G, Ferri C. Flavonoids: antioxidants against atherosclerosis. *Nutrients.* 2010;2[8]:889–902. PubMed PMID: 22254061.)

proliferation and induce differentiation and apoptosis in leukemia cells, and inhibit nitrosamine activation in lung microsomes.[19–22]

Cardiovascular Protection

In addition to protecting against oxidative damage to low-density lipoprotein (LDL) and endothelial cells, PCOs increase erythrocyte membrane fluidity, reduce platelet aggregation, enhance endothelial nitric oxide synthase (eNOS) activity to increase nitric oxide levels, and inhibit angiotensin-I–converting enzyme (ACE) (Fig. 106.2).[23–26] PCO extracts were shown to lower blood cholesterol levels and to shrink the size of cholesterol deposits in arteries in animal and human studies.[1,27,28]

PCOs also significantly lower C-reactive protein (CRP), a major risk factor for cardiovascular disease. In a double-blind study, 29 subjects in the Pycnogenol group and 26 patients in the placebo group had CRP levels higher than 3 mg/L at baseline.[16] After 3-month treatment with Pycnogenol, at a dose of 100 mg/day, CRP significantly decreased plasma free radicals to 70.1% of baseline values. Specifically, plasma CRP levels decreased from 3.9 mg/L at baseline to 1.1 mg/L in the Pycnogenol group, whereas the control group had initial values of 3.9 mg/L that decreased to 3.6 mg/L. Fibrinogen levels were found to be lowered to 62.8% of initial values in the Pycnogenol group.

Protection of Collagen and Cartilage

Collagen, the most abundant protein of the body, is responsible for maintaining the integrity of ground substance as well as the integrity of tendons, ligaments, and cartilage. Collagen is also the support structure of the dermis and blood vessels. PCOs are remarkable in their effects of supporting collagen structures and preventing collagen destruction. They affect collagen metabolism in several ways. They have the unique ability to cross-link collagen fibers, resulting in reinforcement of the natural cross-linking of collagen that forms the so-called collagen matrix of connective tissue.[29,30] They also protect against free radical damage with their potent antioxidant and free-radical-scavenging action, and they inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation and microbes during infection.[8,31] PCOs also prevent the release and synthesis of compounds that promote inflammation and allergies, such as histamine, serine proteases, prostaglandins, and leukotrienes.[1,2,32,33]

PCOs also exert significant chondroprotective effects. In one controlled trial, 33 patients with severe osteoarthritis (OA) scheduled for a knee arthroplasty either received 100 mg of Pycnogenol twice daily or no treatment (control group) 3 weeks before surgery. Results demonstrated that the intake of Pycnogenol downregulated the gene expression of various cartilage degradation markers in the patients' chondrocytes; the decreases of MMP3, MMP13, and the proinflammatory cytokine IL-1β were statistically significant.[34]

CLINICAL APPLICATIONS

The primary clinical applications of PCOs are in the treatment of the following conditions:

- Antioxidant therapy
- Asthma
- Atherosclerosis, hypertension, metabolic syndrome, and type 2 diabetes
- Attention deficit disorder and poor cognition
- Male infertility and erectile function
- Osteoarthritis
- Periodontal disease
- Venous insufficiency and capillary fragility
- Visual function, retinopathy, and macular degeneration

Antioxidant Therapy

PCOs exert broad-spectrum antioxidant activity and are clinically useful in many health conditions because of this action alone. In healthy human subjects, supplementation with PCOs for 6 weeks was shown to considerably improve the plasma oxygen radical absorbance capacity score (ORAC).[28] In one double-blind study, the effect of a standardized formulation of a PCO bound to phosphatidylcholine (Leucoselect Phytosome) was determined on the susceptibility of LDL to oxidation in a group of heavy smokers.[35] Among oxidative indexes, the concentration of thiobarbituric acid reactive substances was significantly reduced in subjects taking the PCO extract, and the lag phase was prolonged compared with the values in subjects taking a placebo, as well as with baseline values.

In another double-blind study, a group of 155 smokers was supplemented with 50 mg Pycnogenol or a placebo for 8 weeks followed by

2 weeks' cessation. Results showed that even at this dosage, Pycnogenol was able to significantly lower reactive oxygen species.[36]

Athletes can also gain benefits from PCOs. One study was designed to evaluate the effects of Pycnogenol on improving physical fitness in normal individuals and athletes training for a triathlon. The study was divided into two parts. In part 1 (Pycnogenol 100 mg/day), the Army Physical Fitness Test (APFT) was used to assess improvement in physical fitness during an 8-week preparation and training program. In part 2 (Pycnogenol 150 mg/day), the study evaluated the effects of Pycnogenol supplementation in athletes in training for a triathlon.

In part 1, results showed that there was a significant improvement in both males and females in the 2-mile running time, sit-ups, and push-ups within both groups, but the group using Pycnogenol performed statistically better than controls. In part 2, the swimming, biking, and running scores in both groups improved with training. However, the Pycnogenol group had more benefits in comparison with controls. The total triathlon time was 89 minutes and 44 seconds in Pycnogenol subjects versus 96 minutes and 5 seconds in controls. Controls improved their performance time by 4.6 minutes on average in comparison with an improvement of 10.8 minutes in Pycnogenol subjects. A significant decrease in cramps and running and postrunning pain was seen in the Pycnogenol group; there were no significant differences in controls. In Pycnogenol subjects, there was a lower increase in oxidative stress and a faster recovery.[37]

The performance benefits are not limited to the body; cognitive function can also improve with PCO supplementation. In a double-blind, placebo-controlled study in 101 elderly participants (60–85 years), consuming a daily dose of 150 mg of Pycnogenol for 3 months produced significant improvements in several memory-based cognitive assessments and lipid peroxidation products (F2-isoprostanes) relative to the control group.[38]

Asthma

PCOs appear to have an affinity for the lungs, indicating a possible benefit in lung disorders, including asthma. In a double-blind study involving 60 subjects (aged 6–18 years old) with mild to moderate asthma, patients were given either Pycnogenol (1 mg/lb body weight per day) or placebo for 3 months. Subjects were instructed to record their peak expiratory flow with an Assess Peak Flow Meter each evening. Compared with subjects taking a placebo, the group that took Pycnogenol had significantly more improvement in pulmonary function and asthma symptoms. Those in the Pycnogenol group were able to reduce or discontinue their use of rescue inhalers more often than the placebo group. There was also a significant reduction of urinary leukotrienes in the Pycnogenol group. The results of this study demonstrate the efficacy of Pycnogenol as an adjunct in the management of mild to moderate childhood asthma. Given the safety of PCOs, higher dosages (e.g., 2–3 mg/lb body weight) may produce better results than the lower dosage used in the clinical trial.[39]

Atherosclerosis, Hypertension, Metabolic Syndrome, and Type 2 Diabetes

PCO extracts, although in a supplement form, should be regarded as a necessary food in the prevention and treatment of atherosclerosis, metabolic syndrome, and type 2 diabetes. PCOs are similar to red wine components that are protective against heart disease, but they are more concentrated.[40] The active components in red wine are thought to be proanthocyanidins. Flavonoid consumption, in general, has an inverse correlation with death due to heart attack.[41] Both Pycnogenol and grape seed extract showed considerable ability to reduce cardiovascular risk factors, especially in patients with type 2 diabetes.[42–44] However, even healthy subjects can take advantage of the beneficial effects of PCOs against cardiovascular risk factors. In one study, when 25 healthy subjects received Pycnogenol (150 mg/day) for 6 weeks, a significant increase in ORAC in plasma was observed throughout the supplementation period (returning to baseline after a 4-week washout period).[28] Pycnogenol also significantly reduced LDL cholesterol levels and increased high-density lipoprotein (HDL) cholesterol levels in the plasma of two thirds of the subjects. Although the LDL changes reversed during washout, the HDL increase did not. Like other flavonoid sources, PCO extracts appear to be very helpful in improving endothelial function. Again, this effect may be particularly important in patients with hypertension, metabolic syndrome, and diabetes. In one double-blind study in 58 patients with hypertension who received supplementation with 100 mg PCO over 12 weeks, endothelin-1 concentrations were significantly lower, and concentrations of 6-keto prostaglandin F_{1a} in plasma were significantly higher, in the PCO group than in the placebo group. Additionally, the PCOs helped reduce the effective dose of the calcium antagonist nifedipine in a statistically significant manner.[41] In another double-blind study, PCOs from grape seed extract were shown to produce a mild hypotensive effect (−11 mm Hg for both systolic and diastolic readings) in patients with metabolic syndrome at dosages of 150 and 300 mg/day.[45]

The benefits of PCOs in hypertension appear to be most significant in pre- to moderate hypertension. In one study, 36 subjects with prehypertension were randomized to ingest a juice containing 0 mg (placebo) or 150 mg PCOs twice daily for 6 weeks preceded by a 2-week period where both groups took the placebo beverage and followed by 4-week no-beverage follow-up. Results showed that subjects taking the GSE for 6 weeks significantly reduced both their systolic (–5.6%) and diastolic blood pressure (BP) (–4.7%). However, subjects with higher initial BP experienced greater BP reduction, nearly double the effect size. The majority of subjects were able to achieve normal BP measurements with PCO supplementation. In contrast, no effect was noted in the placebo group. BP returned to baseline levels after the 4-week discontinuation period of the PCO beverage, indicating that the results are only apparent while the PCOs are being consumed.[46]

PCOs may prove to be vitally important in preserving renal function in hypertensive patients. One double-blind study evaluated the effects of Pycnogenol as an adjunct to ACE inhibitor ramipril treatment of hypertensive patients presenting with early signs of renal failure. One group of 26 patients was medicated with 10 mg/day ramipril only; a second group of 29 patients took Pycnogenol (150 mg/day) in addition to the ACE inhibitor over 6 months. At the end of the trial, lower systolic and diastolic BPs were found in both groups, with a significant further reduction of diastolic pressure in the group given Pycnogenol in addition to ramipril. The study also showed that Pycnogenol was effective in improving BP in patients with metabolic syndrome. The study found that taking Pycnogenol as an adjunct to ramipril significantly further lowered systolic and diastolic BPs compared with the group taking ramipril alone. Although average blood pressure in the ramipril group was lowered to a borderline high of 128.2/90.2 mm Hg, the values in the group taking Pycnogenol with ramipril reached essentially normal values (122.2/85.3 mm Hg) after 6 months of treatment. Kidney function improved in both groups, as judged by a significant reduction of protein detected in collected urine. With ramipril alone, urinary protein decreased by 22%, and with the addition of Pycnogenol, it decreased by 52.7%. Further, the group taking Pycnogenol had a lower fasting blood glucose level, which was reduced from a high average value of 135.6 mg/dL at baseline to an essentially healthy reference value of 102.3 mg/dL after 6 months of treatment. Pycnogenol also led to a remarkable improvement of blood-flow velocity in the kidney arteries. Blood-flow velocity in the kidneys significantly increased with ramipril from 17.2 to 23.8 cm/s for systolic

and 4.2 to 2.0 cm/s for diastolic; the addition of Pycnogenol was more effective, improving blood flow from 18.2 to 27.2 cm/s for systolic and 4.1 to 9.8 cm/s for diastolic.[47]

Other studies showed that PCOs might lower fasting glucose levels. In a study of patients with type 2 diabetes, patients received, in succession, 50, 100, 200, and 300 mg Pycnogenol in intervals of 3 weeks.[48] Every 3 weeks, fasting and postprandial glucose, endothelin-1, glycosylated hemoglobin (HbA_{1c}), and insulin were analyzed. Fasting blood glucose was lowered dose-dependently until a dose of 200 mg Pycnogenol was administered. Increasing the dose from 200 to 300 mg did not further decrease blood glucose. Compared with baseline, 100 to 300 mg of Pycnogenol lowered fasting glucose significantly from 8.64 to 7.54 mmol/L (155–135 mg/dL). The maximum decrease of postprandial glucose was observed with 200 mg of Pycnogenol (0.07 ± 2.69 mmol/dL [180 mg/dL]). HbA_{1c} levels decreased continuously from 8.02% to 7.37%. Endothelin-1 decreased significantly after 100 to 300 mg Pycnogenol, from 104 to 91 pg/mL. Stimulation of insulin secretion was excluded as a cause for lower glucose levels because insulin levels were not affected.

These effects were confirmed in a double-blind, placebo-controlled study with 77 patients with type 2 diabetes. After 8 weeks of treatment, the median drop in fasting blood glucose levels in the Pycnogenol group was 1.96 mmol/L (35.28 mg/dL).[49]

PCOs are particularly useful in addressing the microvascular pathology of diabetes. In one study in patients with severe diabetic microangiopathy, 30 patients received oral Pycnogenol (50 mg capsules, three times daily, for a total of 150 mg/day for 4 weeks), whereas 30 comparable patients were observed as controls.[50] After 4 weeks, microcirculatory and clinical evaluations showed a progressive decrease in skin flux at rest in the foot (indicating an improvement in the level of microangiopathy), a significant decrease in capillary filtration, and a significant improvement in the venoarteriolar response in all treated subjects. There were no visible effects in controls, except a slight reduction in skin flux at rest in the foot.

PCOs are also very much indicated in the treatment of diabetic retinopathy. Early intervention in diabetic retinopathy led to significant improvements in microcirculation, retinal edema, and visual acuity.[51]

Menopause and Postmenopause

PCOs appear clinically indicated in women during and beyond menopause because they have been shown to exert benefit in reducing menopausal symptoms and offering significant cardiovascular benefits during and after menopause. Pycnogenol, 100 mg/day, was used as a supplement for 8 weeks by a group of 35 women. A comparable group of 35 women with identical cardiovascular risk factors was included as the control group.

Almost all menopausal symptoms, scored by the Menopausal Symptoms Questionnaire 34, improved significantly in the Pycnogenol group. Supplementation with Pycnogenol also decreased the slightly elevated cholesterol and triglycerides after 8 weeks ($P < 0.05$). Also, the fasting glucose levels were normalized. The borderline increased BP was reduced to normal values at 8 weeks ($P < 0.05$). Plasma free radicals dropped significantly by 22%. Homocysteine and CRP levels decreased sharply by 43% and 60%, respectively. No significant changes in these risk factors were noted in the control group.[52]

In a double-blind, placebo-controlled study, 170 perimenopausal women were enrolled and treated with 30 mg Pycnogenol or placebo twice daily over a period of 3 months. Menopausal symptoms were evaluated by the Women's Health Questionnaire (WHQ) and by the Kupperman index, accompanied by an investigation of sex hormones and routine blood chemistry. A significant placebo effect was apparent in this study, suggesting an improvement of a majority of the WHQ categories. Compared with baseline, Pycnogenol significantly ($P < 0.05$) improved all symptoms with the exception of formication sensation and abnormal perceptions. Pycnogenol was found to be especially effective in improving vasomotor and insomnia/sleep problem symptoms, which were significantly better after 4 and 12 weeks than with placebo. The total Kupperman's index for perimenopausal symptom severity score decreased significantly by 56% compared with placebo (–39%) after 12 weeks of treatment ($P < 0.05$). The symptom score was also significantly better after only 4 weeks of treatment with Pycnogenol compared with placebo.[53]

In another double-blind study, 96 menopausal women aged 40 to 60 years were randomized to receive grape seed extract tablets containing either low-dose (100 mg/d) or high-dose (200 mg/d) PCOs, or placebo, for 8 weeks. The following significant changes were observed during the course of the study: (1) physical symptom score, hot flash score, and (2) Athens Insomnia Scale score decreased in the high-dose group after 8 weeks of treatment; (3) Hospital Anxiety and Depression Scale Anxiety score and (4) systolic and diastolic BP decreased in the low-dose and high-dose groups after 4 weeks; and lastly, (5) muscle mass increased in the low-dose and high-dose groups after 8 weeks of treatment.[54]

Attention Deficit Disorder

Increased oxidative damage is believed to be a central factor in attention deficit hyperactivity disorder (ADHD), indicating a possible application for PCO therapy. To date, four studies have been conducted in this patient population. In one study, children with ADHD supplementation with PCO (1 mg/kg body weight per day) had an improved ratio of reduced glutathione to oxidized glutathione (an indication of improved antioxidant status).[55] A second study confirmed this effect and also showed a reduced urinary catecholamine concentration, leading to less hyperactivity.[56] Another study showed that PCOs reduced the level of oxidized purines represented by 8-oxo-7,8-dihydroguanine in the urine and also increased total antioxidant status.[57] Finally, 61 children with ADHD supplemented with 1 mg/kg per day Pycnogenol or placebo over 4 weeks showed that 1 month of Pycnogenol administration caused a significant reduction in hyperactivity, improved attention and visual-motoric coordination, and improved the concentration of children with ADHD.[58] No positive effects were found in the placebo group. Standard questionnaires, the Child Attention Problems teacher rating scale, Conner's Teacher Rating Scale, the Conner's Parent Rating Scale, and a modified Wechsler Intelligence Scale for children were used as assessments. These results point to an option for the use of Pycnogenol as a nutritional adjunct in children with ADHD.

Mild Cognitive Impairment

Various flavonoids and polyphenols have been shown to exert beneficial effects in improving cognitive function. There is some evidence that PCOs also exert these benefits, especially in subjects with oxidative stress. In a study with 44 subjects with oxidative stress, the use of Pycnogenol at a dosage of 100 mg/day was associated with a decline in the Informant Questionnaire on Cognitive Decline in the Elderly (IQ Code), along with improvements in daily tasks, cognitive function, and oxidative stress.[59]

Male Infertility and Erectile Function

Pycnogenol alone[60] and in combination with L-arginine[61] was shown to be helpful in improving sperm quality and function (see Chapter 180, Male Infertility, for more information). Benefits have also been noted in erectile dysfunction.[62]

Osteoarthritis

Two double-blind studies have been conducted assessing the effect of PCOs in OA. In the first study, Pycnogenol (100 mg) or placebo was given daily for 3 months to 156 patients with osteoarthritis.[63] The global Western Ontario and McMasters University questionnaire for OA score decreased by 56% in the treatment group versus 9.6% in the placebo group. Walking distance on the treadmill test was prolonged from 68 m at the start of the study to 198 m in the Pycnogenol group compared with 65 to 88 m in the placebo group. The use of drugs decreased by 58% in the Pycnogenol group versus 1% in the placebo group. Foot edema decreased in 79% of Pycnogenol-treated patients versus 1% in controls. Similar results were seen in the second study when Pycnogenol was given at a dosage of 150 mg/day for 3 months.[64]

A pharmacokinetic study showed that procyanidins distribute into the synovial fluid of patients with OA, which supports rationalizing the results of clinical efficacy studies. Thirty-three patients with severe OA scheduled for a knee arthroplasty were randomized to receive either 200 mg per day Pycnogenol or no treatment over 3 weeks before surgery. Catechin and taxifolin primarily resided within the blood cells, whereas the microbial catechin metabolite δ-(3,4-dihydroxy-phenyl)-γ-valerolactone, ferulic, and caffeic acid were mainly present in synovial fluid samples. Taxifolin was detected in serum and synovial fluid exclusively in the Pycnogenol group.[65]

Periodontal Disease

Given the importance of supporting periodontal collagen structures in periodontal disease, PCOs are an important clinical consideration (see Chapter 199 on periodontal disease for more information).

Venous Insufficiency and Capillary Fragility

PCOs are very much indicated for the treatment of varicose veins, venous insufficiency, and capillary fragility because of their ability to:

- Reduce microvascular edema
- Increase the integrity of the venous wall
- Inhibit the breakdown of the compounds composing the ground substance
- Improve the muscular tone of the vein

Numerous double-blind studies with Pycnogenol validated the effectiveness of PCOs in chronic venous insufficiency, including studies showing an ability to decrease venous ulcer size,[66–68] reduce the edema and thrombosis associated with airline travel or prolonged sitting,[69–71] reduce nighttime claudication, and reduce other signs and symptoms of chronic venous insufficiency and microangiopathy.[72–74]

Visual Function, Retinopathy, and Macular Degeneration

Increased intake of PCO is likely to benefit almost everyone. This suggestion is perhaps best illustrated by research evaluating the effects of grape seed PCO extract on visual function in healthy subjects.[75,76] In one of the studies, 100 normal volunteers with no retinal disorder received either 200 mg/day of PCOs or placebo for 5 or 6 weeks. The group receiving PCOs demonstrated significant improvement in visual performance in dark and after-glare tests compared with the placebo group. PCO extracts were also shown to be of benefit in treating retinopathies, especially diabetic retinopathy. In one study, 40 patients with diabetes, atherosclerosis, and other vascular diseases involving the retina were randomly treated with placebo or PCO extract (50 mg three times daily for 2 months). The results demonstrated a beneficial effect of PCOs on the progression of retinopathy. In patients without any treatment (placebo group), the retinopathy progressively worsened during the trial, and the visual acuity significantly decreased. In contrast, the PCO-treated patients showed no deterioration of retinal function, and a significant recovery of visual acuity was also obtained. Fluorangiography showed an improvement of retinal vascularization and reduced endothelial permeability and leakage in the PCO group but not in the placebo-treated patients. Ophthalmoscopy and electroretinography also confirmed the beneficial effects of PCOs. In addition to the PCOs exerting free-radical-scavenging, anti-inflammatory, and capillary protective activities, it was suggested that PCOs might bind to the blood vessel wall proteins and mucopolysaccharides and produce a capillary "sealing" effect, leading to reductions in capillary permeability and edema formation.[77]

Psoriasis

Pycnogenol significantly improved the painful and visible symptoms of psoriasis, including redness, flaking, and the thickness of the total surface area of the affected skin patches.[78] Seventy-three patients (age range 30–45) with moderate/severe plaque psoriasis were included in a 12-week study. Patients either received "standard drug management" alone or with Pycnogenol at a dosage of 150 mg/day (50 mg three times daily). Over 12 weeks, the addition of Pycnogenol was shown to:

- Significantly decrease the area of skin affected by psoriasis in all body regions (Pycnogenol 20%; standard management [SM] 8%)
- Significantly reduce redness (Pycnogenol 44%; SM 28%), skin hardening (Pycnogenol 45%; SM 21%), and flaking (Pycnogenol 45%; SM 16%) of body area affected by psoriasis
- Significantly increase the content of water and oil/lipids in all areas of the skin
- Significantly reduce the need for standard management drugs
- Significantly reduce oxidative stress

In addition to the physical results just listed, supplementation with Pycnogenol was shown to significantly decrease the cost of treatment (decreased 36.4% on average in comparison with SM) and reduce the number of side effects reported for other treatments.

DOSAGE

As antioxidant support, a daily dose of 50 to 100 mg of either the grape seed or pine bark extract is suitable. When PCO extracts are being used for therapeutic purposes, the daily dosage should be increased to 150 to 300 mg/day.

TOXICITY

PCO extracts are without known side effects. In a clinical study with PCOs from grape seed extract, 29 subjects daily received oral dosages of 1000, 1500, or 2500 mg daily for 4 weeks. At this level, PCOs were found to be generally safe and well tolerated in humans. Research with a larger number of subjects is required to confirm these findings.[79]

DRUG INTERACTIONS

There are no documented drug interactions for the procyanidins.

Pygeum africanum (Bitter Almond)

Michael T. Murray, ND

OUTLINE

Pygeum africanum (family: *Rosaceae*)
Synonym: *Prunus africanum*
Common names: bitter almond, red stinkwood

GENERAL DESCRIPTION

Pygeum africanum is an evergreen tree native to Africa that can grow to a height of 120 to 150 ft. It has pendulous branches with thick, oblong, leather-like, matte leaves and creamy white flowers. The fruit (drupe) resembles a cherry when ripe. The dark brown to gray bark of the trunk is the part used for medicinal purposes.

CHEMICAL COMPOSITION

The major active components of the bark are as follows:

- Lipid-soluble pentacyclic triterpenes
- Sterolic triterpenes
- Fatty acids
- Esters of ferulic acid (Fig. 107.1)

The pentacyclic triterpenic components are ursolic acid (Fig. 107.2), oleanolic acid, crataegolic acid, and their derivatives. The sterolic fraction is composed mainly of β-sitosterol and β-sitosterone (Fig. 107.3). The fatty acids range from C12 to C24, and the important ferulic acid esters are those bound to *n*-tetracosanol and *n*-docosanol.[1–4]

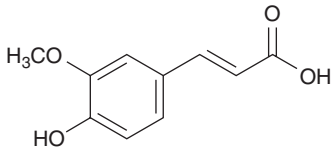

Fig. 107.1 Ferulic acid.

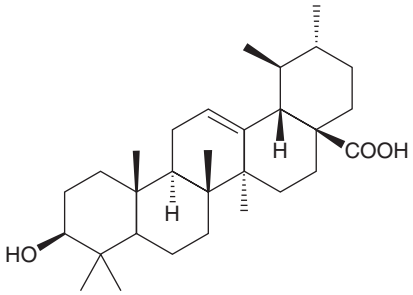

Fig. 107.2 Ursolic acid.

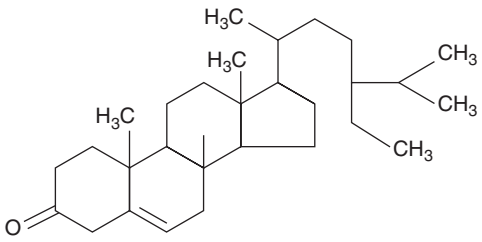

Fig. 107.3 Beta-sitosterone.

HISTORY AND FOLK USE

The powdered bark of *P. africanum* was used by the natives of tropical Africa as a treatment for urinary disorders. It was often given with palm oil or milk. Since about 1970, the bark has been entirely wild-collected, with the major exporters being Cameroon, Madagascar, Equatorial Guinea, and Kenya. Two companies, Groupe Fournier of France and Indena of Italy, produce 86% of the world's bark extract, both for their own products and for the free market. Worldwide exports of dried bark in 2000 were estimated at 1350 to 1525 metric tons per year, down from its peak of 3225 tons in 1997. Bark extracts (6370–7225 kg/year) are worth an estimated $4.36 million per year. However, wild collection of the bark is no longer sustainable. Since 1995, *P. africanum* has been

declared an endangered species. Alternatives to wild collection to meet future market demand include conservation practices, enrichment plantings, and small- and large-scale production. Currently, the species is at the beginning of a transition from an exclusively wild-collected species to that of a cultivated medicinal tree.[5]

PHARMACOLOGY

Pharmacological screening of various extracts prepared with solvents of differing degrees of polarity indicated that the highest activity was found in lipophilic extracts.[1] This finding is interesting in light of pygeum's historical administration in lipophilic media (palm oil or milk). Virtually all of the pharmacological research featured a pygeum extract standardized to contain 14% triterpenes, including β-sitosterol and 0.5% *n*-docosanol. This extract was extensively studied in both experimental animal studies and clinical trials with humans.

The primary target organ for pygeum's effects in men is the prostate. The three major active components of pygeum appear to exert different, yet complementary, effects in benign prostatic hyperplasia (BPH). In addition, pygeum was shown to enhance the secretions of the prostate and bulbourethral glands, in terms of both quantity and quality.

Ferulic Acid Esters

The esters of ferulic acid act primarily on the endocrine system. Studies in animals showed docosanol reduced levels of luteinizing hormone and testosterone while raising adrenal steroid secretion of both adrenal androgens and corticosteroids.[6,7] Docosanol also significantly lowers serum prolactin levels. This reduction of prolactin is quite significant because prolactin increases both the uptake of testosterone and the synthesis of dihydrotestosterone within the prostate. The accumulation of testosterone within the prostate and its subsequent conversion to the more potent dihydrotestosterone is thought to be the major contributing factor to the hyperplasia of the prostatic cells observed in BPH.[8] Although traces of docosanol are present in pygeum, the esterification with ferulic acid results in greater bioavailability and activity.[2,4,9]

Ferulic acid esters and the sterol fraction of pygeum exert cholesterol-lowering action systemically as well as within the prostate.[9] Breakdown products of cholesterol were shown to accumulate in prostate tissue affected with either BPH or cancer.[8] These metabolites of cholesterol initiate degeneration of prostatic cells, which can promote prostatic enlargement. Drugs that lower cholesterol levels were shown to have a favorable influence on BPH, preventing the accumulation of cholesterol in prostatic cells and limiting subsequent formation of damaging cholesterol metabolites. The lowering of intraprostatic cholesterol content is an important aspect of the pharmacology of pygeum.

The sterolic fraction is also endowed with competitive action against testosterone accumulation within the prostate. In addition, the sterols of pygeum were also shown to reduce inflammation by preventing the intraprostatic formation of inflammatory prostaglandins.[9,10]

Other Components

Other components of pygeum are also important. For example, the pentacyclic triterpenes exhibit anti-inflammatory effects within the prostatic epithelium and may be responsible for stimulation of the secretory cells of the prostate, seminal vesicles, and bulbourethral glands.[9–11] Finally, the fatty acid components are similar to those of *Serenoa repens* (see Chapter 122) and may exert similar effects and also improve the oral bioavailability of other components of the lipophilic extract.

CLINICAL APPLICATIONS

Prostate Disorders

The pharmacological actions of the standardized pygeum extract support its use in prostate disorders, BPH in particular. Adding further support are the results of numerous clinical trials in more than 600 patients.[12–34] These studies consistently demonstrated that pygeum effectively reduces the symptoms and clinical signs of BPH, especially in early cases. However, it must be pointed out that improvement is largely symptomatic because the reductions in the size of the prostate and in residual urine content of the bladder are modest. The results of the clinical trials on pygeum are given in Table 107.1. A discussion of some of the most important aspects of these studies follows.

One of the major findings in evaluating the effectiveness of pygeum in BPH was the high rate of response to placebo. This was well demonstrated in one of the larger double-blind studies.[30] As in other double-blind studies, pygeum extract was shown to be statistically superior to placebo in reducing the major symptoms of BPH (nocturnal frequency, difficulty in starting micturition, and incomplete emptying of the bladder). However, there was a high percentage of responses to the placebo (Table 107.2). It seems that simply taking a capsule provides relief to many sufferers.

Another study highlighted the importance of double-blind studies that featured both objective and subjective findings. In the study, both patients and physicians rated the placebo and pygeum extract to be effective in improving subjective symptoms, which were daytime frequency, nocturia, weak stream, after-dribbling, hesitation, and interruption of flow.[29] However, urodynamic variables (flow, frequency, and histogram) clearly demonstrated the superiority of pygeum over placebo.

One of the shortcomings of some of the clinical research on pygeum in BPH was the lack, in many of the studies, of objective measures, such as urine flow rate (milliliters per second), residual urine content, and prostate size. Studies that used objective measurements showed some good results. For example, in one open trial, 30 patients with BPH who were given 100 mg/day of the pygeum extract for 75 days demonstrated significant improvements in objective parameters: maximum urine flow rate increased from 5.43 to 8.20 mL/s, and the residual urine volume dropped from 76 to 33 mL.[23]

Pygeum may emerge as a significant protector against prostate cancer (PCa) because pygeum extract and its components (e.g., atraric acid and *N*-butylbenzene-sulfonamide) inhibit the transactivation mediated by the ligand-activated human androgen receptor (AR). Inhibition of human AR by androgen ablation therapy and synthetic antiandrogens is the primary goal in the treatment of PCa. Both in vitro and in vivo studies showed pygeum components inhibited the nuclear transport of AR and endogenous prostate-specific antigen expression and efficiently repressed the growth of both the androgen-dependent and some types of androgen-independent prostate cancer cells.[35–38] Currently used synthetic AR antagonists bind to the AR and induce a conformational change that leads to the dissociation of key proteins in the AR, but the antagonist-bound AR is still translocated to the nucleus, where it recruits corepressors to block its transcriptional activity. Pygeum components act a little differently, in that they selectively bind to the AR and inhibit the translocation to the nucleus, and in consequence, it functions as an androgen-activated transcription factor. This difference in mechanism may overcome a major shortcoming with antihormone therapy in PCa. Typically, antihormone treatment is effective only for a limited period of about 16 to 24 months, after which PCa becomes androgen independent. Different mechanisms seem to be involved in this process, but AR mutations during

PCa progression render therapeutically used antiandrogens into AR agonists. In consequence, those therapeutics then become useless, and even counterproductive, because they can promote PCa progression.

One of the most interesting studies with pygeum was an investigation on its effect on prostate cell growth in vitro using human serum collected before and after pygeum extract intake at a dosage of at 50 mg twice per day for 5 days. The in vitro analysis consisted of primary and organotypic cultures of human prostatic stromal myofibroblast cell line WPMY and prostatic epithelial cell line PNT2 along with fresh benign prostatic tissue. Results showed that the serum of a treated man induced decreases in the proliferation of primary cells, organotypic cells and WPMY cells but not PNT2 cells. Researchers also analyzed the effect of treated serum on the gene expression profile of WPMY cells. The transcriptome analysis revealed an upregulation of genes involved in multiple tumor-suppression pathways and a downregulation of genes involved in inflammation and oxidative-stress pathways. Hence, the oral intake of pygeum extract resulted in serum levels of active substances that were sufficient to inhibit the proliferation of cultured prostatic cells. This inhibition was associated with changes in the transcriptome.[39]

Male Infertility and Impotence

Pygeum may be effective in improving fertility when diminished prostatic secretion plays a significant role in the problem. Pygeum was shown to increase prostatic secretions and improve the composition of seminal fluid.[40–42] Specifically, pygeum administration to men with decreased prostatic secretion led to higher levels of total seminal fluid plus increases in alkaline phosphatase and protein levels. Pygeum appears to be most effective in cases in which the level of alkaline phosphatase activity is reduced (i.e., less than 400 IU/cm^3) and in which there is no evidence of inflammation or infection (i.e., absence of white blood cells and immunoglobulin-A [IgA]). The lack of IgA in the semen is a good predictor of clinical success. In one study, the patients with no IgA in the semen demonstrated an alkaline phosphatase increase from 265 to 485 IU/cm^3[39] In contrast, subjects whose semen contained IgA showed only a modest increase, from 213 to 281 IU/cm^3.

Pygeum extract also showed an ability to improve the capacity to achieve an erection in patients with BPH or prostatitis, as determined by nocturnal penile tumescence in a double-blind clinical trial.[43] BPH and prostatitis are often associated with erectile dysfunction and other sexual disturbances. Presumably by improving the underlying condition, pygeum can improve sexual function.

Pygeum Versus Serenoa

The standardized liposterolic extract of *Serenoa repens* is another popular botanical treatment for BPH (see Chapter 122). In a double-blind study that compared pygeum extract with extract of serenoa, the serenoa extract produced a greater reduction of symptoms and was better tolerated.[44] In addition, the improvement of objective parameters, especially urine flow rate and residual urine content, was better in the clinical studies of serenoa. However, there may be circumstances in which pygeum is more effective than serenoa. For example, serenoa has not been shown to have the effects on prostate secretion that pygeum has, and the anticancer effects of pygeum may be more significant. Although the two extracts have somewhat overlapping mechanisms of actions, they can be used in combination.

DOSAGE

The dosage of the lipophilic extract of *P. africanum* standardized to contain 14% triterpenes, including β-sitosterol and 0.5% *n*-docosanol, is 100 to 200 mg/day. Typically, the dosage has been divided for twice-a-day administration; however, results were similar in a double-blind study with 100 mg given once a day and 50 mg twice a day, indicating that taking pygeum once a day is equivalent to using divided doses.[45] The crude herb is not used.

TOXICOLOGY

Tests for acute and long-term toxicity in the rat and mouse showed that the standardized extract of *P. africanum* bark is nontoxic. Raising the dosage from 1 to 6 g/kg in the mouse and from 1 to 8 g/kg in the rat caused no deaths within 48 hours. In long-term toxicity studies, giving the animals from 60 to 600 mg/kg for 11 months did not produce any negative effects.

Pygeum extract also demonstrated no significant toxicity in human clinical trials. The most common side effect is gastrointestinal irritation, resulting in symptoms ranging from nausea to severe stomach pains; however, the presence of these side effects rarely leads to discontinuation of therapy.

DRUG INTERACTIONS

There are no documented drug interactions for *P. africanum.*

Pyrroloquinoline quinone (PQQ)

Michael T. Murray, ND

OUTLINE

GENERAL DESCRIPTION

Pyrroloquinoline quinone (PQQ) is a novel vitamin-like compound that acts as a necessary active factor in the functioning of mitochondria (Fig. 108.1). PQQ plays an essential role in human nutrition and will likely be recognized as an essential vitamin in the future.[1,2]

CHEMICAL COMPOSITION

PQQ is a redox active o-quinone that can be reversibly reduced to pyrroloquinoline quinol.[3]

HISTORY AND FOLK USE

Pyrroloquinoline quinone was discovered as the third coenzyme for oxidoreductases, along with nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD), in 1979. PQQ appears to be an essential nutrient for mammals.[4] When PQQ is omitted from chemically defined diets in mammals, it leads to growth impairment, compromised immune status, and abnormal reproductive function.[5] The nutritional requirements for PQQ are probably in line with folic acid and biotin in terms of micrograms per day versus milligrams per day. As with essential nutrients, the immune system seems particularly sensitive to low levels of PQQ. With PQQ deprivation, there are multiple defects in immune function and loss of white blood cells to respond properly.[1] PQQ shows a wide range of clinical benefits to brain and body function based on preclinical studies and initial clinical evaluation.[1,2]

There is no known biosynthesis of PQQ in higher organisms. Hence, the major source of PQQ in both plants and animals is believed to be derived from microorganisms. However, common strains of bacteria in the human intestinal tract appear to synthesize little PQQ. The major source for humans is the diet. PQQ has been found in all plant foods analyzed to date.[1] PPQ-rich foods include parsley, green peppers, kiwi fruit, papaya, and tofu.[6] These foods contain about 2 to 3 mcg per 100 grams. Green tea provides about the same amount per 4 oz serving. It is estimated that humans consume 0.1 to 1.0 mg PQQ and its derivatives per day.

PHARMACOLOGY

PQQ stimulates growth and serves as a cofactor for a special class of enzymes involved in cellular function, including cellular growth, development, differentiation, and survival.[1] One key action of PQQ involves a direct action on key enzymes in mitochondria. As a result, PQQ improves energy production.[1,2,7] PQQ is also an extremely powerful antioxidant capable of catalyzing continuous cycling (i.e., the ability to perform repeated oxidation and reduction reactions) to a much greater degree compared with other antioxidants. For example, PQQ can carry out 20,000 catalytic conversions compared with only 4 for vitamin C.[1,2]

In addition, PQQ's antioxidant effect protects against mitochondrial damage and promotes the spontaneous generation of new mitochondria within aging cells, a process known as mitochondrial biogenesis or mitochondriogenesis.[1,2,8,9] This effect is a "fountain of youth" for mitochondrial function.

Given the nutritional importance and tremendous span of physiological effects of PQQ, there are considerable benefits in conditions that revolve around low mitochondrial function, such as aging, brain

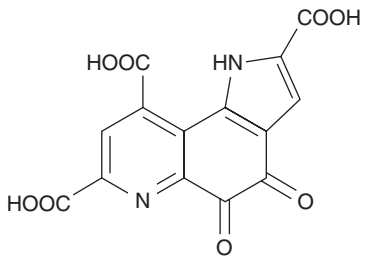

Fig. 108.1 Structure of pyrroloquinoline quinone. (From ResearchGate. Discovery of a eukaryotic pyrroloquinoline quinone-dependent oxidoreductase belonging to a new auxiliary activity family in the database of carbohydrate-active enzymes. <https://www.researchgate.net/Chemical-structure-of-PQQ-doi101371-journalpone0104851g001_fig1_264799310>. Accessed October 1, 2018.)

and neurological disease (e.g., Alzheimer's and Parkinson's disease), and several chronic degenerative diseases. Current research has primarily focused on its ability to protect memory and cognition in both aging animals and humans. In animal studies, PQQ was found to have the following benefits:

- Reverses cognitive impairment caused by chronic oxidative stress and improves performance on memory tests in animal models[1,2,10]
- Stimulates the production and release of nerve growth factor[1,2,11]
- Protects against the self-oxidation of the DJ-1 gene, an early step in the onset of Parkinson's disease[1,12]
- Protects brain cells against oxidative damage in models of strokes[1,2,13]
- Blocks the formation of inducible nitric oxide synthase (iNOS), a major source of reactive nitrogen species (RNS) that are so damaging to brain cells[1,2,14]
- Protects against the likelihood of severe stroke in an experimental animal model for stroke[1,2,15]
- Protects the brain against neurotoxicity induced by other powerful toxins, including mercury, glutamate, and oxidopamine (a potent neurotoxin used by scientists to induce parkinsonism in laboratory animals)[1,2,16,17]
- Prevents development of alpha-synuclein, a protein associated with Parkinson's disease[1,2,18]
- Protects nerve cells from the damaging effects of the beta-amyloid-protein linked with Alzheimer's disease[1,2,19]
- Lowers low-density lipoprotein (LDL) cholesterol, presumably by activating AMP-kinase (AMPk).[2,19]

CLINICAL APPLICATIONS

PQQ activates AMPk, an enzyme that is found inside living cells and serves as a "master regulating switch" in energy metabolism. Low levels of AMPk activity are associated with the following:

- Accelerated aging
- Chronic inflammation
- High blood cholesterol and triglycerides
- Increased visceral "belly" fat
- Insulin resistance
- Mitochondrial insufficiency and dysfunction
- Neurodegeneration
- Obesity
- Poor blood sugar control

Because PQQ increases mitochondrial function and activates AMPk, researchers believe that clinical data will soon produce evidence showing that PQQ is helpful for a long list of health challenges.[1,2]

The ability to enhance mitochondrial energy production is supported by numerous animal studies.[1,2,7,21] In humans, PQQ was administered as a single agent in 10 subjects (5 females, 5 males) between the ages of 21 and 34 years. The subjects were given PQQ (BioPQQ, a form of PQQ produced through a natural fermentation process) in a single dose (0.2 mg PQQ/kg), after which multiple measurements of plasma and urine PQQ levels and changes in antioxidant potential were examined over a 48-hour period.[21] Results indicated a significant increase in antioxidant potential even after one dosage. The same subjects were also given a daily dose of 0.3 mg PQQ/kg and had their blood measured for markers of inflammation (plasma C-reactive protein and interleukin [IL]-6 levels) and urinary metabolites related to energy metabolism before PQQ administration and 72 hours later. PQQ supplementation resulted in significant decreases in the levels of the inflammatory markers of plasma C-reactive protein and IL-6. Furthermore, the changes in urinary metabolites were consistent with enhanced mitochondria-related functions. The data are among the first to link the systemic effects of PQQ in animals to corresponding effects in humans.[21]

In a study with BioPQQ test subjects with an initial level of LDL cholesterol greater than 140 mg/dL, 6 weeks of PQQ supplementation produced a statistically significant decrease in total cholesterol (from an average of 247–216 mg/dL) and LDL cholesterol (from an average of 156–132 mg/dL).[22] Results persisted at 12 weeks and are believed to be caused by PQQ activating AMPk.

Insulin Resistance

PQQ holds great promise in the treatment of insulin resistance, type 2 diabetes, and as an antiobesity agent. There are several additional mechanisms of action that support these clinical applications. It is now well established that type 2 diabetes can be characterized as a mitochondrial disorder.[23] It is also well established that the mitochondrial dysfunction of diabetic subjects is closely related to the degree of hyperglycemia, diet, physical activity, sleep, stress, and other lifestyle factors.[24] As described previously, PQQ supplementation has been revealed to enhance mitochondrial function and biogenesis.

PQQ deficiency increased the plasma glucose level, reduced hepatic mitochondrial content by 20% to 30%, and elevated plasma lipid levels, whereas PQQ supplementation reversed mitochondrial alterations and metabolic impairment and significantly improved the lipid profile in diabetic rats.[20] The mechanisms responsible for the increased mitochondrial biogenesis and function by PQQ are stimulated by the transcriptional coactivator, peroxisome proliferator-activated receptor gamma coactivator-1 alpha (PGC-1α), through activation of the nuclear respiratory factor (NRF-1 and NRF-2). cAMP-responsive element-binding protein (CREB) increases transcription of PGC-1α via a conserved CREB-binding site in the proximal promoter and is activated by exercise or fasting. PQQ elevates PGC-1α promoter activity by the same mechanism. PQQ exposure also increases the levels of NRF-1 and NRF-2, resulting in the upregulation of the mitochondrial transcription factor A and mitochondrial gene expression.[25]

PQQ exerts additional mechanisms on insulin signaling and enhances glucose uptake through the translocation of glucose transporters. Therefore PQQ can be useful in insulin resistance and type 2 diabetes.[2]

Enhancing Cognitive Function

The positive effects of PQQ on the learning and memory function have been demonstrated in animal models.[1,2] Although PQQ was effective on its own in some of these studies, when combined with coenzyme Q10 (CoQ10), better results were observed. This synergistic effect was further demonstrated in a human double-blind, placebo-controlled clinical trial conducted in Japan in 2007.[26] In this study of 71 middle-aged and elderly people aged between 40 and 70, supplementation with 20 mg per day of PQQ (as BioPQQ) resulted in improvements on tests of higher cognitive function using the Stroop test compared with the placebo group. However, in the group receiving 20 mg of PQQ along with 300 mg of CoQ10, the results were even more dramatic. PQQ and CoQ10 are both involved in mitochondrial energy production, which may explain the enhanced results.

Another double-blind study used the repeatable battery for the assessment of neuropsychological status (RBANS) in 65 subjects between 50 and 70 years old who presented with self-identified forgetfulness or forgetfulness identified by a family member, colleague, or acquaintance.[27] The neuropsychological battery questions allow repeated and quick evaluation of disorders in higher-brain function with a variety of brain disease complications. The RBANS consists of five subtests of neurocognitive test paradigms: immediate memory, visuospatial/constructional, language, attention, and delayed memory.

The three arms of the study were PQQ (20 mg/day), PQQ (20 mg/day) + CoQ10 (300 mg/day), and placebo. All three groups showed significantly better total score over time, but the improvement in immediate memory scores at week 8 were significantly better in the PQQ + CoQ10 group than in the placebo group. For analysis of immediate memory, subjects were stratified into two subgroups according to baseline total scores. Although no significant difference was present between groups in the high-scoring subgroup, the PQQ + CoQ10 group in the low-scoring subgroup showed a significantly better score at week 8 and week 16 than the placebo group. This finding shows that individuals with lower RBANS scores may achieve a better degree of improvement in response to PQQ + CoQ10 supplementation than individuals with higher scores.

For patients under 50 years of age, however, there may not be a need for simultaneous use of PQQ and CoQ10 unless the person is taking drugs, such as cholesterol-lowering statins, that interfere with CoQ10 manufacture. Double-blind studies in elderly subjects with PQQ alone show less impressive results than studies when PQQ is combined with CoQ10. In one of these studies, 41 healthy elderly subjects were administered 20 mg of PQQ per day or a placebo for 12 weeks. No significant improvements were noted in the Stroop test or reverse Stroop test, but improvements with PQQ were noted in the assessment of visual-spatial cognitive function via tablet computer.[28]

In another trial relating to cognitive function, 17 healthy middle-aged and elderly subjects ingested 20 mg of PQQ Na2 daily for 8 weeks.[29] The results in the Profile of Mood States–Short Form showed that all six measures of vigor, fatigue, tension/anxiety, depression, anger/hostility, and confusion significantly improved after PQQ supplementation compared with baseline scores. Improvements were also noted for drowsiness at awakening, sleep onset and maintenance, and sleep duration. These improvements correlated with changes in the cortisol awakening response.

PQQ also enhances cerebral blood flow and oxygen utilization in the prefrontal cortex. In a study of 20 healthy subjects between 50 and 70 years of age, subjects were administered 20 mg of PQQ (as BioPQQ) or placebo orally once daily for 12 weeks.[30] Using transcranial near-infrared stimulation (tNIRS), PQQ was shown to increase hemoglobin concentration and reduce absolute tissue oxygen saturation in the right prefrontal cortex, resulting in enhanced cognitive function.

DOSAGE

Although the nutritional requirement for PQQ is likely less than 500 mcg daily, a measured response in mitochondrial function may require increased amounts. The current dosage recommendation of 10 to 20 mg of PQQ daily in humans is based on the equivalent dose in animals that has consistently improved various mitochondrial functions. There are also some clinical and observational studies that justify the dosage.

TOXICITY

There are no known side effects or toxicity with PQQ at recommended levels. In a double-blind safety study, human volunteers were given PQQ at a dosage of either 20 or 60 mg/day, or a placebo, for 4 weeks.[2] No adverse effects were observed in any group. The urinary concentration of N-acetyl-β-d-glucosaminidase (NAG) was also determined in the study. NAG is a sensitive biomarker for renal tubular damage. Levels did not change in any group.

Toxicology studies in animals show an excellent safety profile, with the LD_{50} being 1000 to 2000 mg PQQ/kg body weight in male and 500 to 1000 mg PQQ/kg body weight in female rats. The no-observed-adverse-effect level (NOAEL) in rats is at a dosage of 400 mg PQQ/kg body weight.[31] PQQ exerts no genotoxicity as well.[32]

DRUG INTERACTIONS

There are no known drug interactions with PQQ at recommended levels.

Ruscus aculeatus (Butcher's Broom)

Kathy Abascal, BS, JD, RH(AHG), and *Eric L. Yarnell, ND, RH(AHG)*

OUTLINE

Ruscus aculeatus (family: *Liliaceae*)
Common names: butcher's broom, box holly, knee holly, kneeholy, kneeholm, Jew's myrtle, sweet broom, pettigree, Maeusedornwurzelstock (German)

GENERAL DESCRIPTION

Ruscus aculeatus (butcher's broom) is an evergreen shrub native to Mediterranean Europe and Africa.[1] It has rigid leaves that terminate in a single sharp spine. Its berries remain attached to the plant throughout the winter. The root, the part used medicinally, is thick, typically 2 to 4 inches long, with many woody rootlets growing on its lower surface.

CHEMICAL COMPOSITION

The primary active ingredients of butcher's broom are typically considered to be the steroidal saponin aglycones ruscogenin and neoruscogenin (Fig. 109.1). Recent data, however, suggests that the plant's saponin glycosides ruscin and deglucoruscin and its coumarin glycoside esculin may have greater activity (Figs. 121.2–121.4).[2] The plant also contains fatty acids, sterols, flavonoids, other coumarins, sparteine, tyramine, and glycolic acid.[1,3–6]

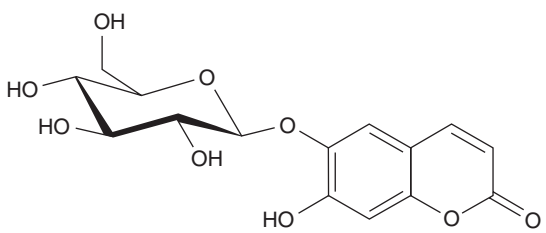

Fig. 109.1 Ruscogenin.

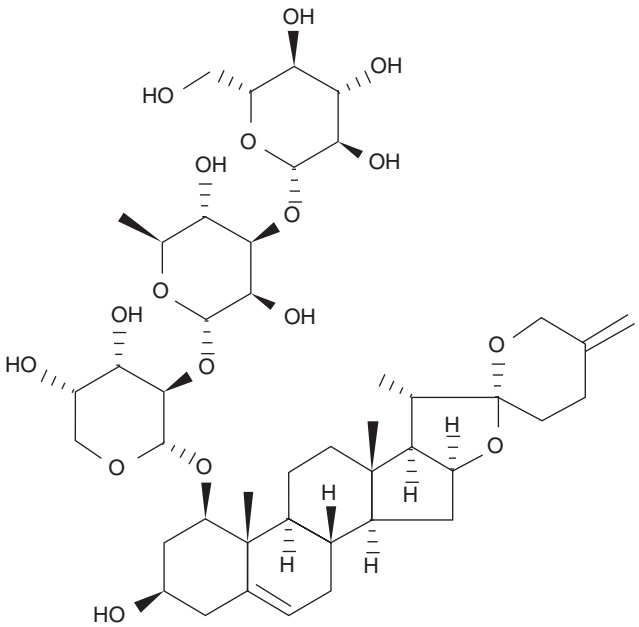

Fig. 109.2 Ruscin.

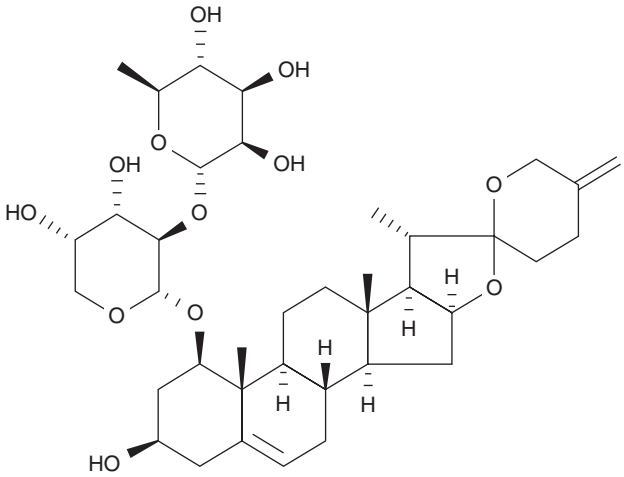

Fig. 109.3 Deglucoruscin.

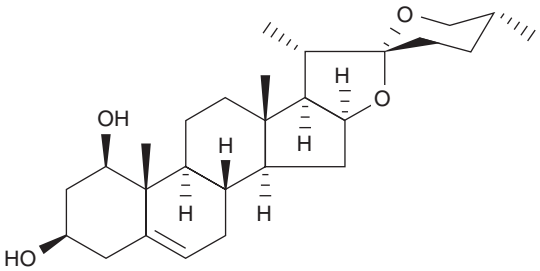

Fig. 109.4 Esculin.

HISTORY AND FOLK USE

In ancient Greece, butcher's broom was used as a laxative and to treat kidney stones.[7] In Europe, a wine decoction of the root was used as a diuretic to treat urinary obstructions, kidney stones, and gravel. It was also used to regulate menses, ameliorate jaundice, and treat headaches. In South America, the roasted root was made into a beverage for prostate tumors.[8]

PHARMACOLOGY

Anticancer Effect

Butcher's broom saponins have a cytostatic effect on leukemia HL-60 cells in vitro.[9]

Antielastase Effect

Ruscinogens isolated from butcher's broom have a remarkable antielastase effect in vitro.[10]

Antihypoxic Effect

Hypoxia-induced activation of endothelial cells may be a cause of venous disease. A proprietary extract of butcher's broom known as Cyclo 3 Fort dose-dependently protected human endothelial cells from induced hypoxia in vitro.[10]

Anti-inflammatory Effect

Butcher's broom extract and its isolated steroidal saponins were anti-inflammatory in several animal models.[11] Injected intravenously, it inhibits the permeability-increasing effects of bradykinin, leukotriene B4, and histamine in hamster cheek pouch preparations.[12]

Antimicrobial Effect

Butcher's broom showed a very low activity against *Candida albicans*.[13]

FIBRINOLYTIC EFFECT

Thrombosis in chronic venous insufficiency (CVI) is associated with reduced levels of tissue plasminogen activator in varicose veins. In a small study, 20 patients scheduled for vein stripping surgery took butcher's broom (150 mg) and methyl hesperidin chalcone (150 mg) or a placebo three times daily for 14 days before surgery.[14] Segments of the great saphenous vein removed from patients in the active group had enhanced levels of tissue plasminogen activator and enhanced fibrinolytic activity compared with the placebo.

Lymphatic Flow Effect

Butcher's broom dose-dependently enhanced the duration and flow intensity of the lymphatic vessels in dogs.[15] This effect did not change when the calcium channel antagonist nifedipine was injected, indicating that butcher's broom's lymphatic effect does not involve the opening of calcium channels but appears to act directly on peripheral lymphatics.

Vasoconstrictive Effect

Topical administration of butcher's broom extract in a hamster cheek preparation dose-dependently inhibited histamine-induced increases in permeability.[16] Research suggested that butcher's broom's vasoconstrictive effect is mediated by calcium and α-1 adrenergic receptors. Heat increases, and cold decreases, butcher's broom's ability to increase the release of norepinephrine from the adrenoreceptors.[17]

CLINICAL APPLICATIONS

There are few clinical studies on the effect of butcher's broom alone. Instead, most of the clinical studies investigated a proprietary combination formula known as Cyclo 3 Fort by Pierre Fabre Medicament of Paris, France, or Phlebodril by Pierre Fabre Pharma GmbH of Freiburg, Germany. These formulas combine butcher's broom with trimethylhesperidin chalcone (a flavonoid precursor) and ascorbic acid. Butcher's broom has action independent of the other compounds in the formula, and some studies indicated that butcher's broom used alone may have a stronger effect. However, other studies indicated that the combination may have a synergistic effect. All discussions of butcher's broom trials in the following content therefore include the possibility that it was not butcher's broom by itself that was active.

Butcher's broom is also paired with *Melilotus* spp. (sweet clover) in some topical preparations. There are no studies indicating whether butcher's broom alone would achieve the same results.

Chronic Venous Insufficiency

Butcher's broom is most commonly used to alleviate the symptoms of CVI, including ankle edema, itching, tension, and cramping of the legs. Both animal and clinical studies support its effectiveness in CVI, and the German Commission E approved butcher's broom as an adjunct treatment for this condition.[1] A meta-analysis evaluated 20 placebo-controlled, double-blind studies and 5 randomized trials against a comparator drug along with 6 single-arm studies without a placebo. The review included information on 10,246 subjects. Although data quality varied, Cyclo 3 Fort significantly reduced CVI symptoms compared with placebos.[17]

Ten of these studies are summarized in Table 109.1.[18–26] All but two were randomized, double-blind trials. In one large multicenter

TABLE 109.1 Studies on Butcher's Broom in Chronic Vascular Insufficiency (CVI)

Study	No. of participants	Type	Product	Focus	Result	Duration
Cappelli et al.[18]	40	Double-blind, crossover placebo-controlled, prospective	2 capsules (16.5 mg ruscinogens, 75 mg hesperidin, 50 mg ascorbic acid) 3 times a day	CVI, varicosities	Itching, edema, and paresthesia improved greatly	2 mo with 15-d washout and 2-mo crossover
Rudofsky[19]	141 + 20 healthy volunteers	Randomized, double-blind, multicenter	2 capsules (450 mg *Ruscus* extract) 3 times daily for 4 wk, then 2 capsules 2 times daily for 8 wk	CVI	Continuous decrease in foot and ankle volume, decrease in leg swelling, improved venous pumping	2-wk washout followed by 12-wk treatment
Haas et al.[20]	20	Placebo-controlled, double-blind	1 capsule (150 mg *Ruscus,* 150 mg methyl hesperidin chalcone) 3 times a day	CVI stage I and II, scheduled for surgery	Significantly increased fibrinolytic activity of removed great saphenous vein	14 d
Kiesewetter et al.[21]	30	Random selection, uncontrolled	3 *Ruscus* capsules twice daily for 5 wk, then 2 capsules twice daily; amount of *Ruscus* in capsules not stated	CVI	Reduced circumferences of lower legs and malleoli, subjective complaints; greater rheologic improvement in patients with advanced stages of CVI	5 mo
Beltramino et al.[22]	80	Open-label, randomized, multicenter	2 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) daily: control 2 tablets of 500 mg hydroxyethyl rutoside daily	CVI (heavy, tired, swollen, or painful legs)	Significant improvement in symptoms, reduction in limb circumference; physicians and patients had a more favorable opinion of *Ruscus* than of rutoside	90 d
Le Devehat et al.[23]	60 + 7 healthy volunteers	Randomized, double-blind, placebo-controlled	2 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) daily	CVI; blood samples drawn from foot before and after provoked venous stasis	Improved blood viscosity disturbances caused by venous stasis	4 wk
Seydewitz et al.[24]	36	Randomized, double-blind, placebo-controlled	3 capsules (150 mg *Ruscus,* 150 mg trimethyl hesperidin chalcone) daily	Stage IV varicosities with stage I or stage II CVI, scheduled for vein stripping	Increase in enzyme activity in the proximal segment of the vein, distinctly higher incidence of subjective improvement of symptoms	4 wk
Guex JJ et al.[25]	917	Observational, multicenter, prospective	150 mg Ruscus aculeatus and 100 mg ascorbic acid	CVI (symptoms, ankle swelling)	Significant improvement in quality of life and symptoms	12 wk
Vanscheidt et al.[26]	148 women	Multicenter, double-blind, randomized, placebo-controlled	36–37 mg butcher's broom extract twice daily	CVI	Significant, positive changes in CVI symptoms	12 wk
Guex JJ et al.[25]	918	Observational, multicenter, prospective	2 capsules (150 mg *Ruscus,* 150 mg trimethyl hesperidin chalcone) daily	CVI, CEAP C0s–C3	All symptoms and quality of life improved significantly	12 wk

CVI, Chronic venous insufficiency; *CEAP,* a clinical venous classification system.

trial, 81.6% of treating physicians rated its efficacy as excellent, and the remaining physicians rated it as good.[22] Butcher's broom acts most strongly when circulation is impaired, but some researchers caution that it is less effective when the disease has compromised the activity of venous wall receptors.[20] Finally, a meta-analysis of randomized, double-blind, placebo-controlled trials of butcher's broom extracts concluded that high-quality evidence exists showing that these extracts are very effective in reducing symptoms and edema in patients with CVI. [27]

Edema and Varicosities

Butcher's broom shows promise as a treatment for a wide variety of edemas and circulatory disturbances of the venous system. The results of these clinical trials are summarized in Table 109.2.[28–37] These trials were also on combination extracts with butcher's broom as a major component. Many of the studies are small, and some are poorly designed, but the overall picture supports the ability of butcher's broom to reduce the swelling and discomfort associated with primary and secondary edema. It has positive effects in pregnancy-related venous insufficiency, varicosities, lymphedema, symptoms of swelling of ankles and breast tenderness in premenstrual syndrome (PMS), edema secondary to calcium channel antagonist therapy for hypertension, and swelling secondary to soft tissue injury.

Hemorrhoids

The German Commission E approved butcher's broom as a treatment for hemorrhoids.[1] In an open-label multicenter study of 124 patients with hemorrhoids, 69% of patients and 75% of the treating physicians rated the butcher's broom combination extract Cyclo 3 Fort as having good or excellent efficacy.[38] Ninety-two percent of physicians rated the treatment as safe and well tolerated. Significant positive effects were observed after 7 days of treatment. Although controlled trials are warranted, butcher's broom may be a useful treatment for patients with hemorrhoids.

Diabetic Retinopathy

Diabetic retinopathy can abruptly cause severe deterioration of vision, and it is estimated that the incidence of retinopathy may be as high as 80% in patients with long-standing, poorly controlled diabetes. In a study of 60 patients with non–insulin-dependent diabetes, butcher's broom compared favorably with troxerutin.[39] Butcher's broom produced a 23% regression of negative changes in the fundus of the eye, with no sign of progression. Troxerutin produced a somewhat larger regression (27.8%) but also had a greater (5.8%) progression rate. Butcher's broom also decreased blood glucose and cholesterol levels and significantly increased high-density lipoproteins in this preliminary study.

Premenstrual Syndrome

Butcher's broom significantly reduced symptoms of breast tenderness in women with diagnosed PMS in a randomized, placebo-controlled, double-blind study of 40 women with PMS of an average duration of 67 months.[34] The amount of butcher's broom administered for 90 days was not stated. Eighty percent of the women in the active group reported a complete resolution of PMS symptoms of mastalgia and breast tension. Unexpectedly, butcher's broom also had a dramatic effect on some of the psychological symptoms associated with PMS (e.g., complete resolution in 85% of the subjects of symptoms such as irritableness, "hair-trigger temper," and "temporary alienation"). In vitro research indicated that butcher's broom acts more efficiently in the presence of progesterone; butcher's broom may be most effective during the luteal phase of a woman's menstrual cycle.

Soft Tissue Injuries

In a small study, butcher's broom applied topically reduced the swelling and pain caused by soft tissue sports injuries.[27] Several in vitro studies showed that butcher's broom's action is enhanced by heat, suggesting that it may be advantageous to apply heat to the site of the injury when using the herb.

DOSAGE

The dosage of butcher's broom for therapeutic use should be based on the ruscogenin content in the range of 16.5 to 33 mg of ruscogenins two to three times daily. Standardized extracts are preferred for therapeutic use because they allow for more accurate dosages. Recommendations for other forms of butcher's broom are as follows:

Dried rootstalk in capsules, tablets or tea: 500 to 1000 mg three times a day
Tincture (1:5): 2 to 4 mL three times a day
Fluid extract (1:1): 1 to 2 mL three times a day

TOXICOLOGY

Butcher's broom is generally considered very safe. It occasionally causes gastrointestinal distress, and in rare instances, it causes lymphatic colitis.[1,40,41] Thus butcher's broom should probably not be combined with nonsteroidal anti-inflammatory drugs or other drugs linked with lymphatic colitis, and use should be discontinued if negative gastrointestinal symptoms are severe or persist.[40] One author cautioned against the use of butcher's broom in pregnancy based on a lack of proof of safety.[3] Although not definitive, preliminary animal and clinical studies cited previously indicated that butcher's broom does not have negative effects when used during pregnancy. Once case report claims that a butcher's broom extract combined with metformin precipitated diabetic ketoacidosis in a 39-year-old woman with a history of poor blood sugar control, although various other complications in her health picture (e.g., recent vomiting and diarrhea) could have been a factor.[42]

DRUG INTERACTIONS

In an in vitro study, adenosine, cocaine, phentolamine, prazosin, and verapamil reduced butcher's broom's vasoconstrictive effect.[43] Acetylcholine and rauwolscine potentiated its vasoconstrictive action. No clinical studies have been conducted to determine whether butcher's broom interferes with or affects the action of the aforementioned, or any other, drugs.

TABLE 109.2 Clinical Studies on Butcher's Broom in Edema and Varicosities

Study	No. of participants	Type	Product	Focus	Result	Length
Berg[28]	18	Placebo- controlled	Melilot and *Ruscus* cream (4–6 g cream/d)	Effect of cream on size of femoral veins in healthy volunteers	Change in size of femoral vein	1 d
Baudet et al.[29]	20	Uncontrolled	2 capsules of *Ruscus* extract/day (amount not stated) from wk 21–24 of pregnancy	Pregnancy-related symptoms of venolymphatic insufficiency	Improved symptoms based on subjective criteria; "absolute harmlessness" to infant	Women monitored from early pregnancy; infants studied before and after birth
Berg[28]	9	Placebo- controlled	Compression stocking, kinesitherapy, and melilot and *Ruscus* cream (4–6 g cream/d)	Pregnant women with painful pregnancy-related varicosity of one limb	Statistically significant reduction in size of femoral vein and pain	Treatment beginning in second trimester
Bohmer[30]	48	Placebo- controlled	4 g *Ruscus* cream (1.6 g *Ruscus* and 1.6 g melilot/100 g) 3 times daily	Sports injuries, patients with sprain or contusions of lower limb or ankle	Increased muscle strength, reduced swelling, decreased temperature, and resolved pain more quickly	14 d
Cluzan et al.[31]	57	Placebo- controlled, double-blind	3 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl-chalcone, 100 mg ascorbic acid) 3 times daily plus physiotherapy	Lymphedema after mastectomy	Reduced edema by second month, positive subjective improvement in symptoms	90 d
Cossio et al.[32]	12	Uncontrolled	Drinkable ampules; week 1: 180 mg *Ruscus* and 900 mg hesperidin methyl chalcone per day; weeks 2–8: 120 mg *Ruscus* and 600 mg hesperidin methyl chalcone per day	Lymphedema of extremities	Significant improvement in symptoms, reduction of edema in 81% of participants	2 mo
Jager et al.[33]	12	Open, uncontrolled	3 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) per day	Primary varicosity of greater saphenous vein	Significant changes in some venous parameters	7 ± 1 d
Weindorf et al.[34]	50	Double-blind, placebo-controlled	450 mg *Ruscus,* 450 mg hesperidin, 300 mg ascorbic acid daily	Trunk or branch varicose veins	Venous capacity and improved at rest; expelled blood volume during exercise improved	2 wk
Lagrue et al.[35]	11	Open, uncontrolled	3 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) daily	Edema secondary to calcium antagonist treatment of hypertension	4/9 showed complete improvement; 3/9 showed partial improvement; 2/9 showed no change in edema	6–8 wk
Le Devehat et al.[36]	25 + 20 healthy controls	Double-blind, placebo- controlled	2 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) daily	Venous insufficiency characterized by varicose veins; blood samples drawn before and after provoked venous stasis	Significant improvement in several microrheologic factors of blood viscosity	Not found
Monteil-Seurin and Ladure[37]	40	Randomized, double-blind, placebo- controlled	2 capsules (150 mg *Ruscus,* 150 mg hesperidin methyl chalcone, 100 mg ascorbic acid) daily	Premenstrual syndrome symptoms for at least 60 months (breast tension, pelvic heaviness, "menstrual psychopathic disorder," ankle edema)	Significantly reduced breast tension, pelvic heaviness, and menstrual "psychopathic disorder"	90 d

SAMe (S-Adenosylmethionine)

Michael T. Murray, ND

OUTLINE

INTRODUCTION

S-Adenosylmethionine (SAMe) is an important physiological agent formed in the body through combination of the essential amino acid methionine with adenosine triphosphate (ATP) (Fig. 110.1). SAMe was discovered in Italy in 1952. Not surprisingly, most of the research on SAMe has been conducted in the country of its discovery.

Because SAMe is manufactured from methionine, one would think that dietary sources of methionine would provide the same benefits as SAMe. However, high doses of methionine have not been shown to raise levels of SAMe, nor do they provide the same pharmacological activity as SAMe and increase homocysteine levels. High doses of methionine are associated with some degree of toxicity.[1]

Normally the body manufactures all the SAMe it needs from the amino acid methionine. However, a deficiency of methionine, vitamin B_{12}, or folic acid can result in decreased SAMe synthesis. In addition, tissue levels of SAMe are typically low in the elderly and in patients with osteoarthritis, depression, and various liver disorders.

PHARMACOLOGY

SAMe is involved in more than 40 biochemical reactions in the body. It functions closely with folic acid and vitamin B_{12} in methylation reactions. Methylation is the process of adding a single carbon unit (a methyl group) to another molecule. SAMe is many times more effective in transferring methyl groups than are other methyl donors. Methylation reactions are critical in the manufacture of many body components, especially brain chemicals, as well as in detoxification reactions.

SAMe is also required in the manufacture of sulfur-containing compounds in the human body, including glutathione (discussed later) and various sulfur-containing cartilage components.

The beneficial effects of SAMe supplementation are far-reaching owing to this agent's central role in so many metabolic processes.

Available Forms

SAMe has been available commercially in Europe since 1975 and in the United States since 1999. The commercial form of SAMe is a stabilized salt produced under US patents no. 3,954,726 (1976) and no. 4,057,686 (1977).

CLINICAL INDICATIONS

The five principal uses of SAMe are for depression, osteoarthritis, fibromyalgia, liver disorders, and migraine headaches.

Depression

SAMe is necessary in the manufacture of important brain compounds, such as neurotransmitters and phospholipids like phosphatidylcholine and phosphatidylserine. Adding SAMe to the diet of depressed patients raises levels of serotonin, dopamine, and phosphatidylserine and improves binding of neurotransmitters to receptor sites, resulting in increased serotonin and dopamine activity and better brain-cell membrane fluidity, leading to significant clinical improvement.[2-4]

The antidepressant effects of folic acid (see Chapter 142) are mild compared with the effects noted in clinical trials of SAMe. In these clinical studies SAMe has shown promise as an antidepressant agent.[4-6] One study, however, indicates that there may be significant gender differences in the response to SAMe. Data from a 12-week double-blind trial assessed the efficacy of SAMe versus placebo and a comparator selective serotonin reuptake inhibitor (escitalopram) included a post hoc analysis to evaluate effects of patient gender on treatment response. SAMe was found superior to placebo among males (n = 51), but not among females (n = 62).[7] Men have shown a significantly lower SAMe to S-adenosylhomocysteine (SAH) ratio than women, suggesting SAMe supplementation may affect men's biochemistry more significantly. A 6-week double-blind study of SAMe augmentation for selective serotonin reuptake inhibitors (SSRI)/serotonin norepinephrine reuptake inhibitor nonresponders revealed that males treated with adjunctive SAMe demonstrated significantly improved sexual arousal compared with the adjunctive placebo group.[8] It was suggested that because SAMe is a regulator of cystathionine beta-synthase, it may result in improved nitric oxide-mediated vasodilation of penile tissues. SAMe may also enhance dopamine's role in enhancing sexual function in men. Not all of the research shows a better response in men. For

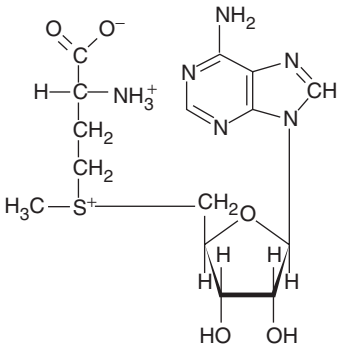

Fig. 110.1 S-Adenosylmethionine.

example, a small, 8-week double-blind study in patients with chronic schizophrenia given either SAMe 800 mg or placebo found improvement of depressive symptoms only in females.[9]

Although most of the early studies used injectable SAMe, most recent studies have used an oral dose of 400 mg four times daily (1600 mg total) and have demonstrated that SAMe is just as effective given orally as when it is given intravenously.[4,10-15] That is not surprising, because there are no significant differences in the pharmacokinetic parameters of SAMe 1000 mg administered orally or intravenously.[16]

Several studies have compared SAMe with tricyclic antidepressants. Before the rise of SSRIs, tricyclics were the mainstay pharmaceutical treatment for depression. A 2002 review concluded that, "at doses of 200 to 1600 mg/day, SAMe is superior to placebo and is as effective as tricyclic antidepressants in alleviating depression, although some individuals may require higher doses."[10] The reviewers found six of eight placebo-controlled studies, featuring anywhere from 40 to 100 participants, demonstrating that SAMe was superior to placebo; moreover, six of eight comparison studies showed that SAMe was just as effective as tricyclic antidepressants. These studies have shown that SAMe is better tolerated than the tricyclics and has a quicker onset of antidepressant action.[11]

In one study comparing SAMe with desipramine, in addition to determining the clinical response, the blood level of SAMe was determined in both groups. At the end of the 4-week trial, 62% of the patients treated with SAMe and 50% of those treated with desipramine had significantly improved. Regardless of the type of treatment, patients with a 50% decrease in scores on the Hamilton Depression Scale showed a significant rise in plasma SAMe concentration. These results suggest that one of the ways in which tricyclic antidepressant agents exert their antidepressant effects is by raising SAMe levels.[17]

In two separate double-blind studies, SAMe was given orally (1600 mg daily) or intramuscularly (400 mg daily) and compared with 150 mg of imipramine given orally daily. In both studies, the results of SAMe and imipramine treatment did not differ significantly for any efficacy measure. However, significantly fewer adverse events were observed in the patients treated with SAMe. The researchers concluded that the antidepressant efficacy of 1600 mg SAMe orally and 400 mg SAMe intramuscularly is comparable with that of 150 mg of imipramine but that SAMe is significantly better tolerated.[18]

Several studies have compared SAMe with SSRIs. In one double-blind study, 144 subjects with major depressive disorder were given SAMe (1600–3200 mg/daily), escitalopram (10–20 mg/daily), or matching placebo for 12 weeks.[19] Using the Hamilton Depression Rating Scale (HAMD-17), SAMe showed a moderate to large effect size from baseline to the end of 12 weeks. Response rates (HAMD-17 ≥50% reduction) at endpoint were 45%, 31%, and 26% for SAMe, escitalopram, and placebo, respectively; whereas remission rates (HAM-D ≤7) were 34% for SAMe, 23% for escitalopram, and 6% for placebo.

A similar study did not show nearly the same advantage, as neither SAMe nor escitalopram showed a better effect than a placebo.[20]

SAMe can be used safely with SSRIs and may have a synergistic effect. In a double-blind, randomized clinical trial lasting 6 weeks, 73 depressed patients who were unresponsive to SSRI medications alone were given 800 mg of SAMe or placebo twice daily along with their SSRIs.[21] The response and remission rates according to the Hamilton Depression Scale were higher for patients treated with adjunctive SAMe (36.1% and 25.8%, respectively) than adjunctive placebo (17.6% vs. 11.7%, respectively). These results indicate that SAMe can be used safely with SSRIs and may have a synergistic effect.

In a study on 20 HIV-seropositive individuals with depression, SAMe as a sole antidepressant medication showed significant effect. There was a significant reduction in acute depressive symptomatology, reaching the defined clinical treatment response threshold of a greater than 50% reduction in symptom scores. The researchers also noted that SAMe had a rapid effect as early as after only 1 week, with progressive decreases in symptom scores throughout the study.[22]

SAMe has also been shown to produce significant effects in other conditions associated with depression, such as during the postpartum period and in drug rehabilitation. SAMe's benefits in these conditions are probably due to a combination of its effects on brain chemistry and liver function (discussed later). In the study in postpartum depression, the administration of SAMe (1600 mg/day) was associated with significantly better mood scores compared with placebo.[23] In another study, SAMe (1200 mg/day) was shown to significantly reduce psychological distress (chiefly anxiety and depression) in the detoxification and rehabilitation of opiate abusers.[24]

SAMe may also be helpful in managing the symptomatology of schizophrenia. In one double-blind study, 18 patients with chronic schizophrenia were randomly assigned to receive either SAMe (800 mg) or placebo for 8 weeks. Results indicated some reduction in aggressive behavior and improved quality of life after SAMe administration. Female patients showed improvement of depressive symptoms, whereas male patients showed no change compared with placebo. Blood dopamine levels increased in women but decreased in men receiving SAMe. Clinical improvement did not correlate with serum SAMe levels. Two patients receiving SAMe exhibited some exacerbation of irritability; therefore, it should be used with caution in these patients.[9]

Detailed clinical evaluations using electroencephalography, event-related potentials, and low-resolution brain electromagnetic tomography have clearly indicated a central nervous system antidepressant action of SAMe.[18]

Osteoarthritis

SAMe has also demonstrated impressive results in the treatment of osteoarthritis.[25] A deficiency of SAMe in the joint tissue, just like a deficiency of glucosamine, leads to loss of the gel-like nature and shock-absorbing qualities of cartilage. As a result, osteoarthritis can develop.

In vitro studies have shown that SAMe exerts a number of effects that appear to be highly relevant in the treatment of osteoarthritis.[26] First, the agent has been shown to be important in the manufacture of cartilage components. This effect has been demonstrated very well in humans. In one double-blind study conducted in Germany, the 14 patients with osteoarthritis of the hands who were given SAMe showed greater cartilage formation on magnetic resonance imaging.[27] These results indicate that SAMe is capable of improving the structure and function of cartilage in joints affected by osteoarthritis. Second, SAMe has shown some mild pain-relieving and anti-inflammatory effects in animal studies.[1] All of these effects combine to produce clinical benefits.

In double-blind trials, SAMe has demonstrated similar reductions in pain scores and clinical symptoms to those produced by nonsteroidal anti-inflammatory drugs (NSAIDs) like ibuprofen, indomethacin, naproxen, nabumetone, celecoxib, and piroxicam.[25] In one double-blind study, SAMe was compared with ibuprofen.[28] The 36 subjects with osteoarthritis of the knee, hip, and/or spine received a daily oral dose of 1200 mg of SAMe or 1200 mg of ibuprofen for 4 weeks. Morning stiffness, pain at rest, pain on motion, crepitation (crackling noise upon movement of a joint), swelling, and limitation of motion of the affected joints were assessed before and after treatment. The total score obtained by evaluating all the individual clinical parameters improved to the same extent in patients treated with SAMe and in those treated with ibuprofen. In two other studies, SAMe was actually shown to produce slightly better results.[29,30]

SAMe has also been compared with naproxen (Naprosyn). In one double-blind study, 20 patients with osteoarthritis of the knee were given either SAMe or naproxen for 6 weeks.[31] During the first week, SAMe was administered at a dose of 400 mg three times daily and afterward at a dose of 400 mg twice daily, whereas the dose of naproxen during the first week was 250 mg three times daily and subsequently 250 mg twice daily. During the first 2 weeks, the patients were allowed to take acetaminophen as an additional analgesic if the pain was severe. The patients were examined at the beginning of the study and after 2, 4, and 6 weeks. The parameters tested were pain, crepitation, joint swelling, circumference of joint, extent of motility, and 10-meter walking time. At the end of the sixth week, no statistically significant difference between the two patient groups was found; both groups exhibited a marked improvement on all parameters.

Another double-blind study compared SAMe with both naproxen and placebo in the treatment of osteoarthritis of the hip, knee, spine, and hand. The study involved 33 rheumatologic and orthopedic medical centers and a total of 734 subjects. SAMe administered orally at a dose of 1200 mg daily was shown to exert the same analgesic (pain-relieving) activity as naproxen at a dose of 750 mg daily. However, SAMe was found to be significantly more effective than naproxen, both in terms of physicians' and patients' judgments and in terms of the number of patients with side effects. In fact, SAMe was better tolerated than placebo. A total of 10 patients in the SAMe group and 13 in the placebo group withdrew from the study because of intolerance to the intervention.[32] Other double-blind studies have shown SAMe to offer pain-relieving and anti-inflammatory benefits similar to those of drugs like indomethacin and piroxicam while also being generally much better tolerated than these potent NSAIDs.[33,34]

Perhaps the most meaningful study of SAMe in the treatment of osteoarthritis was a long-term multicenter open 2-year trial involving 97 patients with osteoarthritis of the knee, hip, and spine.[35] The patients received 600 mg of SAMe daily for the first 2 weeks and thereafter 400 mg daily until the end of the 24th month of treatment. Separate evaluations were made for osteoarthritis of the knee, hip, cervical spine, and dorsal-lumbar spine. The severity of the clinical symptoms (morning stiffness, pain at rest, and pain on movement) was assessed with scoring before the start of the treatment, at the end of the first and second weeks of treatment, and then monthly until the end of the 24-month period. SAMe showed good clinical effectiveness and was well tolerated. Improvement in the clinical symptoms during therapy with SAMe was already evident after the first weeks and continued to the end of treatment. Nonspecific side effects occurred in 20 patients, but in no case did therapy have to be discontinued. Most side effects disappeared during the course of therapy. Moreover, during the last 6 months of treatment, no adverse effect was recorded. Detailed laboratory tests carried out at the start and after 6, 12, 18, and 24 months of treatment showed no pathological changes. SAMe administration also improved the depressive feelings often associated with osteoarthritis.

One study compared the efficacy and tolerability of SAMe (1200 mg/day) and nabumetone (Relafene, 1000 mg/day) in 134 patients with osteoarthritis of the knee for 8 weeks.[36] An analysis of changes in pain intensity between weeks 0 and 8 found that both SAMe and nabumetone effectively reduced pain intensity from baseline in each group and that the degree of decrease in pain intensity was not significantly different between the groups. The patients' global assessments of disease status, physician's global assessment of response to therapy, and Western Ontario and McMaster Universities Arthritis Index (WOMAC) index scores were not significantly different between the groups.

A randomized, double-blind, crossover study comparing SAMe (1200 mg) with celecoxib (Celebrex 200 mg) for 16 weeks to reduce pain associated with osteoarthritis of the knee in 56 subjects showed that SAMe has a slower onset of action but is as effective as celecoxib in the management of symptoms of knee osteoarthritis.[37]

Finally, in the largest study, 20,641 patients with osteoarthritis of the knee, hip, and spine and also with osteoarthritic polyarthritis of the fingers were studied over 8 weeks.[38] The patients were given 400 mg of SAMe three times daily for the first week, 400 mg twice daily for the second week, and 200 mg twice daily from the third week onward. No additional analgesic or anti-inflammatory treatment was allowed. The efficacy of SAMe was comparable with results achieved with NSAIDs. Efficacy was described as very good or good in 71% of cases, moderate in 21%, and poor in 9%; tolerance of the agent was assessed as very good or good in 87%, moderate in 8%, and poor in 5%.

What all of these studies indicate is that SAMe appears to offer significant advantages over NSAIDs. The latter drugs are associated with significant risks of toxicity, side effects, and actual promotion of the disease process in osteoarthritis, but SAMe offers similar benefits without risks or side effects.

Fibromyalgia

SAMe has been shown in four double-blind clinical studies to produce excellent benefits in patients suffering from fibromyalgia.[39-42] In two of the studies, injectable SAMe (200 mg daily) was used. During treatment, subjects demonstrated significant reductions in the number of trigger points and painful areas as well as improvements in mood.[39,40]

In one of the studies, oral SAMe (800 mg/day) was compared with a placebo for 6 weeks in 44 patients with fibromyalgia.[41] Tender-point score, muscle strength, disease activity, subjective symptoms, mood parameters, and side effects were evaluated. Patients given SAMe demonstrated improvements in clinical disease activity, pain experienced during the last week, fatigue, morning stiffness, and mood; however, the tender-point score and muscle strength did not differ in the two treatment groups. SAMe was without side effects.

In one of the studies, SAMe was compared with transcutaneous electrical nerve stimulation—a popular treatment for fibromyalgia—in 30 patients with this disorder.[43] Patients receiving SAMe (200 mg by injection and 400 mg/day orally) experienced significantly greater clinical benefit as shown by a decreased number of tender points, diminished subjective feelings of pain and fatigue, and improved mood. Transcutaneous electrical nerve stimulation offered little benefit for most symptoms, whereas SAMe was deemed "effective in relieving the signs and symptoms of primary fibromyalgia."[42]

Liver Disorders

SAMe has been shown to be beneficial in several liver disorders, including cirrhosis, Gilbert syndrome, and oral contraceptive–induced liver damage. Its benefits are related to its function as the major methyl donor in the liver as well as restoring hepatic glutathione concentrations, thereby reducing liver injury. It also possesses lipotropic activity.

One of the leading contributors to impaired liver function is diminished bile flow, or cholestasis. SAMe is beneficial for a variety of liver disorders because of its lipotropic ability to promote bile flow and relieve cholestasis.[43,44]

Another key function of SAMe in the liver is the inactivation of estrogens. Clinical studies have shown that SAMe is useful in protecting the liver from damage and improving liver function in conditions associated with estrogen excess—namely, oral contraceptive use, pregnancy, and premenstrual syndrome.[45-48] SAMe has shown benefit in the treatment of intrahepatic cholestasis of pregnancy, a special complication of pregnancy characterized by skin pruritus, abnormal liver function tests, and bile acids. Alhtough helpful, SAMe is not as effective as a monotherapy as ursodeoxycholic acid or the two agents combined.[47,48]

Another key indication for the use of SAMe is in the treatment of Gilbert syndrome, a common disorder characterized by a chronically elevated serum bilirubin level (1.2–3.0 mg/dL) typically due to underactivity of uridine disphosphate-glucuronosyltransferase-1A1. Previously considered rare, this disorder is now known to affect as many as 5% of the general population. The condition is usually without symptoms, although some patients complain of loss of appetite, malaise, and fatigue (typical symptoms of impaired liver function). Also to be considered is the decreased ability to detoxify environmental toxins normally neutralized by this pathway. SAMe at a dosage of 400 mg three times daily has resulted in a significant decrease in serum bilirubin in patients with Gilbert syndrome.[49]

In addition to these relatively minor disturbances in liver function, SAMe offers some benefits in the treatment of chronic liver disorders, including cirrhosis.[50] Its effect in cirrhosis appears to be due to an ability to overcome the SAMe depletion characterized by the disorder. Because SAMe is involved in so many liver processes, the depletion of levels of SAMe within the liver has serious consequences. Supplementation with SAMe in patients with liver cirrhosis not only improves bile flow and clinical signs and symptoms but also promotes membrane function and increases levels of glutathione.[51-54] Glutathione assumes a critical role in detoxification as well as in the defense against a variety of injurious agents by combining directly with these toxic substances to eventually form water-soluble compounds. Because many of the toxic compounds are lipid (fat) soluble, conversion to water-soluble compounds results in more efficient excretion via the kidneys. When higher levels of toxic compounds are present or liver function is impaired, higher glutathione levels are required.

One of the greatest risks of chronic liver diseases such as chronic hepatitis is liver cancer. Supplementation with SAMe appears to be strongly indicated in patients with such diseases in the attempt to reduce the risk of liver cancer. Animal studies have shown a significant protective effect of supplemental SAMe against liver cancer in animals exposed to liver carcinogens.[55]

Migraine

SAMe has also been shown to be of benefit in the treatment of migraine headaches. The benefit arises gradually and long-term treatment is required for therapeutic effectiveness.[56]

DOSAGE

In general, the longer SAMe is used, the more beneficial the results. This agent is perfectly suited for long-term use because of its excellent safety profile. Although some studies have used intravenous dosages, there were no significant differences in the pharmacokinetic parameters of SAMe between single- and multiple-dose administration of a standard 1000-mg dose administered orally or intravenously. No evidence of accumulation of SAMe in plasma was found on multiple dosing. The dosage ranges for the various clinical indications are as follows:

Depression: 400 to 1600 mg daily. Because SAMe can cause nausea and gastrointestinal disturbances in some people, it is recommended that it be started at a dosage of 200 mg twice daily for the first day, increased to 400 mg twice daily on day 3, and finally raised to the full dosage of 800 mg twice daily after 10 days if needed

Osteoarthritis: The dosage is best started out as mentioned previously for depression. After 21 days at a dosage of 1600 mg daily, the maintenance dosage is reduced to 200 mg twice a day

Fibromyalgia: 200 to 400 mg two times a day

Liver disorders: 200 to 400 mg two to three times a day

Migraine headaches: 200 to 400 mg two times a day

TOXICOLOGY

No significant side effects have been reported with oral SAMe other than occasional nausea and gastrointestinal disturbances. However, individuals with bipolar (manic) depression should not take SAMe unless they are under strict medical supervision, because SAMe's antidepressant activity may lead to the manic phase in these individuals; this effect is seen only in some people with bipolar depression.

INTERACTIONS AND CONTRAINDICATIONS

SAMe functions very closely with vitamin B_{12}, folic acid, vitamin B_6, and choline in methylation reactions. Because of SAMe's effects on the liver, it may enhance the elimination of various drugs from the body.[57] The clinical significance of this effect has not been fully determined.

It has been cautioned that SAMe should be avoided in patients with Parkinson's disease. Animal studies indicate that excessive methylation is associated with Parkinson's disease, and SAMe excess has caused Parkinson's disease–like effects in animal studies.[57] In addition, both animal and human studies indicate that increased methylation can cause the depletion of dopamine and block the effects of L-dopa.[53,58,59] This line of research is somewhat contradicted, however, by preliminary evidence that SAMe may improve the emotional depression and impaired mental function often associated with this disorder.[60] Nonetheless, it is recommended that patients with Parkinson's disease avoid supplementing with SAMe until more is known.

Sarsaparilla Species

Michael T. Murray, ND

OUTLINE

Smilax aristolochiifolia (family: Liliaceae)
Synonym: *Smilax medica*
Common name: Mexican sarsaparilla
Smilax chinensis (family: Liliaceae)
Common name: Chinese sarasaparilla
Smilax officinalis (family: Liliaceae)
Synonym: *Smilax regelii*
Common name: Honduras sarsaparilla

GENERAL DESCRIPTION

Sarsaparilla is a tropical American perennial plant. Its long slender root and short thick rhizomes produce a vine that trails on the ground and climbs by means of tendrils growing in pairs from the petioles of the alternate obicular-to-ovate evergreen leaves. The root is the part of the plant used for medicinal purposes.

CHEMICAL COMPOSITION

Sarsaparilla contains 1.8% to 2.4% steroid saponins, including the following:

- Sarsaponin
- Smilasaponin
- Sarsaparilloside and its aglycones, sarsapogenin (Fig. 111.1), smilagenin, and pollinastanol

Other constituents are starch, resins, polyphenols (stilbenes, including resveratrol), flavonoids, and a trace of volatile oil.[1–3]

HISTORY AND FOLK USE

Smilax species are distributed widely in tropical and temperate regions throughout the world and have been used in many different cultures for the same conditions—namely gout, arthritis, fevers, digestive disorders, skin disease, and cancer.[1] From a historic perspective, sarsaparilla's medicinal use has been as a tonic and blood purifier. *Tonics* are defined as agents that "permanently exalt the energies of the body at large, without vitally affecting any one organ in particular. In short, tonics tone the whole system. A blood purifier or depurative [is] an agent that cleanses and purifies the system."[4] Sarsaparilla's reputation in this regard probably stems from its importation from the Caribbean and South America to Europe in the 16th century for the treatment of syphilis.[5]

Historic Use in the Treatment of Syphilis

Nicholas Monardes, a French physician, published a comprehensive account of sarsaparilla and several other "new" drugs for the treatment of syphilis in 1574. Many Europeans at the time believed that syphilis had come to Europe from the West Indies, with Columbus' sailors. Because there was a general belief that whatever disease was native to a country might be cured by the medicinal herbs grown in that region, it was only natural for sarsaparilla to become a popular remedy. Furthermore, use of the standard treatment for syphilis, mercury, often resulted in greater morbidity and mortality than the disease itself.

Sarsaparilla was a welcome alternative, but despite initial excitement, Monardes' sarsaparilla cure fell out of favor. This was probably because of other aspects of the cure, which involved confinement to a warm room for 30 days, followed by 40 days of abstinence from both wine and sexual intercourse.[5]

However, sarsaparilla continued to be used in the treatment of syphilis. During military operations in Portugal in 1812, a British inspector general of hospitals noted that the Portuguese soldiers suffering from syphilis who used sarsaparilla recovered much faster and more completely than their British counterparts, who were treated with mercury.[5]

Sarsaparilla was also used by the Chinese in the treatment of syphilis. Clinical observations in China show that sarsaparilla was effective, according to blood tests, in about 90% of acute cases and 50% of chronic cases.[1,6]

Although sarsaparilla was clearly more beneficial than mercury in the treatment of syphilis, it was mercury that established itself as the standard treatment for more than four and a half centuries. It has been stated that "the use of mercury in the treatment of syphilis may have been the most colossal hoax ever perpetrated" in the history of medicine.[5] Mercury represented a new kind of medicine, one formulated and prepared in a laboratory using the new techniques of chemistry. It helped prepare the way for the future use of drugs rather than herbal medicines.

PHARMACOLOGY

Various steroidal saponins, polyphenols, and flavonoids from *Smilax* species have shown anti-inflammatory and cytotoxic effects against

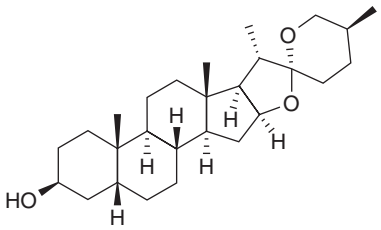

Fig. 111.1 Sarsasapogenin.

several tumor cell lines.[7–10] Yet, sarsaparilla's mechanism of action is largely unknown. Clinically, it has been shown to be effective in the treatment of psoriasis.[1,11,12] This evidence points to a possible effect on the binding of cholesterol and bacterial toxins in the intestines. Sarsaparilla has also demonstrated hepatoprotective effects[13] and an ability to protect against lead-induced oxidative stress in an animal model.[14]

Endotoxin Binding

Evidence seems to support sarsaparilla as an endotoxin binder. Endotoxins are cell wall constituents of bacteria absorbed from the gut. Normally, the liver plays a vital role by filtering these and other gut-derived compounds before they reach the general circulation. If the amount of endotoxin absorbed is excessive or the liver is not functioning adequately, it can become overwhelmed, and endotoxins then spill into the blood.

If endotoxins are allowed to circulate, activation of the alternate complement system occurs. This system plays a critical role in aggravating inflammatory processes, and activation of complement is responsible for much of the inflammation and cell damage seen in many diseases, including gout, arthritis, and psoriasis. Historically, these conditions have been treated with sarsaparilla.

In further support of sarsaparilla's effect as a binder of endotoxin is its historic use in the treatment of fever, because absorbed endotoxins produce fever. Sarsaparilla also exhibits some immune enhancing activity. *Smilax glabra* root contains a heteropolysaccharide that promotes phagocytosis and increased macrophage-derived biological factors including nitric oxide, interleukin-6, tumor necrosis factor-α, and interleukin-1β. This activation of macrophages enhances systemic host immune system function.[1]

CLINICAL APPLICATION

Sarsaparilla's medicinal action appears to be a result of its binding of bacterial endotoxins in the gut, which makes them unabsorbable. This action greatly reduces the stress on the liver and other organs and is probably responsible for sarsaparilla's historic use as a tonic and blood purifier. The ability to bind endotoxins is also probably the reason that sarsaparilla is effective in many cases of psoriasis, gout, and arthritis.

Psoriasis

Individuals with psoriasis have been shown to have high levels of circulating endotoxins. Binding of endotoxin in the gut is associated with clinical improvement in these individuals. In a controlled study of 92 patients, an endotoxin-binding saponin (sarsaponin) from sarsaparilla greatly improved the psoriasis in 62% of the patients and resulted in complete clearance in 18%.[12]

DOSAGE

- Dried root: 1 to 4 g or by decoction three times a day
- Liquid extract (1:1): 2 to 4 mL three times a day
- Solid extract (4:1): 250 to 500 mg three times a day

TOXICOLOGY

Although no adverse effects have been reported for sarsaparilla, it is possible that problems can arise if large doses are used over a long time.

DRUG INTERACTIONS

No drug interactions have been reported for sarsaparilla. However, it has been theorized that sarsaparilla may increase the absorption of certain drugs, notably digitalis and bismuth, thereby potentially increasing the chance of drug toxicity.

Serenoa repens (Saw Palmetto)

Kathy Abascal, BS, JD, RH(AHG), and *Eric L. Yarnell, ND, RH(AHG)*

OUTLINE

Serenoa repens (family: *Arecaceae*)
Common names: saw palmetto, palmetto scrub, Sabal serrulata

GENERAL DESCRIPTION

Serenoa repens is a small palm tree native to the West Indies and southeastern United States, particularly Florida (Fig. 112.1). The deep red-brown to black fruits, the medicinal parts, are wrinkled and oblong, measuring 0.5 to 1 in. in length with a diameter of 0.5 in.[1] They are technically considered drupes (Fig. 112.2).

CHEMICAL COMPOSITION

Saw palmetto drupes contain about 1.5% of a fruity-smelling oil containing saturated and unsaturated fatty acids and sterols.[1] About 63% of this oil is composed of free fatty acids, including capric, caprylic, caproic, lauric, palmitic, and oleic acids. The remaining portion is composed of ethyl esters of these fatty acids and sterols, including beta-sitosterol and its glucoside. The lipid-soluble compounds are thought to be the major pharmacological components. Other components of the fruit are proanthocyanidins, carotenes, lipase, tannins, and sugars.

The purified fat-soluble extract, the most researched medicinal product, contains 85% to 95% fatty acids and sterols. It is made up predominantly of a complex mixture of saturated and unsaturated free fatty acids, their methyl- and ethyl-esters (approximately 7%), long-chain alcohols in free and esterified forms, and various free and esterified sterol derivatives.

HISTORY AND FOLK USE

The American Indians, and later Eclectic and naturopathic physicians, used saw palmetto drupes in the treatment of genitourinary tract disturbances and as a tonic to support the body nutritionally.[2,3] This substance was strongly recommended as a remedy for symptoms of benign prostatic hyperplasia as early as 1919.[4] It was used in men to increase the function of the testicles and relieve irritation in mucous membranes, particularly those of the genitourinary tract and prostate. Saw palmetto has been used in women with disorders of the mammary glands; long-term use was reputed to cause the breasts to enlarge slowly.[2] Many herbalists have regarded saw palmetto as an aphrodisiac.[1]

Fig. 112.1 Serenoa repens.

PHARMACOLOGY

A standardized liposterolic (fat-soluble), saw palmetto drupe extract has demonstrated numerous pharmacological effects relating to its primary clinical application in the treatment of benign prostatic hyperplasia (BPH), a common disorder of the prostate gland (Fig. 112.3). Saw palmetto extract affects BPH through multiple mechanisms, including inhibition of the intraprostatic conversion of testosterone to DHT and of its intracellular binding and transport, antiestrogenic, and receptor site–binding effects.[5–7]

Estrogen may contribute to BPH because it inhibits the hydroxylation and subsequent elimination of DHT among other mechanisms. *Serenoa* inhibits the activity of estrogen in the prostate. In one double-blind study, 35 men with BPH were randomized to saw palmetto extract 160 mg twice daily or placebo for 90 days.[5] Men receiving the saw palmetto extract had significantly lower cytosol and receptor values for estrogen and progesterone than the placebo group. The results imply that at least part of the efficacy of the saw palmetto extract is because of its antiestrogenic effect.

There was no change in the number of cytosol androgen receptors, but the number of nuclear androgen receptors was significantly lower in the saw palmetto group (60% of the placebo group tested positive for the nuclear receptor compared with 10% of the saw palmetto group). These results indicate that the saw palmetto extract probably competitively blocks the translocation of the cytosol androgen receptor to the nucleus.

Preliminary analysis of the extract demonstrates that separate fractions are responsible for the antiandrogenic and antiestrogenic effects. Researchers in this study said, "It cannot be excluded, however, that the primary effect is antiestrogenic and that the inactivation of androgen receptors and progesterone receptors and of the 5-α-reductase activity is secondary to the estrogen receptor blockade."[7]

Serenoa standardized extracts do not affect systemic levels of androgens, follicle-stimulating hormone, or luteinizing hormone in men with BPH.[8] This may help explain the relatively low incidence of adverse effects of this substance in clinical trials. These findings do not, however, rule out localized effects of saw palmetto on androgen or estrogen effects in other tissues of the body.

Various locally produced growth factors also play a role in the pathogenesis of BPH, and liposterolic extracts of *Serenoa* block the ability of one of them, basic fibroblast growth factor, to induce prostatic hyperplasia in vitro.[9] High prolactin levels may also stimulate prostate hyperplasia; *Serenoa* extracts interfere with this process in rats, unlike finasteride.[10]

Saw palmetto extracts exert antispasmodic effects on smooth muscle. Rat smooth muscle was originally shown to be inhibited by two *Serenoa* extracts owing to inhibition of calcium ion influx.[11] A later study found that *Serenoa* extract but not pumpkin seed extract, stinging nettle root extract, or β-sitosterol consistently inhibited human α_1-adrenergic receptors in vitro.[12] Whether this effect is relevant clinically is still unknown.

The standardized extract has demonstrated anti-inflammatory effects, and the polysaccharide components have been shown to have immunostimulatory effects.[13–16] *Serenoa* extract and myristoleic acid–induced apoptosis and necrosis in an androgen-sensitive human prostate cancer cell line in vitro.[17]

Fig. 112.2 Dried fruit (drupes). (From *Serenoa repens*.)

CLINICAL APPLICATIONS

The primary clinical application of saw palmetto drupes (specifically the fat-soluble extract) is in the treatment of men with BPH. There

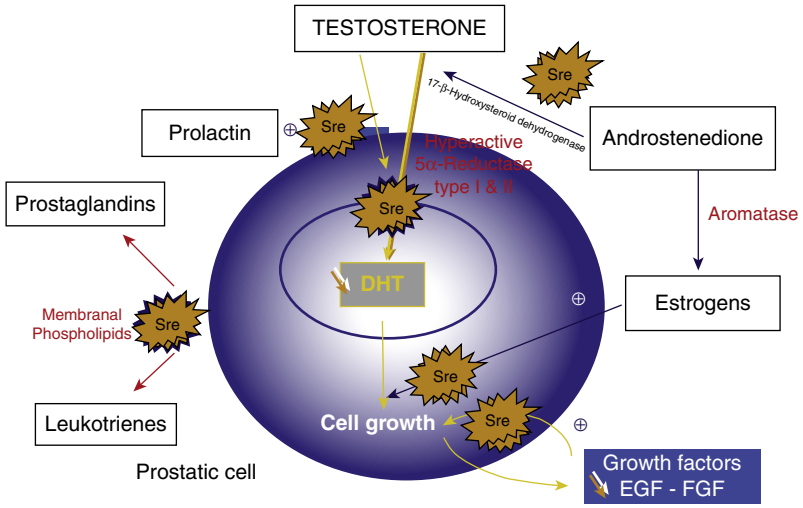

Fig. 112.3 Some of the *Serenoa repens* (Sre) extract targets at the level of the prostate cell. *DHT,* dihydrotestosterone; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor. (From Habib FK. *Serenoa repens*: the scientific basis for the treatment of benign prostatic hyperplasia. *European Urology Supplements.* 2009;8[13]:887–893.)

is also preliminary evidence that saw palmetto may also help counter male-pattern baldness and chronic prostatitis. On the basis of its pharmacology, this extract may also be of benefit in conditions of androgen excess in women, such as hirsutism and polycystic ovary disease.

Benign Prostatic Hyperplasia

The major symptoms of BPH (increased urinary frequency, nighttime awakening to empty the bladder, and reduced force and caliber of urination; see Chapter 154), have been shown to be significantly improved by saw palmetto extract in more than a dozen double-blind placebo-controlled clinical trials (summarized in Table 112.1).[18–31] At least four meta-analyses have combined data from these and other trials and concluded that, despite some limitations in trial design, *Serenoa* extracts have been shown to reduce symptoms of BPH and increase urine flow in comparison with placebo without affecting prostate volume.[32–36] One of these analyses also concluded that *Serenoa* extracts are as effective as the 5-α-reductase–inhibiting drug finasteride (Proscar), with significantly fewer adverse effects.[37] In another meta-analysis, it was concluded that saw palmetto extracts were not superior to a placebo for symptoms of BPH but were just as effective as finasteride and tamsulosin.[35] However, this analysis was strongly affected by a single negative trial involving 225 men with moderate to severe BPH randomized to receive *Serenoa* extract 160 mg twice daily or a placebo.[19] After 1 year of treatment, there was no significant difference in the scores on the American Urological Association Symptom Index and the maximal urinary flow rate in men receiving 320 mg per day of the liposterolic *Serenoa* extract or the placebo. Secondary outcome measures, including changes in prostate size, residual urinary volume after voiding, quality of life, laboratory values, and the rate of reported adverse effects also did not differ between the two groups.

TABLE 112.1 Clinical Studies Evaluating the Efficacy of *Serenoa repens* Extract[a] for Benign Prostatic Hyperplasia

Study	Type of Study	No. of Patients	Length of Study	Results
Controlled Trials				
Boeri et al.[55]	Double-blind, silodosin control	189	1 yr	Silodosin + *Serenoa* superior to silodosin
Barry et al.[38]	Double-blind, placebo-controlled	369	72 wk	Equal to placebo
Shi et al.[18]	Double-blind, placebo-controlled	92	12 wk	Significant for flow rate
Hizli and Uygur[42]	Double-blind, tamsulosin control	60	24 wk	Equal to tamsulosin
Engelmann et al.[54]	Double-blind, tamsulosin control	140	60 wk	Equal to tamsulosin
Bent et al.[19]	Double-blind, placebo-controlled	225	1 yr	Equal to placebo
Willetts et al.[20]	Double-blind	91	12 wk	Equal to placebo
Debruyne et al.[39]	Double-blind, tamsulosin control	542	1 yr	Equal to tamsulosin
Glemain et al.[41]	Double-blind, tamsulosin control	329	1 yr	Tamsulosin superior to *Serenoa*
Carraro et al.[37]	Double-blind, finasteride control	1,069	26 wk	Equal to finasteride for symptoms; only finasteride shrank prostate
Boccafoschi and Annoscia[21]	Double-blind, placebo-controlled	22	60 d	Significant difference for volume voided, maximum flow, mean flow, dysuria, nocturia
Emili et al.[22]	Double-blind, placebo-controlled	30	30 d	Significant difference for number of voided, strangury, maximum and mean urine flow, residual urine
Duvia et al.[23]	Controlled	30	30 d	Significant difference for voiding rate vs. *Pygeum africanum*
Tasca et al.[24]	Double-blind, placebo-controlled	30	31–90 d	Significant difference for frequency, urine flow measurement
Cukier et al.[25]	Double-blind, placebo-controlled	168	60–90 d	Significant difference for dysuria, frequency, residual urine
Champault et al.[27]	Double-blind, placebo-controlled	168	60–90 d	Significant difference for objective and subjective parameters
Champault et al.[27]	Double-blind, placebo-controlled	110	28 d	Significant difference for dysuria, nocturia, flow measurement, residual urine
Mattei et al.[28]	Double-blind, placebo-controlled	40	3 mo	Significant difference for dysuria, nocturia, residual urine
Open Long-Term Trials				
Djavan et al.[29]	Open, watchful waiting control	189	2 yr	Significant for symptom relief, reduction in surgical rates compared with control
Pytel et al.[30]	Open	255	2 yr	Significant for symptom relief
Pierre Fabre[31]	Open	154	2 yr	Significant for symptom relief

[a]Extract contained 85% to 95% fatty acids and sterols at a dosage of 320 mg/day.

These results may simply indicate that treatment of moderate to severe BPH is likely unresponsive to *Serenoa* therapy. A large negative clinical trial of *Serenoa* in 369 men with mild to moderate BPH failed to show a benefit for up to 960 mg/day of standardized extracts compared with the placebo.[38]

The single largest (n = 1069) clinical trial of *Serenoa* extract compared 160 mg of *Serenoa* twice daily with finasteride 5 mg daily for 26 weeks.[37] The two agents were equally effective at improving symptoms (by 37%–39% on average) and increasing peak urine flow (by 38%–41% on average). Although finasteride decreased prostate volume and levels of prostate-specific antigen (PSA) significantly, *Serenoa* extract had no such effect. Finasteride caused significantly more sexual side effects than saw palmetto.

In a double-blind comparison trial, 542 men with BPH symptoms were randomly assigned to receive either the α blocker tamsulosin or *Serenoa* extract for 1 year.[39] The two groups showed identical levels of improvement in symptoms. Tamsulosin was more frequently associated with ejaculatory disorders than *Serenoa* extract. In the subset of patients with the most severe BPH in this trial, *Serenoa* extract was actually statistically significantly superior to tamsulosin at relieving symptoms.[40] In a separate double-blind trial involving 329 men with BPH symptoms, tamsulosin combined with placebo was just as effective as tamsulosin combined with *Serenoa* extract at relieving symptoms.[41] Adding *Serenoa* extract to tamsulosin caused no alteration in adverse effects. A 6-month double-blind trial of *Serenoa* extract with 60 men found results very similar to those of the prior two studies, although it also demonstrated an equivalent improvement in maximum flow rate between the groups.[42]

Serenoa may work most effectively in combination with *Urtica urens* root extract. In a long-term study, the efficacy and tolerability of this combination were investigated in a prospective multicenter trial comprising elderly male patients suffering from lower urinary tract symptoms (LUTS) caused by BPH. A total of 257 patients were randomized to treatment with the combination (320 mg of *Serenoa* and 240 mg of *U. urens* extracts per day) or placebo. After a single-blind placebo run-in phase of 2 weeks, the patients received either the study medication or placebo under double-blind conditions over 24 weeks. The double-blind treatment was followed by an open control period of 24 weeks during which all patients were given the *Serenoa* and *U. urens* combination. Outcome measures for treatment efficacy included the assessment of the patients' LUTS by means of a self-rating questionnaire and a quality-of-life index in addition to uroflow and sonographic parameters. Using the International Prostate Symptom Score (I-PSS), patients treated with the *Serenoa* and *U. urens* combination exhibited a substantially higher total score reduction after 24 weeks of double-blind treatment than patients of the placebo group (6 points vs. 4 points; $P = 0.003$), with a tendency in the same direction after 16 weeks. This applied to obstructive and to irritative symptoms and to patients with moderate or severe symptoms at baseline. Patients randomized to placebo showed a marked improvement in LUTS (as measured by the I-PSS) after being switched to the *Serenoa* and *U. urens* combination during the control period.[43]

Chronic Prostatitis

Several clinical trials indicate that *S. repens* may have clinical benefit in chronic prostatitis or pelvic pain. One double-blind, randomized trial compared *S. repens* extract alone with a combination of *S. repens,* selenium, and lycopene in men with nonbacterial chronic pelvic pain.[44] After 8 weeks, the two groups had equivalent improvements in symptoms, whereas only the combination product lowered PSA and levels of white blood cell in urine.

One study used a combination of *S. repens* extract 160 mg, *Urtica dioica* root extract 120 mg, quercetin 100 mg, and curcumin 200 mg once daily with the antibiotic prufloxacin 600 mg once daily in men with bacterial prostatitis.[45] One fourth of the 143 subjects were randomly assigned to take prufloxacin alone. Treatment lasted 14 days. One month after treatment, patients in the combination group were dramatically more likely (88% vs. 27%) to be symptom-free than the antibiotic-only group. Subsequent randomized trials confirm that saw palmetto extract by itself and in combination with selenium, lycopene, bromelain, and methylsulfonylmethane or arbutin and *Lactobacillus sporogenes* enhance the efficacy of antibiotics in patients with chronic prostatitis.[46–48]

Male-Pattern Baldness

A combination of 400 mg *S. repens* extract and 100 mg beta-sitosterol daily was found effective for male-pattern baldness in a pilot double-blind, placebo-controlled trial.[49] The 5-month trial involved 19 men with mild to moderate baldness. Sixty percent (6 of 10) of the men in the treatment group were rated as having improved by blinded observers, whereas only 11% (1 of 9) of men in the placebo group were rated as improved. Thirty-three percent (3 of 9) of the men in the placebo group showed deterioration compared with none in the treatment group. There were no major adverse effects. A comparative trial in 100 men over 2 years found that finasteride 1 mg was superior to *S. repens* extract 320 mg for improving baldness, but both extracts did lead to significant increases in hair growth compared with baseline.[50] An open trial in 50 men found that a topical *S. repens* extract applied for 4 weeks effectively improved hair growth lasting 24 weeks.[51]

Dosage

The dosage for the liposterolic extract of saw palmetto fruit (containing 85%–95% fatty acids and sterols) is 160 mg twice daily or 320 mg daily; the two regimens have been shown to be equally effective.[52] A similar dosage using fluid extracts and tinctures would require extremely large quantities of alcohol if the liposterolic components were the primary active constituents. The Eclectics used comparatively small dosages of saw palmetto in crude extracts effectively for BPH with apparent clinical success. Ellingwood[4] lists a dose as 10 drops to 1 dram of specific *S. repens* (meaning basically a fresh drupe tincture). We are unaware of any published clinical study of a crude extract.

Dosages are as follows:

- Crude drupes: 10 g twice a day
- Liposterolic extract (standardized at 85%–95% fatty acids and sterols): 160 mg twice a day or 320 mg once a day

The dosage of fluid extracts or tinctures is typically 3 to 5 mL two to three times per day, although there is a lack of research on this dose form.

TOXICOLOGY

No significant adverse effects have been reported in clinical trials of the saw palmetto fruit extract or for saw palmetto drupe ingestion; rates of mild adverse effects are no different than those seen with placebo treatment.[53] Mild gastrointestinal upset and erectile dysfunction (in approximately 1% of users in clinical trials)[3] occasionally occur.

DRUG INTERACTIONS

No drug–herb interactions had been reported as of 2019. One clinical trial found no effect of saw palmetto liposterolic extract on CYP3A4 or 2D6 in healthy adults.[56]

Silybum marianum (Milk Thistle)

Michael T. Murray, ND

OUTLINE

Silybum marianum (family: *Compositae*)
Synonym: *Carduus marianus*
Common names: milk thistle, marian thistle, St. Mary's thistle

GENERAL DESCRIPTION

Silybum marianum is a stout annual or biennial plant found in dry, rocky soils in southern and western Europe and some parts of the United States. The branched stem grows 1 to 3 ft high and bears alternate dark green, shiny leaves with spiny, scalloped edges that are markedly streaked with white along the veins (Fig. 113.1). The solitary flower heads are reddish purple with bracts ending in sharp spines. The flowering season is from June to August. The seeds, fruit, and leaves are used for medicinal purposes.

CHEMICAL COMPOSITION

S. marianum contains *silymarin,* a mixture of flavanolignans, consisting chiefly of silybin, silydianin, and silychristine. The concentration of silymarin is highest in the fruit, but it is also found in the seeds and leaves. Other flavanolignans contained in *Silybum* include silandrin, silyhermin, silymonin, and neosilyhermin. Silybin is the silymarin component with the greatest degree of biological activity.[1]

HISTORY AND FOLK USE

Perhaps the most widespread folk use of this plant has been in assisting the nursing mother in the production of milk. It was also used in Germany for curing jaundice and biliary derangements. It is interesting to note that the discovery of the liver-protecting flavanolignans in *S. marianum* was the result not of systemic pharmacological screening but rather of investigation of *Silybum*'s empiric effects in liver disorders.

PHARMACOLOGY

Currently, *S. marianum* extracts (usually standardized to contain 70% silymarin) are widely used in supporting liver health and for hepatic disorders. Silymarin is one of the most potent liver-protecting substances known.[1,2] *S. marianum* extracts exert beneficial properties in a wide variety of other disorders, such as renal protection, hypolipidemic and antiatherosclerosis activities, cardiovascular protection, and prevention of insulin resistance, especially in cirrhotic patients, cancer, and Alzheimer's prevention.[3]

Hepatoprotection Effects

Free-Radical Scavenging

Silybum's ability to prevent liver destruction and enhance liver function is due largely to silymarin's inhibition of the factors responsible for hepatic damage—free radicals and leukotrienes—coupled with its ability to stimulate liver protein synthesis (Fig. 113.2). *Silybum* components prevent free-radical damage by acting as antioxidants.[1–3] Silymarin is many times more potent in antioxidant activity than vitamin E.

Effects on Hepatic Glutathione

Silymarin prevents the depletion of glutathione (GSH) induced by alcohol and other liver toxins. Even in normal people, silymarin has been shown to raise the basal GSH level in the liver by 35%.

Protection from Liver-Damaging Chemicals and Drugs

The protective effect of *Silybum* against liver damage has been demonstrated in several experimental and clinical studies. Experimental liver damage in animals can be produced by such diverse toxic chemicals as carbon tetrachloride, galactosamine, ethanol, and praseodymium nitrate. Silymarin has been shown to protect the liver from all these toxins.

Perhaps the most impressive of silymarin's protective effects is against the severe poisoning by *Amanita phalloides* (the "death cap" or toadstool mushroom), an effect that has long been recognized in folk medicine. Ingestion of *A. phalloides* or its toxins causes severe poisoning and, in approximately 30% of victims, death.

Among the experimental models for measuring protection against liver damage, those based on amanitin or phalloidin toxicity are the most important because these two peptides from *A. phalloides* are the most powerful liver-damaging substances known. Silymarin has demonstrated impressive results in these experimental models. When silymarin was administered before amanita toxin poisoning, it was 100% effective in preventing toxicity.[4] Even if given 10 minutes after the amanita toxin, it completely counteracted the toxic effects.

In two cases reported in the literature, silymarin prevented death and greatly reduced the amount of liver damage up to 24 hours after ingestion of *A. phalloides*.[5] This study reported on a husband and wife who ate toxic mushrooms and experienced gastrointestinal symptoms 18 hours later. Despite initial conventional treatment with gastric emptying, intravenous fluids, activated charcoal, and a duodenal tube, both patients' laboratory parameters showed deteriorating liver and renal function. Mild hepatic encephalopathy developed in one of the patients. Treatment with intravenous silybinin at a dose of 20 mg/kg body weight, penicillin, and glucose for 3 days resulted in a reversal of both the organ failures and encephalopathy.

Silymarin may also be of great value as an adjunct in patients receiving long-term drug therapy. A very interesting study found that silymarin, in an unusually high dose of 800 mg/day, given to psychiatric patients receiving phenothiazines or butyrophenones resulted in significant protection of the liver as measured by malondialdehyde serum liver enzyme levels.[6] The silymarin did not interfere with the efficacy of the antidepressants.

Fig. 113.1 *Silybum marianum*. (From iStock.)

Stimulation of Hepatic Protein Synthesis

Perhaps the most interesting effect of *Silybum* components on the liver is their ability to stimulate protein synthesis. This results in an increase in the production of new liver cells to replace the damaged old ones. Sonnenbichler and Zetl[7] have suggested that "silybinin imitates in some way a physiological regulator in animal cells, so that the structure fits into a specific binding site on the polymerase and in such a way causes the observed effects on rRNA synthesis making the drug from *Silybum marianum* indeed interesting for liver therapy." Interestingly, silybinin does not have a stimulatory effect on malignant hepatic tissue.[8]

Anti-Inflammatory Effects

Leukotrienes, key chemical mediators of inflammation produced by the transfer of oxygen to polyunsaturated fatty acids (a reaction catalyzed

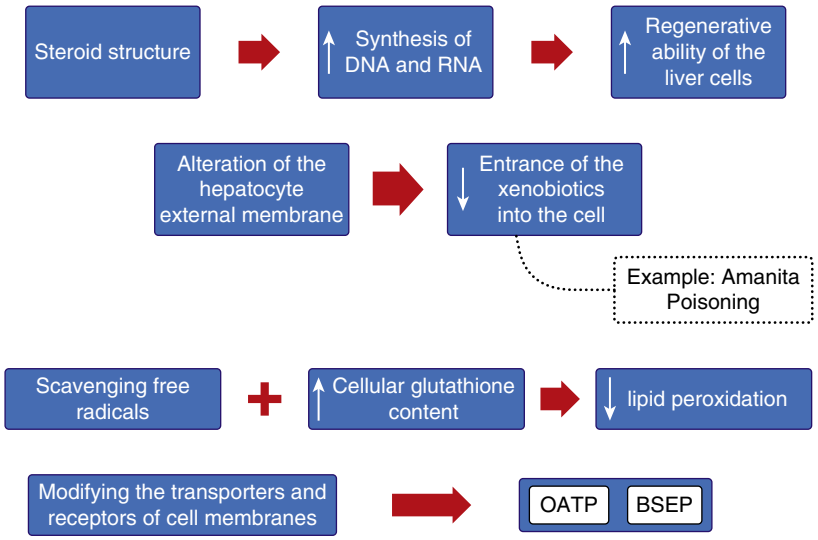

Fig. 113.2 Different mechanisms of action of silymarin. Mechanisms include increasing the regenerative ability of the liver cells by enhancing the synthesis of DNA and RNA, as silymarin has a steroid structure; altering the structure of the hepatocyte external membrane, which prevents entrance of the xenobiotics into the cell (poisoning with *Amanita* mushroom is a noteworthy example of such mechanism); and scavenging free radicals and increasing the cellular content of glutathione, which leads to the inhibition of lipid peroxidation. Another mechanism of action of silymarin is modifying the transporters and receptors of cell membranes such as ABC transporters (P-gp), organic anion uptake transporter peptides (OATPs), bile salt export pump, and tumor necrosis factor-α–dependent transporters. (From Karimi G, Vahabzadeh M, Lari P, Rashedinia M, Moshiri M. "Silymarin," a promising pharmacological agent for treatment of diseases. *Iran J Basic Med Sci.* 2011;14[4]:308–317. PubMed PMID: 23492971.)

by the enzyme lipoxygenase), can also damage the liver. Silymarin has been shown to be a potent inhibitor of this enzyme, thereby inhibiting the formation of damaging leukotrienes.

Silymarin has also been demonstrated to inhibit prostaglandin synthesis during inflammation. Free-radical damage to membrane structures due to organic disease or intoxication results in an increased release, through lipolysis, of fatty acids. This leads, among other things, to greater prostaglandin and leukotriene synthesis. Silymarin counteracts this deleterious process by suppressing the pathological decomposition of membrane lipids and inhibiting prostaglandin formation. Leukotrienes and inflammatory prostaglandins are also involved in damage of the liver by toxins, so their neutralization by silybin is another mechanism for its protection of the liver.

Anticancer Effects

Silymarin has shown significant anticancer effects in both in vivo and in vitro cancer models—including skin, breast, lung, colon, bladder, prostate, and kidney carcinomas—as well as adjunctive actions when combined with standard cancer therapies.[9] Some of the effects noted include that it:

- Prevents the expression of genes and enzymes pivotal in cancer development
- Modulates imbalance between cell survival and apoptosis through interference with the expression of cell-cycle regulators and proteins involved in apoptosis
- Exerts significant antimetastatic effects
- Has a synergistic effect when combined with conventional chemotherapy agents, including growth inhibition, reversal of chemoresistance, apoptosis induction, and reduced chemotherapy side effects in a variety of models

These preliminary studies suggest a clinical application in cancer patients as an adjunct to established therapies to prevent or reduce chemotherapy as well as radiotherapy-induced toxicity.[6] Considering the significant problem of serious nephrotoxicity from cisplatin and other chemotherapeutic agents, silybinin may be of great value as an adjunct in the treatment of cancer.

Other Pharmacological Actions

Silymarin shows antiviral effects against hepatitis C virus (HCV) cell culture infection, including inhibition of virus entry, RNA and protein expression, and infectious virus production.[10]

In animal studies, silymarin has been shown to increase the proliferation of lymphocytes as well as levels of interferon-gamma, interleukin (IL)-4, and IL-10 cytokines in a dose-dependent manner.[11]

Silymarin is a strong inhibitor of cyclic adenosine monophosphate (cAMP) phosphodiesterase, being 13 to 50 times more active than theophylline and 1 to 3 times more active than papaverine.[11] Silymarin has also been shown to prevent the toxic effects of a variety of compounds, such as hemolysis induced by phenylhydrazine, damage from x-irradiation, and brain edema induced by triethyltinsulfate. Presumably these effects are related to silymarin's significant membrane-stabilizing and antioxidant actions. Its action in increasing the osmotic resistance of red blood cells is also quite significant.

S. marianum extracts are particularly indicated for metabolic syndrome because they have been found to exhibit antioxidant, lipid-lowering, antihypertensive, antidiabetic, antiatherosclerotic, antiobesity, and hepatoprotective effects.[12]

Silymarin exerts significant immunomodulatory effects. As an immunomodulator agent, silymarin inhibits T-lymphocyte function at low doses, whereas it stimulates inflammatory processes at high doses. Studies have shown that silymarin has attenuated autoimmune, allergic, preeclampsia, cancer, and immune-mediated liver diseases and also has suppressed oxidative and nitrosative immunotoxicity. Silymarin also has indicated dual effects on proliferation and apoptosis of different cells.[13]

In patients with hemochromatosis, silybin administration at meals was shown to reduce iron absorption.[14]

CLINICAL APPLICATIONS

Silymarin's primary use is as an aid to the liver, although additional clinical applications are regularly being discovered. This substance can be used to support detoxification reactions or in the treatment of more severe liver disease. In numerous clinical studies, silymarin has been shown to have positive effects in treating several types of liver disease, including the following[2]:

- Cirrhosis
- Chronic hepatitis
- Chemically induced liver damage
- Alcohol-induced fatty liver
- Nonalcoholic hepatosteatosis
- Subclinical cholestasis of pregnancy
- Cholangitis and pericholangitis

The therapeutic effect of silymarin in these disorders has been confirmed by histological, clinical, and laboratory data. Silymarin may also be useful in improving the solubility of the bile in the treatment of gallstones as well as in psoriasis and as a galactagogue.

Alcohol- and Chemically Induced Liver Damage

In one of the first extensive double-blind clinical trials investigating silymarin's therapeutic effect in liver disorders, the substance demonstrated impressive results in 129 patients with toxic metabolic liver damage, fatty degeneration of the liver of various origins, or chronic hepatitis who were compared with a control group of 56 patients. The results might have been even more impressive if the study had lasted longer than 35 days.[15]

A follow-up study of patients with liver damage due to alcohol, diabetes, viruses, or toxic exposure yielded even more striking results. Patients were monitored for 7 weeks. Not only were clinical findings markedly improved in the silymarin-treated groups, but laboratory and liver biopsy data improved as well. Highly significant results were obtained in bromsulphalein retention as well as in measurements of alanine transaminase (ALT), iron, and cholesterol levels. Biopsy showed remarkable tissue-restorative effects. Upon completion of silymarin therapy, restitution of normal cell structure was found even in severely damaged livers. These effects on the tissue level correlated well with improvements in blood chemistry values.[16]

Another study highlighted the benefit of silymarin in individuals exposed to toxic chemicals. In this study, abnormal results of liver function tests (elevated levels of aspartate aminotransferase [AST] and ALT activity) and/or abnormal hematological values (low platelet counts, increased white blood cell [WBC] counts, and a relative increase of lymphocytes compared with other WBCs) were observed in 49 of 200 workers exposed to toxic toluene and/or xylene vapors for 5 to 20 years.[17] Thirty of the affected workers were treated with silymarin, and the remaining 19 were left without treatment. Under the influence of silymarin, liver function parameters and platelet counts significantly improved. The WBC counts also showed a tendency toward improvement.

Pooled data from case record studies involving 452 patients with *A. phalloides* poisoning show a highly significant difference in mortality in favor of silymarin therapy. The mortality rate for silymarin therapy is 9.8%, compared with 18.3% for standard treatment.[18]

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatosis

Silymarin is also helpful in nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatosis (NASH). In a randomized, double-blind, placebo-controlled trial of consecutive adults with biopsy-proven NASH and an NAFLD activity score (NAS) of 4 or more, patients were randomly assigned to groups given silymarin (700 mg) or placebo ($n = 50$ patients) three times daily for 48 weeks. After this 48-week period, liver biopsies were repeated. Although there was no effect on the primary efficacy outcome of a decrease of 30% or more in NAS, the findings from 48-week liver biopsies showed that a significantly higher proportion of patients in the silymarin group had reductions in fibrosis based on histology, and based on liver stiffness measurements, than did the placebo group. The silymarin group also had significant reductions in mean ratio of aspartate aminotransferase to platelet index, Fibrosis-4 score, and NAFLD fibrosis score; these changes were not observed in the placebo group.[19]

Cirrhosis

As previously described, silymarin is quite effective in treating alcohol-related liver disease. There is a tremendous range in the severity of alcohol-related liver disease, from relatively mild to serious damage, such as cirrhosis. Even in this severe state, silymarin has shown benefit. Perhaps the most significant benefit is in extending the life spans of patients with these disorders.

In one study, 87 patients with cirrhosis (46 with alcoholic-related cirrhosis) received silymarin, whereas 83 patients (45 with alcoholic cirrhosis) received a placebo.[20] The mean observation period was 41 months. In the treatment group, there were 24 deaths, 18 related to liver disease; in the control group, there were 37 deaths, 31 related to liver disease. The 4-year survival rate was 58% in the treatment group compared with 39% in the controls.

Analysis of the results of five trials involving a total of 602 patients with liver cirrhosis demonstrated that although silymarin produced a statistically insignificant reduction of total mortality by 4.2% in comparison with placebo, it did lead to a statistically significant reduction in liver-related mortality of 7%.[21] Silymarin can also improve immune function in patients with cirrhosis.[2]

Viral Hepatitis

Silymarin is useful in helping reverse virally induced liver damage. It is effective in both acute and chronic viral hepatitis. In one study of acute viral hepatitis, 29 patients treated with silymarin showed a definite therapeutic influence on the characteristic increased serum levels of bilirubin and liver enzymes compared with a placebo group.[22] The laboratory parameters had regressed more in the silymarin group than in the placebo group by the fifth day of treatment. The number of patients attaining normal liver values after 3 weeks of treatment was significantly higher in the silymarin group than in the placebo group.

In a double-blind study of various causes of acute hepatitis, patients were given either a standard recommended dose of 140 mg of silymarin or a placebo three times daily for 4 weeks. Patients randomized to the silymarin group had a quicker resolution of symptoms related to biliary retention: dark urine, jaundice, and scleral icterus. There was a reduction in indirect bilirubin among those assigned to silymarin, but other variables, including direct bilirubin, ALT, and AST, were not significantly reduced.[23]

In a study of chronic viral hepatitis, silymarin was shown to result in dramatic improvement. Used at a high dose (420 mg) for periods of 3 to 12 months, silymarin resulted in a reversal of liver cell damage (as noted on biopsy), a rise in protein level in the blood, and a lowering of liver enzyme values. Common symptoms of hepatitis (e.g., abdominal discomfort, decreased appetite, and fatigue) were all improved.[24]

Silymarin has been studied in hepatitis C, with little evidence of efficacy. In a meta-analysis of five double-blind, placebo-controlled trials, 389 patients were randomly treated with silymarin or placebo. Silymarin was well tolerated in chronic HCV-infected patients, but there was no evidence of positive effects for oral silymarin, although intravenous silybin did show some benefits.[25]

Gallstones

Silymarin may help prevent or treat gallstones through its ability to increase the solubility of the bile. In one study, the composition of the bile was assayed in 19 patients with a history of gallstones (4 patients) or removal of the gallbladder due to gallstones (15) before and after silymarin (420 mg/day for 30 days) or placebo. Silymarin treatment led to a significant reduction in the biliary cholesterol concentration and bile saturation index.[26]

Psoriasis

Correction of abnormal liver function is indicated in the treatment of psoriasis. Silymarin has been reported to be of value in the treatment of psoriasis; this effect may be due to its ability to inhibit the synthesis of leukotrienes and improve liver function.[27]

The connection between the liver and psoriasis relates to one of the liver's basic tasks, filtering of the blood. Psoriasis has been shown to be linked to high levels of circulating endotoxins, such as those found in the cell walls of gut bacteria. If the liver is overwhelmed by an increased number of endotoxins or chemical toxins or if the liver's functional ability to filter and detoxify is decreased, the psoriasis is aggravated. Another factor in psoriasis is excessive production of leukotrienes. Silymarin has been shown to reduce leukotriene formation by inhibiting lipoxygenase. Therefore silymarin would inhibit one of the causes of the excessive cellular replication.

Silymarin has other effects of value in patients with psoriasis. Most of them revolve around correcting the abnormal ratio of cAMP to cyclic guanosine monophosphate (cGMP) observed in the skin of patients with psoriasis. The ratio of these two cellular control agents governs cellular replication. In psoriasis, cGMP levels are high relative to cAMP levels. Silymarin works to lower cGMP levels and raise cAMP levels.

Silymarin as a Galactagogue

A micronized form of silymarin has been shown to exert clear galactagogue effects. In a double-blind study in 50 healthy lactating women, micronized silymarin (420 mg/day) increased daily milk production by 86%, compared with 32% for the placebo. Milk quality was unaffected. The galactagogue effect may be the result of increased circulating prolactin levels.[28]

Type 2 Diabetes and Metabolic Syndrome

Given the liver's involvement in type 2 diabetes (T2D) and metabolic syndrome, silymarin is almost assuredly of benefit in these conditions. Several clinical trials have been conducted. In the most recent, 40 patients with T2D were randomly assigned to the silymarin (140 mg three times daily) or placebo groups for 45 days. Silymarin supplementation led to a significant reduction in fasting blood sugar (–11), serum insulin (–14%), the homeostatic model assessment for insulin resistance (–26%), serum triglycerides (–24%), and the ratio of triglycerides to high-density lipoprotein cholesterol (–28%) compared with the placebo. There was a significant increase in high-density lipoprotein cholesterol levels and the quantitative insulin sensitivity check index in the silymarin group compared with the placebo group, by 6.88% and 5.64% respectively. Total cholesterol and low-density lipoprotein cholesterol concentrations significantly decreased in the silymarin group

compared with the baseline, by 7.93% and 7.15%, respectively.[29] In the same study, silymarin supplementation also improved some antioxidant indices (SOD, GPX, and TAC) and decreased high-sensitive C-reactive protein (hs-CRP) levels.[30]

Silymarin may also help reduce the complications of diabetes, including nephropathy, neuropathy, healing delays, oxidative stress, hepatotoxicity, and cardiomyopathy.[31]

Silybin Bound to Phosphatidylcholine

Given the poor relative bioavailability of silymarin components, methods are being developed to increase their bioavailability to improve clinical effects. One enhanced form of silymarin binds silybin to phosphatidylcholine. Research indicates that phosphatidylcholine-bound silybin is better absorbed and produces better clinical results than other forms.

Absorption Studies

Several human and animal studies have shown that phosphatidylcholine-bound silybin is better absorbed. In one study, the excretion of silybin, the major component of silymarin, in the bile was evaluated in patients undergoing gallbladder removal (cholecystectomy). A drainage tube, the T-tube, was used to sample the bile. Patients were given either a single oral dose of the silybin-phosphatidylcholine complex or silymarin. The amount of silybin recovered in the bile in free and conjugated form within 48 hours was 11% for the silybin-phosphatidylcholine group and 3% for unmodified silybin group.[32]

One of the significant features of this study is the fact that silymarin has been shown to improve the solubility of the bile. Because more silybin is being delivered to the liver and gallbladder when the phosphatidylcholine-bound silybin is used, this form is ideal for individuals with gallstones or fatty infiltration of the liver, two conditions characterized by decreased bile solubility.

In another study, plasma silybin levels were determined after administration of single oral doses of silybin-phosphatidylcholine complex and a similar amount of silymarin to nine healthy volunteers. Although absorption was rapid with both preparations, the bioavailability of the silybin-phosphatidylcholine complex was much greater than that of silymarin, as indicated by higher plasma silybin levels at all sampling times after intake of the complex. The researchers in this study concluded that complexation with phosphatidylcholine greatly increases the oral bioavailability of silybin, probably by facilitating its passage across the gastrointestinal mucosa.[33]

Clinical Studies

Several clinical studies have shown phosphatidylcholine-bound silybin to be more effective than silymarin. In one study, eight patients with chronic viral hepatitis (three with hepatitis B, three with both hepatitis B and hepatitis C, and two with hepatitis C) were given one capsule of phosphatidylcholine-bound silybin (equivalent to 140 mg silymarin) between meals for 2 months.[34] After treatment, serum malondialdehyde levels (an indicator of lipid peroxidation) decreased by 36%, and the quantitative liver function evaluation as measured by galactose elimination capacity increased by 15%. A statistically significant reduction of liver enzymes was also seen: AST diminished by 17%, and ALT rose by 16%.

In another study designed primarily to evaluate the dose–response relationship of phosphatidylcholine-bound silybin, positive effects were again displayed.[35] In this study, patients with chronic hepatitis due to either a virus or alcohol were given different doses for 2 weeks: 20 patients received 80 mg twice daily, 20 received 120 mg twice daily, and 20 received 120 mg three times daily. At all tested doses, phosphatidylcholine-bound silybin produced remarkable and statistically significant decreases in mean serum and total bilirubin levels. When used at the dose of 240 or 360 mg/day, it also resulted in remarkable and statistically significant decreases in the liver enzymes ALT and gamma-glutamyl-transpeptidase. These results indicate that even short-term treatment of viral- or alcohol-induced hepatitis with relatively low doses of phosphatidylcholine-bound silybin can be effective; for the best results, however, higher doses are needed.

Treatment with phosphatidylcholine-bound silybin is associated with reduced body iron stores, especially among patients with the advanced fibrosis stage of chronic viral hepatitis.[36]

DOSAGE

The standard dose of milk thistle is based on its silymarin content (70–210 mg three times daily). For this reason, standardized extracts are preferred. The best results are achieved at higher dosages—210 to 700 mg of silymarin three times daily.

The dosage for silybin bound to phosphatidylcholine is 120 to 240 mg twice daily.

Alcohol-based extracts are virtually always contraindicated in liver disease because a relatively large amount of alcohol is administered to obtain an adequate dose of silymarin in this form.

TOXICITY

Silymarin preparations are widely used, with a considerable body of evidence pointing to very low toxicity. When used at high doses for short periods, silymarin given by various routes to mice, rats, rabbits, and dogs has shown no toxic effects. Studies in rats receiving silymarin for protracted periods have also demonstrated a complete lack of toxicity.[1]

Because silymarin possesses choleretic activity, it may produce a looser stool as a result of greater bile flow and secretion. If higher doses are used, it may be appropriate to use bile-sequestering fiber compounds (e.g., guar gum, pectin, psyllium, oat bran) to prevent mucosal irritation and loose stools. Because of silymarin's lack of toxicity, its long-term use is feasible when necessary.

DRUG INTERACTIONS

Although silymarin components have been shown to interact with drug-metabolizing cytochrome P_{450} enzymes in in vitro studies, the concentrations showing inhibitory effects are not achieved with normal dosage recommendations.[37] Clinical studies have shown that coadministration of silymarin with drugs metabolized by P_{450} enzymes (e.g., indinavir) causes no adverse interactions.[38,39]

Soy Isoflavones and Other Constituents

Cheryl Kos, ND

OUTLINE

INTRODUCTION

Soybeans have a history of human food use spanning millennia, particularly in Asia, where they are prepared as foods, beverages, and medicines. Epidemiological data indicating that people from Asian cultures have lower rates of breast, prostate, and colon cancer have sparked an interest in soy foods as a contributing factor. Greater dietary utilization of both soy foods and isolated soy phytonutrients has drawn attention to their benefits as well as to potential health risks for subpopulations that may be sensitive to their effects. Recent research has investigated not only individual soy constituents for their influences on hormonal and cardiometabolic parameters but is also increasingly considering the effect of whole soy foods on the human microbiome, which may have a significant effect on their biological activities.

Thousands of scientific papers have been published on soy and its components, and the National Library of Medicine's online clinical trials database typically lists hundreds of ongoing or planned studies involving soy. Although many soy constituents have been investigated, those that seem to hold the greatest therapeutic promise are the isoflavones genistein and daidzein. There is also increasing interest in equol, a human metabolite of daidzein, and the possibility that the ability to produce equol may mediate some of the effects of soy.

Research methods have evolved tremendously during the decades of research on soy, and a 2010 guidance paper from a National Institutes of Health (NIH) workshop on designing and reporting on soy intervention trials meticulously outlines methods for conducting studies that can take into account crucial factors such as differences among soy preparations and individual variations in the human response to soy as well as recommending ways to better standardize the evaluation and interpretation of results.[1] This guidance will facilitate the generation of higher-quality data to help answer remaining questions about the health effects and safety considerations of consuming soy and its bioactive constituents.

CHEMICAL COMPOSITION OF SOY

Hundreds of nutrients and phytochemicals have been identified in the soy plant, including proteins, fibers, fatty acids, isoflavones and other polyphenolic substances, phytosterols, saponins, coumestans (including coumestrol), choline, chlorophyll, resistant starch, sugars and saccharides, enzymes, enzyme inhibitors, nucleotides, minerals, vitamins and provitamins, oxalate, phytate, all essential amino acids, arginine, and many others.[2] The principal isoflavones in soy are genistein (4′,5,7-trihydroxyisoflavone) and daidzein (4′,7-dihydroxyisoflavone) (Fig. 114.1).

Isoflavones are the most abundant subcategory of isoflavonoids, which are in turn members of the greater family of flavonoids, themselves a subset of the large group of plant polyphenols (Fig. 114.2). Approximately 600 isoflavonoids have been identified and categorized. Soybeans generally provide around 1 to 3 mg of isoflavones

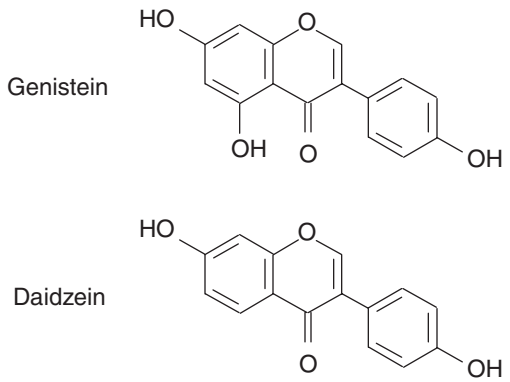

Fig. 114.1 Chemical structure of genistein and daidzein.

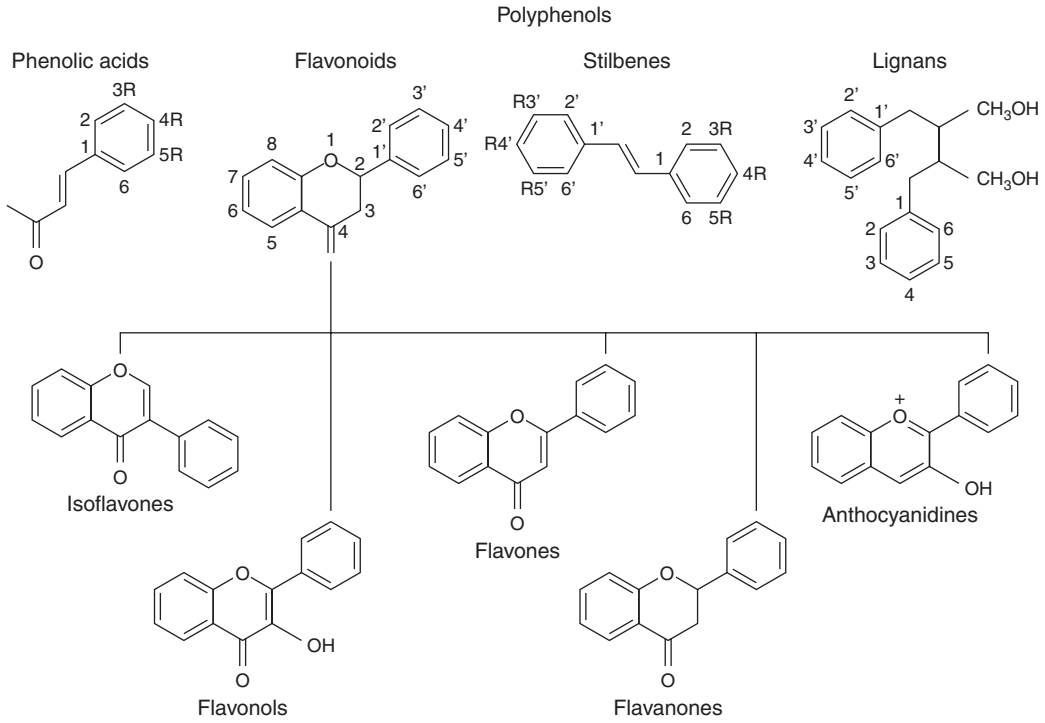

Fig. 114.2 Chemical structure of polyphenols, with emphasis on flavonoids.

TABLE 114.1 Percentage and Ratio of Principle Isoflavones in Common Soy Products

Soy Product	Isoflavone Content	Genistein:Daidzein
Whole soybeans	0.1%–0.2%	1:1
Soy flour (defatted)	0.07%–0.3%	1:1
Soy germ	5%	1:4
Synthetic genistein	100%	1:0
Soy protein isolate	0.01%–0.3%	1:1
Tofu	0.02%–0.07%	1:0.7
Soy milk	0.001%–0.02%	1:1
Miso (dry)	0.02%–0.09%	1:0.9

Data from Empie MW. Compositional specificity in soy isoflavone supplements. Soy/protein/isoflavone research: challenges in designing and evaluating intervention studies. NIH Workshop, Bethesda, MD, July 28–29, 2009.

(the aglycones genistein, daidzein, and glycitein, and their glycoside forms genistin, daidzin, and glycitin) per gram of protein, and considering all forms of each individual isoflavone, the breakdown of genistein, daidzein, and glycitein supplied by soy foods is approximately 50%, 40%, and 10%, respectively.[3] Commonly consumed soy foods are generally considered rich sources of dietary isoflavones.[4] In fermented soy foods like tempeh, miso, soy sauce, and natto, aglycone forms generally dominate, whereas glycosides are the major forms in nonfermented foods such as soy milk, soy flour, protein powders, edamame, soy nuts, and tofu, as well as in most dietary supplements.[5]

Isoflavone contents and proportions in soy foods vary according to plant parts and genetics; growing and harvesting conditions; and storage, extraction, and processing methods. The typical isoflavone contents of several soy products and their relative provisions of genistein and daidzein are given in Table 114.1. For those interested in learning the isoflavone contents of hundreds of foods and beverages, the most recent version of the U.S. Department of Agriculture (USDA) Database on the Isoflavone Content of Selected Foods is available online at https://www.ars.usda.gov/nutrientdata, under Flavonoid Databases.

The average daily intake of isoflavones among Japanese women is 20 to 80 mg, whereas that of American women is about 1 to 3 mg,[6] a manifold difference. Isoflavone intakes among various Chinese populations are estimated to range from around 10 to 40 mg daily[7] but are quite low among Europeans and Canadians, averaging less than 1 mg daily.[8,9] Among Westerners, many health-conscious consumers are eating soy foods more frequently, and in one British study, vegans and vegetarians showed the highest intakes, receiving up to 30 g soy protein and 130 mg soy isoflavones daily.[10] Patients with breast cancer at one U.S. hospital were found to have mean daily genistein and daidzein intakes of 11.6 mg and 7.4 mg, respectively—much higher than the American average.[11] Americans consume less soy than the Chinese and Japanese but tend to ingest more in dietary supplements and in processed food forms such as texturized vegetable protein and isolated soy protein, which are added to meat substitutes, breads, processed meats, and other foods. Up to 25% of formula-fed infants consume soy-based formula, and these infants can show higher isoflavone concentrations on a body-weight basis than those of adults with high soy intakes.[12]

Isolated soy protein contains all essential amino acids and has a Protein Digestibility Corrected Amino Acid Score (PDCAAS) of 1.0, the highest score possible, although other soy protein preparations may display PDCAAS scores of as low as 0.9.[13–15] Soy is considered one of the eight major food allergens, with albumin, globulin, and prolamin proteins being its primary allergenic constituents in sensitive individuals.

Other soy constituents of interest include phytosterols, saponins, protease inhibitors, and phytates. Phytosterols bind cholesterol in the gut, and although the U.S. Food and Drug Administration (FDA),[16] Health Canada,[17] and the European Union's European Food Safety Authority (EFSA)[18] have approved health claims regarding the cholesterol-lowering effects of plant sterols added to foods, naturally occurring levels in soy may be insufficient to derive such benefits. Soy

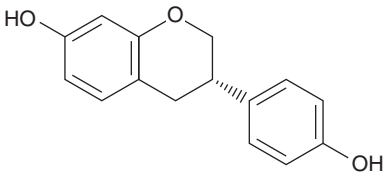

Fig. 114.3 Chemical structure of equol.

saponins may also contribute to the influence of soy foods through their anticholesterol effects.[19] Raw soybeans contain several protease inhibitors, but their inactivation during processing into soy food products makes it unlikely that they have much effect in humans. Phytates have been shown to interfere with the absorption of some minerals, yet they also display strong antioxidant and antitumor properties.[20,21]

Absorption, Metabolism, and Excretion of Isoflavones

Primary human exposure to isoflavones comes from the diet, and although other plants such as red clover (*Trifolium pratense*) and kudzu (*Pueraria lobata*) contain isoflavones, only soy foods supply physiologically relevant amounts of isoflavones in the human diet. Much evidence indicates wide individual variation in absorption and metabolism of isoflavones, which is influenced by the composition of the intestinal microbiome, liver metabolism, enterohepatic circulation, and habitual intakes of soy foods, and coingestion of prebiotic and probiotic foods may also have effect.[22,23]

Dietary soy isoflavones occur bound to sugars that are not readily absorbed and may be modified extensively in the gastrointestinal tract, although the degree of metabolism and absorption varies considerably among individuals.[24,25] Intestinal and bacterial glucosidases release genistein and daidzein from genistin and daidzin, after which they may be conjugated through sulfation or glucuronidation, dehydroxylated, reduced, or demethylated to give rise to metabolites of varying biological activity, including S-(-)equol, 5-hydroxyequol, O-desmethylangolensin, dihydrogenistein, and others. Genistein and daidzein may also circulate freely or be bound to plasma proteins and are distributed widely in body tissues.[26] Isoflavones attain maximal plasma levels 4 to 8 hours after ingestion and are excreted within 24 hours, mainly in urine but also in feces.[27] Metabolites of soy isoflavones include compounds with molecular structures similar to those of reproductive steroid hormones (Fig. 114.3).

The relative bioavailability of isoflavone glycoside and aglycone forms is debated, and numerous articles have weighed in on both sides of this question. Aglycones from soy products were absorbed more quickly and completely than glycosides in several studies,[28–31] although others have shown the converse or no difference.[32–34] Further research and survey of the evidence may reveal differences among individuals or populations that account for these seemingly conflicting findings.

A number of clinical trials in both genders in various disease states have hinted that the ability to produce the human metabolite S-(-) equol from its isoflavone precursor daidzein (through the intermediate dihydroequol) may hold unique health benefits. Franke et al. cite studies showing that about 60% of vegetarians and Asians produce equol, whereas only about 30% to 35% of omnivores do so.[35] Infants and children aged 6 to 36 months showed gradually increasing equol production in one study, particularly those receiving soy milk– or cow's milk–based formula and those not receiving antibiotics.[36] It may be useful to note that the R-(+)equol isomer is not an endogenous human form.

Setchell et al. found that S-(-)equol is a selective estrogen receptor-β agonist (with about one-fifth the affinity of estradiol)[37] and yet also noted, with interest, that it is an androgen antagonist.[38] Lampe reports that although research findings are mixed, equol production has been associated with lower breast density in response to weekly soy consumption as well as better bone protection with isoflavone intake and greater improvements in cholesterol levels and brachial artery flow-mediated vasodilation with soy germ supplementation in hypercholesterolemic subjects. Equol producers among postmenopausal women in Hong Kong had significantly higher fat-free body mass and significantly lower systolic and diastolic blood pressures, as well as lower levels of triglycerides, high-sensitivity C-reactive protein (hsCRP), and free fatty acids compared with nonproducers.[39] Miller et al. did not find a significant association between equol production status and body mass index (BMI) or obesity in peri- and postmenopausal women, although BMI and obesity related to the inability to convert daidzein into a different metabolite, O-desmethylangolensin.[40] Although genetic, dietary, and lifestyle factors relating to equol production status are still unclear, Lampe has suggested that it may correlate with lactose malabsorption.[41]

Several research groups have noted that adults also may change from nonproducer to producer status after heightened soy consumption, although not all studies concur. Franke et al. found that both post- and premenopausal women may begin to produce equol with increased isoflavone exposure.[42,43] Healthy Caucasian men with isoflavone intakes above 30 mg daily for at least 2 years were over five times likelier to produce equol than those consuming 5 mg or less daily.[44] Tanaka et al. found that after 3 months of isoflavone supplementation, healthy Japanese male nonproducers showed detectable serum equol levels.[45] Development of a recognized, validated testing method and threshold equol value or equol-to-daidzein ratio will aid future interpretation of evidence.

Early in vitro research suggests that soy isoflavones may constitute an energy substrate for the proliferation of equol-producing intestinal microbes and enhance the production of short-chain fatty acids (SCFAs); both equol and SCFAs are increasingly considered pivotal in delivering isoflavone benefits.[46] Nakatsu et al. found significant increases in fecal *Bifidobacteria* in postmenopausal women after just 1 week of consuming bars containing 160 mg soy isoflavones and 1 g saponin, particularly among equol producers; this team noted associations of *Bifidobacteria, Collinsella,* and *Lactococcus* with equol or other isoflavone metabolites, although the significance of these relationships is not yet fully understood.[47] However, consistent global changes in gut populations of major bacterial groups were not seen in menopausal equol producers or nonproducers given 80 mg isoflavones for 6 months, although equol producers showed increased counts for total microbial fecal populations, whereas overall counts in nonproducers decreased significantly. In some women, growth of phytoestrogen-metabolizing microorganisms such as *Bifidobacteria, Faecalibacterium prausnitzii,* and *Collinsella* may have been facilitated by increased exposure to isoflavones and/or their metabolites, although in several cases this appeared to depend more on the individual microbiome than metabolite producer status.[48]

PHARMACOLOGY

Soy isoflavones (and their metabolites) and other soy constituents have shown varied activities in humans, animals, tissues, and cells (Table 114.2).

Hormonal Effects of Soy

The degree to which soy foods modify endogenous hormone influences in both genders is of prime importance in evaluating their benefits, and long-term observation of populations that consume considerable amounts of soy foods may hold the most complete answers

TABLE 114.2 Activities of Soy Constituents and Metabolites

Protein Isolate	Activation of mTOR[303]
Protein with isoflavones	Cholesterol metabolism modulation
	Progesterone receptor expression modulation[304]
	Possible adiponectin raising[305]
	Possible IL-6 lowering[306]
Isoflavones	Estrogenic and antiestrogenic
	Possible FSH and LH lowering (postmenopausal)[307]
	Possible 2-hydroxyestrone raising[308]
	Estrogen receptor-β agonism[309]
	Angiogenesis inhibition[310]
	5α-reductase inhibition[311]
	Stimulation of mitochondrial biogenesis[312]
	Possible IL-6 and TNF-α lowering (perimenopausal)[313]
	Inhibit bone resorption and stimulate bone formation[314,315]
	Modulation of bone-related gene expression[316]
	Possible improved endothelial function[317]
	Upregulation of PPARα/γ, LXR, and PGC-1α expression[318–320]
	Modification of DNA methylation and other epigenetic events[321]
	Inhibition of matrix metalloproteinase production in cancer cells[322]
	Modulation of thyroid hormone production
	Antioxidant
Genistein	Progesterone receptor upregulation[323]
	Inhibition of LDL-c oxidation[324]
	COX inhibition[325]
	Antithyroglobulin (in iodine insufficiency)[326]
	Pancreatic beta cell protection[327]
	Human sirtuin 1 activation[328]
	Inhibition of cancer cell detachment and metastasis[329]
	Upregulation of *BRCA1* expression[330]
	Modulation of activities of kinases related to cancer cell cycle and apoptosis[331,332]
	Possible chemo-, radio-, and phototherapeutic synergist[333]
Daidzein	Modulation of cholesterol-related gene expression[334]
	Aldehyde dehydrogenase inhibition[335]
Equol	Estrogen receptor-β agonism and androgen antagonism[336]
	Dihydrotestosterone binding and sequestration[337]
	Inhibition of PSA expression[338]
	Substrate for SCFA production[339]
	Possible bifidogenic effects[340]
Phytosterols	Cholesterol binding[341]
	5α-reductase inhibition[342]
	Antiproliferative[343]
Coumestrol	Estrogenic/antiestrogenic[344]
Saponins	Anticholesterol[345]
Protease inhibitors	Anticarcinogenic[346]
Phytates	Possible anti–colon cancer effect[347]
	Iron chelation, antioxidant[348]

COX, Cyclooxygenase; *FSH,* follicle-stimulating hormone; *IL-6,* interleukin-6; *LDL-c,* low-density lipoprotein cholesterol; *LH,* luteinizing hormone; *LXR,* liver X receptor; *PPARα/γ,* peroxisome proliferator-activated receptor-α/γ; *PGC-1α,* peroxisome proliferator-activated receptor γ coactivator 1α; *PSA,* prostrate-specific antigen; *SCFA,* short-chain fatty acid; *TNF-α,* tumor necrosis factor-α.

to this question. The possibility that long-term or lifelong soy food use may alter the composition of the gut microbiome to induce equol production points toward greater impacts from lifestyles rather than simply "grafting" single foods like soybeans into a Westernized diet. Research is also increasingly considering genetic characteristics that interact with diet and lifestyle to change disease risk for certain subpopulations. Much evidence suggests that soy foods generally exert a mild to moderate inhibitory effect on reproductive hormones and their binding proteins in most populations and that this may explain the reduced risk for breast and prostate cancers enjoyed by people in countries consuming higher levels of soy foods.

Infants

Soy protein–based infant formula has been employed for almost a century and may comprise up to 25% of the U.S. formula market, and soy-based infant formula preparations have been approved by both

the FDA and EFSA for safe use.[49,50] However, the potential for estrogenic effects in infants given soy formula has raised long-term safety concerns.

The relative proportions of genistein, daidzein, and glycitein in soy formula are about 58% to 70%, 22% to 44%, and 4% to 16%, respectively. Infants fed soy formula show higher levels of genistein and daidzein compared with most other populations, although Asian infants consuming traditional diets and vegan infants also have relatively high levels.[51,52] A safety review and meta-analysis by Vandenplas et al. concluded that children given modern soy infant formula show growth and development patterns similar to those seen in infants fed cow's milk or breastmilk in regard to immune, neurological, reproductive, endocrine, bone, and metabolic parameters,[53] and the Arkansas Children's Nutrition Center 5-year study of the same forms of infant nutrition reached a similar conclusion.[54] A 2008 statement updating the American Academy of Pediatrics' 1998 review of soy-based infant formula found no conclusive evidence that soy formula adversely affects human development or endocrine (including thyroid) or reproductive functions but noted the following:

1. Soy formula is not recommended for use in preterm infants.
2. Soy formula is contraindicated for use in infants with hereditary fructose intolerance or sucrase-isomaltase deficiency (although it is safe in infants with galactosemia or primary lactase deficiency).
3. Soy formula is not needed by infants with lactose intolerance (as opposed to overt lactase deficiency).
4. Soy formula should not be given to infants with cow's milk enteropathy or enterocolitis due to the likelihood of cross-sensitivity.
5. The use of an extensively hydrolyzed soy protein–based formula (although not nonhydrolyzed) can be considered for infants with immunoglobulin E–mediated cow's milk allergy.[55]

Andres et al. found that 1-year-old infants given cow's milk– or soy-based formula showed no differences in mental, motor, or language development, and although breastfed infants showed slightly higher scores in some areas, all three groups scored within normal ranges.[56] Portman et al. identified a significantly increased risk for Kawasaki disease in ethnically diverse U.S. children with high intakes of total isoflavones and of genistein compared with those with low intake levels, whereas maternal intakes during pregnancy did not show a relationship with the incidence of the disease in offspring.[57]

Women

Findings among women vary considerably by life stage, lifestyle, and genetic individuality. A 2009 meta-analysis by Hooper et al. of soy's effects in 579 premenopausal, 69 perimenopausal, and 1165 postmenopausal women concluded that soy isoflavones may lower follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels and extend the menstrual cycle by about 1 day premenopausally and may nonsignificantly increase total (but not free) estradiol levels postmenopausally.[58] A randomized controlled trial (RCT) in more than 200 postmenopausal women given 80 or 120 mg isoflavones over 3 years showed no evidence of changes in endometrial thickness, estradiol or estrone sulfate levels, thyroid-stimulating hormone (TSH) levels, or incidence of adverse events compared with placebo.[59] Fuhrman et al. showed in 2009 that regular soy intake in Asian American women aged 20 to 55 is associated with increased formation of the weakly estrogenic 2-hydroxyestrone (2-OHE1) and decreased production of the more potent, more persistent, and more genotoxic 16α-hydroxyestrone (16α-OHE1) for an overall significant increase in the 2/16α-OHE1ratio.[60] Nettleton et al. found that breast cancer survivors consuming soy protein isolate with isoflavones show increased 2-OHE1 and 16α-OHE1 levels without a change in ratio, although subjects with high plasma equol levels also showed a significant increase in the 2/16α-OHE1 ratio; an interesting finding was that breast cancer survivors generally demonstrated lower baseline 2/16α-OHE1 ratios compared with controls.[61] Postmenopausal Thai women given a fermented soybean preparation providing about 60 mg isoflavones showed no change in estradiol levels but a significant increase in progesterone levels and a significant decrease in total cholesterol, and the researchers suggested that soy supplementation may induce progesterone receptor expression.[62]

A 2010 meta-analysis of eight RCTs found no effect of dietary isoflavones on breast density in women in general and postmenopausally but showed a possible modest increase in breast density (a mean of 1.83%) in premenopausal women with higher intakes,[63] although a review of 14 observational studies by Maskarinec et al. did not find an association between soy intake and mammographic density.[64]

Men

Noted soy researcher Mark Messina in 2010 found no evidence that isoflavone supplements or isoflavone-rich soy foods affect levels of estrogens or total or free testosterone in men, and that they have no effect on sperm, semen, or erectile function in men, even considering intake levels above those commonly consumed by male Asian populations.[65] Dillingham et al. observed that healthy young men supplemented with soy protein isolate with either low or high levels of isoflavones showed significantly decreased dihydrotestosterone (DHT) levels as well as DHT/testosterone ratios compared with those given milk protein isolate, and the low-isoflavone soy group also showed significantly increased dehydroepiandrosterone sulfate levels as well as smaller increases in estradiol and estrone sulfate relative to the milk protein isolate group.[66] A 2010 meta-analysis of clinical studies on the effects of soy on testosterone-related values in men found no significant influence of either soy protein or isoflavones on free androgen index or testosterone, free testosterone, or sex hormone–binding globulin (SHBG) levels, although inclusion of small and/or short-term trials may have limited the findings.[67] However, in healthy Japanese males aged 30 to 59 given 60 mg soy isoflavones daily for 3 months, levels of DHT and free testosterone decreased, whereas SHBG levels increased significantly in equol producers but not nonproducers; an intriguing finding was that serum equol levels in 2 of 10 previous nonproducers became detectable by the end of this trial.[68]

CLINICAL APPLICATIONS

Cardiovascular Disease

Soy foods are considered heart-healthy overall due to their generous contents of fiber, polyunsaturated fats, vitamins, minerals, and phytonutrients as well as their low saturated fat levels.[70] Interest in the potential role of soy protein and isoflavones to reduce risk factors associated with cardiovascular and related metabolic diseases stems from decades of human and preclinical research that formed the basis for the 1999 FDA-approved health claim for soy foods and coronary heart disease, stating that "25 g of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease."[71] In 2008 the FDA received a petition to revoke this health claim, but despite denying that petition, the FDA decided to reconsider its 1999 position and to again review the scientific evidence. Late in 2017 the FDA announced a proposal to revoke the claim, mainly due to difficulty in achieving "significant scientific agreement" among the mixed results seen among heterogeneously designed intervention studies regarding soy intake and cardiovascular outcomes.[72] The American Heart Association (AHA) has acknowledged that soy foods are beneficial for cardiovascular and overall health but concluded that the direct cholesterol-lowering effects of soy protein were of relatively little

significance.[73] On the other hand, a 2017 study of cost-effectiveness of plant sterol- or stanol-enriched foods determined that encouraging and subsidizing preventive use of such products would likely bring cost savings to healthcare systems and improve cardiovascular disease (CVD) outcomes, particularly among men and older age groups; it estimated that at only 50% compliance, 69 CVD events could be avoided per 10,000 men over 20 years.[74]

Beneficial cardiovascular effects of consuming soy foods seen in many human studies appear to be stronger when they replace (rather than merely supplement) common dietary proteins with higher saturated fat contents. Epidemiological studies in populations that commonly consume soy foods have shown that higher intakes may be inversely related to incidences of coronary events such as nonfatal myocardial infarction[75,76] and heart disease mortality,[77] although some suggest that results may be gender dependent.

In 2011 Hodis et al. found after a 3-year clinical trial that 25 g soy protein enriched with 99 mg isoflavones nonsignificantly reduced the progression of atherosclerosis (via carotid intima media thickness) in postmenopausal women and proposed that a longer exposure period may have resulted in more significant differences because changes observed between the treatment groups increased as the study progressed.[78] In two studies, higher soy intake was found to significantly correlate to reduced incidence of heart disease,[79,80] and another concluded that consumption of soy phytoestrogens might prevent the progression of coronary artery atherosclerosis in postmenopausal women.[81] A Japanese study of more than 40,000 adults aged 40 to 59 found that women consuming soy foods at least five times weekly had a relative risk for CVD mortality of about 0.31 times that of women eating soy foods two or fewer times per week; women (especially postmenopausal) with higher soy food consumption also showed significantly decreased risks for myocardial and cerebral infarction in this study.[82] However, a 2015 nested case-control study in postmenopausal Chinese women aged 40 to 70 who had never used hormone replacement therapy found that a high intake of soy isoflavones was modestly yet significantly associated with increased risk for ischemic stroke; from the lowest to highest consumption levels, the relative risk ranged from 1.0 to 1.24 compared with baseline, yet no relation was found between urinary isoflavone metabolite excretion and risk.[83] A 2014 study in Singaporean Chinese adults did not find significant associations between soy protein intake and cardiovascular mortality or isoflavone intake and death from coronary heart disease.[84]

Cholesterol Metabolism

An enormous amount of research has examined the influences of soy on cholesterol metabolism. Despite broad variety in soy preparations and great heterogeneity among study designs, a fairly consistent result has been that regular intake of soy foods, especially in place of more common animal protein sources, leads to modest yet meaningful cholesterol reductions in hypercholesterolemic individuals. Soy's main mechanisms of action for this appear to be interfering with cholesterol absorption, increasing fecal bile acid excretion, and upregulating low-density lipoprotein (LDL) receptor expression.

A 2008 meta-analysis evaluating the provision of 25 grams of soy protein daily concluded that it resulted in a small but significant 6% decrease in total and LDL cholesterol levels in normocholesterolemic and hypercholesterolemic adults.[85] A large meta-analysis by Anderson et al. comparing soy and animal protein diets found a significant 12.9% decrease in serum lipids with soy protein, especially in subjects with hypercholesterolemia.[86] More recent meta-analyses show consistent LDL lowering with soy protein but at a more modest average reduction of 3% at a daily intake of about 50 grams.[87,88] A 2007 meta-analysis of soy isoflavones by Taku et al. found that they significantly reduced total and LDL cholesterol levels, with larger changes in hypercholesterolemic subjects,[89] and a meta-analysis of soy protein containing isoflavones by Zhan et al. arrived at a similar conclusion.[90]

Individual studies can provide detailed insights. Jenkins et al. found that hyperlipidemic men and women receiving soy protein with isoflavones in addition to National Cholesterol Education Program (NCEP) Step II diets showed significantly lower total cholesterol, estimated coronary artery disease (CAD) risk, total/high-density lipoprotein (HDL) ratio, LDL/HDL ratio, and apolipoprotein B/A-1 ratio than those using the Step II diet alone; LDL cholesterol, apolipoprotein B, homocysteine, and oxidized LDL levels were also lower with soy than during the Step II diet alone. This study also demonstrated that men receiving soy showed a significant decrease in systolic blood pressure compared with the Step II diet alone and that during high-isoflavone intakes, LDL cholesterol and apolipoprotein B levels were lower than during the Step II diet alone.[91] In a study of a similar design by Baum et al., hypercholesterolemic postmenopausal women receiving soy protein and isoflavones in addition to NCEP Step I diets showed a greater decrease in non-HDL cholesterol than those receiving Step I diets alone, and those receiving soy protein and isoflavones also showed increases in HDL cholesterol as well as in LDL receptor RNA levels compared with decreases in both measures in those receiving Step I diets alone.[92] Those with type 2 diabetes receiving soy protein isolate showed reduced LDL cholesterol, LDL/HDL cholesterol ratio, and apolipoprotein B/A-1 ratio compared with those receiving milk protein isolate.[93] In 2012, Wong et al. found that although soy foods reduced LDL cholesterol levels equally in hyperlipidemic equol producers and nonproducers, equol producers maintained higher HDL levels than nonproducers.[94] In postmenopausal women, Allen et al. found that those receiving soy protein containing isoflavones rather than casein showed significant reductions in total and LDL cholesterol levels as well as in LDL particle number.[95] Puska et al. found that hypercholesterolemic subjects receiving soy protein plus isoflavones and fiber showed significant decreases in total and LDL cholesterol levels compared with controls, and the soy group also showed a significant decrease in homocysteine levels, whereas controls showed an increase.[96] In a study of healthy U.S. adults, those receiving soy protein showed significantly better improvement in HDL cholesterol levels and HDL/total cholesterol ratios compared with subjects given milk protein.[97] Chinese equol-producing postmenopausal women receiving 40 g soy flour showed significant reductions in LDL cholesterol and hs-CRP compared with subjects receiving either milk powder plus 63 mg daidzein or milk powder alone.[98]

The results of a 2010 study by Wong et al. suggest that soy foods' potential benefits to lipid profiles may be significantly improved by combination with a prebiotic like inulin. Hyperlipidemic men and women given 30 g soy protein, 61 mg soy isoflavones, and 10 g oligofructose-enriched inulin showed significant improvements in measures of LDL and HDL cholesterol compared with either soy or prebiotic alone.[99]

Although the Japanese Ministry of Health, Labor and Welfare has approved the use of cholesterol-lowering claims on certain soy products in Japan, the EFSA does not allow such claims on EU food products.

Blood Pressure

Soy protein and/or isoflavones may also have modest effects on blood pressure (BP), although research results have been mixed. Considerable heterogeneity in study design, as well as dosage and form of soy used, may interfere with the interpretation of overall study results, and adequately powered studies comparing the effects of different soy preparations could provide further clarification.

Healthy 50- to 75-year-old men and postmenopausal women receiving 40 g soy protein with 118 mg isoflavones versus casein showed significant reductions in BP.[100] Soy milk consumption for 3 months has also lowered mean, systolic, and diastolic BP values in hypertensive men and women compared with those receiving cow's milk; urinary genistein levels correlated significantly with decreases in BP.[101] Sagara et al. found that middle-aged men with elevated total cholesterol and/or BP levels receiving soy protein plus soy isoflavones showed significant reductions in systolic and diastolic BP, total cholesterol, and non-HDL cholesterol levels compared with active placebo, and they also showed significant increases in HDL-cholesterol.[102] Soy protein has been shown to lower BP in perimenopausal women, and soy protein with dietary fiber may reduce BP in both men and women.[103,104] Not all studies agree, though, and both the Agency for Health Research and Quality (which evaluates evidence presented for FDA health claims) and the AHA have concluded that neither soy protein nor isoflavones have hypotensive effects.[105,106] However, an interesting 2017 study of Japanese adults aged 40 to 69 found that fermented (but not unfermented) soy product intake was inversely associated with the development of hypertension, with an odds ratio of 0.72 in the highest tertile of intake.[107] A 12-month RCT in postmenopausal women aged 60 to 75 found that among those receiving soy protein containing 99 mg isoflavones, systolic and diastolic BP decreased in equol producers and increased in nonproducers compared with subjects receiving milk protein.[108]

Cardiometabolic Disease Factors

Studies exploring soy foods and cardiometabolic outcomes are increasingly examining soy constituents' mechanisms of action beyond cholesterol-lowering, looking more closely at their influences on macronutrient metabolism, endothelial function, and inflammatory markers.

A 2017 review by Ramdath et al. found that soy isoflavones and their metabolites appear to improve blood pressure, glycemic control, obesity, and inflammation and may act in synergy with soy protein and other constituents to modulate plasma lipids as well as satiety.[109] Another 2017 systematic review by Chalvon-Demersay et al. found evidence that consuming soy protein associated with isoflavones in place of more common animal proteins may help prevent the onset of risk factors associated with cardiovascular conditions and metabolic syndrome, such as hypertension and hypercholesterolemia.[110] A 2010 meta-analysis of isoflavones in postmenopausal women found that daily intake levels of about 50 to 100 mg markedly improved endothelial function in subjects with impairment,[111] and a 2015 crossover RCT showed that adults at cardiometabolic risk consuming soy nuts providing 101 mg total isoflavones daily for 1 month displayed significantly improved arterial stiffness as measured by peripheral arterial tonometry.[112] In middle-aged and older Chinese women, higher soy food intake is inversely associated with levels of tumor necrosis factor (TNF)-α and interleukin (IL)-6, proinflammatory markers for metabolic and cardiovascular risk.[113]

Body Composition, Weight, and Glucose Metabolism

In studies relating to energy metabolism and weight, soy protein and isoflavones have displayed a number of intriguing properties that could potentially aid in the maintenance of glycemic control, weight, and body composition, perhaps especially during aging. This growing evidence represents an exciting opportunity for populations challenged by dysglycemia, weight concerns, and excess adiposity. As detailed in this section, soy has shown effects on peroxisome proliferator-activated receptors (PPARs), sirtuins, mTOR, and other cellular targets, which suggests complementary and even synergistic effects of soy on these energy-sensing and metabolism-altering pathways.

A review of clinical and preclinical evidence found that higher intakes of soy isoflavones may inhibit enlargement of adipose tissue through modifying signaling in pathways relating to fatty-acid and glucose metabolism, although some of these effects may be mediated by equol production.[114] Soy protein has been shown to spare muscle mass in overweight and obese subjects losing weight,[115] and subjects receiving a diet high in soy protein demonstrated improved glycemic control and lipid profiles.[116] A randomized, controlled weight-loss study of soy milk–based meal replacements (MRs) versus cow's milk–based MRs found that soy milk MRs resulted in slightly greater weight loss and significant reductions in serum triglyceride levels compared with cow's milk MRs.[117] A 12-week study conducted by Charles et al. in healthy postmenopausal women found that daily consumption of 20 grams of soy protein containing 160 mg total soy isoflavones significantly increased levels of adiponectin (an adipokine hormone considered to have anti-inflammatory and antiatherogenic properties), whereas those receiving soy protein without isoflavones showed significant improvements in levels of the proinflammatory marker TNF-α.[118] Another study using the same 20 g soy protein plus 160 mg isoflavones daily dosing versus casein protein in normal or overweight postmenopausal women found that the soy combination reduced total and subcutaneous abdominal fat, whereas casein increased both measures, with a significant difference between treatments.[119] A third study, again using the same dosing, in obese African American and white postmenopausal women found that compared with casein, soy reduced total or abdominal fat (in African American and white women, respectively) and significantly lowered levels of IL-6, increasingly considered a biomarker for cardiovascular risk.[120] Overweight Chinese adults receiving a low-calorie diet based on soy protein showed significantly greater reductions in body fat, total cholesterol, and LDL cholesterol and on liver function tests compared with subjects receiving a low-calorie diet based on traditional protein sources; both groups experienced significant drops in weight, waist circumference, and body mass index (BMI).[121] A 12-week trial of soy nuts or texturized soy protein in older women with metabolic syndrome found that either type of soy food mildly improved overall body composition and lipid profile compared with controls.[122,123] Perimenopausal women receiving 40 g soy protein plus 80 mg isoflavones showed significantly increased hip lean tissue and reduced thigh fat over 24 weeks compared with those receiving low-isoflavone soy protein and whey protein.[124] In postmenopausal women, genistein supplementation significantly decreased fasting glucose, fasting insulin, and fibrinogen levels as well as HOMA-IR values.[125] Women with polycystic ovary syndrome (PCOS) given 50 mg isoflavones daily for 12 weeks showed significant improvements in markers of insulin resistance and oxidative stress as well as significant reductions in free androgen index and triglyceride levels compared with controls.[126]

It is worthwhile to note that soybeans have a low glycemic index of about 14 to 20 (against glucose) or 20 to 29 (against white bread) as well as a low glycemic load.[127] Asian women consuming higher levels of soy foods display lower risks for type 2 diabetes,[128,129] and a 2011 meta-analysis by Liu et al. found that consumption of whole soy foods was associated with significantly reduced fasting glucose concentrations.[130] Soy protein with high isoflavone content lowers fasting insulin, hemoglobin A1c, insulin resistance, and LDL cholesterol levels in postmenopausal women with type 2 diabetes, and postmenopausal women with higher intakes of genistein seem to have lower BMIs, waist circumferences, and fasting insulin levels than those with lower intakes.[131,132]

Proposed mechanisms for soy's effects on weight, body composition, and glycemic control include increased beta-oxidation of fatty acids; slowing gastric emptying; activation of mTOR to aid skeletal

muscle anabolic processes[133]; improving glucose transport; increasing tissue insulin sensitivity; improving insulin receptor affinity; upregulation of PPARα,[134] PPARγ/PGC-1α,[135] and LXR expression[136]; stimulation of adiponectin; and inhibition of hepatic fatty acid synthesis, among others.[137] In animals fed a high-fat Western diet, those given soy protein isolate developed less insulin resistance, hypercholesterolemia, and hepatosteatosis compared with those given casein.[138] In rats fed a high-sucrose diet, soy protein reversed the resulting hepatosteatosis, normalized glucose homeostasis and skeletal muscle glucose oxidation, improved insulin sensitivity, and limited weight and visceral fat gain.[139] Genistein has displayed protective effects on pancreatic beta cells, improvement of insulin and glucose metabolism, improvement of endothelial function, and reduction of leptin levels, and it may also potentiate insulin secretion; these effects may account for some of the reduced risk for type 2 diabetes and beneficial effects on insulin and glucose metabolism observed in humans consuming soy or soy components.[140–144]

Early research suggests that soy or its components may indirectly and/or directly activate or upregulate human sirtuin 1, although the significance of these findings is not yet known.[145–147] Sirtuins are NAD-dependent enzymes involved in genomic stability, cell cycles, gene transcription, and glucose and lipid metabolism[148] and may be implicated in the benefits of full-nutrition caloric restriction.

Cancer

The first clue that soy might convey protection from cancer came from epidemiological studies of Asian cultures with high soy food intakes showing lower rates of several types of cancers. In an important 1994 review, Messina et al. identified 10 studies demonstrating that nonfermented soy products were associated with decreased risks for breast, prostate, lung, stomach, colon, and rectal cancers, although results were mixed for fermented soy foods, which showed positive relationships to esophageal, stomach, pancreatic, and colorectal cancers in some studies.[149]

Breast Cancer

Breast cancer occurs in Chinese women at one-third to one-half the rate seen in Caucasian women, and evidence suggests that dietary and lifestyle factors, including lifelong soy intakes, outweigh genetic factors in this difference.[150] Because breast tumor tissue may elaborate much higher concentrations of 17β-estradiol, especially in postmenopausal women,[151] and the estrogen-modulating effects of soy isoflavones may be useful for them, thorough evaluation of individual variations in metabolism, genetics, and receptor sensitivity is advisable.

In a 2011 meta-analysis of prospective studies on soy isoflavone intake and breast cancer risk, Dong et al. found a protective effect of soy for both the incidence and recurrence of breast cancer in Asian populations.[152] Trock et al. conducted a meta-analysis of soy protein intake and breast cancer risk and found a modest but significant risk reduction (odds ratio of 0.86) at high intake levels, with stronger effects in premenopausal women.[153] Examining a wider range of studies, Qin et al. also found a relative breast cancer risk of 0.75 among those with higher soy food intakes, with isoflavone intakes contributing to this effect.[154] A 2013 study of Japanese women showed lower breast cancer risk among postmenopausal (although not premenopausal) women with moderate or higher soy intakes,[155] and a 2014 systematic review of studies in Japanese women reached an analogous conclusion.[156] A 2011 study among Chinese women found that soy isoflavone and protein intakes decreased overall breast cancer risk, with the strongest associations in postmenopausal women and for estrogen- and progesterone-receptor positive breast cancer,[157] and a 2010 study among Korean women had similar findings.[158] In a multiethnic U.S. population with considerably lower isoflavone intakes than in Asian populations, no significant relationships were seen between isoflavones and overall breast cancer risk, although the data suggested that subpopulations with higher intakes may enjoy greater protection[159]; among those later diagnosed, prediagnostic soy intake was not related to breast cancer mortality.[160] In an RCT of U.S. women with increased breast cancer risk, Khan et al. found that soy isoflavones altered the activities of genes related to proliferation, apoptosis, and estrogenic effect, yet the researchers did not observe either positive or negative effects on breast epithelial cell proliferation over 6 months.[161] A 2013 systematic review of isoflavones concluded that soy intakes comparable to those among the Japanese (providing ~25–50 mg isoflavones daily) may protect against the incidence and recurrence of breast cancer as well as mortality.[162] Although most studies have found more postmenopausal benefits relating to soy and breast cancer, studies in Shanghai and Guangzhou have also uncovered evidence for reduced premenopausal breast cancer risk at higher intakes of soy isoflavones and protein; the Guangzhou study also noted protective effects for all subtypes of estrogen- and progesterone-receptor status.[163,164] A few studies also suggest an inverse relationship between exposure to soy and/or its constituents during childhood or adolescence and future breast cancer risk.[165–167]

A 2012 pooled analysis of 9514 breast cancer survivors in the United States and China found that intakes of at least 10 mg isoflavones daily were associated with significantly reduced risk of breast cancer recurrence and nonsignificantly reduced risks for breast cancer–specific and all-cause mortalities.[168] Two studies included in this analysis found especially strong protection among tamoxifen users, thus contributing to the evidence that isoflavones may not interfere with this important therapy.[169,170] Women with invasive breast cancer or ductal carcinoma in situ aged 30 to 75 receiving 50 mg soy isoflavones for 12 months showed no significant changes in breast mammographic density or magnetic resonance imaging (MRI) fibroglandular tissue density.[171] Kang et al. found that postmenopausal patients with breast cancer with estrogen- and progesterone-receptor–positive disease and high isoflavone intakes receiving tamoxifen or anastrozole had a significantly reduced risk for recurrence compared with those with lower intakes, although such associations were not seen in premenopausal patients.[172] A U.S. study of postmenopausal women with abnormal mammograms found no association between equol production and breast pathology but also noted that isoflavone intakes among these women were quite low (mean value 0.3 mg), which likely precluded findings.[173]

The intestinal milieu may play an important role in the effects of soy foods on breast cancer risk. In a very interesting 2013 study conducted by Toi et al., regular consumption of both soy isoflavones and the probiotic *Lactobacillus casei* Shirota showed a significant dose-dependent reduction in breast cancer risk, with relative risk decreasing from 0.76 to 0.48 through the second to fourth quartiles of intake[174]; this probiotic strain may help convert soy isoflavone glycosides into their aglycone forms and beneficially influence the microbiota in which isoflavone metabolism takes place.[175]

Soy may also modulate breast cancer recurrence or mortality. Among Korean women with breast cancer, Woo et al. noted in 2012 that although isoflavone intake was inversely associated with recurrence in HER2-negative patients, among HER2-positive patients, high isoflavone intake increased recurrence risk.[176] Single-nucleotide polymorphisms (SNPs) in genes coding for the growth hormone insulin-like growth factor (IGF) and its binding proteins may affect the risk for breast cancer. In 2016 Wang et al. found that one such polymorphism combined with being either overweight or underweight and having a low isoflavone intake could virtually double breast cancer risk in general Chinese female populations as well as postmenopausal women.[177] Another Chinese study also found that higher soy intake interacted

with another IGF-related polymorphism to significantly reduce IGF-1 levels, which, when elevated, increase breast cancer risk.[178] Soy intake may also interact with genetic variation in SNPs for PPARγ; Lee et al. found one that, combined with high soy consumption, was associated with reduced mammographic density compared with low soy consumption, with a decrease of almost 4% in density per copy of the allele in the highest quartile of intake.[179] Other relationships among breast cancer risk, soy intake, and SNPs are being discovered as well.[180,181]

Prostate Cancer

The incidence of prostate cancer is much lower in Japan than in Western nations; however, among Japanese migrants to areas where a Western diet is consumed, prostate cancer rates are six times higher than in their native population.[183] High soy intake among Japanese men is thought to contribute to these findings.

A comprehensive 2018 meta-analysis of 30 studies examining the relationship between soy and prostate cancer concluded that total soy food intake, as well as genistein, daidzein, and unfermented soy food intakes, are associated with a significantly reduced risk for prostate cancer; it further clarified that circulating isoflavone levels were not related to advanced prostate cancer risk.[182]

A 2014 meta-analysis by van Die et al. found modest support for soy and soy isoflavones in reducing prostate cancer risk, and although the researchers concluded that soy and isoflavone supplementation displayed a good safety profile, they noted that soy's effects on prostate-specific antigen (PSA), testosterone, and SHBG levels were not clear.[184] Two 2009 meta-analyses also cautiously concluded that higher soy food intakes reduced prostate cancer risk.[185,186] In 2012 Miyanaga et al. found that Japanese men aged 50 to 75 with PSA levels of 2.5 to 10 ng/mL receiving 60 mg soy isoflavones daily showed a nonsignificant reduction in the risk of prostate cancer compared with placebo, but significantly reduced risk was seen in subjects aged 65 or older; the relatively low incidence of prostate cancer among Japanese men may have precluded significant overall results.[187] In 2015 Wu et al. found that patients with prostate cancer in China had significantly lower median genistein levels in plasma compared with nonprostate cancer patients, suggesting that genistein intake may potentially contribute to the low incidence of prostate cancer in China.[188] In a 2008 Japanese nested case-control study by Kurahashi et al. of men at least 40 years old, higher levels of genistein and equol were dose-dependently associated with significantly reduced risk for total and localized prostate cancer,[189] and similar results were seen in an earlier study by Ozasa et al.[190] In examining diet and lifestyle effects on prostate cancer risk, Leitzmann and Rohrmann concluded that the lack of risk reduction seen in Western countries was due to Western soy intakes not being high enough to produce comparable inverse associations.[191] The 2009 European Prospective Investigation into Cancer and Nutrition (EPIC) study did, however, find a significant inverse relationship between plasma genistein concentrations and prostate cancer risk.[192] A 2013 systematic review suggests that equol producers may have significantly less risk for developing prostate cancer[193]; in rats, equol binds dihydrotestosterone and prevents it from interacting with the androgen receptor.[194]

A 2004 Australian study in men with prostate cancer given bread made with soy grits found that the soy bread lowered total PSA levels and increased the free/total PSA ratio compared with wheat bread.[195] A 2013 multicenter RCT of the effects of 20 g soy protein with 160 mg isoflavones on hot flashes in men with prostate cancer found no effect, although several quality-of-life scores significantly improved over the 12-week study.[196]

Soy intake may also interact with SNPs relating to estrogen and aromatic hydrocarbon metabolism to modify prostate cancer risk. Sonoda et al. discovered a CYP1A1 polymorphism associated with reduced prostate cancer risk despite soy isoflavone intake under 60 mg daily, but a different polymorphism at the same location in combination with an estrogen-receptor SNP may connote high prostate cancer risk even at higher isoflavone intakes.[197]

Other Cancers

Dietary intakes of soy and its components have also generally been associated with reduced risk for other cancers, although the potential for estrogen-modulating effects to contribute to hepatocellular carcinoma risk in women should be noted.

A 2016 meta-analysis of 22 case-control and 18 cohort studies relating soy intakes and gastrointestinal (GI) cancers found small reductions in combined GI cancers as well as colon and colorectal cancers in pooled analysis, whereas subgroup analysis for isoflavones found stronger protective associations with higher intake levels.[198] A case-control study by Shin et al. concluded that compared with lower isoflavone intakes, Korean men and women in the highest quartile showed a reduced risk for colorectal cancer. Stronger relations between soy food intake were found for postmenopausal women, distal colon cancer in men, and rectal cancer in women, but high intake of fermented soy paste was associated with an elevated risk of colorectal cancer in men.[199] In a Chinese population, data trended toward protective effects of nonfermented soy foods on gastric cancer, although overall findings did not reach significance,[200] but an earlier study found that soy foods may reduce colorectal cancer risk in postmenopausal women.[201] A study in a Japanese population found that high intake of soy, especially nonfermented forms, was associated with significantly reduced risk for stomach cancer, which occurs with a higher incidence in Japan than in Western regions.[202] Although an earlier Japanese study in an older population did not reach this same conclusion, it uncovered a trend toward increased gastric cancer risk among women with high isoflavone intakes taking exogenous female hormones.[203] A 2008 study of Japanese men and women aged 45 to 74 found no substantial effect of soy foods and isoflavones on overall colorectal cancer risk, although proximal colon cancer risk in men was inversely related to soy and isoflavone intakes.[204] Among Dutch men aged 40 to 75 at increased risk for colorectal cancer, Vrieling et al. noted that equol producers receiving 84 mg of isoflavones showed an inverse association between serum equol level and that of IGF-1,[203] which is positively linked to increased risk for colorectal and other cancers.

In a multiethnic population of postmenopausal U.S. women aged 45 to 75, higher isoflavone intakes were associated with reduced risk for endometrial cancer,[206] although analogous findings for isoflavones from traditional soy foods were not seen in a Japanese study of women of similar age, which may be partially attributable to the low incidence of this disease in Japan.[207] A 3-year RCT of soy protein with isoflavones in postmenopausal women in the United States found no significant influence on endometrial thickness or incidences of endometrial cancer or hyperplasia,[208] although results of an earlier case-control study suggest that total isoflavone intake may reduce endometrial cancer risk among lean women.[209] A 2014 meta-analysis and a 2011 case-control study have found some evidence that soy foods or isoflavones may reduce the risk for ovarian cancer,[210,211] but a prospective Swedish study showed no significant relationship between soy foods and ovarian cancer risk at any age.[212]

A 2013 meta-analysis showed a borderline inverse association between soy protein intake and the risk for lung cancer, which was significant in nonsmokers.[213] Yang et al. found a significant inverse relationship between soy food intake and the risk for lung cancer (particularly aggressive forms) in Chinese women (especially nonsmokers),[214] and the same research team also demonstrated significant soy

food and isoflavone protection from lung cancer mortality in women with lung cancer, which was stronger among never-smokers.[215] Other studies have shown that estrogen therapy increased the incidence of and mortality from lung cancer,[216] whereas tamoxifen reduced lung cancer deaths in patients with breast cancer,[217] supporting an estrogenic link to lung cancer etiology.

In 2009 Kurahashi et al. identified a dose-dependent positive association between genistein and daidzein intakes in women (but not in men) and the risk for hepatocellular carcinoma (HCC). Natto and tofu consumption showed the strongest associations among soy food types, and the relationship was also seen in women positive for either or both hepatitis virus B (HBV) and hepatitis virus C (HCV); the authors suggested, based on previous research in Asian populations, that estrogen may play a protective role against HCC.[218]

A distinctive 2003 study by Haselkorn et al. showed an inverse relationship between soy isoflavone intake and the risk for thyroid cancer in Southeast Asian women living in the United States, although contributions from other factors were also important.[219] Genistein has shown in vitro synergy with photodynamic therapy used to induce apoptosis in thyroid cancer cells.[220]

One accepted mechanism by which soy isoflavones modulate the risk for hormone-related conditions is by competing with endogenous estrogens for estrogen receptor binding while providing a fraction of the hormonal influence of estrogen, thereby modulating estrogen's stronger influences on cell growth and proliferation; isoflavones are estimated to have about 1/1000th the potency of estradiol activation at estrogen receptor (ER)-α and around one third of estrogen's potency at ERβ.[221] Direct chemopreventive and antiproliferative mechanisms of action for soy components and metabolites have also been investigated, including inhibition of angiogenesis[222]; antagonism of steroid hormone and growth factor signaling pathways; modulation of prostaglandin metabolism; dihydrotestosterone binding and sequestration[223]; modification of DNA methylation and other epigenetic events[224,225]; encouraging cell differentiation; inhibiting matrix metalloprotease (MMP) production and related cancer cell detachment, invasion, and metastasis[226,227]; DNA repair; upregulation of *BRCA1* expression[228]; inhibiting androgen receptor and PSA expression[229]; inhibition of nuclear factor (NF)-κB pathway activation, DNA topoisomerase,[230] and 5α-reductase[231]; antioxidative effects; and influencing a variety of kinases related to cell cycles, cellular energy production, and apoptosis.[232–234] Fan et al. found that genistein may inhibit breast cancer cell proliferation and encourage apoptosis in these cells by inhibiting stem cell activation and early tissue development.[235] Genistein, soy isoflavones, and equol have been shown to modulate aromatase activity both positively and negatively in laboratory work, and although there is little clinical evidence to confirm how soy influences aromatase in humans, genistein could potentially interact with drugs used to inhibit aromatase.[236–240] Genistein may also enhance the activities of other chemo-, photo-, and radiotherapies, although the specificity and extent of these effects are not fully understood.[241]

Menopausal Symptoms

The observation that Japanese women experience around one-tenth the incidence of vasomotor symptoms in menopause compared with women consuming Western diets led to great interest in causative factors, including phytoestrogens such as those in soy.[242] More recent research has focused on soy isoflavones and on the daidzein metabolite equol. Considering the risks associated with hormone replacement, soy foods and their ingredients may present a reasonable alternative to many women.

In a 2016 crossover RCT by Tranche et al., postmenopausal women with menopausal symptoms receiving 15 g soy protein with 50 mg isoflavones showed significant reductions in climacteric and urogenital symptoms and significantly improved health-related quality-of-life scores on the Menopause Rating Scale compared with controls.[243] A 2012 meta-analysis by Taku et al. found that soy isoflavone supplementation (generally more than 50 mg daily) decreased the frequency and severity of menopausal hot flashes by 20.62% and 20.19% over placebo, respectively,[244] and a 2014 review of clinical trials of isoflavones for menopausal symptoms came to a similar conclusion.[245] Postmenopausal Brazilian women receiving 60 mg soy isoflavones daily showed significant reductions in hot flashes compared with placebo as well as increased estradiol and HDL levels, reduced LDL levels, and no changes in vaginal cytology.[246]

S-Equol has been commercially produced using a human strain of *Lactococcus* on soy germ, and Japanese nonequol producers with menopausal symptoms receiving 10 mg of this S-equol preparation experienced fewer and less severe hot flashes and less neck and shoulder stiffness and showed trends toward the improvement of other symptoms as well.[247] A 2015 study of perimenopausal women found that about 35% produced equol, and that among equol producers, those in the highest quartile of daidzein intake were 76% less likely to have vasomotor symptoms than those in the lowest quartile, whereas there was no association between daidzein and vasomotor symptoms in nonproducers.[248] An earlier study employing S-equol for menopausal symptoms found that in nonproducers, supplementing 30 mg S-equol significantly decreased all symptom scores except for depression, whereas overall results in producers and nonproducers showed significant improvements in measures of depression, tension/anxiety, fatigue, and vigor.[249]

A 2017 cross-sectional study of breast cancer survivors found that the highest soy food intake correlated with halving of menopausal symptoms and fatigue[250]; however, in a study of Chinese women aged 20 to 75 being treated for breast cancer, higher soy food intake was not found to reduce menopausal symptoms and was associated with an increased number of hot flashes in premenopausal patients.[251]

Osteoporosis

A considerable body of research has been devoted to investigating the impact of isoflavones with or without soy protein on measures of bone mineral density (BMD), bone formation, and bone resorption.

Several meta-analyses and RCTs in peri- and postmenopausal women have concluded that soy isoflavones (with or without soy protein) can attenuate spinal bone loss (especially lumbar), decrease levels of bone resorption markers, and/or increase levels of bone formation in these at-risk populations.[252–258] A 2010 meta-analysis of isoflavones including 1240 menopausal women indicated that an average intake of 82 mg soy isoflavones significantly increased spinal BMD by 22.25 mg/cm (2.38%) over 6 to 12 months compared with controls, although similar results were not found at the hip.[259] A 2009 randomized crossover trial in postmenopausal women found that isoflavones from soy suppressed net bone resorption, although to a lesser extent than 5 mg risedronate or 1 mg estradiol plus 2.5 mg medroxyprogesterone. The researchers noted that serum genistein levels reflected antiresorptive effects, whereas those of daidzein, equol, and O-desmethylangolensin did not.[260] A 2-year multicenter trial of 120 mg soy isoflavones in menopausal women found reduced whole-body bone loss yet not at the hip or lumbar spine; other evidence suggested that higher genistein delivery may have contributed to isoflavone effects previously seen in the lumbar spine.[261] This contrasts the 2015 conclusion of Pawlowski et al. that mixed isoflavones were more effective than a genistein-rich isoflavone preparation in increasing bone calcium retention in postmenopausal women. In this randomized trial, equol production status did not alter the effects.[262] A review of 15 clinical trials by Messina

et al. reported that although clinical data indicate daily intake of approximately 80 mg isoflavones is needed to derive skeletal benefits, epidemiological evidence suggests that lower amounts may also be efficacious.[263] Sathyapalan et al. showed that women experiencing early menopause and receiving 15 g soy protein with 66 mg isoflavones daily for 6 months showed significant reductions in a marker of bone resorption as well as reductions in fasting insulin and glucose, insulin resistance, and systolic blood pressure, whereas no changes in insulin resistance or blood pressure were seen in women receiving soy protein alone.[264] The same research team provided this treatment to men with type 2 diabetes with hypogonadism and found that it also significantly reduced the same marker of bone resorption in this population and that the drop correlated positively with reductions in Hb A_{1c} levels and HOMA-IR scores.[265] In pre- or early menopausal Chinese women, Chi et al. noted that 90 mg isoflavones daily increased tibial bone density, reduced menopause-related symptom scores, and lowered levels of alkaline phosphatase, IL-6, and TNF-α.[266] In Taiwanese women in early postmenopause (a particularly susceptible period), 100 mg isoflavones significantly increased lumbar and femoral neck BMD after 1 year of supplementation.[267] In breast cancer survivors, however, soy isoflavone intakes over ~62 mg daily have been associated with lower proximal forearm BMD, especially early in menopause.[268]

The evidence thus points to isoflavones as the soy component responsible for the beneficial bone effects observed.[269] They may act by binding estrogen receptors, regulating estrogen receptor gene expression, increasing serum osteocalcin levels, influencing alkaline phosphatase activity, increasing insulin-like growth factor transcription in bone, decreasing TNF-α levels, and modulating gene expression of bone-related genes, among other mechanisms.[270] In vitro research by Tadaishi et al. suggests that carotenoids such as beta-carotene, lutein, and zeaxanthin may cooperate with soy isoflavones in suppressing the formation of osteoclasts and thereby reducing bone resorption.[271] It may be interesting to note that although soy milk contains oxalate and phytate, which are known to inhibit calcium absorption, these compounds did not negatively affect the uptake of this mineral from calcium-fortified soy milk in women.[272]

Cognitive Function

Despite modest positive trial results in the early 2000s,[273–275] more recent direct evidence for cognitive benefit from soy and isoflavones is lacking. However, the indirect effects of soy constituents on estrogen and energy metabolism, cardiovascular function, and redox homeostasis may contribute to overall cognitive health.

A 2015 meta-analysis of lifestyle contributions to cognitive decline concluded that soy isoflavones may improve memory without affecting global cognition.[276] The largest and longest trial in this analysis found improvements in measures of visual memory,[277] although further analysis found an inverse association between urinary isoflavonoids and general intelligence test scores.[278] Healthy men receiving 116 mg isoflavones daily showed improvements in measures of spatial working memory.[279] Postmenopausal women in the United States receiving 20 g soy protein with 160 mg isoflavones for 12 weeks showed no significant change in cognition.[280] Follow-up analyses on data collected in the Women's Health Initiative and its Memory Study found evidence of a positive effect on cognitive function from isoflavones, although not all studies concurred.[281] Two 2007 studies found no cognitive changes in postmenopausal women after isoflavone supplementation.[282,283] A notable recent finding is that, among older Japanese, equol production has been identified as an independent risk factor for mild cognitive impairment (MCI).[284] Men and women with Alzheimer's disease receiving 100 mg isoflavones daily for 6 months showed no changes in cognition compared with placebo, although plasma equol levels correlated positively with measures of speeded dexterity and verbal fluency.[285]

Fatty Liver Disease

Limited research suggests that soy consumption may hold benefits for fatty liver disease. A 2014 study in patients with nonalcoholic fatty liver disease (NAFLD) compared the effects of a low-calorie diet (LCD), a low-carbohydrate LCD, and low-carbohydrate LCD containing soy found that the soy-containing diet produced greater reductions in alanine and aspartate aminotransferases (ALT and AST), fibrinogen, and malondialdehyde compared with the other diets.[286] A 2012 review of the mechanisms of NAFLD concluded that soy constituents may prevent or even reduce fatty accumulation in the liver by modifying lipid metabolism and the genetic expression of sterol regulatory-element binding proteins and PPARα.[287] In patients with hepatitis C given 32 g soy protein daily, significant reductions in ALT levels were seen, and in a subgroup (34.7%) with steatosis, it significantly improved associated measures, including gamma-glutamyltransferase (GGT) levels.[288]

Soy Isoflavone Safety

(Please also refer to Pharmacology and Clinical Applications sections.)

Soy products are generally well tolerated, and the most common adverse effects are constipation, bloating, and nausea, although insomnia, migraines, rash, itching, and hypersensitivity reactions have also been reported.

In perhaps the most comprehensive review of soy isoflavone safety in relation to menopausal health in women, the EFSA in 2015 found no effects on endometrial thickness and no histopathological uterine changes considering intakes of up to 150 mg soy isoflavones per day for up to 30 months. Additionally, the EFSA found no support for the hypothesis that isoflavone supplementation increases the risk for breast cancer or alters mammographic density or thyroid hormone levels. The EFSA concluded that dosages of soy isoflavones used in intervention studies (ranging from around 40 to 100 mg isoflavones daily) could guide consumers as to daily supplementation levels.[289]

Recent clinical and preclinical studies suggest that isoflavones can influence the production and regulation of thyroid hormones both positively and negatively.[290–295] Although not frequently seen in humans, it is important to respect the potential for high soy intake to precipitate or exacerbate thyroid dysfunction, especially among women, children, and iodine-deficient individuals. In those with low-iodine status, soy products may increase TSH levels, and TSH may need to be monitored. A 2006 review of 14 clinical trials concluded that in euthyroid individuals receiving sufficient iodine, there was no evidence that isoflavones affect thyroid function.[296] Women experiencing early menopause and given 15 g soy protein with 66 mg isoflavones showed significant increases in TSH as well as a reduction in free thyroxine levels, although no hypothyroid symptoms or changes in free T3 levels were seen.[297] High soy intake may lower parathyroid hormone levels in postmenopausal women.[298]

DRUG–NUTRIENT INTERACTIONS

Soy in various forms has been reported to interact with several types of drugs, and some soy constituents' mechanisms of action may have additive effects with some drugs. Soy may have additive effects with antidiabetic drugs and may increase the risk for hypoglycemia, and drug dosages may need to be adjusted. Soy protein may have additive effects with hypotensive drugs and may increase the risk for hypotension, and drug dosages may need to be adjusted. Soy products may competitively inhibit estrogens and may have additive effects with antiestrogenic drugs, and drug dosages may need to be adjusted. Some

soy products may inhibit platelet aggregation and may interact with blood clotting agents; blood clotting function may need to be monitored and drug dosages adjusted.[299] Soy protein may decrease the absorption of oral levothyroxine, and these substances should be used at separate times.[300] Those with cancer or other hormone-sensitive health conditions should discuss soy with their physicians because soy components may interact with hormone therapies. Very high intake of soy may increase the risk of bladder cancer. Women testing positive for HBV or HCV may be advised to avoid isoflavone supplementation.

Cadmium Content

Chronic, low-level cadmium exposure has been associated with an increased risk of several conditions, including osteoporosis, kidney damage, hypertension, insulin resistance, cancer, diabetes, uterine fibroids, and increased rates of miscarriage. A study from the Fred Hutchinson Cancer Research Center in Seattle, Washington, discovered that the greatest dietary contributor of cadmium was tofu.[69] This study included several other food sources of soy, such as tempeh, tofu hot dogs, tofu cheese, and soy burgers. The data revealed that once-weekly consumption of tofu increased urinary cadmium by 0.11 μg/g, only 0.02 μg/g less than the increase attributed to smoking. In women who ingested any of the listed tofu products twice weekly or more, the urinary cadmium burden increased by 0.30 μg/g, more than twice the increase found from smoking. Presumably (the research is inconsistent) this was due to the soy being grown conventionally with high-phosphate fertilizers that are commonly contaminated with cadmium. Those consuming soy foods are recommended to select soy products from organically grown soybeans or products that have been shown to have no cadmium contamination.

CONCLUSION

From early interest in soy as an alternative protein source to curiosity about whether or not one can be converted into a producer of beneficial soy metabolites, studies conducted in humans, animals, test tubes, and in silico are increasingly reassuring about soy's benefits for most populations while also clarifying the characteristics of individuals who may be at risk for its uncommon hazards. Science is additionally seeking ways to increase soy foods' palatability as well as the bioavailability of their isoflavones.[301]

Unlocking the benefits of soy foods is relatively easy for the majority with no sensitivity to soy: enjoy more of the broad variety of food choices, from creamy yuba (skimmed from tofu-making) and fermented soy milk to high-fiber soy hulls and chewy texturized vegetable protein used in meat-mimicking foods and snacks. Longtime soy researcher Mark Messina has recommended the following optimal intakes for soy and its components for women: 15 to 20 g soy protein (more if cholesterol reduction is the goal) and 50 to 90 mg soy isoflavones daily,[302] which corresponds to a few servings of soy foods.

Tabebuia avellanedae (syn. *T. Impetiginosa,* Lapacho, Pau d'Arco, Ipe Roxo)

Terry Willard, CIH, PhD, and *Michael T. Murray*, ND*

OUTLINE

INTRODUCTION

The taxonomic division of plants with medicinal uses in the *Bignoniaceae* family is confusing. The literature often interchanges the genera of *Tecoma* and *Tabebuia.* Some are now using the name *Tabebuia impetiginosa* as a synonym. At least four species have been called lapacho:

- *Tecoma ochracea*
- *Tecoma ipe*
- *Tabebuia cassinoides*
- *Tabebuia avellanedae* syn. *Tabebuia impetiginosa*

This chapter considers the *Tabebuia* genus.

GENERAL DESCRIPTION

The tree from which lapacho is obtained is a member of the *Bignoniaceae* family known as *T. avellanedae, T. impetiginosa,* or *T. ipe.* There are about 100 species of these evergreen trees or shrubs, native to tropical America. They can grow up to 125 ft tall and have very showy rose- to violet-colored flowers that bloom in profusion just before the new leaves appear.

Because the taxonomy of these plants is so difficult, it is quite possible that there is confusion even among trained gatherers.

CHEMICAL COMPOSITION

Many of the studies and chemical analyses on *Tabebuia* species have been performed on the heartwood, but the bark and inner bark are the products available in the marketplace and the parts used in folklore. The major components of *T. avellanedae* are 16 quinones (mostly with C_{15} skeleton) containing both naphthoquinones (seven, C_{10}–C_5) and anthraquinones (nine, C_{14}–C_1). Both of these groups of quinones rarely occur in the same plant. The lapachol content is usually 2% to 7%. The quinones are listed in Box 115.1. Other compounds found are lapachenole, quercetin, and *o*- and *p*-hydroxybenzoic acids.[1] The action of lapacho comes from an array of quinones and other constituents, not just one or two.

HISTORY AND FOLK USE

The indigenous peoples of Brazil also refer to this tree as pau d'arco or ipe roxo. The inner bark has been used for medicinal purposes for centuries as a folk remedy for a wide variety of afflictions, including the following[2–5]:

- Boils
- Chlorosis
- Colitis
- Diarrhea
- Dysentery
- Enuresis
- Fever
- Pharyngitis
- Snakebite
- Syphilis
- Wounds
- Ulcers
- Respiratory problems
- Arthritis
- Cystitis
- Constipation
- Prostatitis
- Poor circulation
- Constipation

* Previous edition contributor

BOX 115.1 Quinones in *Tabebuia avellanedae*

Naphthoquinones

- Lapachol
- Menaquinone-I
- Deoxylapachol
- Beta-lapachone
- Alpha-lapachone
- Dehydro-α-lapachone

Anthraquinones

- 2-Methylanthraquinone
- 2-Hydroxymethylanthraquinone
- 2-Acetoxymethylanthraquinone
- Anthraquinone-2-aldehyde
- 1-Hydroxyanthraquinone
- 1-Methoxyanthraquinone
- 2-Hydroxy-3-methylquinone
- Tabebuin (a newly discovered compound)

Fig. 115.1 *Tabebuia avellanedae.*

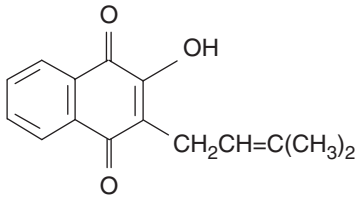

Fig. 115.2 Lapachol.

- Cancers of the esophagus, head, intestine, lung, prostate, and tongue

Lapacho is reported to be alexiteric, analgesic, anodyne, antidotal, antimicrobial, diuretic, and fungicidal.[2]

PHARMACOLOGY

During the 19th century, lapacho was subjected to scientific scrutiny, with the first active constituent, lapachol, isolated by Paterno in 1882 (Fig. 115.1 and Fig 115.2).

Interestingly, many of the scientific studies have found lapacho and lapachol to be more effective in treating malaria and cancerous tumors through oral ingestion rather than intravenous or intramuscular injection.[6]

An herbalist's interpretation would be that the body's recuperative powers are more effectively stimulated by the natural route of nutrient plant material absorption through the digestive tract. Although most of the studies have been of individual chemicals, some show significantly better results with the whole extract and diminishing effectiveness as the extracts are refined or individual chemicals are tested.[6,7]

Antimicrobial Activity

Antibacterial Activity

Lapachol isolated from the *T. avellanedae* tree has exhibited antimicrobial activity against gram-positive and acid-fast bacteria and *Brucella* species as well as fungistatic behavior.[8,9] It is important to note that the research team found that progressive purification reduced the antimicrobial activity of the extract. This finding led to the conclusion that more than one active substance was present in the original extract.

It was eventually found that along with lapachol, the extract of the *Tabebuia* tree contained α-lapachone, β-lapachone, and a newly discovered quinone called xyloidone.

Several of the naphthoquinones[1] exhibit strong microbicidal and fungicidal activities (Table 115.1).

Lapachol has been shown to have both antimicrobial and antiviral activity.[8,10,11] Beta-lapachone shows diversified antiparasitic activity as well as antiviral action.[12,13] Alpha-lapachone is also active against certain parasites, and xyloidone is active against numerous bacteria and fungi.[14,15] Another lapacho component, the flavonoid quercetin, is cytotoxic for certain parasites.[16]

Xyloidone is effective against a wide array of organisms, including *Staphylococcus aureus* and the *Brucella* species. This component also inhibits the causative agents of tuberculosis, dysentery, and anthrax.

Mechanism of action. Lapachol, like many naphthoquinones, acts as a respiratory poison by interfering with electron transport in microbes.[17,18] At concentrations of 100 mg/L, lapachol was found to inhibit O_2 uptake by *Plasmodium knowles* by 74% and succinate oxidase systems by 26% and thus to exhibit antimalarial activity.[19,20] Mitochondrial respiration is inhibited by 50% at a lapachol concentration of less than 110 μmol/L.[21] Increasing doses of lapachol produced progressive respiratory inhibition in tumor cells isolated from animals. Oxygen consumption and oxygen metabolite production are inhibited in neutrophils on the administration of lapachol.[22]

Lapachol has now been shown to act as an uncoupler of oxidative phosphorylation. Lapachol prevents the synthesis of adenosine triphosphate by stimulating respiration in the absence of a phosphate acceptor. This effect is most pronounced at a high pH, at which lipid solubility is the lowest.[23]

Lapachol inhibits certain enzymes; in particular, it is a competitive inhibitor of glycolase I in erythrocytes. Lapachol also demonstrates noncompetitive inhibition of α-keto-aldehyde dehydrogenase, leading to the accumulation of toxic α-ketoaldehydes.[24] Lapachol demonstrated 64% inhibition of 3-α-hydroxysteroid–mediated transhydrogenase at a concentration of 10^{-5}M (well within the dosage range).[25]

Antiviral Activity

Lapachol has proved to be active against certain viral strains, including herpesvirus hominis types I and II.[25] Hydroxynaphthoquinone has been shown to effectively inhibit four influenza viruses. Lapachol also significantly inhibits poliovirus and vesicular stomatitis virus.[10]

Beta-lapachone's antiviral activity has been demonstrated by its ability to inhibit certain enzymes, such as DNA and RNA polymerases.[26] Beta-lapachone was tested against avian myeloblastosis virus and Rauscho murine leukemia virus and found to inhibit retrovirus reverse transcriptase.[27] In the presence of dithioreitol, β-lapachone inhibits eukaryotic DNA polymerase-alpha activity. Although

TABLE 115.1 Antimicrobial Activity of *Tabebuia avellanedae*[a]

Microorganism	Lapachol	Chorohidro-Lapachol	Alpha-Lapachone	Beta-Lapachone	Xyloidone

[a]Minimum inhibitory concentration (mcg/mL).

the mechanism of action for enzyme inhibition is complex, it may be related to superoxide production.[26] This issue has great significance for possible treatment of both human immunodeficiency virus and Epstein–Barr virus (the implicated viruses in acquired immunodeficiency syndrome and Epstein–Barr syndrome, respectively).

Beta-lapachone also inhibits Friend virus and was the only substance among a number tested that prolonged the survival time of chickens infected intraperitoneally with Rous sarcoma virus.[28]

Antiparasitic Activity

The trematode *Schistosoma mansoni* is the causative agent of the common tropical disease schistosomiasis. The cercariae of this blood fluke live in water and enter the host by penetrating the skin. This debilitating disease, a serious problem in many tropical areas, causes weakening of the host and increases susceptibility to a variety of other pathogens, some of which may be fatal.

Lapachol has been tested as a topical barrier to the cercariae and has been found to be highly effective at preventing its penetration.[26,29] Oral lapachol was also tested and found to significantly reduce penetration. After being consumed, the lapachol was secreted onto the skin, apparently by the sebaceous glands, where it again acted as a topical barrier. The cercariae seek to penetrate the host through or near the sebaceous glands, suggesting that dietary administration of lapachol would be an efficient means of protecting against infection. Alpha-lapachone and β-lapachone, also components of lapacho, both exhibited activity against *S. mansoni.*[8] Beta-lapachone is notably effective against *Trypanosoma cruzi,* a zoomastigote responsible for trypanosomiasis, or Chagas' disease, which occurs in both acute and chronic forms and has no known cure.

Beta-lapachone causes complete inhibition of *T. cruzi* at concentrations of 0.8 to 5.0 μg/mL and progressively inhibits motility with increasing concentrations. When *T. cruzi* epimastigotes were incubated with the quinone, they were subjected to nuclear, mitochondrial, endoplasmic reticular, and cytoplasmic membrane damage and underwent alterations in the chromatin distribution. Respiration rates were lowered, the mitochondria became swollen, and glucose and pyruvate oxidation was inhibited. Lipid peroxidation was stimulated, leading to decreased cell viability.

In addition, in vitro testing resulted in the rapid decay of DNA, RNA, and protein as well as DNA breakage in *T. cruzi.* This was accompanied by inhibition of DNA, RNA, and protein synthesis and the instigation of "unscheduled" DNA synthesis.[30,31]

It is thought that this toxic action against parasites is at least partly due to superoxide production.[32] Both O_2^- and H_2O_2 are intermediates of oxygen reduction, and both are toxic to living organisms. When β-lapachone is introduced to *T. cruzi,* it rapidly enters the epimastigote and is reduced to its semiquinone form in the mitochondria and microsomes of the pathogen.[33] Superoxide is produced by the reduction of molecular oxygen, which is facilitated by autooxidation of the semiquinone free radical. Superoxide is then converted to hydrogen peroxide via superoxide dismutase. Stimulation of lipid peroxidation follows, and the cell degenerates.

Antifungal Activity

In addition to its activity against a variety of bacteria, components of lapacho are known to possess potent antifungal capabilities.[11,34] The quinone xyloidone inhibits several species of fungus (including *Candida albicans, Candida krusei,* and *Cryptococcus neoformans*).[11] The antifungal activity of aqueous, dichloromethane, and methanol extracts from *T. avellanedae* were also compared, and it was found that the aqueous and methanol extracts showed the highest antifungal activity.[35] *T. avellanedae* bark was found to be active against *Aspergillus fumigatus, C. neoformans, Microsporum gypseum, Penicillium purpurogenum, Saccharomyces cerevisiae,* and *Trichophyton mentagrophytes.*[35]

Antineoplastic Effects

Because of the folklore information surrounding the tumor-reducing qualities of the herb lapacho, it underwent extensive study by the National Cancer Institute (NCI). After the initial positive results, lapachol was judged to be the most active antineoplastic agent. Lapachol

entered Phase I clinical trials at the NCI in 1968 on the basis of its activity against Walker 256 tumors (with a confidence rate exceeding 90%). During these trials, it was difficult to obtain therapeutic blood levels of lapachol without some mild toxic side effects, such as nausea, vomiting, and anti–vitamin K activity. This occurrence is quite difficult to understand because later studies found the toxicity to be very low.[2] The investigative new drug (IND) status for the drug was closed in 1970 due to these toxicity issues.[36]

It has been shown, however, that some of the anthraquinones in lapacho have vitamin K activity; therefore use of the whole herb would compensate for lapachol's effect on vitamin K.[37]

The approach just described indicates a flaw in the underlying philosophy of the pharmaceutical sciences and the NCI program. Because the initial studies came from a whole plant, the detailed studies should have been undertaken on the whole plant. Some of the other quinones have also been shown to have antineoplastic activities. Was it too complex to consider the chemical reactions of the more than 20 components found in lapacho? Or was the standard economic/political incentive for patenting an analog an impediment to the investigation of a plant species?

Lapachol is rapidly absorbed through the gastrointestinal tract after oral administration to rats bearing Walker 256 tumors. It is taken up by all tissues except the brain and blood cells. A significant amount appears in the tumor after 6 hours, with most of the drug disappearing from the other body tissues. The half-life of intravenous lapachol is 33 minutes in mice (75 minutes in dogs). Lapachol is extensively metabolized and excreted mostly in the feces.[38] Beta-lapachone has been shown to inhibit the growth of a large variety of tumor cells, including epidermoid laryngeal cancer; prostate, colon, ovary, and breast cancers; and also different types of leukemia cells.[39]

The theories on how lapachol works as an antineoplastic agent vary considerably. One of the most prominent involves reduction-oxidation (redox) cycle capabilities. Lapachol was found to be an in vivo inhibitor of respiration at chemotherapeutic doses.[5] Later, lapachol was shown to augment the flow of electrons from reduced nicotinamide adenine dinucleotide phosphate to form oxygen-related free radicals. These seem to be site-specific free radicals that bind to the cancerous DNA or RNA, producing either superoxides or free hydroxyl radicals.[40,41]

There seems to be a redox potential that is important for the inhibition of electron transfer in coenzyme Q_{10}.[42] Bennett et al.[43] argued that this respiration poisoning is not the mechanism of antitumor activity. In their study, lapachol was shown to significantly reduce the pool of uridine triphosphate, the largest pool of the pyrimidine nucleotides (exposure time was very short, 2–4 hours).

Lapachol is theorized to be like dichloroallyl lawsone in that it blocks pyrimidine biosynthesis through inhibition of dihydroorotate dehydrogenase.[17] It is also believed that the antineoplastic activities of lapachol might stem from its interaction with nucleic acids,[41] and it has been proposed that interaction of the naphthoquinone moiety between base pairs of the DNA helix occurs with subsequent inhibition of DNA replication and/or RNA synthesis. Free amino groups in the sugar moiety are necessary for DNA binding.[44]

Beta-lapachone has an effect on the modulation of cell growth and apoptosis in human colon carcinoma tumor (HCT-116) cell lines. Exposure of HCT-116 cells to β-lapachone resulted in growth inhibition and induction of apoptosis in a dose-dependent manner. The researchers suggest therefore that β-lapachone–induced apoptosis may be partly regulated through the inactivation of the second messenger nuclear factor (NF)-κβ system.[45]

Beta-lapachone was also shown to decrease the viability of sarcoma cells by stimulating lipid peroxidation. This was accomplished through the following activities[32]:

- Reduction of lapachone at the mitochondrial and microsomal membranes with the generation of the semiquinone form
- Autooxidation to produce O_2
- Production of H_2O_2 via superoxide dismutase

More than one mechanism has been shown to underlie the antineoplastic effect.[7] There is ongoing positive research on cancers of the liver,[46,47] bladder,[48] prostate,[49,50] lung,[51] colon,[45] and breast (estrogen receptor site inhibition).[52]

Anti-Inflammatory Activity

Extracts of the bark from *T. avellanedae* demonstrate clear anti-inflammatory activity with low toxicity.[53] Pau d'arco douching and the use of tampons soaked in an alcoholic extract of lapacho have been shown to be very successful against a wide range of inflammations, such as vaginitis, cervicitis, and cervicovaginitis.[1,27,34]

An aqueous extract of the inner bark of *T. avellanedae* has demonstrated antinociceptive and antiedematogenic activities in mouse models, with a possible antinociceptive effect correlated with the adenosine system.[54] Adenosine itself is posited to interact with receptors coupled with G protein for this effect.[53,55] Two animal studies using carrageenan-induced subplantar edema have also exhibited the anti-inflammatory abilities of lapachol.[54,56] In one study, the second phase of inflammation, which is correlated with the appearance of prostaglandins and kinins, was where lapachol seemed to exert the greatest anti-inflammatory effect.[56] Lapacho compounds have also demonstrated potent activity against the growth of human keratinocytes and appear to be promising as effective antipsoriatic agents; β-lapachone displayed activity comparable with that of the antipsoriatic drug anthralin. It has been shown that the decoction similar to ethnobotanical use suppresses PGE_2.[57] Beta-lapachone has been found effective in wound healing by inducing cell proliferation, including keratinocytes, fibroblasts, and endothelial cells.[58]

Other Studied Actions

T. avellanedae has been investigated as a possible antidepressant[59] and is also active against ulcers (as well as *Heliobacter pylori*),[60,61] immune modulation,[62] platelet aggregation,[63] and antioxidant volatile fractions.[64]

Quercetin

Quercetin is a highly active flavonoid that inhibits a wide range of enzymes and suppresses the synthesis of DNA, RNA, and proteins.[65] Quercetin's cytotoxicity may be due to the fact that it inhibits mitochondrial electron transport.[66] Hodnick et al.[66] have noted that quercetin produced a substrate-independent potassium cyanide–insensitive respiratory burst in mitochondria. Other flavonoids that have demonstrated this activity produced O_{2^-} and H_2O_2, suggesting that quercetin may also generate these cytotoxic chemicals.

The following are among the enzymes inhibited by quercetin[30,32,67]:

- Nicotinamide adenine dinucleotide (NADH) oxidase
- Phosphodiesterase
- Cyclic adenosine monophosphate (cAMP)–independent protein kinases
- $Ca2^+$ phospholipid–dependent protein kinase
- Tyrosine-protein kinases

Shapiro et al.[16] suggested that the cytotoxicity of quercetin may be due to its chelating abilities. This agent is trypanocidal to *Trypanosoma brucei,* a livestock parasite belonging to the same genus as *T. cruzi.* Soon after the parasite enters the host, the host's unsaturated iron-building proteins remove iron from the hemoflagellate. Because the parasite is unable to synthesize heme, it encounters a shortage of iron. By chelating the host's iron, quercetin blocks utilization of iron by the parasite

yet does not adversely affect the host. This flavonoid is also cytotoxic against *Crithidia fasciculata.* The fact that quercetin is small and lithophilic seems to be important to its activity.

Like lapachol, quercetin inhibited O_2 consumption and H_2O_2 production in neutrophils.[68] Many flavonoids exhibit antiviral activity. When mice that had been intracerebrally infected with attenuated viruses, including rabies, were given quercetin in their diet, a prophylactic effect was observed.[69] Quercetin inactivates the following viruses (*inactivation* is defined as reducing viral infectivity tenfold):

- Herpes simplex type 1
- Respiratory syncytial virus
- Pseudorabies/Aujeszky's virus
- Poliovirus type 1
- Parainfluenza type 3
- Sindbis virus
- Potato virus x

CLINICAL APPLICATIONS

The spectrum of clinical applications of *T. avellanedae* is quite broad. Current use has focused on lapacho's antineoplastic and antimicrobial activity. Its use is extremely popular in the treatment (both topical and internal) of intestinal candidiasis and vaginal candidiasis. Research has also focused on antipsoriatic and antiedema properties. There are also many anecdotal reports of remission of different forms of cancer with the use of this botanical.[68]

Unfortunately, because of the lack of quality control and confusion about the portion of the plant to use, it is highly likely that many practitioners are not using effective materials. This likelihood could explain varying clinical results.

Cancer

Only one recent clinical study appears to be indexed in PubMed. In this Phase II trial, *T. avellanedae* was used an adjunct to conventional cancer treatment. It was shown to be safe and effective in preventing and/or reducing oral mucositis during radiotherapy for head and neck cancer.[70]

Dosage

The usual form of administration of lapacho is as a decoction, with the standard dose being 1 cup of decocted bark two to eight times per day. The decoction is made by boiling 1 teaspoon of lapacho for each cup of water for 5 to 15 minutes.

A more precise dosage based on a lapachol content of 2% to 4% would be 15 to 20 g of bark boiled in 500 mL or 1 pint of water for 5 to 15 minutes three to four times daily.

Dosages of other forms (aqueous extract, fluid extract, solid extract) should be based on lapachol content, providing a daily lapachol intake of 1.5 to 2 g/day.

A tampon that has been soaked in the decoction or fluid extract is used in the treatment of vaginitis and cervicitis. The tampon is inserted vaginally and changed every 24 hours until resolution.

TOXICOLOGY

Although anti–vitamin K activity has been reported for lapachol, the presence of several vitamin K–like substances in the whole plant suggests that this is not a problem.

Long-term administration of lapachol at a dose of 0.0625 to 0.25 g/kg per day to monkeys was found to produce moderate to severe anemia. The anemia was most pronounced during the first 2 weeks of treatment. Death occurred in monkeys after six doses of lapachol at 0.5 g/kg per day and after five doses of 1 g/kg per day.[6]

There have been no reports in the literature of human toxicity when the whole bark is used as a decoction. Long-term use of large doses of the decoction by indigenous peoples has shown no adverse reactions. Because low doses have been reported to cause nausea and vomiting,[71] only a qualified naturopathic physician, herbalist, or other practitioner experienced in its use should attempt to use this botanical medicine.

DRUG INTERACTIONS

No interactions with pharmaceutical drugs have been reported, but because of its known anti–vitamin K–like activity, there may be an interaction with anticoagulant medications, such as warfarin, that could theoretically result in increased bleeding tendencies. This effect would probably be minimized if treatment involved the whole herb rather than specific components. In any case, caution is warranted.

Tanacetum parthenium (Feverfew)

Kathy Abascal, BS, JD, RH(AHG), and *Eric L. Yarnell, ND, RH(AHG)*

OUTLINE

GENERAL DESCRIPTION

Fever few *(Tanacetum parthenium)* is a composite plant cultivated in flower gardens throughout Europe and the United States (Figs. 116.1 and 116.2).

CHEMICAL COMPOSITION

The major active chemicals in the plant have been hypothesized to be sesquiterpene lactones, principally parthenolide. However, many investigators have found evidence of other active constituents, including both lipophilic compounds (e.g., sesquiterpene lactones) and hydrophilic compounds, although their exact identity has not been determined.[1–3] The flowering herb also contains 0.02% to 0.07% volatile oils (L-camphor, L-borneol, terpenes, and miscellaneous esters).[4,5] Various compounds in the volatile oil have shown pharmacological activity (Fig. 116.3).[6]

Fig. 116.1 *Tanacetum parthenium* (family: *Asteraceae*); synonym: *Chrysanthemum parthenium*; common names: feverfew, featherfew. (Image from Eric Yarnell.)

HISTORY AND FOLK USE

Feverfew has been used for centuries as a febrifuge and for the treatment of migraines and arthritis. Other historical uses of feverfew have been in the treatment of anemia, earache, dysmenorrhea, dyspepsia, trauma, and intestinal parasites.[4] It has also been used as an abortifacient and in gardens to control noxious pests (its pyrethrin component is an effective insecticide and herbicide).

PHARMACOLOGY

Feverfew has demonstrated some remarkable pharmacological effects in experimental studies. Extracts of feverfew have been shown to inhibit the synthesis of compounds that promote inflammation, including inflammatory prostaglandins, leukotrienes, and thromboxanes. No adverse effects reported for feverfew mimic those of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs), suggesting that the effects of feverfew are in some way distinct from those of the drugs. Inhibition of phospholipase A_2 is more like the effects of corticosteroids.[7] Many other inflammation-modulating effects of feverfew and parthenolide have been shown over the years.[8,9]

Feverfew also has favorable effects on the behavior of blood platelets in vitro,[7,10] including inhibition of platelet aggregation and the secretion of inflammatory and allergic mediators like histamine and serotonin. Parthenolide components also exert a tonic effect on vascular smooth muscle.[11]

A growing body of preclinical research also supports that feverfew extracts and parthenolide have significant anticancer effects. This includes induction of apoptosis in and inhibition of growth of cancer cells as well as decreasing angiogenesis.[12–16]

CLINICAL APPLICATIONS

Feverfew has been used for centuries to relieve fever, migraines, and arthritis. The only condition with confirmed scientific documentation at present is in the prevention and treatment of migraine headache.

MIGRAINE HEADACHE

Physician John Hill, in his book *The Family Herbal* (1772), noted, "In the worst headache this herb exceeds whatever else is known." A 1983 survey found that 70% of 270 migraine sufferers who had eaten feverfew daily for prolonged periods claimed that the herb decreased the frequency and/or intensity of their attacks.[17] Many of these patients had shown no response to orthodox medicines.

Numerous double-blind trials have been conducted on the efficacy of feverfew in patients with migraine,[17–22] the results of which have been assessed in three meta-analyses.[23–25] The first two of these concluded that the majority of studies show that feverfew extracts are superior to placebo for decreasing the frequency and severity of migraine headaches, although most of the studies were of relatively

low methodological quality, and efficacy was not proved beyond a reasonable doubt.[21,24] The third meta-analysis concluded that feverfew extracts have not been proved in controlled trials to prevent migraine better than placebo.[25]

The highest-quality study among feverfew clinical trials used a granulated ethanol extract of feverfew and found it ineffective compared with placebo, whereas all the other trials used unextracted powdered feverfew. As a result, careful attention must be paid in future studies to the types of products used, and the results of trials using different products should probably not be combined in meta-analyses.

One double-blind, randomized clinical trial compared the effects of a combination of a feverfew extract (100 mg) with riboflavin 400 mg and magnesium 300 mg taken daily with riboflavin 25 mg.[26] The control, riboflavin 25 mg, appeared to be just as active as the combination formula, and the trial showed that combining feverfew and magnesium with riboflavin adds no additional benefits for preventing migraine headaches.

In an open trial, feverfew combined with *Salix alba* (white willow) extracts, 300 mg of each twice a day, has been shown effective at preventing and reducing the severity of migraine without aura.[27] A combination of homeopathic dilutions of *Zingiber officinale* (ginger) and feverfew was effective in one open and one double-blind, randomized, placebo-controlled trial for relieving acute migraine pain.[28,29] It is not known if either homeopathic is superior to feverfew alone or how they would compare with botanical extracts in a head-to-head comparative trial.

RHEUMATOID ARTHRITIS

Inflammatory compounds released by white blood cells and platelets contribute greatly to the inflammation and cellular damage found in rheumatoid arthritis. Inhibition of the release of inflammatory particles by feverfew is much greater than that achieved by NSAIDs like aspirin.[10] This finding, coupled with many of feverfew's other effects, indicates that feverfew can reduce inflammation in rheumatoid arthritis.

Although a double-blind, placebo-controlled study demonstrated no apparent benefit from oral feverfew in rheumatoid arthritis, the dosage used was small (76 mg dried powdered feverfew leaf, corresponding to two medium-sized leaves), the level of parthenolide was not determined in the product, and patients continued to take NSAIDs, a practice that has been suggested to reduce the efficacy of feverfew.[30] Therefore the benefit of feverfew in rheumatoid arthritis has not yet been determined.

DOSAGE

The effectiveness of feverfew was thought to depend on adequate levels of parthenolide, although multiple studies confirm that there are multiple active compounds in feverfew and that parthenolide-free extracts are still active.[31,32] It is difficult to determine the relevance of measuring parthenolide in extracts; assessments of activity of extracts would perhaps be superior, although more expensive.

The preparations used in some successful clinical trials had a parthenolide content of 0.4% to 0.66%. The dosage of feverfew used in the London Migraine Clinic study was one capsule containing 25 mg of the freeze-dried pulverized leaves given twice a day.[6] In the Nottingham study it was one capsule containing 82 mg of dried powdered leaves given once a day.[7] Therefore the daily dosage of parthenolide that may be effective in preventing a migraine headache is roughly 0.25 to 0.5 mg.

Although these low dosages may be effective in preventing an attack, a higher dose (1–2 g) is necessary during an acute attack: dried pulverized leaves 25 to 50 mg given twice a day.

TOXICITY

There were no reports of toxic reactions in patients taking feverfew in the 6-month migraine study. Feverfew has been used by large numbers of people for many years without reports of toxicity. Chewing the leaves, however, may result in aphthous ulcerations, and some sensitive persons experience an exudative dermatitis from external contact.[33] In clinical trials, neither mouth ulcers nor dermatitis was more common in the feverfew groups than the placebo groups; in one trial, aphthous ulcers were actually more common in the placebo group.[19]

DRUG INTERACTIONS

Because feverfew affects the activity of several of the CYP liver enzymes involved in drug metabolism, a number of interactions are theoretically possible.

Taraxacum officinale (Dandelion)

Michael T. Murray, ND

OUTLINE

Taraxacum officinale (family: *Compositae*)
Common names:

- English: dandelion, wet-a-bed, lion's tooth
- French: *dent-de-lion, pissenlit*
- German: *Lowenzahn, Pfaffenrohrlein*
- Spanish: *diente de leon*
- Italian: *tarassaco*
- Chinese: *p'u kung ying, Ching p'o po, chiang-nou-ts'ao, huang-hua-tii-ting*

GENERAL DESCRIPTION

Dandelion *(Taraxacum officinale)* is a member of the *Compositae* family and is closely related to chicory. Several origins have been attributed to the name *Taraxacum,* the most likely being from the Greek *taraxo* ("disorder," "disturbance"), *akos* ("remedy"), and *akeomai* ("I heal") and from *tharakhcharkon,* possibly a derivative of a Persian-Arabic word for "edible" and the name by which the plant is referred to in a 13th-century Arabian botanical work.[1]

Taraxacum is known around the world by a variety of names. In English-speaking countries, dandelion (from the French *dent-de-lion,* referring to the plant's lion's tooth leaves) is its most common name. It is also known as wet-a-bed (after its diuretic action), lion's tooth, fairy clock, priest's crown, swine's snout, blowball, milk gowan, wild endive, white endive, cankerwort, puffball, and Irish daisy.

Dandelion is a variable perennial growing to a height of 12 in. Its spatula-like leaves are deeply toothed, shiny, and hairless and are arranged in a ground-level rosette. The yellow flowers bloom for most of the year and are sensitive to light and weather—opening at daybreak and closing at nightfall and opening in dry weather and closing in wet weather (a closed dandelion flower signals rain). When the flower matures, it closes up, the petals wither, and it forms into a puffball containing seeds that are dispersed by the breeze.

The rosette formation of grooved leaves channels rainwater into the center and down to a taproot, which is thick and dark brown, almost black on the outside. The root is cylindrical, tapering, and somewhat branched. It has a slight odor and sweetish taste. The inside of dried dandelion root is yellowish, very porous, and without pith. It is believed that the plant originated in Central Asia and spread throughout most of the world, preferring the cooler climates. Although *Taraxacum* is very adaptable, it prefers moist, nitrogen-rich soils at altitudes less than 6000 ft. Most species occur in the temperate zones of the northern hemisphere, with the greatest concentration in northwest Europe.

The portion of the plant that is most commonly used is the root; however, the leaves and whole plant can also be used. In addition to its medicinal use, dandelion is a nutritious food and beverage. Tender leaves are used raw in salads and sandwiches or lightly cooked as a vegetable. Tea is made from the leaves, coffee substitute from the roots, and wine and schnapps from the flowers.

CHEMICAL COMPOSITION

Dandelion root's calorie count is exceptionally low—a cup is only 25 calories—and its nutrient content is exceptionally high. In fact, dandelion root has greater nutritional value than many other vegetables. It is particularly high in vitamins and minerals, protein, choline, inulin, and pectin. Its carotenoid content is extremely high, as reflected by the fact that it has a higher vitamin A content (as beta-carotene) than carrots (dandelion has 14,000 IU of vitamin A per 100 grams, compared with 11,000 IU for carrots). Dandelion greens are an outstanding source of vitamin A and an excellent source of vitamin C, riboflavin, vitamin B_6, and thiamine as well as calcium, copper, manganese, and iron.

The primary therapeutic actions of dandelion are believed to be due to the bitter principle of taraxacin, various terpenoids, inulin, and its high concentration of nutrients, especially choline. Other constituents of dandelion that may contribute to its pharmacological effects are resins, pectin, taraxanthin (a carotenoid pigment in the flowers), fatty acids, and flavonoids.[2,3]

The roots of *T. officinale* contain the triterpenes b-amyrin, taraxasterol, and taraxerol and the sterols sitosterin, stigmasterin, and phytosterin (Figs. 117.1 and 117.2).[4]

Later research has elicited several compounds that are likely to be clinically significant. Three flavonoid glycosides—luteolin 7-glucoside and two luteolin 7-diglucosides—have been isolated from dandelion flowers and leaves, together with free luteolin and chrysoeriol

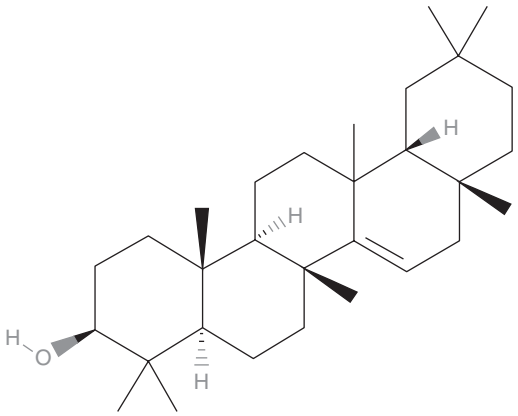

Fig. 117.1 Taraxerol.

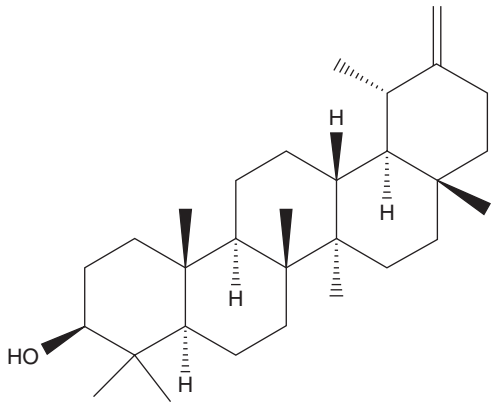

Fig. 117.2 Taraxasterol.

in the flower tissue. Three hydroxycinnamic acids—chicoric acid, monocaffeyltartaric acid, and chlorogenic acid—have been found throughout the plant, and the coumarins cichoriin and aesculin have been identified in leaf extracts. Chicoric acid and the related monocaffeyltartaric acid were found to be the major phenolic constituents in dandelion flowers, roots, leaves, and involucral bracts and also in the medicinal preparations tested.[5]

HISTORY AND FOLK USE

Although many individuals may consider the common dandelion an unwanted weed, herbalists all over the world have revered this valuable herb. Generally regarded as a liver remedy, dandelion has a long history of folk use throughout the world. In Europe, dandelion has been used in the treatment of the following conditions:

- Fevers
- Boils
- Eye problems
- Diarrhea
- Fluid retention
- Liver congestion
- Heartburn
- Various skin problems

In China, dandelion has been used to treat the following disorders:

- Breast problems (cancer, inflammation, lack of milk flow, etc.)
- Liver diseases
- Appendicitis
- Digestive ailments

Dandelion's use in India, Russia, and most other parts of the world has revolved primarily around its action on the liver.

PHARMACOLOGY

The primary pharmacological actions of dandelion relate to digestion, liver function, and diuresis.

Digestive Effects

Bitter herbs like dandelion are used to aid digestion on the basis of the belief that bitter principles stimulate the initial phase of digestion, including the secretion of salivary and gastric juices. Dandelion goes beyond this initial phase by stimulating the release of bile by the liver and gallbladder.

The digestive tonic properties attributed to dandelion are now believed to be due to a bitter principle researchers have named *taraxacin* and have identified as belonging to a class of active substances called guaianolides, which have intestinal antiseptic, germicidal, and expectorant effects.[6]

Dandelion root contains a very high concentration (up to 40%) of inulin, which serves as a food source for the "friendly" colonic bacteria species *Bifidobacterium* and *Lactobacillus* and thus promotes their growth. Aqueous root extracts of *Taraxacum officinale* were tested for their activity in stimulating the growth of 14 different strains of bifidobacteria. The growth of six strains (*B. adolescentis* 1 and 2, *B. bifidum* 1, *B. catenulatum,* and *B. longum* 2) was significantly enhanced; two strains were slightly enhanced, whereas the remaining six strains exhibited no enhancement.[7]

Blood Sugar Control

A number of components in dandelion have demonstrated antidiabetic effects.[8] Foremost are inulin and taxasterol, but also the sesquiterpene lactones, phenols, flavonoids, and phenolic acids. Inulin is also helpful in improving blood sugar control and diabetes.[9] Studies on dandelion extracts showed an ability to stimulate the release of insulin in pancreatic β-cells as well as improve blood sugar control in a number of different animal models.[8]

Liver Tonic

Studies in humans and laboratory animals have shown that dandelion root enhances the flow of bile, improving such conditions as liver congestion, bile duct inflammation, hepatitis, gallstones, and jaundice.[1,2,10,11] Dandelion's action in increasing bile flow is twofold: it has a direct effect on the liver, causing rises in bile production and flow to the gallbladder (choleretic effect), and a direct effect on the gallbladder, causing its contraction and the release of stored bile (cholagogue effect). The high choline content of the root may be a major factor in dandelion's ability to act as a "tonic" to the liver. Historically, dandelion's positive effect on such a wide variety of conditions is probably closely related to its ability to improve liver function.

In one animal study, dandelion significantly improved the liver's ability to clear toxins by 244%. Dandelion's effectiveness in improving the liver's ability to clear potentially toxic agents was also demonstrated in a study in which rats were given the antimicrobial drug ciprofloxacin (Cipro). In those rats that also received dandelion, levels of the drug were rapidly and significantly lowered by 73% compared with the rats that did not receive the dandelion.[12] Several studies have shown that the aqueous extract of *T. officinale* root has protective action against alcohol or chemically induced toxicity in the liver by elevating antioxidative potentials and decreasing lipid peroxidation.[13,14] In carbon tetrachloride–induced liver fibrosis, *Taraxacum* extract also inactivated the hepatic stellate cells responsible for fibrosis and enhanced hepatic regenerative capabilities.[15,16]

Diuretic and Weight Loss Effects

The leaves of dandelion have confirmed diuretic activity. In one study in mice, dandelion exerted a diuretic effect comparable with that of furosemide (Lasix).[17] Because dandelion replaces potassium lost through diuresis, it does not have the potential side effects of furosemide, such as hepatic coma and circulatory collapse. The dose given was 8 mL/kg body weight of the aqueous fluid extract of the leaves. This dose produced a 30% loss of body weight in mice and rats in a 30-day period. Much of the weight loss was attributed to the significant diuretic effect.

Anticancer and Immune-Enhancing Effects

Various dandelion extracts and components have demonstrated antitumor properties in animal experiments.[18–20] Evidence also indicates that dandelion enhances cell-mediated, humoral, and nonspecific immunity; induces the secretion of tumor necrosis factor-alpha; and influences the production of nitric oxide.[21,22] In one study, three aqueous extracts were prepared from the mature leaves, flowers, and roots and tested for their effects on tumor progression–related processes such as proliferation and invasion.[23] Dandelion leaf extract decreased the growth of breast cancer cells, whereas the aqueous extracts of dandelion flower and root had no effect on such growth. Dandelion root extract was found to block the invasion of breast cancer cells, and the leaf extract blocked the invasion of prostate cancer cells.

CLINICAL APPLICATIONS

Dandelion's specific action is on the liver, but as an alterative or tonic, it benefits the body as a whole. It is often used as follows:

- As a diuretic
- As a laxative
- As a cholagogue
- As a general stimulant for the urinary system
- As a choleretic
- As a depurative (purifier)
- As a hypoglycemic agent
- As an antitumor agent

Two human studies have demonstrated the liver-healing properties of dandelion. In a 1938 study in Italy, 12 patients with severe liver imbalances—many exhibiting classic symptoms such as loss of appetite, low energy, and jaundice—were treated with dandelion extract (one 5-mL injection daily for 20 days).[1] Of the 12 patients, 11 showed a considerable drop in blood cholesterol. In the other study, dandelion extract was shown to successfully treat hepatitis, swelling of the liver, jaundice, and dyspepsia with deficient bile secretion.[9]

In a pilot study to assess its diuretic activity in humans, dandelion leaf extract at a dosage of 8 mL three times a day produced a significant increase in the frequency of urination in the 5-hour period after the first dose, a significant increase in the excretion ratio in the 5-hour period after the second dose, and no effect after the third dose.[24] These results indicate that dandelion produces an acute diuretic effect.

DOSAGE

As a general tonic and mild liver remedy, dandelion root can be used at the following dosages three times per day:

- Dried root: 2 to 8 g by infusion or decoction
- Fluid extract (1:1): 4 to 8 mL (1–2 tsp)
- Tincture: Alcohol-based tinctures of dandelion are not recommended because of the extremely high dosage required.
- Juice of fresh root: 4 to 8 mL (1–2 tsp)
- Powdered solid extract (4:1): 250 to 500 mg

Preparations of the leaves can be used as a mild diuretic and weight-loss agent at the following dosages three times a day:

- Dried leaf: 4 to 10 g by infusion
- Fluid extract (1:1): 4 to 8 mL (1–2 tsp)

TOXICITY

No toxic or adverse effects have been reported for either the external or internal use of dandelion. It is considered safe to use even in large amounts, with virtually no documented side effects.[1] There has been one case report of an atopic individual experiencing an anaphylactic reaction after the oral ingestion of an herbal combination containing *T. officinale*. In this case the herbal compound was found to have trace amounts of pollen from *T. officinale* and several other medicinal plants, which resulted in this systemic reaction.[25] This single case report indicates a possible need for caution in individuals with pollen allergy to other plants of the *Compositae* family.

The carcinogenicity of *T. officinale* has been investigated in an animal model. No carcinogenic activity was observed after 120 days of administration.[26]

DRUG INTERACTIONS

In an animal study, administration of an extract of the whole dandelion plant concomitantly with ciprofloxacin decreased absorption of the drug.[27] The investigators found that this effect was due to the high mineral content of the dandelion herb. Until further information is available, ciprofloxacin should not be taken within 2 hours of any dandelion supplement, including tea.

In general, it is often recommended that botanical medicines having a diuretic effect be avoided by anyone taking diuretic medications because the former may enhance the effect of the latter and lead to possible cardiovascular side effects.

Dandelion ingestion may increase the hypoglycemic effect of insulin. A single case report exists describing a 58-year-old-woman with type 2 diabetes mellitus on insulin therapy presenting to an emergency department with a hypoglycemic episode after 2 weeks of daily ingestion of fresh dandelion leaves in salad.[28]

Taxus brevifolia (Pacific Yew)

Eric L. Yarnell, ND, RH(AHG)

OUTLINE

Taxus brevifolia (family: *Taxaceae*)
Common names: Pacific yew

GENERAL DESCRIPTION

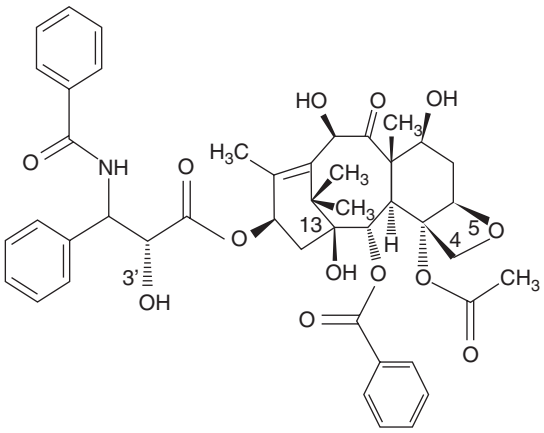
The Pacific yew is now well known as the original source of the chemotherapy agent paclitaxel. Because of the low yield, cost of extraction, and environmental concerns, alternative sources were developed. Nonetheless, the success of paclitaxel provides strong support that mining nature for new medicines is an extremely viable approach to drug development.

Yews are evergreen trees or shrubs that were difficult to classify taxonomically because they look like conifers, but because of the absence of cones and resin ducts, they were placed in a separate order (Fig. 118.1). Although the yew appears to be tenacious, it is slow to reproduce. The species is dioecious, with female trees producing relatively scarce fruits. Seedlings are rare. Most often, new yew trees come from offshoots of a "mother tree," which is why they are usually found in clusters. They grow best on deep, moist, rich rocky or gravelly soils. The largest known living Pacific yew is in Lewis County, in Washington State, near Mount Rainier. It stands 21.3 m tall, has a girth of 4.5 m, and is estimated to be 1000 years old.

Paclitaxel (Taxol) and complex diterpenoid taxanes are compounds found in *Taxus brevifolia.* Docetaxel (Taxotere) is a semisynthetic agent similar in action to paclitaxel derived from 10-deacetylbaccatin III, a taxane isolated from the needles of *Taxus baccata,* the English yew. Before their formal drug development, these compounds were cited as among the most promising plant compounds tested for anticancer properties in 1990.[1] The Pacific yew was first collected in 1962 by a U.S. Department of Agriculture team in Washington State as part of the large natural products screening program of the U.S. National Cancer Institute. Confirmed activity by a bark extract against the KB cell line in tissue culture was reported in 1964. Isolation studies began in 1965, and by 1971, Wall et al.[2] at the Research Triangle Institute (Durham, NC) had identified paclitaxel as the active constituent.[2] Paclitaxel became big news in 1989 when investigators at the Johns Hopkins Oncology Center in Baltimore reported a 30% response rate in cases of refractory ovarian cancer, a remarkable rate for this type of cancer.[3] The development of docetaxel began in 1981 in France. Taxanes used in conjunction with chemotherapy and irradiation have demonstrated improved results compared with either of these therapies alone and better tolerance of these therapies.[4]

From 1967 to 1993, almost all paclitaxel produced was derived from the bark of the Pacific yew, the harvesting of which kills the tree. Currently, all paclitaxel production uses plant cell fermentation technology. This starts from a specific *Taxus* cell line propagated in an aqueous medium in large fermentation tanks. Paclitaxel is then extracted directly, purified by chromatography, and isolated by crystallization.

Fig. 118.1 Taxus brevifolia. (From <https://www.istockphoto.com/photo/yew-tree-branches-with-red-berries-gm488999880-74478915>. Accessed October 2, 2018.)



Empirical formula: $C_{47}H_{51}NO_{14}$
Molecular weight: 853.9 g/mol
Average mass: 853.9 Da
Systemic name: (2α, 5β, 7β, 10β, 13α)-4,10-Diacetoxy-13-{[(2R, 3S)-3-(benzoylamino)-2-hydroxy-3-phenylpropanoyl]oxy}-1,7-dihydroxy-9-oxo-5,20-epoxytax-11-en-2-yl benzoate

Fig. 118.2 Structure of paclitaxel. (From ResearchGate. Paclitaxel and its evolving role in the management of ovarian cancer. <https://www.researchgate.net/Chemical-structure-of-paclitaxel-Paclitaxel-consist-of-taxane-ring-with-a-four-membered_fig3_279153612>. Accessed October 2, 2018.)

CHEMICAL COMPOSITION

The Pacific yew is poisonous because it contains at least 11 diterpene alkaloids, known collectively as *taxines*. The structure of only two of the alkaloid constituents is known: taxine A, which accounts for 30%, and taxine B, which accounts for 2%. Paclitaxel (Fig. 118.2), like all taxines, is a pseudoalkaloid because its nitrogen is a pseudoalkaloid but not a constituent of taxine because its nitrogen is acylated with benzoic acid and has no basic principle. The concentration of paclitaxel in yew bark is low, only 0.01%. Pacific yew needles contain a similar concentration of paclitaxel.[4a]

HISTORY AND FOLK USE

Historically, the yew has been highly valued for its dense, resilient, decay-resistant, tight-grained wood and its medicinal properties. The Greeks named the yew *toxus* in reference to its use for making a strong bow *(toxon)*, and its poisonous nature *(toxikon)*.[2] It was used as an animal and fish poison by primitive cultures and also for murder and suicide. In the 1st century AD, Claudius suggested its use as an antidote for viper bites. Europeans used it as an abortifacient and to treat heart ailments and hydrophobia.[2] Native Americans used the yew for many ailments including the following:

- Rheumatism
- Lung ailments
- Colds and fever
- Pain and numbness
- Paralysis
- Scurvy
- Stomachache
- Bowel ailments
- Dysmenorrhea
- Gonorrhea

Women ate yew arils to prevent conception. Youths rubbed smooth sticks of yew on their developing bodies to gain its strength. Both the bark and the leaves have been brewed for tea, and powders have been made from the bark alone. The fleshy red aril that surrounds the seed is not poisonous, although the seed itself is.[5]

There is a lot of folklore about the yew's supernatural powers. Because it is a slow-growing, long-lived tree, it was associated with immortality and used in spells to raise the dead.[6] Because it was regarded as among the most potent of trees for protection against evil, it was considered unlucky to cut down or damage a yew tree. Many were planted in churchyards/graveyards and alongside homes for protection. Specimens survive today despite main trunks being hollowed out from decay after hundreds of years of existence.

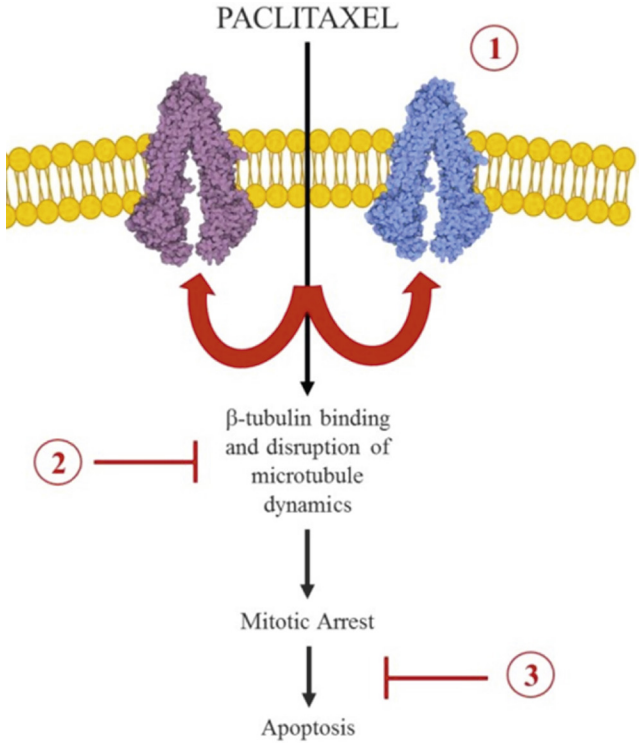


Fig. 118.3 The cellular mechanism of action by which paclitaxel serves as an anticancer drug. (From Barbuti AM, Chen ZS. Paclitaxel through the ages of anticancer therapy: exploring its role in chemoresistance and radiation therapy. *Cancers (Basel)*. 2015;7[4]:2360–2371. PubMed PMID: 26633515. <https://openi.nlm.nih.gov/detailedresult.php?img=PMC4695897_cancers-07-00897-g002&query=paclitaxel&req=4&npos=484>. Accessed October 2, 2018.)

PHARMACOLOGY

Paclitaxel's anticancer action is unique in that it inhibits cell division by promoting the formation of microtubules, the rod-like structures that function as a cell skeleton, making cells more stable and resistant to depolymerization (Fig. 118.3). In contrast, other anticancer phytoagents (e.g., colchicine and vinca alkaloids) induce the polymerization

of microtubules. In addition, under the influence of paclitaxel, the microtubules polymerize independently of the microtubule-organizing center, which is in a perinuclear area, and instead localize predominantly in the cell's periphery.[7] This interferes with the mitotic spindle and selectively blocks cells in the G_2 and M phases of the cell cycle, the most radiosensitive phases. Additionally, paclitaxel induces the formation of abnormal spindle asters that do not require centrioles for enucleation and are reversible after treatment.[8–11] Furthermore, in vivo, paclitaxel has demonstrated an ability to activate the local release of an apoptosis-inducing cytokine.[12] Studies on cancer cell lines induced with *gml,* a novel gene, have demonstrated a marked increase in sensitivity to paclitaxel via apoptosis. An assay for *gml* expression could serve as a clinically useful predictor of chemotherapeutic sensitivity.[13]

CLINICAL APPLICATIONS

Paclitaxel has demonstrated a broad spectrum of antitumor activity. Phase I trials, begun in 1983, demonstrated paclitaxel's antineoplastic activity against several tumor types, such as the following[14–21]:

- Melanoma
- Adenocarcinoma of unknown origin
- Refractory ovarian carcinoma
- Small-cell and non–small-cell lung carcinoma
- Gastric, colon, prostate, breast, and head and neck carcinomas
- Lymphoblastic and myeloblastic leukemias

In early studies, impressive results were seen using paclitaxel in combination with other antineoplastic agents, such as cisplatin.[22] Having treated patients who were previously resistant to cisplatin with the combination of cisplatin and paclitaxel, the Gynecology Oncology Group reported a 33% response rate.[23] Trials were quickly conducted on a number of solid tumor types, including small-cell and non–small-cell lung, renal, gastric, breast, advanced ovarian, colon, and cervical carcinomas; head and neck cancers; small-cell prostate carcinomas; and low-grade non-Hodgkin lymphoma.[24] Paclitaxel also has activity in other malignancies that are refractory to conventional chemotherapy, including previously treated lymphoma; small-cell lung cancers; and esophageal, gastric, endometrial, bladder, and germ-cell tumors. Paclitaxel is also active against AIDS-associated Kaposi's sarcoma. Although paclitaxel is a well-accepted treatment option for these cancers and others, significant toxicities, such as myelosuppression and peripheral neuropathy, limit the effectiveness of paclitaxel-based treatment regimens.[25,26] These toxicities will be discussed further.

TOXICITY

Human poisoning from the deliberate consumption of yew leaves or seeds is now rare.[27] Published cases involving psychiatric patients and prisoners describe the first symptoms of intoxication as appearing 1 hour after ingestion. The manifestations include mydriasis, nausea, vomiting, abdominal cramping, and arrhythmia. Death occurs from cardiac arrest 3 to 24 hours after ingestion.[28] The lethal dose in humans is approximately four or five handfuls of leaves, corresponding to 150 needles. No specific antidote is known.

Paclitaxel binds 95% to 98% with plasma proteins yet is readily eliminated through hepatic metabolism, biliary excretion, and/or extensive tissue binding. Total urinary excretion has been insignificant, indicating that renal clearance contributes minimally to systemic clearance.[21,29–31] Hepatic metabolism via cytochrome P450 (CYP) is involved for both paclitaxel and docetaxel. However, the former is hydroxylated by CYP2C8, whereas the latter is hydroxylated by CYP3A4.[32]

The role of whole yew preparations in clinical practice today is uncertain. While tincture is being used empirically for cancer patients, there is no clinical research regarding efficacy or safety. Non-paclitaxel taxanes have been shown to reverse resistance to paclitaxel in cancer cells in vitro, giving an experimental basis for the potential importance of whole-plant (at very low doses) compared to using just the isolated constituents.[31a] Non-paclitaxel taxanes enhance the absorption of paclitaxel experimentally, another reason to research whole plant extracts for clinical use.[31b]

Toxicity manifests as follows:

- Bone marrow suppression
- Hypersensitivity
- Cardiovascular abnormalities
- Neurotoxicity
- Arthralgias and myalgias
- Alopecia
- Gastrointestinal upset

Junctional tachycardia via conduction block rather than direct primary toxicity on myocytes has been suggested.[33] Hypersensitivity, skin reactions, and accumulated fluid retention syndrome are minimized with a 3- to 5-day regimen of corticosteroids before paclitaxel infusion.[34]

Patients with leukemia who are treated with high doses of paclitaxel exhibited mucositis, which has also appeared in response to lower, cumulative dosing. An accumulation of epidermal cells with abnormal paclitaxel-induced spindle asters has been evident in ulcerated mucosa, indicating that the cell cycle was arrested in mitosis.[35]

Paclitaxel has been known to inhibit neurite growth and induce prominent morphological effects, such as microtubule bundles in neurons, satellite cells, and Schwann cells in organotypic dorsal root ganglion cultures.[35–41] Clinically, the most common symptoms have been glove-and-stocking paresthesias and perioral numbness. Distal sensory loss to large-fiber (proprioception, vibration) and small-fiber (pinprick, temperature) modalities and loss or decrease of distal deep tendon reflexes have been noted, although motor nerves seem to be spared. In general, the clinical incidence and severity of peripheral neurotoxicity have been dose-related. Patients with a history of substantial alcohol use have appeared to be more predisposed to the development of the neurosensory toxic effects of cisplatin and paclitaxel.[14–17,42–44]

The development of a suitable clinical formulation has been hampered by paclitaxel's poor aqueous solubility. Cremophor is being used as the vehicle for administration and has been implicated in side effects, such as type 1 hypersensitivity reactions.[45]

Neutropenia, the principal dose-limiting toxic effect of paclitaxel, resolves rapidly (in 15–21 days) after treatment is stopped.[42] The major clinical risk factor for neutropenia seems to be the extent of prior myelotoxic chemotherapy and/or irradiation.

Bradyarrhythmias, which have been noted as transient and asymptomatic, have been reported during paclitaxel infusion in at least 29% of patients with ovarian cancer.[42] This development appears to be related more to paclitaxel because other agents formulated with Cremophor have not been associated with similar arrhythmias. Atypical chest pains during paclitaxel infusion have been observed, but they are believed to be a manifestation of a hypersensitivity reaction.[27,43]

Other paclitaxel- or Cremophor-related side effects are sudden and complete alopecia, often occurring in a single day; local venous toxic effects such as erythema, tenderness, and cellulitis in areas of dermal extravasation; and fatigue, headaches, taste perversions, significant elevations in serum triglycerides, and minor rises in hepatic and renal function values.[21]

Medical problems that may affect the use of paclitaxel are listed in Box 118.2. Studies in rats and rabbits have shown that paclitaxel causes miscarriages and fetal deaths. Breastfeeding is contraindicated during paclitaxel therapy. Paclitaxel bound to albumin rather than using a solvent results in fewer and less severe side effects, with much-reduced allergic reactions.[46]

BOX 118.1 Medications That Should Be Avoided With Paclitaxel

- Deferiprone
- Dexrazoxane
- Ganciclovir
- Palifermin
- Primaquine
- Radium Ra 223 dichloride
- Sipuleucel-T
- Thiotepa
- Valganciclovir

BOX 118.2 Medical Problems That May Affect the Use of Paclitaxel

- Chickenpox
- Herpes zoster
- Cardiac arrhythmias
- Infection

DRUG INTERACTIONS

There are conflicting reports regarding drug interactions of *Taxus brevifolia*. Considering paclitaxel is metabolized by CYP450 enzymes, administration with other drugs can alter metabolism depending on the target molecule, schedule, and sequence of administration. The pharmaceutical drug, Taxol, interacts with more than 200 different medications. Because of enhanced toxicity, paclitaxel should be administered 24 hours after other chemotherapeutic agents, such as doxorubicin and epirubicin.[47] Vaccinations that include live viruses are contraindicated because the risk of disseminated infection is increased, resulting from the immunosuppressive effects of paclitaxel. Box 118.1 includes a list of medications that should also be avoided with concurrent use of paclitaxel.

Urtica dioica (Stinging Nettle)

Eric L. Yarnell, ND, RH(AHG) and *Kathy Abascal, BS, JD, RH(AHG)*

OUTLINE

Urtica dioica ssp. *dioica* (family: *Urticaceae*)
Synonym: *Urtica dioica*
Common names: stinging nettle, nettle, great nettle

GENERAL DESCRIPTION

Urtica dioica is a prolific Eurasian perennial that has become naturalized around the globe. Two major subspecies are recognized as important in medicine in the West: *dioica,* the standard stinging nettle; and *gracilis,* the California nettle. *Urtica urens,* the dwarf or dog nettle, is also used interchangeably. The leaves, fruit (often inappropriately called seeds), and root are all used, each somewhat differently (Fig. 119.1).

CHEMICAL COMPOSITION

Nettle leaves are known to contain flavonoid glycosides (including quercetin and kaempferol), phenylpropanoids (including caffeic malic acid), sterols, carotenoids, vitamins, and minerals.[1] The stinging hairs contain formic acid, histamine, serotonin, and choline, among other irritants. Very little is known about the chemistry of the fruits except that they contain protein, carbohydrate, and 30% fatty acids.[1]

The chemistry of the roots of stinging nettle has been the most thoroughly examined.[2] Acidic polysaccharides, lectins, sterols (including β-sitosterol), triterpenoids, the coumarin-like compound scopoletin, phenylpropanoids, ceramides, and lignans are all potentially related to the physiological effects of the roots (Figs. 119.2 and 119.3).[3] Lignans of potential importance include neoolivil and secoisolariciresinol, which are metabolized by human gut flora to enterodiol and enterolactone, well-characterized phytoestrogenic compounds.[4]

HISTORY AND FOLK USE

Urtica species have long been employed as medicine in Europe and Asia. The steamed or dried leaves were eaten as a vegetable or seasoning and often still are.[4] Nettle fiber was formerly processed into thread used to make clothing, rope, and sailcloth, although it was ultimately replaced by flax. The source of the fiber known as "ramie" comes from the plant *Boehmeria nivea,* which is also in the *Urticaceae* family. The word *nettle* appears to be derived from the old Anglo-Saxon *noedl,* "needle," and even before that to the common Indo-European verb *ne,* "to spin/sew." There is little record of the use of the roots in traditional cultures except as a source of yellow dye.[4]

Medicinally, stinging nettle leaves were once considered a spring tonic, taken each year in particular by patients with chronic skin or rheumatic conditions.[5] The leaves' diuretic (also ascribed to the fruits), tonifying, lactagogue, antiasthmatic, antihemorrhagic, antidiabetic, and "blood-building" properties are consistently referenced by European herbalists.[6,7] Up to modern times, there are descriptions of applications of fresh leaves to aching joints, intentionally causing stings to relieve symptoms. Stinging nettle leaves are also frequently said to promote hair growth.

PHARMACOLOGY

The two principal effects of stinging nettle leaves are inhibition of inflammation and promotion of diuresis. Most research has involved a proprietary 50% ethanol 10:1 extract of the leaves known as IDS 23 (Strathmann AG & Co, Hamburg, Germany). In vitro, IDS 23 extract and caffeic malic acid inhibit 5-lipoxygenase and cyclooxygenase (isotype not determined); the whole extracts are more potent than caffeic malic acid alone.[8] IDS 23 also inhibits the secretion of tumor necrosis factor-α and interleukin-1-β induced by lipopolysaccharide in human blood; phenylpropanoids and flavonoids isolated from the leaves were not effective in this system.[9] Perhaps even more important, IDS 23 has been shown to inhibit activation of nuclear factor kappa B (NFκB) by preventing degradation of its inhibitory subunit, IκB, in vitro.[10]

In vitro, IDS 23 stimulated the production of interleukin (IL)-4 by monocytes and inhibited the production of IL-2 and interferon-γ (IFN-γ).[11] IL-4 production promotes the formation of type 2 helper T cells, which are associated with much less inflammation than type 1 helper T cells. Preliminary in vitro research also shows that nettle leaves are strong antioxidants.[12] The multiple inflammation-modulating,

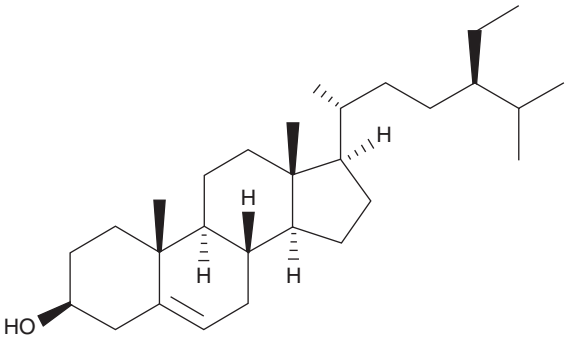

Fig. 119.3 Structure of beta-sitosterol.

immunomodulating, and antioxidant effects of stinging nettle leaves help explain how they could be helpful for so many inflammatory diseases.

A continuous intravenous infusion of an aqueous stinging nettle leaf extract increased natriuresis and urine volume in rats, leading to a reduction in blood pressure.[13] In a small uncontrolled trial of patients with congestive heart failure, stinging nettle leaf juice showed a diuretic effect.[14] Although much more work is needed, existing data support the traditional belief that stinging nettle leaves are a mild diuretic. An extract combining stinging nettle root and *Prunus africanum* (pygeum) bark weakly inhibited 5-α-reductase and moderately inhibited aromatase in prostate tissue.[15] A separate study found that stinging nettle root extract inhibited aromatase in vitro, although much less potently than *Serenoa repens* (saw palmetto) extract.[16] The two combined showed some additive effects. No effect was noted for another stinging nettle root extract on prostatic α_1-adrenergic receptors.[17]

A double-blind placebo-controlled trial confirms that stinging nettle root extracts inhibit or reduce sex hormone–binding globulin (SHBG) levels in men with benign prostatic hyperplasia (BPH).[18] In vitro, ethanolic extracts were shown to decrease the binding of dihydrotestosterone by SHBG.[19,20] Lignans and trihydroxyoctadecenoic acids but not triterpenoids were active in this study. Stinging nettle root extracts have also been repeatedly shown to interfere with the binding of epidermal growth factor, a major stimulus of BPH, to its receptor on prostate cells.[4,21] Lectins appeared to be the most active compounds isolated in these studies.

CLINICAL APPLICATIONS

The major uses of stinging nettle, organized according to the part being used and the route of administration, are shown in Table 119.1.[22]

Benign Prostatic Hyperplasia

Extracts of stinging nettle root have been the subject of several clinical trials showing its benefit for the symptoms of BPH (Table 119.2). Many of these are small, older, short trials, although longer, modern trials have also been conducted, and all show at least some benefit over placebo. The three most rigorous trials are reviewed in more depth here.

In one double-blind trial, 50 men with stage I or II (mild to moderate) BPH symptoms were randomly assigned to receive either placebo or 300 mg of an extract of stinging nettle root standardized to an unspecified amount of an unspecified steroid glycoside twice a day.[23] SHBG levels were significantly lower and urine volume and maximum flow (but not average flow) significantly higher in the stinging nettle group than in the placebo group. Residual urine volume rose slightly and nonsignificantly in both groups. No adverse effects were reported.

The most rigorous trial to date was a 1-year trial involving 246 men in which 459 mg of a stinging nettle root extract was significantly more effective than placebo at improving BPH symptoms.[24] Urine flow and residual volume were minimally affected, with no statistical difference between the nettle extract and placebo. Adverse effect rates did not differ between the treatment groups.

In a large double-blind trial, 558 men with BPH were randomized to take either 120 mg of a 20:1 diethyl ether extract in 18 drops of liquid three times a day or placebo for 1 year.[25] Symptoms, maximum flow rate, and postvoid residual urine amounts improved significantly in the nettle group compared with placebo. There was also a small decrease in prostate volume (approximately 3 mL) versus none in the placebo group, a significant difference. There were no adverse effects in either group.

No clinical trial has compared nettle root alone with available drugs for the treatment of BPH, although combination studies have done so. Stinging nettle combined with saw palmetto was as effective as finasteride (Proscar) and had significantly fewer adverse effects in a double-blind trial.[26] This trial ran for 1 year and involved 543 men with symptomatic BPH. An uncontrolled postmarketing study that monitored 2080 patients with mildly symptomatic BPH who took the same saw palmetto and stinging nettle extract documented only 15 mild adverse events.[27] The extract combination was very helpful in relieving symptoms. Other double-blind trials confirm that a combination of saw palmetto and nettle root extracts are superior to placebo at relieving the symptoms of BPH, with minimal adverse effects.[28,29]

In summary, these trials support the notion that stinging nettle root has some benefit in men with symptomatic BPH, although higher-quality clinical trials are needed to confirm this benefit.

It should also be noted that a combination of nettle root and saw palmetto extracts, quercetin, and curcumin along with the

TABLE 119.1 Major Uses of *Urtica dioica* by Plant Part

Plant Part	Route of Administration	Major Action	Main Indications	Level of Clinical Support[a]	Approved by Commission E[b]
Leaf	Internal	Anti-inflammatory, diuretic	Urinary tract Infection	Absent	Yes
			Allergic rhinitis	Poor	No
			Arthritis	Poor	Yes
			Kidney stone prevention	Absent	Yes
Leaf	Topical	Anti-inflammatory, counterirritant	Arthritis	Poor	No
Seed	Internal	Nephroprotective	Chronic renal failure	Absent	No
Root	Internal	Interference with sex hormone–binding globulin and growth factors, aromatase inhibition	Benign prostatic hyperplasia	Good	Yes

[a]Level of clinical support refers to the number of published clinical trials with positive results. Poor = one or two trials and mostly of low quality; good = more than two trials of good or high quality.

TABLE 119.2 Randomized Controlled Trials of Nettle Root for Benign Prostatic Hyperplasia

Trial	Subjects (*n*, on nettle; *p*, on placebo)	Extract and Dose	Duration	Outcome
Vontobel et al.[23]	*n* = 25, *p* = 25	300 mg bid (5:1 methanol extract)	9 wk	Nettle improves maximum flow better than placebo
Dathe and Schmid[47]	*n* = 35, *p* = 37	300 mg bid (5:1 methanol extract)	6–8 wk	Nettle not superior to placebo
Fischer and Wilbert[18]	*n* = 20, *p* = 20	300 mg bid (5:1 methanol extract)	7 mo	Nettle superior to placebo for symptoms, mean flow improvement
Engelmann[48]	n = 47, p = 47	459 mg qd of a 7–14:1 methanol extract	6 mo	Nettle superior to placebo for IPSS[a] > and maximum flow
Schneider and Rübben[24]	*n* = 124, *p* = 122	459 mg qd of a 7–14:1 methanol extract	12 mo	Nettle superior to placebo for IPSS reduction
Safarinejad[25]	*n* = 287, *p* = 271	120 mg tid of 20:1 diethyl ether extract	6 mo	Nettle superior to placebo for IPSS and maximum flow

[a]*IPSS,* International Prostate Symptom Score, a standardized seven-item questionnaire used to monitor symptoms of BPH.

fluoroquinolone antibiotic prulifloxacin was significantly more likely to result in resolution of chronic prostatitis symptoms than prulifloxacin alone in one randomized trial.[30] The combination group was also significantly less likely to have recurrent symptoms 6 months later. More research is needed to determine to what extent nettle root has a beneficial role in chronic prostatitis.

Arthritis

Stinging nettle leaves have been used internally and topically to treat arthritis. An initial uncontrolled clinical trial found that 1340 mg a day of a nettle leaf extract (6.4:1–8.1:1) reduced the need for nonsteroidal anti-inflammatory drugs (NSAIDs) by 50% in patients with osteoarthritis of the knee.[31]

A subsequent open trial involving patients with acute exacerbations of various forms of arthritis compared the use of a standard 200-mg dose of the NSAID diclofenac (Cambia, Cataflam, Voltaren, Voltarol, Zipsor) with a subtherapeutic 50-mg dose of diclofenac combined with 50-g of freeze-dried nettle once a day for 2 weeks.[32] The two groups had similar levels of improvement (no significant differences between the groups) compared with baseline on various pain rating scales. There were no serious adverse events. Double-blind trials to confirm these results are warranted.

Two case studies published in 1994 heralded the first mention in the modern medical literature of topical stinging nettles as potentially effective pain relievers for patients with arthritis.[33] The practitioner who noted these cases went on to publish a case series, again showing that many patients treating themselves with topical nettle stings were experiencing noticeable pain relief, allowing for reductions in NSAID dosage.[34]

A double-blind trial has been conducted evaluating the effects of nettles in patients with osteoarthritis of the thumb or index finger.[35] The placebo chosen was *Lamium album* (white deadnettle) leaf, a stingless mimic of *U. dioica.* Each patient used the leaf of the plant he or she was being treated with once a day, applying it to three different spots for 30 seconds each. After 1 week of treatment, there was a 5-week washout period, followed by a 1-week crossover treatment with the other plant. When patients were treated with stinging nettle, their pain and disability scores were significantly better than during deadnettle treatment. Although the use of a nonstinging placebo may have compromised this trial, it does provide support for the folk use of topical application of nettles to reduce arthritis symptoms.

A similar single-blind, randomized trial using nonstinging *Urtica galeopsifolia* as a control did not find that stinging nettle leaves were more effective for patients with knee osteoarthritis, although treatment was considered tolerable.[36] A formula combining nettle leaf extract, rose hips concentrate, and *Harpagophytum procumbens/H. zeyheri* (devil's claw) was tested against placebo in a double-blind, randomized trial in patients with knee osteoarthritis.[37] After 3 months, the herbal combination significantly reduced symptoms compared with the placebo with minimal adverse effects.

Diabetes Mellitus

Numerous studies have investigated the traditional use of nettle leaf for people with diabetes. A double-blind, randomized trial of 500 mg of nettle leaf extract three times a day for 3 months found that it significantly improved glycemic control in patients with type 2 diabetes compared with placebo.[38] It was safely combined with a range of oral hypoglycemic medications in this trial. In another double-blind, randomized trial, a formula combining nettle leaf, *Silybum marianum* (milk thistle), and *Boswellia serrata* (frankincense) was similarly found to improve glycemic control, while also lowering triglyceride levels, compared with placebo.[39] Other double-blind trials in patients with type 2 diabetes have found that nettle leaf extracts can reduce inflammatory markers, reduce excessive oxidation, improve blood lipid parameters, lower serum transaminases, and lower blood glucose levels significantly compared with placebo.[40–42] Hypoglycemia did not occur with nettle leaf.

Allergic Rhinitis

One double-blind trial reported on the efficacy of stinging nettle leaves for allergic rhinitis.[43] A total of 69 patients with acute onset of allergic rhinitis symptoms took 600 mg of freeze-dried stinging nettle or placebo at the onset of symptoms, then recorded their responses 1 hour later. The total number of doses and general responses were recorded over the remaining week. Overall assessment of the efficacy of stinging nettle was better than that of a placebo, although differences in daily symptom logs did not show a strong difference. No statistical analysis was provided. Two patients in the nettle group dropped out owing to an intensification of symptoms, but no other significant adverse effects were noted. A second double-blind, randomized trial of 40 patients found no difference between a nettle root extract and placebo for allergic rhinitis symptoms after 1 month.[44] There was a significant reduction in interferon-gamma levels with nettle root over placebo, suggesting a longer or larger trial (or using a different dose or extract) might ultimately show benefit.

Chronic Renal Failure

The seed of nettle may have the ability to nonspecifically protect nephrons from multiple insults and thus delay the progression of chronic renal failure. Two case studies have been published, one patient having lupus nephritis and a kidney transplant and another who underwent nephrectomy for cancer and whose serum creatinine levels declined during treatment with a nettle seed tincture.[45] The dosage used was 5 mL three times a day.

Galactagogue

An herbal tea containing nettle leaf, *Melissa officinalis* (lemon balm), *Carum carvi* (caraway), *Pimpinella anisum* (anise), *Foeniculum vulgare* (fennel), *Galega officinalis* (goat's rue), and *Cymbopogon citratus* (lemongrass) was compared with a tea containing hibiscus and rose hips or supportive measures only in 95 women with preterm infants in a randomized open trial.[46] Breast milk production increased by 80% with the herbal tea, compared with 30% to 34% in the control groups. Infant weight gain did not vary between groups because mothers who were not able to produce enough milk supplemented with formula.

TABLE 119.3 Dosage Forms of Stinging Nettle

Dosage Form	Leaf	Root
Tea	Infuse 4 g in 150 mL water three times a day[49]	Decoct 4–6 g in 150 mL water once a day[49]
Freeze-dried capsules	300 mg twice a day, up to 50 g once a day[32,43]	Not available
Concentrated extracts	Not available	5:1–10:1 extract 500 mg three times a day[31]
Tincture	30% ethanol, 1:2–1:5 weight to volume, 3–14 mL three times a day[50]	50% ethanol, 1:2–1:5, 4–9 mL three times a day[50]

DOSAGE

Stinging nettle leaf and root are available in several dosage forms, as summarized in Table 119.3. Fresh leaves are applied one to two times a day to every few days depending on symptoms, so treatment obviously requires ongoing access to growing plants.

TOXICITY

Oral use of stinging nettle leaf, fruit, or root is not associated with any significant adverse effects. Topical application of fresh leaf raises mildly painful, inflamed wheals because of the stinging hairs. As previously noted, this effect is sometimes exploited therapeutically. The welts usually clear completely within 2 hours, with lessening of symptoms after 30 minutes. As with all herbal medicines, it is possible for patients to be allergic to stinging nettle, although this reaction is exceedingly rare.

DRUG INTERACTIONS

There are no documented negative interactions between stinging nettle and any other medication. Some open trials (described previously) suggest that stinging nettle leaves potentiate NSAIDs, allowing for dose reductions of these agents.

Uva ursi (Bearberry)

Michael T. Murray, ND

OUTLINE

Arctostaphylos uva ursi (family: *Ericaceae*)
Common names: bearberry, upland cranberry

GENERAL DESCRIPTION

Arctostaphylos uva ursi is a small evergreen shrub found in the northern United States and in Europe. A single long, fibrous main root sends out several prostrate or buried stems 4 to 6 inches long. The bark is dark brown, the leaves are obovate to spatulate and 0.5 to 1 inch long, the flowers are pink or white and grow in sparse terminal clusters, and the fruit is a bright red or pink (Figs. 120.1A and B).

CHEMICAL COMPOSITION

The most active ingredient of *uva ursi* is arbutin, which typically composes 7% to 9% of the leaves (Fig. 120.2). Other constituents are as follows[1–4]:

- Tannins (6%–7%)
- Flavonoids (quercetin)
- Allantoin
- Gallic and ellagic acids
- Volatile oils
- A resin (urvone)

HISTORY AND FOLK USE

This plant has a long history of use for its diuretic and astringent properties. Conditions for which *uva ursi* was used include chronic cystitis, nephritis, kidney stones, and bronchitis.[1]

PHARMACOLOGY

Antimicrobial Effects

Although pharmacological research has focused primarily on arbutin, the pharmacology of the whole plant is different from that of arbutin alone. The crude plant extracts are much more effective medicinally than the isolated constituent arbutin.[5] This fact appears to be related to the activity of gallic acid, which prevents the splitting of arbutin by such enzymes as β-glucosidase contained in gut bacteria.[2] Arbutin undergoes hydrolysis in the stomach or intestinal tract to produce hydroquinone, its aglycone, which has urinary antiseptic properties.[6] The hydrolysis of arbutin is responsible for much of the therapeutic effect of *uva ursi*.[1,6] By preventing the splitting of arbutin, the flavonoid components allow more arbutin to be hydrolyzed and absorbed than when arbutin is administered as an isolated component. Approximately 65% of an arbutin dosage is excreted in the urine as hydroquinone glucuronide or sulfate.[7,8]

Arbutin alone has been reported to be an effective urinary antibiotic, but only if taken in large doses and if the urine is alkaline (once again documenting the value of whole-plant medicines).[1] It is reported to be active against *Candida albicans* and *Staphylococcus aureus* and especially against *Escherichia coli*.[5,9] *Uva ursi* also has diuretic properties.[1]

Anti-Inflammatory Effects

Some early animal research is now showing that arbutin, and possibly other constituents of *uva ursi,* potentiate the activity of commonly prescribed anti-inflammatory drugs. One study found that an aqueous extract increased the inhibitory activity of dexamethasone in allergic and inflammatory models without increasing any of the side effects.[10] Similar results have been demonstrated with isolated arbutin combined with indomethacin.[11]

Inhibition of Melanin Synthesis

Uva ursi extract has been shown to inhibit the enzyme tyrosinase.[12] This effect impairs melanin synthesis, which indicates that *uva ursi* extract may be effective as a whitening agent for the skin. In fact, hydroquinone is approved by the U.S. Food and Drug Administration as an agent in over-the-counter skin products for bleaching age spots and hyperpigmentation.

CLINICAL APPLICATIONS

Crude extracts are widely used in Europe as components in certain diuretic and laxative products, but the major use of *uva ursi* is as a urinary disinfectant in cases of urinary tract infection.[1]

Fig. 120.1 (A) *Arctostaphylos uva-ursi* flower leaf. (B) *A. uva-ursi* habit.

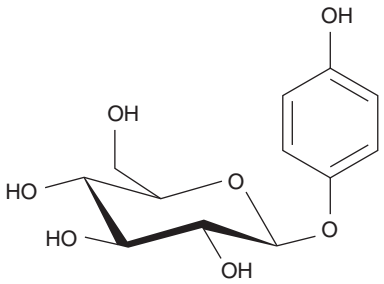

Fig. 120.2 Arbutin.

Urinary Tract Infections

Uva ursi is reported to be especially active against *E. coli*.[6] As well as exerting direct antibiotic effects, *uva ursi* extract promotes the aggregation of *E. coli* in vitro.[9] These combined effects indicate that *uva ursi* can be used both in the immediate treatment and in the prevention of recurrent cystitis. In one double-blind study, the prophylactic effects of a standardized *uva ursi* extract and a placebo on recurrent cystitis were evaluated in 57 women.[13] At the end of 1 year, 5 of 27 women in the placebo group had a recurrence, whereas none of the 30 women receiving *uva ursi* extract had a recurrence. No side effects were reported in either group. These impressive results indicate that regular use of *uva ursi* is a safe and effective measure to prevent recurrent cystitis. In a study of normal subjects, consuming *uva ursi* tea was shown to have bacteriostatic effects greater than normal urine.[6] The effectiveness of the tea in inhibiting bacterial growth (*S. aureus* and *E. coli*) depended on adequate excretion products of arbutin (hydroquinone paired with glucuronate or sulfur) and a pH above 8. Alkalinization of the urine with bicarbonate or citrate salts in conjunction with *uva ursi* may enhance the therapeutic effects in acute urinary tract infections.

DOSAGES

The dosages for *uva ursi* are as follows:

- Dried leaves or as an infusion: 1.5 to 4.0 g (1–2 tsp) three times daily
- Freeze-dried leaves: 500 to 1000 mg three times daily
- Tincture (1:5): 4 to 68 mL (1–2 tsp) three times daily
- Fluid extract (1:1): 2 to 4 mL (1/2–1 tsp) three times daily
- Powdered solid extract (10% arbutin): 250 to 500 mg three times daily

TOXICOLOGY

The toxicological concern with *uva ursi* is related to the conversion of arbutin to hydroquinone, but toxicity is extremely unlikely with the consumption of commercial preparations.[7,14] In the most recent evaluation, *uva ursi* was judged to be very safe in the treatment of urinary tract infections.[15] Hydroquinone is metabolized in the liver by Phase II enzymes into hydroquinone glucuronate or sulfate and then excreted in the urine. At therapeutic levels of *uva ursi* leaf extract, the high range may provide 420 mg hydroquinone derivatives calculated as anhydrous arbutin. The calculation is that which would liberate free hydroquinone in the urine at a maximum exposure level of 11 μg/kg body weight. In contrast, in various laboratory animals, the oral LD_{50} of hydroquinone in 2% aqueous solution is between 320 and 550 mg/kg body weight.

Signs and symptoms of *uva ursi* toxicity include the following:

- Tinnitus
- Nausea
- Vomiting
- Sense of suffocation
- Shortness of breath
- Cyanosis
- Convulsions
- Delirium
- Collapse

The only significant side effect reported in the medical literature with *uva ursi* consumption was that of a 56-year-old woman who ingested *uva ursi* for 3 years and presented with vision loss.[16] Diagnosis indicated bilateral bull's-eye maculopathy, presumably due to inhibition of retinal melanin synthesis. This report raises the question of the appropriateness of long-term therapy with *uva ursi*.

DRUG INTERACTIONS

An extract of *uva ursi* has been found to markedly potentiate the effects of beta-lactam antibiotics, such as oxacillin (Bactocil) and cefmetazole (Zefazone), against methicillin-resistant *S. aureus.*[17] The effective compound was identified as the polyphenol corilagin. Corilagin reduced the mean inhibitory concentrations (MICs) of various beta-lactams 100- to 2000-fold but not the MICs of other antimicrobial agents tested. The effect of corilagin and oxacillin was synergistic. Corilagin showed a bactericidal action when added to the growth medium in combination with oxacillin.[18]

Vaccinium macrocarpon (Cranberry)

Sherry Torkos, BSc, Phm, RPh, Rhonda Dorren, BScPharm,* and *Michael T. Murray*, ND*

OUTLINE

GENERAL DESCRIPTION

The shiny scarlet cranberry, like its cousin the blueberry, belongs to the genus *Vaccinium* and is found growing in the wild in northern Europe, northern Asia, and North America. The American cranberry *(Vaccinium macrocarpon)* is the species associated with the majority of the scientific research on health benefits. Cultivated cranberries are grown in huge sandy bogs on low, trailing vines. Cranberries have also been called "bounce berries," because ripe berries bounce, and "crane berries," a reference to the cranberry shrub's pale pink blossoms, which resemble the heads of the cranes that frequent cranberry bogs.

Cranberry has garnered a lot of attention as a possible alternative to antibiotics in the prevention of urinary tract infections (UTIs). Low-dose antibiotics are often prescribed for prevention of infections, but this regime leads to increases in antibiotic resistance as well as side effects and treatment complications for the patient. The emergence of multiple antibiotic–resistant organisms in the general community is a potentially serious threat to public health.[1] A paradigm shift in the prevention and treatment of infectious disease, particularly chronic infections, may be required to prevent antibiotics from becoming obsolete; where appropriate, alternatives to antibiotics require consideration.[2] As a result, for prevention of infections, there has been an increase in the use of natural products as well as the consumption of cranberries (processed and fresh) in North America (Fig. 121.1).

The majority of research on cranberry involves urinary tract health. However, the historical bibliography of investigations on cranberry also includes but is not limited to type 2 diabetes; prevention of blockage in urinary catheters; deodorizing of offensive urine; healing skin around urostomy stomas; and as an anticarcinogen, antifungal, and antioxidant agent.[3–9]

CHEMICAL COMPOSITION

In addition to ascorbic acid, cranberry juice contains a variety of substances that may be biologically active. Cranberries contain flavonoids and other phenolic compounds.[10] The quantity of flavonoids in cranberry juice (approximately 31.9 mg per serving) is higher than in red wine (approximately 22 mg) but lower than in dark chocolate containing high flavanol levels (approximately 165 mg) and apples (approximately 147 mg). In a sample of freshly squeezed cranberry juice, one study found 400 mg of total flavonoids and phenolic compounds per liter of sample, which was distributed as about 44% of phenolic acids and 56% of flavonoids. Benzoic acid was the major phenolic compound, and the major flavonols were quercetin and myricetin. Anthocyanins are also found in cranberry and are responsible for the red pigmentation of the fruit. They are abundant in the form of cyanidin glycosides (sugar groups attached).[11,12] Cranberries also contain organic acids, including quinic, malic, and citric acids.[13]

Cranberries contain proanthocyanidins (also referred to as condensed tannins), which are composed of epicatechins linked together by unusual A-type bonds, not found in most other tannin-containing foods. These different forms of polyphenols are often mentioned in the scientific literature on cranberry.

HISTORY AND FOLK USE

Native Americans used cranberry both as food and for the treatment of bladder and kidney diseases. The Pilgrims learned about cranberry from local tribes for a condition referred to as "bladder gravel" (small bladder stones) and to remove blood toxins. Cranberries were served to ships' crews as a source of vitamin C to prevent scurvy. Other documented medical applications in the 17th century include the relief of stomach ailments, liver problems, blood disorders, and cancer. The boiled berry and seal oil were used to reduce the severity of gallbladder attacks.[14]

Cranberry's beneficial effects on urinary tract health were initially thought to be due to acidification of the urine. Direct antibacterial and antifungal effects of cranberry juice have been shown.[15–17] Hippuric acid, converted from the quinic and benzoic acids in cranberry, is a strong bacteriostatic agent, and its potential to acidify urine has been investigated.[5,18–20] In brief, these early studies focused on the ability of cranberry juice to lower urinary pH, on the basis of its apparent ability to suppress infections and enhance antibiotic activity.[21–24] Yet

*Previous edition contributor

Fig. 121.1 *Vaccinium macrocarpon* Fruit.

clinically, the concentration of hippuric acid in cranberry does not routinely reach levels adequate for antibacterial action.

Further research failed to validate the proposed theory that cranberry reduced urinary pH. Cranberry continued to be a popular remedy for urinary health, and only in the past decade has its true mechanism of action been elucidated. Current evidence is strongest for its effectiveness in promoting urinary tract health and reducing the risk of UTIs while sparing the patient the experience of unwanted side effects and the continued use of prophylactic low-dose prescription drugs.[25]

PHARMACOLOGY

The primary application of cranberry is in the prevention of UTIs. Cranberry components interfere with bacterial adherence to mucosal cells—an important step in the development of infection. For bacteria to successfully attach to the host, they must identify and attach to epithelial cell receptor sites. Proteinaceous fibers on the cell wall of uropathogenic *Escherichia coli,* called fimbriae, produce adhesion molecules that attach to these monosaccharide or oligosaccharide receptors on uroepithelial cells. Two different fimbrial types are most important for initiating UTI: type 1 fimbriae, which adhere to mannose-specific receptors; and P fimbriae, which adhere to disaccharide α-D-Gal(1,4)-β-D-Gal (Gal-Gal) receptors.

Modern research has revealed that the proanthocyanidins (PACs) in cranberries can inhibit the adhesion of uropathogenic P-fimbriated strains of *E. coli* to bladder cells.[26–28] Cranberry contains two different inhibitors: fructose, effective for inhibiting the type 1 fimbriae; and a second, unidentified inhibitor that is effective for obstructing the Gal-Gal–specific fimbriae.[29] However, fructose is fully metabolized after consumption and does not reach the urine. Therefore it does not influence bacterial adhesion in the body. In addition, scientific evidence suggests that cranberry acts on the cell wall not only by preventing attachment of the fimbrial subunits but also by serving as a genetic control, preventing the expression of normal fimbrial subunits, or both.[30–33]

In animal models, investigations of approximately 77 clinical isolates of *E. coli* demonstrated that cranberry juice inhibited bacterial adhesion to the bladder by more than 75% for more than 60% of the strains of bacteria.[34] Further research demonstrated that cranberry significantly reduced the adherence of pathogens to urinary epithelial cells isolated from patients with UTIs, including *Proteus mirabilis, Staphylococcus aureus, Klebsiella pneumoniae, Enterobacter* species, and *Pseudomonas aeruginosa.*[35,36]

The cumulative effects of cranberry have now been demonstrated as successfully acting on cell walls to prevent the proper attachment of the fimbrial subunits, thus inhibiting bacterial adherence to uroepithelial cells, and cellular elongation.[37]

The role of PACs in UTIs has been debated because of their size, poor bioavailability, and extensive metabolism and limited knowledge about their urinary excretion.[38]

In vivo research has demonstrated that consumption of cranberry PACs results in an antiadhesion response in the urine to provide protective effects from bacteria that migrate from the perineum and vagina.[39] Research continues to investigate whether the PACs induce a direct urinary response or are broken down to smaller bioactive metabolites that reach the urine.

Larger PACs that are eliminated through the colon may bind to rectal uropathogenic bacterial isolates in the gut, thus decreasing the virulence of these microbes if they come in contact with the uroepithelium. Researchers in Finland who studied the UTI preventive effects of a commercially available cranberry-lingonberry juice concentrate stated that their findings support bacterial selection in the stool because subjects in the cranberry group had no increase in UTI recurrence during the 6 months after they had stopped the cranberry prophylaxis.[40]

More recently, a study was undertaken to determine whether the polyphenols follow a dose response in vivo at different levels of intake. A double-blind, randomized controlled trial in 10 healthy men with cranberry juice containing 409, 787, 1238, 1534, and 1910 mg total polyphenols was performed. The results demonstrated that plasma polyphenol metabolites are linearly related to the amount of polyphenols consumed and that individual variations may occur due to the gut microbiome.[41]

Emerging concepts regarding preventive considerations for the management of recurrent UTIs (RUTIs) suggest taking cranberry supplements as part of the protocol.[42]

Numerous investigations have been completed on cranberry. The following discussion provides an overview of some of the recent data, including a review of studies on cranberry and urinary tract health.

CLINICAL APPLICATIONS

Urinary Tract Applications

Reduction of Bacteriuria and Pyuria After Ingestion of Cranberry Juice

An early study conducted by Avorn et al.[43] evaluated the effects of cranberry on bacteriuria in 153 elderly women. Participants consumed 300 mL/day of either a commercially available cranberry beverage or a placebo drink that was similar in taste and contained vitamin C but no cranberry content. After 1 month of treatment, 15% of the urine samples of those who had been drinking cranberry juice had bacteriuria with pyuria, compared with 28% of those in the placebo group. Most patients with bacteriuria were asymptomatic. Although statistical significance was not achieved, there was a trend toward less antibiotic use for the treatment of UTIs in the cranberry group (1.7 vs. 3.2 antibiotics per 100 patient-months). A criticism of this trial is that the control group had a higher rate of urinary infection before the study, suggesting there may have been sampling bias, and the main outcome, identified as asymptomatic bacteriuria, does not generally require treatment.[44] Although there was a trend toward fewer clinically relevant urinary infections, the study was not designed to demonstrate that effect. This trial, like others, had a high dropout rate, which casts doubt on the long-term tolerability of cranberry juice.[45,46]

Urinary Tract Infections and Sexual Activity

Foxman et al.[47] randomly sampled 288 control subjects (college students), studying first-time UTIs in young unmarried women. Participants were recruited from a university health service, and all had engaged in sexual intercourse at least once. Compared with the general

population of students, intercourse significantly increased the risk of UTIs (43%), as did drinking carbonated soft drinks (237%), but it was found that drinking cranberry juice reduced the risk (52%).

A study in France investigated the effect of consuming a single postcoital dose of cranberry on the development of UTIs. This double-blind study evaluated 120 female patients with recurrent UTI (six or more in the previous 12 months). Patients were randomized to one of three groups and received either one capsule of infused cranberry powder made by a patented procedure (Bio-Shield, Cran-Max, known commercially in France as GynDelta), one capsule of dry cranberry extract containing 36 mg of PAC, or one capsule containing a placebo. Patients were instructed to take their test product within 6 hours after intercourse. Over the course of the study period of 45 days, 10.8% of patients in the GynDelta group suffered a UTI, compared with 18.9% in the cranberry PAC group and 43.2% in the placebo group. The results for the GynDelta were statistically significant ($P = 0.005$).[48]

Cranberry Juice and the Adhesion of Antibiotic-Resistant Uropathogens

Howell et al.[49] carried out an ex vivo study verifying cranberry's ability to prevent the adhesion of certain *E. coli* strains that are resistant to trimethoprim-sulfamethoxazole.[49] The researchers obtained 39 uropathogenic P-fimbriated *E. coli* isolates, 24 of which were resistant, from women with culture-confirmed UTIs. Incubation of the bacteria in the urine collected from participants who consumed 240 mL of cranberry juice cocktail prevented adhesion in 31 of 39 isolates, including 19 of 24 resistant isolates; antiadhesion activity began within 2 hours of exposure and persisted for up to 10 hours. Because the mechanism of action is not bactericidal, the use of cranberry does not increase the selection for antibiotic-resistant bacterial strains. A reduction in the frequency of infections may decrease the frequency of antibiotic use, saving first-line antibiotics for other infections.[50]

Trials Involving Catheterization, Neurogenic Bladders, and Spinal Cord–Injured Patients

Rates of bacteriuria and symptomatic UTIs in individuals who receive clean intermittent catheterization are an enduring concern. Schlager et al.,[51] comparing cranberry with placebo, completed a 3-month double-blind, placebo-controlled crossover trial of children ($n = 15$) with neurogenic bladders treated with intermittent catheterization. The researchers reported that 75% of 151 cultures indicated bacteriuria at both sample intervals. In this case, there was no difference between the children drinking cranberry concentrate and those receiving a placebo. Reid et al.[52] examined 15 spinal cord–injured (SCI) patients to ascertain whether cranberry juice altered bacterial biofilm load in the bladder. They found that cranberry juice significantly diminished biofilm load compared with baseline, with a reduction in the adhesion of both gram-positive and gram-negative bacteria to cells. Water intake did not affect bacterial adhesion.

Linsenmeyer et al.[53] completed a prospective, double-blind, placebo-controlled crossover study of 21 individuals with neurogenic bladders secondary to SCI who were randomly assigned to receive either 400-mg cranberry tablets or placebo three times a day for 4 weeks.[53] Cranberry tablets did not modify urinary pH or reduce bacterial counts, urinary white blood cell counts, or the number of UTIs in individuals with neurogenic bladder.

The most recent study evaluated the effect of cranberry tablets for the prevention of UTI in SCI patients with neurogenic bladder. Patients were randomized to receive 6 months of cranberry tablets (Cran-Max) or placebo, followed by the alternate preparation for an additional 6 months. Forty-seven subjects completed the trial. The researchers found a reduction in the likelihood of UTI and symptoms for any month in patients receiving the cranberry tablet ($P < 0.05$ for all). During the cranberry period, 6 subjects had 7 UTIs, compared with 16 subjects and 21 UTIs in the placebo period ($P < 0.05$ for both number of subjects and incidence). The frequency of UTI was reduced to 0.3 UTIs per year versus 1 UTI per year in those receiving placebo. Subjects with a glomerular filtration rate (GFR) greater than 75 mL/min received the most benefit.[54]

Further long-term studies evaluating specific types of bladder management and UTI will help determine the role of cranberries in individuals who have neurogenic bladder, require catheterization, or have a spinal cord injury.

Comparative Trial Subsequent to Antibiotic Therapy

The use of cranberry supplements in women with UTI after antibiotic treatment may reduce the recurrence of UTI. In an open-label trial in Finland, Kontiokari et al.[55] treated 150 women with UTI due to *E. coli* with a standard antimicrobial regimen; then the participants were randomly assigned to receive 50 mL of cranberry-lingonberry juice concentrate daily for 6 months, 100 mL of *Lactobacillus* drink 5 days a week for 1 year, or no intervention. At 6 months, 16% of the women in the cranberry group, 39% in the *Lactobacillus* group, and 36% in the control group had UTIs. This finding demonstrates that a regular intake of cranberry juice but not *Lactobacillus* seems to reduce the recurrence of UTI.

Comparative Trials—Antibiotic Versus Cranberry for UTI Prevention

McMurdo et al.[56] compared the effectiveness of cranberry extract or low-dose trimethoprim in the prevention of recurrent UTIs in a group of 137 women with two or more antibiotic-treated UTIs in the previous 12 months. Subjects were randomized to receive either 500 mg of cranberry (Cran-Max) or 100 mg of trimethoprim for 6 months.

Thirty-nine of 137 participants (28%) had an antibiotic-treated UTI (25 in the cranberry group and 14 in the trimethoprim group; difference in proportions relative risk 1.616 [95% confidence interval: 0.93, 2.79], $P = 0.084$). The time to the first recurrence of UTI was not significantly different between the groups ($P = 0.100$). The median time to recurrence of UTI was 84.5 days for the cranberry group and 91 days for the trimethoprim group ($U = 166$, $P = 0.479$).

The researchers concluded that trimethoprim had a very limited advantage over cranberry extract in the prevention of recurrent UTIs in older women and that it had more adverse effects.[56]

Beerepoot et al.[57] conducted a double-blind study of 221 premenopausal women with recurrent UTIs who were randomized to 12-month prophylaxis use of trimethoprim-sulfamethoxazole (TMP-SMX), 480 mg once a day, or cranberry capsules (Cran-Max), 500 mg twice a day. Primary end points were the mean number of symptomatic UTIs over 12 months, the proportion of patients with at least 1 symptomatic UTI, the median time to first UTI, and development of antibiotic resistance in indigenous *E. coli*.

After 12 months, the mean number of patients with at least one symptomatic UTI was higher in the cranberry than in the TMP-SMX group (4.0 vs. 1.8; $P = .02$), and the proportion of patients with at least one symptomatic UTI was higher in the cranberry than in the TMP-SMX group (78.2% vs. 71.1%). Median time to the first symptomatic UTI was 4 months for the cranberry and 8 months for the TMP-SMX group. Although the antibiotic was slightly more effective in preventing UTI, the subjects receiving antibiotics developed significant resistance to several antibiotics primarily used to prevent and treat UTIs.

After 1 month, in the TMP-SMX group, 86.3% of fecal and 90.5% of asymptomatic bacteriuria *E. coli* isolates were TMP-SMX resistant. There were also significantly increased resistance rates for

trimethoprim alone, amoxicillin, and ciprofloxacin in these *E. coli* isolates after 1 month in the TMP-SMX group. Antibiotic resistance did not increase in the cranberry group. The cranberry product and TMP-SMX were equally well tolerated.

Effectiveness as a Prophylactic Against Urinary Tract Infection

Stothers[58] executed a randomized, placebo-controlled trial that evaluated, from a societal perspective, the comparative effectiveness and cost-effectiveness of concentrated cranberry tablets, cranberry juice, and placebo for prophylaxis against lower UTI in adult women. Sexually active women (n = 150) aged 21 to 72 years were randomly assigned for 1 year to one of the following three groups:

- Placebo juice + placebo tablets
- Placebo juice + cranberry tablets
- Cranberry juice + placebo tablets

The tablets were a proprietary extract of cranberry (30:1), given twice a day. The juice was a pure unsweetened cranberry juice (not cranberry cocktail) given in doses of 250 mL three times a day. Outcome measures demonstrated greater than 50% decreases in both symptomatic UTIs per year and annual antibiotic consumption. Both cranberry juice and cranberry tablets, in a statistically significant manner, decreased the number of patients experiencing at least one symptomatic UTI per year (20% and 18%, respectively) compared with placebo (32%). Total annual antibiotic consumption was lower in both treatment groups than in the placebo group. Cost-effectiveness ratios showed that cranberry tablets were twice as cost-effective as juice for the prevention of UTIs.

Ledda et al. investigated the prophylactic effects of a standardized cranberry extract in young subjects (age 12–18 years) with a previous history of recurrent UTIs, over a 2-month follow-up. Subjects received either standard management (SM) (control group, n = 17) or SM with daily oral supplementation (supplementation group, n = 19). Oral supplementation consisted of one capsule containing 120 mg of cranberry extract (Anthocran), standardized to 36 mg proanthocyanidins, for 60 days. The effectiveness in the prevention of UTIs was determined by the number of UTIs evaluated 2 months before the inclusion in the registry and during the supplementation period and the number of symptom-free subjects during the registry period. Safety considerations were included, and measurement of adherence to treatment was also performed.[59]

The mean number of UTIs observed during the registry in the supplemented group (0.31 ± 0.2) was significantly lower compared with the control group (2.3 ± 1.3) and with the mean number of UTIs assessed before inclusion (1.74 ± 1.1) (p-value = 0.0001 for both). Moreover, 63.1% of supplemented subjects were symptom-free during the registry period, whereas 23.5% subjects were asymptomatic in the control group (p-value < 0.05). This study provides encouraging evidence on the efficacy of cranberry for prevention in young subjects experiencing recurrent UTIs.

A Cochrane review of clinical trials on cranberry for preventing UTIs was conducted in 2008. Ten studies (n = 1049) met the inclusion criteria (five crossover, five parallel-group). Cranberry/cranberry-lingonberry juice versus placebo, juice, or water was evaluated in seven studies, and cranberry tablets versus placebo in four studies (one study evaluated both juice and tablets). Cranberry products significantly reduced the incidence of UTIs at 12 months (risk ratio [RR] 0.65, 95% confidence interval [CI] 0.46–0.90) compared with placebo. Cranberry products were more effective in reducing the incidence of UTIs in women with recurrent UTIs compared with elderly men and women or people requiring catheterization. Side effects and dropouts or withdrawals were common in all studies and were high in several of the studies. The authors concluded, "there is some evidence that cranberry juice may decrease the number of symptomatic UTIs over a 12-month period, particularly for women with recurrent UTIs. Its effectiveness for other groups is less certain. The large number of drop-outs/withdrawals indicates that cranberry juice may not be acceptable over long periods of time. It is not clear what the optimum dosage or method of administration (e.g., juice, tablets, or capsules) is. Further properly designed studies with relevant outcomes are needed."[60] A more recent 2017 Cochrane review reported similar benefit in reducing UTIs (weighted RR 0.67, $p < 0.0001$), with the best results seen in those who, for whatever reason, were more susceptible to UTIs.[61]

Subsequent to Cochrane's earlier review, further studies have evaluated the effect of cranberry supplements, including two studies that compared cranberry (Cran-Max) to antibiotics (as previously discussed) for reducing UTI recurrence.

Sengupta et al.[62] evaluated the effects of a standardized cranberry product (PACran) on reducing the recurrence of symptomatic UTI in culture-positive subjects. This 90-day randomized clinical trial involved 60 female subjects aged 18 to 40 years who were randomly assigned to three groups: an untreated control group (n = 16), a low-dose (500 mg daily, n = 21) treatment group, and a high-dose (1000 mg daily, n = 23) treatment group. The safety of the cranberry product was assessed by evaluation of biochemical and hematological parameters on days 10, 30, 60, and 90, comparing the values with those at the baseline. The occurrence of UTI at baseline and during the follow-up period was characterized by the presence of symptoms and *E. coli* in the culture of urine samples. At the end of the study, the change in the presence of *E. coli* in the untreated control group was not significant, whereas there was significant reduction ($P < 0.05$) in the subjects positive for *E. coli* in both the high- and low-dose treatment groups, compared with baseline evaluation. However, there were no significant differences in bacteriuria in the urine between in the cranberry groups and the untreated control group at any time point after the study commenced. Symptomatic relief was also reported in the low- and high-dose treatment groups, whereas none was reported by subjects in the untreated control group.[62]

Prophylaxis Urinary Tract Infections in Men With Prostate Disease

Lower urinary tract symptoms (LUTSs) are a common condition in older men, particularly among those with benign prostatic hyperplasia (BPH) and chronic prostatitis (CP). It is postulated that cranberry may offer benefits for men with prostate disease above and beyond its ability to inhibit uroepithelial bacterial adhesion and reduce UTI occurrence. Among the recently reported effects of cranberry are its anti-inflammatory action through reduced cyclooxygenase-2 expression, suppression of IkBa degradation in human colon cancer cells,[63] and inhibition of the growth and proliferation of several types of tumor cells, including prostate cancer cells.[64]

A study was conducted to evaluate the effect of a 6-month daily consumption of 1500 mg cranberry fruit powder (PACran) on urinary tract function in men with LUTSs based on the International Prostate Symptom Score (IPSS), elevated prostate-specific antigen (PSA), BPH, and histopathologically confirmed nonbacterial CP. In contrast to the control group, patients in the cranberry group had statistically significant improvement in the IPSS; quality-of-life score; urination parameters, including voiding parameters (rate of urine flow, average flow, total volume, and postvoid residual urine volume); and lower total PSA level on day 180 of the study. There was no statistically significant improvement in the control group. The results of this preliminary trial are the first firm evidence that cranberries may ameliorate LUTSs, independent of BPH or C-reactive protein level.[65]

Reducing Asymptomatic Bacteriuria in Ileal Enterocystoplasty

Bacteriuria is a usual complication of enterocystoplasty after cystectomy. Botto et al.[66] evaluated the effectiveness of treatment with a cranberry supplement in the prevention of repeated bacteriuria in patients with an ileal enterocystoplasty. This open study included 15 patients with a history of repeated urinary infection and/or bacteriuria during the pretreatment phase. During the treatment phase, patients received a cranberry preparation with 36 mg PACs (Urell), one capsule a day. The primary end point was the absence of bacteria in urine culture. The secondary end points were the presence or absence of symptoms (pain, fever), continence status, and upper excretory tract enlargement. There was a significant decrease in the number of positive urine cultures during cranberry compound treatment. These results need to be validated by further double-blind, randomized studies.

Reduction in Urinary Odor

Urinary odor, common in elderly people, may be reduced after the administration of cranberry.[4,67,68] Ammonia odor may be reduced by cranberry because the bacterial populations are decreased, and they produce less ammonia as a by-product of metabolism.

Other Clinical Applications

Although much of the focus on the benefits of cranberry has been on UTIs, cranberry may offer other health benefits, some of which are described in the following subsections.

Antioxidant

Oxidation, or the production of free radicals, is involved in the progression of many bodily processes that can lead to disease and afflictions, especially as we age. Cranberry contains antioxidants that can scavenge free radicals. Of the berries, blackberries, blueberries, cranberries, and raspberries have the highest levels of antioxidants.[69–71] Pedersen et al.[72] studied the effects of blueberry and cranberry consumption on the plasma antioxidant capacity of healthy female volunteers.[72] Daily ingestion of 500 mL of cranberry juice increased plasma phenolic content and antioxidant capacity. Consumption of a similar amount of blueberry did not have this effect.

Cancer

Cranberries contain salicylic acid, the active metabolite of acetylsalicylic acid (aspirin), which has been used historically to treat pain, inflammation, and fever.

More recently, researchers have shown that regular intake of salicylic acid may be associated with a reduced risk of certain types of cancer, particularly colon cancer. Although the exact mechanism of salicylic acid is unknown, research has shown that it inhibits the expression of cyclooxygenase 2 (COX-2), thereby decreasing the synthesis of proinflammatory prostaglandins.

A study was conducted to measure the bioavailability of these anti-inflammatory compounds in cranberry juice. Two groups of healthy female subjects consumed either 250 mL of cranberry juice or a placebo solution three times a day for 2 weeks. Blood and urine samples were collected from the subjects and measured for salicylic acid and its urinary metabolite, salicyluric acid. After 1 week, researchers saw a marked increase in urinary salicylic acid and salicyluric acid in those consuming cranberry juice over those consuming placebo solution. Concentrations of the urinary metabolite were significantly greater than salicylic acid, which is a good indicator of bioavailability. The increase in plasma concentrations of the cranberry group was less extreme but still statistically significant after 2 weeks of consumption.[73]

Researchers have questioned whether sufficient amounts of salicylic acid can be obtained from the diet to exert anti-inflammatory effects similar to those seen from aspirin. Salicylic acid is present in many plant-based foods in varying amounts, and little is known about the bioavailability of these active compounds when obtained from food sources. However, serum and urinary concentrations of salicylic and salicyluric acids are greater in vegetarians than in nonvegetarians and overlap with those in individuals taking up to 150 mg of aspirin per day (a baby aspirin contains 81 mg). This suggests that potentially therapeutic levels of salicylic acid could be achieved by consuming salicylic acid–rich foods, such as cranberries.

Antiangiogenic approaches to prevent and treat cancer represent a priority area in investigative tumor biology. Vascular endothelial growth factor plays a crucial role in the vascularization of tumors. In vitro research on human dermal microvascular endothelial cells has shown that edible berries impair angiogenesis.[74] Several in vitro studies on cranberry have reported similar promising outcomes.

Researchers at the University of Western Ontario discovered that mice receiving cranberry juice and cranberry products had a significantly lower incidence of breast cancer than the control group, and the development of tumors was delayed in the cranberry-fed group. The proliferation of tumors to the lungs and lymph nodes was markedly reduced in the cranberry-fed group. A greater effect was demonstrated by the cranberry solids than the juice. Ongoing research is examining whether the activity of the berry solids traces largely to one component or to several potentially acting in synergy.[75]

A PAC fraction, an extract of concentrated flavonoids, and triterpenoid esters of cranberry were evaluated in an in vitro cell culture model and exhibited potential anticarcinogenic activity, demonstrating an ability to inhibit tumor cell growth.[76–78] A synergistic or additive antiproliferative interaction of the anthocyanins, PACs, and flavonol glycosides within cranberry extract has also been demonstrated by in vitro research on human tumor cells.[79]

A combination of six berry extracts (wild blueberry, bilberry, cranberry, elderberry, raspberry seeds, strawberry) was studied for antioxidant efficacy, cytotoxic potential, cellular uptake, and antiangiogenic properties. The combination of anthocyanin-rich berries was reported to show antiangiogenic, antioxidant, and anticarcinogenic potentials.[80]

Vascular Disease

Research indicates that the consumption of flavonoids in foods and beverages may reduce the risk of atherosclerosis.[81] In vitro and in vivo experiments with cranberry flavonoids demonstrate that they inhibit the oxidation of low-density lipoprotein cholesterol (LDL-c), platelet aggregation and adhesion, and enzymes involved in lipid/lipoprotein metabolism (which affects the immune response to oxidized LDL-c and its uptake by endothelial macrophages). It may also induce endothelium-dependent vasorelaxation and increase reverse cholesterol transport, thereby decreasing total cholesterol and LDL-c values. Wilson et al.[82] showed in vitro that cranberry extracts reduce oxidation of LDL-c.[82] A review by Reed[83] examined the effects of flavonoids on atherosclerosis, with an emphasis on the potential positive effects of the flavonols and PACs in cranberries.[83]

Youdim et al.[84] investigated the putative antioxidant and anti-inflammatory effects of blueberry and cranberry anthocyanins and hydroxycinnamic acids. The polyphenols isolated from both berries afforded protection for endothelial cells against stressor-induced upregulation of oxidative and inflammatory insults. This may have beneficial actions against the initiation and development of vascular diseases and may be a contributing factor in the reduction of age-related deficits in neurological impairments.[84]

Ruel et al.[85] examined the effect of daily consumption of a low-calorie cranberry juice cocktail on plasma oxidized LDL (oxLDL), intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion

molecule-1 (VCAM-1), and E-selectin concentrations in men. Thirty men (mean age 51 years) were recruited and asked to consume increasing daily doses of cranberry juice cocktail (125, 250, and 500 mL/d) over three successive periods of 4 weeks. Plasma oxLDL and adhesion molecule concentrations were measured by enzyme-linked immunosorbent assay (ELISA) before and after each phase. The researchers noted a statistically significant decrease in plasma oxLDL, ICAM-1, and VCAM-1.

Glycemic Control and Insulin Resistance

There is mounting evidence from animal studies supporting the benefits of dietary polyphenols for the prevention and management of type 2 diabetes by improving glycemic control and reducing postprandial hyperglycemia. The benefits may be due to inhibition of carbohydrate digestion by inhibiting salivary and pancreatic α-amylase and α-glucosidase in the small intestinal brush border, inhibition of glucose absorption, and stimulation of insulin secretion and protection of pancreatic β-cells against glucotoxicity. Polyphenols may suppress glucose release from the liver and improve glucose uptake in peripheral tissues by modulating intracellular signaling. Polyphenols have antioxidant activity and can inhibit advanced glycation endproduct (AGE) formation.[86,87]

A study by Paquette et al. evaluated the effects of strawberry and cranberry polyphenols (SCPs) on insulin sensitivity, glucose tolerance, insulin secretion, lipid profile, inflammation, and oxidative stress markers in free-living insulin-resistant overweight or obese human subjects (n = 41) in a parallel, double-blind, controlled, randomized clinical trial. The experimental group consumed an SCP beverage (333 mg SCP) daily for 6 weeks, whereas the control group received a flavor-matched control beverage that contained 0 mg SCP. At the beginning and end of the experimental period, insulin sensitivity was assessed by a hyperinsulinemic-euglycemic clamp, and glucose tolerance and insulin secretion were assessed by a 2-h oral glucose tolerance test (OGTT). Insulin sensitivity increased in the SCP group compared with the control group ($+0.9$ [sem 0.5] $\times 10^{-3}$ vs. -0.5 [sem 0.5] $\times 10^{-3}$ mg/kg per min per pmol, respectively, $P = 0.03$). Compared with the control group, the SCP group had a lower first-phase insulin secretion response as measured by C-peptide levels during the first 30 min of the OGTT ($P = 0.002$). No differences were detected between the two groups for lipids and markers of inflammation and oxidative stress. The authors concluded that a 6-week dietary intervention with 333 mg of polyphenols from strawberries and cranberries improved insulin sensitivity in overweight and obese nondiabetic, insulin-resistant human subjects but was not effective in improving other cardiometabolic risk factors.[88]

Helicobacter Pylori

Burger et al.[89] argue that because cranberry has been shown to inhibit bacterial adhesion to uroepithelial cells, it may also be useful as antiadhesion therapy in *H. pylori* infections. In a number of small in vitro studies, the investigators demonstrated that a high-molecular-weight (HMW) constituent of cranberry inhibits sialyllactose-specific adhesion of *Heliobacter pylori* to a human gastric cell line and mucus as well as human erythrocytes.[89] This research warrants further investigation into the use of cranberry as it relates to *H. pylori.*

Oral Bacteria

The effect of cranberry on the coaggregation (massing together) of oral bacteria has been tested. Weiss et al.[90] discovered an HMW nondialyzable material, composed mainly of PACs isolated from cranberry juice. Although the molecular structure of this material and its mechanism of action are not known, in vitro studies showed that coaggregation of pairs of bacteria was inhibited, and pilot in vivo studies showed that coaggregation of a large number of different pairs was reversed.[91]

Studies using mouthwash demonstrated positive results and warrant additional research. Weiss[92] conducted a small pilot study of individuals (n = 59) using a standard mouthwash that contained this HMW constituent.[92] After 6 weeks of daily use, results showed a reduction in colony-forming units of bacteria in saliva compared with placebo. These data and those of more recent studies provide evidence that inhibition of oral streptococci colonization and attachment to the tooth surface in vivo is due to the antiadhesion activity of the cranberry constituent.[93] Another study hypothesized the inhibition of extracellular polysaccharide synthesis, which promotes the sucrose-dependent adhesion of oral bacteria.[94,95]

Peristomal Problems

Tsukada et al.[6] conducted a small study on the incidence of peristomal problems in 13 patients who had undergone urostomy. Patients drank 160 to 320 g/day of cranberry juice for an average of 6 months. Four of six patients who initially had erythema, maceration, or pseudoepithelial hyperplasia at the stoma site showed improvement. This apparent protective effect for the skin against urine may be relevant for patients who are immobile and incontinent and suffer skin damage as a result. Additional studies to confirm this finding are warranted.[28]

Managing Calcium Oxalate Urolithiasis

Investigations of the potential influence of cranberry juice on urinary biochemical and physicochemical risk factors associated with the formation of calcium oxalate kidney stones have been reported. Older research with renal stones reported a reduction in urinary calcium excretion after the studied patients drank cranberry juice, suggesting that it may be useful in the treatment of recurrent renal stones.[96]

Urinary variables were assessed by McHarg et al.[97] in a randomized crossover trial (n = 20) in participants with no previous history of kidney stones. The ingestion of cranberry juice significantly and uniquely altered three key urinary risk factors. Oxalate and phosphate excretion decreased, whereas citrate excretion increased. In addition, there was a reduction in the relative supersaturation of calcium oxalate, which tended to be significantly lower than that induced by water alone. Each of these outcomes is desirable in patients at risk for nephrolithiasis (urolithiasis). The investigators concluded that cranberry juice has antilithogenic properties and deserves consideration as a conservative therapeutic protocol in managing calcium oxalate urolithiasis. The use of cranberry may be warranted in some patients with recurrent renal stones, but supplementary research is needed.[28]

DOSAGE

There are a variety of cranberry products to choose from that vary greatly in quality, potency, and activity. Differences exist between the level of bioactives (PACs) and formulation in commercially available tablets, capsules, and juices. Many products on the market are not standardized, being either dried whole-fruit powders, juice powders, or mixed juices with undefined amounts of cranberry juice.

Although drinking cranberry juice is one way to get the health benefits of this berry, it may not be ideal for all people. Most commercial cranberry juice cocktails contain only 27% to 33% pure cranberry juice, with sugar and water making up the rest of the volume. Such drinks are often high in calories. Encapsulated cranberry powders can be a convenient alternative to cranberry juice cocktail, especially for people who do not like the taste of cranberry; those who are traveling; or those concerned about the calories, sugar, or other sweeteners.

Healthcare providers directing their patients in selecting effective products should ensure that they find the most palatable product and should encourage long-term adherence. In the case of UTI prevention,

this strategy may reduce an individual's potential for the development of the disorder while also decreasing the need for antibiotics.

On the basis of the clinical studies, the amount of cranberry juice recommended for the prevention of UTIs is 1 to 10 oz a day; however, the ideal dosage has not yet been determined.[43,59,98] For use as a urinary deodorizer for incontinent patients, 3 to 6 oz (90–180 mL) per day of cranberry juice has been used.[63]

Tablets and capsules are often taken in doses of 500 mg once or twice a day, depending on the concentration of cranberry. Approximately 1500 g of fresh fruit produces 1 L of juice.[14,98]

ADVERSE EFFECTS

Taken orally, cranberry is generally well tolerated. No significant adverse effects have thus far been reported. However, cranberry juice at high doses of 3 to 4 L per day may cause gastrointestinal upset and diarrhea.[5]

Patients with diabetes should minimize cranberry juice sweetened with sugar or fruit juice.[98]

In theory, regular cranberry juice intake may precipitate the formation of urinary stones. However, urinary oxalate excretion does not rise after the drinking of cranberry juice, and no studies have reported stone formation as a complication.

Cranberry contains salicylic acid, which is structurally similar to acetylsalicylic acid (aspirin) and thus should be used cautiously in those with an allergy to aspirin.

DRUG INTERACTIONS

Cranberry contains flavonoids, which are known to inhibit cytochrome P450 enzymes; thus various drug interactions have been theorized.

One recent study investigated the effect of cranberry on the cytochrome P450 3A4 enzymes. Human CYP3A4 is the most important human CYP isozyme because it is involved in the metabolism of approximately 50% of drugs and some environmental toxins. Several brands of cranberry supplements were included in this study. The researchers found that cranberry had no significant inhibitory effect on human CYP3A4, and thus it is unlikely to cause significant interactions with drugs metabolized by CYP3A4, such as felodipine, nifedipine, midazolam, cyclosporine, and atorvastatin.

A few case reports have suggested an interaction between cranberry and warfarin, affecting international normalized ratio (INR) values and increasing the risk of bruising and bleeding. Warfarin is metabolized by the cytochrome P450 2C9 enzymes. These reports were poorly documented, and confounding factors may have been involved.[99–101]

Recently, several researchers have examined the potential interaction between cranberry and warfarin. Seven separate interaction studies assessed valid and accepted pharmacodynamic (PD) and/or pharmacokinetic end points, examining a total exposure of 75 patients and healthy volunteers. Six of these studies concluded that a cranberry juice–warfarin interaction is unlikely.[102–107] One study claimed a potential PD interaction on the basis of the assessment of an inappropriate and unconventional AUC-based PD parameter and the use of a single, very high dose (25 mg) of warfarin in healthy volunteers.[108]

A review of the body of research on the potential interaction between cranberry and warfarin concluded that there is no evidence of the risk of a clinically relevant interaction between warfarin and cranberry products from peer-reviewed interaction studies when cranberry juice is consumed in moderation. One cannot exclude the possibility of an interaction with the consumption of excessive quantities of cranberry products; however, it does not appear necessary to avoid normal levels of consumption of cranberry products (two 8-ounce glasses a day).[109]

Cranberry is often recommended along with low-dose oral antibiotics for prophylaxis for recurrent UTIs. One recent study evaluated the potential risk of pharmacokinetic interactions between cranberry juice and the β-lactams amoxicillin (amoxicillin) and cefaclor and determined that concurrent use of cranberry juice had no significant effect on the extent of oral absorption or the renal clearance of amoxicillin and cefaclor.[110]

Vaccinium myrtillus (Bilberry)

Michael T. Murray, ND

OUTLINE

Vaccinium myrtillus (family: *Ericaceae*)
Common names: bilberry, huckleberry, European blueberry, whortleberry, blueberry

GENERAL DESCRIPTION

The genus *Vaccinium* in the family *Ericaceae* comprises nearly 200 species, most of which are found in the northern hemisphere. This chapter focuses on *Vaccinium myrtillus* and the medicinal use of extracts of its fruit.

V. myrtillus, or bilberry, is a shrubby perennial plant that grows in the sandy areas of the northern United States and in the woods and forest meadows of Europe (Fig. 122.1). The angular, green, branched stem grows from a creeping rootstock to a height of 1 to 1.5 ft. The 0.5- to 1-in-long leaves are oval, slightly dentate, and bright green, whereas the flowers are reddish- or greenish-pink and bell-shaped. The bilberry's flowering season is April through June. The fruit is a blue-black berry.[1]

CHEMICAL COMPOSITION

The pharmacologically active constituents of bilberries are its flavonoid components, specifically its anthocyanosides. An anthocyanoside is composed of an aglycone (e.g., anthocyanidin) bound to one of three glycosides (arabinoside, glucoside, or galactoside). More than 15 different anthocyanosides originate from the five aglycones found in *V. myrtillus*.[2] Other members of the genus *Vaccinium,* as well as *Ribes nigrum* (black currant) and *Vitis vinifera* (grape), contain similar anthocyanosides.[3] Extracts of these fruits are also used for medicinal purposes in Europe.

The concentration of anthocyanosides in the fresh fruit is approximately 0.1% to 0.25%, whereas concentrated extracts of *V. myrtillus* are produced that yield an anthocyanidin content of 25%.[2] An extract with an anthocyanidin content of 25% contains about 37% anthocyanosides owing to the conjugation of the anthocyanidin with a glycoside. (For analytic purposes, the anthocyanosides content should always be expressed in terms of anthocyanidin.) Only very small amounts of free anthocyanidins exist in nature and in *V. myrtillus* extracts.

Bilberries are also good sources of bioavailable resveratrol[4] and quercetin,[5] although the levels of these compounds are lower than those found in other foods (e.g., the level of resveratrol in bilberry is less than 10% of that reported for grapes). Nonetheless, consumption of bilberries may lead to significant elevations of these compounds in the serum because they are more bioavailable. In one study, 40 healthy men consumed 100 g/day of berries (black currants, lingonberries, and bilberries) for 8 weeks.[5] Twenty subjects consuming their habitual diets served as controls. Blood levels of quercetin were obtained at baseline and at 2, 4, and 8 weeks. During the berry-consumption period, mean serum concentrations of quercetin ranged between 21.4 and 25.3 mg/L in the berry group, which translated into 32% to 51% higher than in the control group—indicating that the berries used in this study were a good source of bioavailable quercetin.

HISTORY AND FOLK USE

Bilberries have, of course, been used as food and for their high nutritive value. Medicinally, they have been used in the treatment of scurvy and urinary complaints (including infection and stones).[1] The dried berries have been used primarily for their astringent qualities in the treatment of diarrhea and dysentery. Decoctions of the leaves have been used in the treatment of diabetes.[1]

PHARMACOLOGY

The pharmacology of *V. myrtillus* is discussed almost entirely in relation to its anthocyanoside content because research has focused primarily on the anthocyanosides.

Collagen-Stabilizing Action

Anthocyanosides possess significant collagen-stabilizing action.[6–12] Collagen, the most abundant protein of the body, is responsible for maintaining the integrity of "ground substance" as well as tendons,

ligaments, and cartilage. Collagen is destroyed during the inflammatory processes that occur in rheumatoid arthritis, periodontal disease, and other inflammatory conditions involving bones, joints, cartilage, and other connective tissue.

Anthocyanidins, proanthocyanidins, and other flavonoids are remarkable in their ability to prevent collagen destruction. The anthocyanidins in *V. myrtillus* extracts have been shown to affect collagen metabolism in the following ways:

- Anthocyanosides cross-link collagen fibers, resulting in strengthening of the natural cross-linking of the collagen that forms the collagen matrix of connective tissue (ground substance, cartilage, tendon, etc.).[6–10]
- Anthocyanosides, with their potent antioxidant and free-radical–scavenging action, prevent free-radical damage.[6–9,11,60]
- Anthocyanosides inhibit enzymatic cleavage of collagen by enzymes secreted by leukocytes during inflammation.[6–8,10–12]
- Anthocyanosides and other flavonoid components of *V. myrtillus* prevent the release and synthesis of compounds that promote inflammation, such as histamine, serine proteases, prostaglandins, and leukotrienes.[6–8,13,14]
- Anthocyanosides promote mucopolysaccharide and collagen biosynthesis and stimulate reticulation of collagen fibrils.[15–17]

Normalization of Capillary Permeability

Anthocyanosides have strong "vitamin P" activity.[6] Included in their effects is the ability to raise intracellular vitamin C levels and reduce capillary permeability and fragility.[6–8] Their effect in reducing capillary fragility and permeability is roughly twice that of rutin in both intensity and duration of action.[18]

Fig. 122.1 *Vaccinium myrtillus.* (silkfactory/iStock.com)

V. myrtillus extracts have been widely used in Europe in the treatment of various arterial, venous, and capillary disorders. Clinical studies have demonstrated a positive effect in the treatment of the following conditions[19–24]:

- Capillary fragility
- Blood purpuras
- Various encephalic circulation disturbances (similar to *Ginkgo biloba*)
- Venous insufficiency
- Varicose veins
- Microscopical hematuria caused by diffuse and kidney capillary fragility

V. myrtillus's efficacy in the treatment of a variety of venous disorders relates to the ability of anthocyanosides to protect altered veins (postphlebitic veins as well as varicose veins) via two mechanisms[17]: (1) increasing the endothelial barrier effect by stabilizing the membrane phospholipids and (2) increasing the biosynthesis of the acid mucopolysaccharides of the connective ground substance, thus restoring the altered mucopolysaccharide pericapillary sheath. This latter effect leads to a marked increase in newly formed capillaries and collagen fibrils.

One interesting effect of the normalization of collagen structures and capillaries is the demonstration that anthocyanosides from *V. myrtillus* reduce the permeability of the blood–brain barrier.[10,25] Greater blood–brain permeability has been linked to autoimmune diseases of the central nervous system (CNS), schizophrenia, "cerebral allergies," and a variety of other CNS disorders. Presumably, the anthocyanosides inhibit both enzymatic and nonenzymatic degradation of the basement membrane collagen of brain capillaries, thus helping maintain or restore the brain's protection from drugs, pollutants, naturally occurring degradation products, and other cerebral toxins.[9–12,25]

Another study further demonstrated the remarkable efficacy of bilberry in protecting and strengthening the capillaries and microcirculation. In this study, the effects of anthocyanidins on hamster cheek microcirculation after ischemia and reperfusion were investigated. The treated group had diminished adherence of leukocytes to the venules after reperfusion, resulting in prevention of the markedly increased capillary permeability seen in the placebo group.[26]

Antiaggregation Effect on Platelets

Anthocyanosides, like many other flavonoids, have been shown to have significant antiaggregation effects on platelets.[27–29] Their action in vivo appears to be direct antiaggregation effects on the platelets and an indirect effect via prostacyclin-like action.[27–29] Prostacyclin is a potent stimulator of adenyl cyclase, the enzyme that catalyzes the production of cyclic adenosine monophosphate from adenosine triphosphate. Cyclic adenosine monophosphate prevents platelets from aggregating and adhering to the endothelial surface.

Smooth Muscle–Relaxing Activity

Anthocyanoside extracts have demonstrated significant vascular smooth muscle–relaxing effects in a variety of experimental models.[30–32] The clinical application of this research may be in the treatment of dysmenorrhea, for which a preliminary study demonstrated positive effects.[33]

Effects on Cancer Cells

An in vitro study demonstrated that among ethanol extracts of 10 edible berries, bilberry extract was the most effective at inhibiting the growth of human leukemia cells and colon carcinoma cells.[34] Bilberry extract was shown to possess dual action in this regard through the induction of apoptosis (programmed cell death) and promotion of nucleosomal DNA fragmentation (Fig. 122.2). Bilberry anthocyanidins have also been shown to inhibit angiogenesis.[35] Bilberry extract was the most potent of the extracts tested because it contained the largest amounts of phenolic compounds, including anthocyanins, and showed the greatest free-radical–scavenging activity. Pure delphinidin and malvidin, like the glycosides isolated from the bilberry extract, induced apoptosis in the leukemia cells. However, only pure delphinidin and the glycoside isolated from the bilberry extract, but not malvidin and the glycoside, inhibited the growth of human colon cancer cells. Twenty-five patients with colorectal cancer scheduled to undergo resection of primary tumors or liver metastases received 1.4, 2.8, or 5.6 g

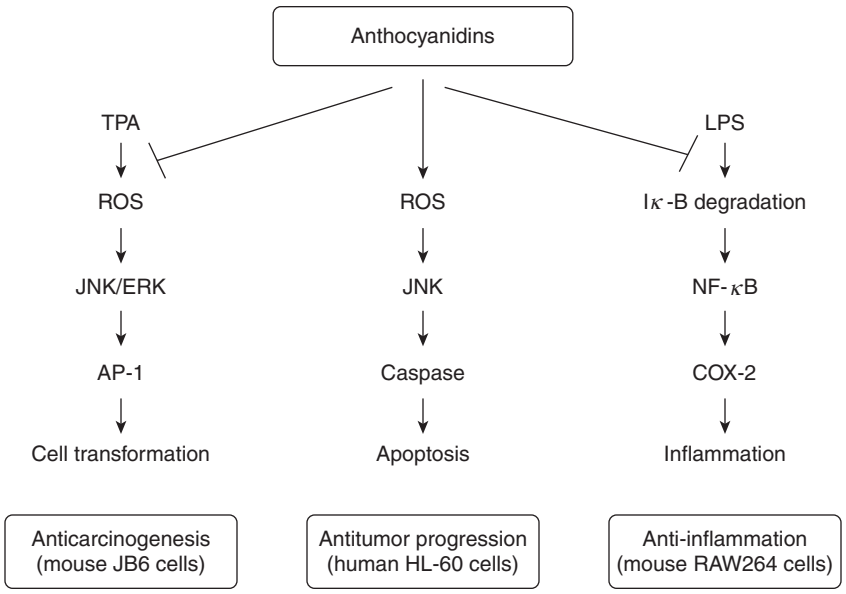

Fig. 122.2 A schematic molecular view of cancer chemoprevention by anthocyanidins. Anthocyanidins may contribute to cancer chemoprevention by targeting three different signal transduction pathways and downstream genes. *AP-1,* activator protein-1; *ERK,* extracellular signal-regulated kinase; *JNK,* c-Jun NH2-terminal kinase; *LPS,* lipopolysaccharide; *NF-κB,* nuclear factor κB; *ROS,* reactive oxygen species; *TPA,*12-O-tetradecanoylphorbol-13-acetate. (From Hou DX, Fujii M, Terahara N, Yoshimoto M. Molecular mechanisms behind the chemopreventive effects of anthocyanidins. *J Biomed Biotech.* 2004[5]:321–325. PubMed PMID: 15577196.)

(containing 0.5–2.0 g of anthocyanins) daily for 7 days before surgery. In tumor tissue from all patients, proliferation was decreased by 7% compared with preintervention values.[36]

CLINICAL APPLICATIONS

The primary clinical application of bilberry extracts has been in the prevention and treatment of a diverse group of disorders of the eye and vision. However, the same mechanisms of action that benefit the eye are of value for other health problems, especially those involving capillary dysfunction or inflammation.

Ophthalmological Applications

Night Vision and Eye Fatigue

Perhaps the most significant clinical applications for *V. myrtillus* extracts are in the field of ophthalmology. Interest in *V. myrtillus* anthocyanosides was first aroused when it was observed that the administration of bilberry extracts to healthy subjects resulted in improved nighttime visual acuity, quicker adjustment to darkness, and faster restoration of visual acuity after exposure to glare.[37,38] Further studies confirmed these results,[39–42] which were most impressive in individuals with pigmentary retinitis and hemeralopia. (*Hemeralopia* refers to "day blindness," or an inability to see as distinctly in bright light as in dim light.)

It appears that in addition to their effect on capillaries, *V. myrtillus* anthocyanosides have an affinity for the pigmented epithelium of the retina, which makes up the optical or functional part of the retina.[43] This feature is consistent with several of the clinical effects observed.

Anthocyanoside extracts of *V. myrtillus* appear to be of great value in both poor night vision and poor day vision. In a double-blind study in patients with eye strain and clinical symptoms of low to moderate myopia, 30 subjects were given either a purified high-dose anthocyanoside oligomer (a 100-mg tablet comprising 85% anthocyanoside oligomer) or a placebo tablet twice daily for 4 weeks. Before the treatment, the placebo and anthocyanoside groups were similar in terms of age and contrast sensitivity. Before and after treatment, subjects completed a questionnaire to determine their clinical symptoms and were also assessed for nocturnal visual function using contrast sensitivity testing. Questionnaire data analysis showed that after treatment, 22 (73.3%) anthocyanoside subjects showed improved symptoms, whereas only 1 placebo subject showed an improvement. Contrast sensitivity levels significantly improved in the anthocyanoside group and remained stable in the placebo group. The mean change in contrast sensitivity in the anthocyanoside group was 2.41, compared with −0.66 decibels (dB) for the placebo group. At all cycle-per-degree levels, there were greater improvements in contrast sensitivity in the anthocyanoside group than in the placebo group. This very detailed clinical assessment demonstrated that the administration of anthocyanoside oligomer improves both subjective symptoms and objective contrast sensitivity in myopia subjects with asthenopia.[44]

One of the more practical applications of the beneficial effects of anthocyanosides and eye health is reducing eye fatigue from looking at a computer screen. In one double-blind trial, 88 office workers aged 20 to 40 years who used computer terminals and displayed low critical flicker fusion (CFF) and near-point accommodation (NPA) were randomized to either a bilberry extract (480 mg/day) or placebo (vehicle) group for 8 weeks. The reduction in CFF was alleviated after 8 weeks of bilberry extract supplementation in contrast to placebo supplementation, whereas NPA variation was not. Of the subjective symptoms of eye fatigue, computer screen load–induced ocular fatigue sensation, ocular pain, eye heaviness, uncomfortable sensation, and foreign-body sensation were mitigated more in the bilberry extract group than in the control group.[45]

Glaucoma

V. myrtillus may play a significant role in the prevention and treatment of glaucoma via its effect on ocular collagen structures. In the eye,

collagen provides tensile strength and integrity to the tissues—cornea, sclera, lamina cribrosa, trabecular meshwork, and vitreous.

Morphological changes in the collagen of the eye precede clinically detectable abnormalities. These changes may result in elevated intraocular pressure (IOP) readings or, perhaps more significantly, the progression of peripheral vision loss. Changes in collagen structure would explain the following observations:

- Similar peripheral vision loss in patients with normal and elevated IOP
- Cupping of the optic disc even at low IOP levels
- No apparent anatomical reason for decreased aqueous outflow (see Chapter 175 for complete discussion and references)

Therefore primary prevention of glaucoma involves maintaining the integrity of the ground substance and collagen framework. It appears that preventing the breakdown of the collagen matrix is as important here as it is in other conditions involving collagen abnormalities, such as atherosclerosis, rheumatoid arthritis, and periodontal disease.

Consumption of *V. myrtillus* may offer significant protection against the development of glaucoma because of its collagen-enhancing actions. In addition, anthocyanosides may be of benefit in the treatment of chronic glaucoma because rutin has been demonstrated to lower IOP when used as an adjunct in patients who are unresponsive to miotics alone.[46] *V. myrtillus* anthocyanosides are generally much more biologically active than rutin.[18]

Cataracts and Retinal Degeneration

V. myrtillus anthocyanosides may offer significant protection against the development of retinal (macular) degeneration and cataracts, particularly diabetic retinopathy and cataracts.[47] Both the rate of retinal degeneration and the occurrence of cataracts in rats can be retarded by changing their diet from a commercial laboratory chow to a "well-defined diet."[48,49] Preliminary research suggests that flavonoid components in the well-defined diet may be responsible for the protective effects against cataracts and retinal degeneration.[50] Limited research has shown that when combined with vitamin E, bilberry significantly slows the progression of senile cataracts in humans.[51]

V. myrtillus anthocyanoside extracts are widely used in Europe for the prevention of diabetic retinopathy.[51–53] The positive effects noted in clinical trials may be due to improved capillary integrity as well as inhibition of sorbitol production (see Chapter 165). Flavonoids have been shown to be potent in vitro and in vivo inhibitors of sorbitol accumulation. In laboratory experiments, they have been found capable of inhibiting the development of diabetic cataracts.[54–56]

Other Clinical Applications

Diabetes Mellitus

A decoction of bilberry leaves has a long history of folk use in the treatment of diabetes. This use is supported by research, which has shown that oral administration reduces hyperglycemia in normal and depancreatized dogs even when glucose is concurrently injected intravenously.[53,57]

Bilberry extract ameliorates hyperglycemia and insulin sensitivity via activation of adenosine monophosphate (AMP)–activated protein kinase.[58] The anthocyanoside myrtillin (3-glucoside of delphinidin) is apparently the most active hypoglycemic component of *V. myrtillus.* Upon injection, it is somewhat weaker than insulin, but it is also less toxic, even at 50 times the therapeutic dose of 1 g/day. It is of interest to note that a single dose can have beneficial effects lasting for several weeks.[53]

However, the most important benefits from the use of anthocyanosides in the treatment of diabetes relate to their ability to improve collagen integrity and capillary permeability. Benefit also possibly derives from their ability to inhibit sorbitol accumulation, thus providing protection from the serious vascular and neurological sequelae of diabetes.

V. myrtillus anthocyanosides have also been shown to have a protective effect on capillary fragility in diabetes and to reduce serum cholesterol and triglyceride levels in primary dyslipidemia.[59]

In animal studies, anthocyanosides significantly decrease the intimal proliferation, extracellular matrix production, and calcium and lipid deposition found in the aorta of untreated atherosclerotic rabbits. Presumably, this decrease is a result of greater collagen cross-linking, which thus diminishes the permeability in small and large blood vessels.[60]

Atherosclerosis and Metabolic Syndrome

Consumption of bilberries (like blueberries) or anthocyanoside extracts has been shown to protect against atherosclerosis through a number of mechanisms, including by decreasing total cholesterol, glucose, C-reactive protein, and platelet aggregation.[61–64] The ability to reduce C-reactive protein and other markers of low-grade inflammation was confirmed in patients with metabolic syndrome.[63]

Another very novel effect noted in the protection against vascular disease is improved endothelial function. Individuals given oral anthocyanins (320 mg) for 12 weeks showed significant improvements in brachial artery flow-mediated dilation (FMD) and cyclic guanosine monophosphate (cGMP).[65] Vascular dilation is directly stimulated by nitric oxide (NO) released from the vascular endothelial cells. The vasodilator activity of NO is attributed to its diffusion to the vascular smooth muscle cells and the production of cGMP and cGMP-mediated vasodilation. Because the half-life of NO is extremely short, the circulating cGMP concentration is used as the index of NO activity and thus as an indirect marker of endothelium-dependent vasodilation. Compared with the control group, the treatment group showed significant increases in FMD (28.4% vs. 2.2%), cGMP (12.6% vs. −1.2%), and high-density lipoprotein (HDL)-cholesterol concentrations but decreases in the serum soluble vascular adhesion molecule-1 and low-density lipoprotein (LDL)-cholesterol levels. Another piece of evidence indicating that anthocyanins increase NO vasodilation is that in the presence of inhibitors of NO-cGMP vasodilators, the effects of anthocyanin on endothelial function were not seen.

Inflammatory Joint Disease

The effects of anthocyanosides on collagen structures and their potent antioxidant activity make *V. myrtillus* anthocyanoside extracts very useful in the treatment of a wide variety of inflammatory conditions, most notably rheumatoid arthritis. Bioflavonoids have been found to increase collagen synthesis and inhibit collagen catabolism in rats with adjuvant-induced arthritis (a chronic progressive polyarthritis with some similarities to rheumatoid arthritis).[15]

Bilberries, like cherries, are particularly indicated in the treatment of gout because their flavonoid components can reduce both uric acid levels and tissue destruction (see Chapter 191).

Inflammatory Bowel Disease

Bilberries or anthocyanin-rich extracts may have benefits in patients with inflammatory bowel disease. In an open pilot trial with a total follow-up of 9 weeks, the effect of a daily standardized anthocyanin-rich bilberry extract was tested in 13 patients with mild to moderate ulcerative colitis (UC).[66] At the end of the 6-week treatment interval, 63.4% of patients achieved remission, and 90.9% of patients showed a response. In all patients, a decrease in total Mayo score was detected (mean: 6.5 and 3.6 at screening and week 7, respectively; $p < 0.001$).

Levels of fecal calprotectin, a marker of intestinal inflammation, significantly decreased during the treatment phase (baseline: mean 778 µg/g; end of treatment: mean 305 µg/g), including four patients achieving undetectable levels at the end of treatment. Bilberry anthocyanins inhibit interferon-induced signaling and downstream effects in human macrophages cells as well as modulate intestinal cytokine activity.[67]

Microscopical Hematuria

The effect of *V. myrtillus* in the reduction of microscopical hematuria may reflect its tissue distribution. Pharmacokinetic studies in rats have demonstrated an affinity for the skin and kidneys.[68] Anthocyanosides' affinity for these tissues reflects the high concentration of collagen and mucopolysaccharides in the skin and kidneys and the fact that they are excreted via the kidneys.

Other Effects

As mentioned previously, the smooth muscle–relaxing effects of bilberry extract have been put to good use in the treatment of dysmenorrhea.[33] A significant improvement in pelvic-lumbosacral pain, mammary tension, nausea, and lower-limb heaviness was noted when women with dysmenorrhea were given bilberry extract (115 mg anthocyanosides per day) for 3 days before and during menstruation.

Bilberry extracts have demonstrated antiulcer effects in various experimental models and have been promoted as an ulcer medication in Italy.[69]

Summary of Clinical Applications

V. myrtillus anthocyanosides exhibit significant pharmacological activity, particularly on collagen structures. Research has demonstrated a positive effect in the treatment of the following problems:

- Capillary fragility
- Blood purpuras
- Various encephalic circulation disturbances
- Venous insufficiency
- Varicose veins
- Microscopical hematuria caused by diffuse and kidney capillary fragility
- Poor night vision
- Hemeralopia
- Diabetic retinopathy

Experimental studies indicate that anthocyanosides should also be useful in most inflammatory or degenerative conditions involving connective tissues (e.g., osteoarthritis, gout, rheumatoid arthritis, periodontal disease) as well as in glaucoma, diabetes, cataracts, retinal degeneration, and schizophrenia.

DOSAGE

The standard dose for *V. myrtillus* is based on its anthocyanoside content, as calculated from its anthocyanidin percentage. Widely used pharmaceutical preparations in Europe are typically standardized for a 25% anthocyanidin content. Dosages are as follows:

- Anthocyanosides (calculated as anthocyanidin): 20 to 40 mg three times a day
- *V. myrtillus* extract (25% anthocyanidin content): 80 to 160 mg three times a day
- Fresh berries: 55 to 115 g three times a day

TOXICOLOGY

Extensive toxicological investigation has demonstrated that *V. myrtillus* anthocyanoside extracts are devoid of toxic effects. Administration to rats of dosages as high as 400 mg/kg has no apparent side effects, and excess levels are quickly excreted through the urine and bile.[18,26]

DRUG INTERACTIONS

No drug interactions have been reported for *V. myrtillus*.

Valeriana officinalis (Valerian)

Michael T. Murray, ND

OUTLINE

Valeriana officinalis (family: *Valerianaceae*)
Common names: valerian, all heal

GENERAL DESCRIPTION

Valerian is a perennial plant native to North America and Europe. The yellow-brown tuberous rootstock produces a flowering stem 2 to 4 ft high. The stem is round but grooved and hollow, with leaves arranged in pairs. The small rose-colored flowers are in bloom from June to September. The rootstock is the portion used medicinally (Fig. 123.1A and B).

CHEMICAL COMPOSITION

The important active compounds of valerian are the valepotriates (iridoid molecules) (Fig. 123.2) and valerenic acid. These compounds are found exclusively in valerian. Originally it was thought that just the valepotriates were responsible for valerian's sedative effects, but an aqueous extract of valerian has also been shown to have a sedative effect. Because the valepotriates are not soluble in water, it was concluded that valerenic acid also possesses sedative action and is the chemical factor responsible for the sedative effect noted in human clinical trials with aqueous extracts of valerian root (see later discussion).

Moreover, because the safety of valepotriates was questioned after studies demonstrated mutagenicity, most commercial extracts feature water-soluble extracts standardized for valerenic acids.[1–3]

Other components of valerian are a volatile oil (0.5%–2%), choline (3%), flavonoids, sterols, and several alkaloids (actinidine, valerianine, valerine, and chatinine).[1]

HISTORY AND FOLK USE

Valerian's primary traditional use has been as a sedative for the relief of insomnia, anxiety, and conditions associated with pain. Specific conditions for which it has been used are migraine, insomnia, hysteria, fatigue, intestinal cramps, and other nervous conditions.

PHARMACOLOGY

Valerian has demonstrated a number of pharmacological effects, such as the following[4–7]:

- Normalizing of the central nervous system (it acts as a sedative in states of agitation and as a stimulant in cases of extreme fatigue)
- Lowering of blood pressure
- Enhancement of the flow of bile (choleretic effect)
- Relaxing the intestinal muscles
- Antitumor and antibiotic activity

Its prime pharmacological effect, however, is consistent with its historical use as a sedative. Pharmacological studies indicated that both valepotriates and valerenic acid are capable of binding to gamma-aminobutyric acid (GABA) receptors, much like the benzodiazepines.[8] However, valerian does not appear to act in a similar fashion in that side effects such as impaired mental function, morning hangover, and dependency have not been reported with valerian. In addition, valerian compounds that do not bind to GABA receptors have also been shown to produce sedative effects. Therefore other mechanisms may be more important, including valerenic acids modulating GABA receptors or promoting the release of GABA.[9]

In a double-blind, randomized, crossover, placebo-controlled study, a dosage of 900 mg of valerian extract (valerenic acid 0.8%) was shown to significantly reduce intracortical facilitation induced by transcranial magnetic stimulation (TMS), thereby indicating reduced cortical excitability. This effect may be a key mechanism for valerian's effects on sleep and anxiety.[10]

Another key mechanism of action of valerian components is acting as an agonist to adenosine receptors. Adenosine is not a typical hormone or neurotransmitter but is probably the most important neuromodulator in the central and peripheral nervous systems. A neuromodulator is a compound that has a modulatory effect on neuronal activity, increasing or decreasing the rate at which a nerve cell fires.

Neuromodulators are distinct from neurotransmitters (e.g., glutamate), which are typically stored in the presynaptic terminal, are released into the synaptic cleft, and then interact with postsynaptic

Fig. 123.1 (A) *Valeriana officinalis* inflorescence. (B) *V. officinalis* leaf.

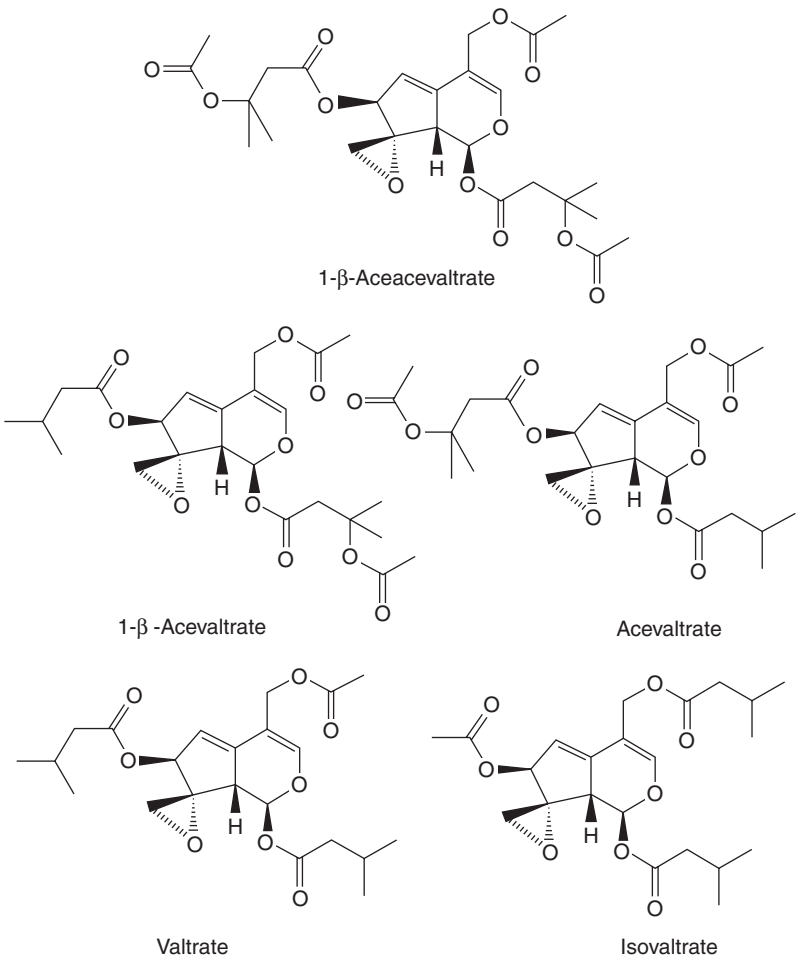

Fig. 123.2 Valepotriates in *Valeriana officinalis*.

receptors and are either taken up or metabolized. A neuromodulator such as adenosine is more likely to be either constitutively released or released at times of high or low metabolic activity. Neuromodulators may act presynaptically or postsynaptically and may then be either taken up or metabolized. The stimulant properties of the methylxanthines (caffeine, theophylline, theobromine, etc.) are partially explained by their antagonism of adenosine receptors. In contrast, valerian has been shown to act as an adenosine agonist.[11]

CLINICAL APPLICATIONS

The primary clinical application for valerian is as a sedative in the treatment of insomnia. It can also be used in the treatment of stress and anxiety.

Insomnia

More than 20 double-blind clinical studies have now substantiated valerian's ability to improve sleep quality and relieve insomnia.[12–23] Most of these studies have shown positive results.[24] Several recent double-blind studies have shown no significant benefit with valerian in improving sleep parameters in insomnia. In one study, a dosage of 300 mg valerian extract failed to show any statistically significant difference versus a placebo after a single dose or after 2 weeks of nightly dosing on any measure of sleep latency, wake after sleep onset, sleep efficiency, and self-rated sleep quality.[25] In another very detailed clinical study, standardized sleep electroencephalographic (EEG) and psychometric tests were used to evaluate the clinical efficacy of valerian extract 300 mg, valerian extract 600 mg, or placebo.[26] Results showed no significant effect between valerian 300 mg, valerian 600 mg, or placebo on any EEG parameter or psychometric measure. Nonetheless, these results are not viewed as being conclusive, given the results of other trials and valerian's long history of use.[24]

The initial studies were performed on subjects who did not have insomnia. These studies showed quite clearly that extracts of valerian root improved subjective ratings of sleep quality and sleep latency (the time required to go to sleep) but left no "hangover" the next morning.[12] In one early study, the effects of valerian on sleep were studied in two groups of healthy young subjects.[13] One group slept at home and the other in a sleep laboratory. Sleep was evaluated on the basis of questionnaires, self-rating scales, and nighttime motor activity. Under home conditions, both doses of an aqueous valerian extract (450 and 900 mg) reduced perceived sleep latency and wake time after sleep onset. Nighttime motor activity was enhanced in the middle third of the night and reduced in the last third. The data suggest a dose-dependent effect. In the sleep laboratory, where only the higher dose of valerian was tested, no significant differences from placebo were obtained. However, the directions of the changes in the subjective and objective measures of sleep latency and wake time after sleep onset, as well as in nighttime motor activity, corresponded to those observed under home conditions. There was no evidence of a change in sleep stages or EEG spectra. The results indicate that the aqueous valerian extract exerts a mild sedative effect.

Although the initial studies demonstrated that valerian could improve sleep quality in normal subjects, they failed to answer the question of whether valerian can improve sleep patterns in people suffering from insomnia. In a follow-up to these two preliminary studies, in more than 15 double-blind studies, valerian extract has been shown to significantly reduce sleep latency, improve sleep quality, and reduce nighttime awakenings in sufferers of insomnia.[14] These studies were usually performed under strict laboratory conditions and demonstrated quite clearly that valerian is as effective in reducing sleep latency as are small doses of barbiturates or benzodiazepines. However, although the latter compounds also increase morning sleepiness, valerian usually reduces morning sleepiness.

In one of the better-designed double-blind trials, patients 18 to 73 years of age diagnosed with nonorganic insomnia, according to the *International Classification of Diseases,* 10th edition, were treated at night with either 600 mg of valerian extract or 10 mg of oxazepam (Serax) for 6 weeks.[17] A total of 202 outpatients with a mean duration of insomnia of 3.5 months at baseline were involved in the study. Sleep quality after 6 weeks measured by Sleep Questionnaire B showed that the 600-mg dose of valerian extract was at least as efficacious as a treatment with 10 mg of oxazepam. Both treatments markedly increased sleep quality compared with baseline ($P < 0.01$). The other sleep function subscales—feeling of refreshment after sleep, psychic stability in the evening, psychic exhaustion in the evening, psychosomatic symptoms in the sleep phase, dream recall, and duration of sleep—confirmed similar effects of both treatments. The Clinical Global Impressions scale and Global Assessment of Efficacy completed by investigators and patients again showed similar effects of both treatments. No significant side effects or serious adverse reactions were reported in either group. Most patients assessed their respective treatment as very good (82.8% in the valerian group, 73.4% in the oxazepam group). These results show that valerian extract displays a comparable efficacy with that of 10 mg of oxazepam in the therapy of nonorganic insomnia.

In another study comparing the effects of valerian and oxazepam, 75 patients with nonorganic and nonpsychiatric insomnia between 18 and 70 years of age were randomly allocated to receive either 600 mg of valerian extract or 10 mg of oxazepam every day 30 minutes before going to bed over a period of 28 days. The results of this study were consistent with those of the other in that both groups' measures of sleep quality improved significantly, but there was no statistically significant difference between groups.[22]

Valerian extract has also been shown to help improve sleep and relieve insomnia in people withdrawing from chronic benzodiazepine use.[18] The study consisted of patients with insomnia who complained of poor sleep despite long-term use of benzodiazepines. These patients had taken benzodiazepines nightly for an average of 7 years. The sleep electroencephalograms of the patients were analyzed with period amplitude analysis and associated algorithms during chronic benzodiazepine use (night 1) and then after 15 days of a valerian-placebo trial (initiated after washout of benzodiazepines; night 2). The subjects given valerian extract reported significantly better subjective sleep quality than those given placebo. The EEG results also showed significant less wake time after sleep onset in valerian subjects than in placebo subjects, and the valerian-treated patients experienced longer sleep latency and increased alpha counts in slow-wave sleep. Taken together, these results indicate that valerian extract has a positive effect on withdrawal from benzodiazepine use.

Valerian may be helpful in patients with restless legs syndrome (RLS). In one study,[27] patients with RLS were randomly assigned to receive 800 mg of valerian extract or placebo for 8 weeks. The results indicated that valerian supplementation for 8 weeks improved symptoms of RLS and decreased daytime sleepiness.[28]

Valerian extract also appears to be useful in children. Serious sleep disturbances are particularly problematic for children with intellectual deficits and are often the source of much distress for both the children and caregivers. Conventional drugs are not suitable for long-term treatment, making valerian an attractive alternative. In one small double-blind study in five children with varying intellectual deficits and different primary sleep problems, treatment with valerian extract led to significant reductions in sleep latencies and nocturnal time awake, lengthened total sleep time, and improved sleep quality.[19] The treatment was apparently most effective in children with deficits that

involved hyperactivity. Although the findings were preliminary and are in need of replication, the results imply that valerian may be useful in the safe and effective long-term treatment of sleep difficulties in children with intellectual deficits.

One of the major advantages of valerian extract is that it rarely has a negative effect on reaction time, alertness, or concentration the morning after intake. In one double-blind trial, 102 male and female volunteers were studied to determine whether reaction time, alertness, and concentration might be impaired by treatment with a valerian root extract.[29] The effect was first examined the morning after a single evening dose of either valerian extract (600 mg), flunitrazepam (Rohypnol) (1 mg), or a placebo and then after 2 weeks of evening administration of valerian extract (600 mg) or a placebo. Evaluation of the primary criterion (the median of reaction time measured with the Vienna Determination Test) and secondary criteria (alertness test, tracking test, sleep quality, additional Vienna Determination Test parameters, and safety criteria) all demonstrated that neither a single administration nor 14 days of valerian extract treatment produced an impairment in reaction abilities, concentration, or coordination.

Anxiety and/or Depression

Valerian extracts, based on preliminary studies, have shown some evidence of usefulness in the treatment of generalized anxiety and depression. For example, in one study involving 36 outpatients with generalized anxiety disorder, patients underwent a 2-week washout period and then were randomly assigned to one of the following three treatments for 4 weeks: valepotriates (mean daily dose: 81.3 mg), diazepam (Valium) (mean daily dose: 6.5 mg), and placebo.[30] Although no significant difference was observed among the three groups at baseline or in the change from baseline on the Hamilton Anxiety Scale—probably because of the small sample size in each group—there was some evidence of benefit nonetheless. Specifically, only the diazepam and valepotriates groups showed a significant reduction in the psychic factor of the Hamilton Anxiety Scale.

In one study, valerian extract was shown to be effective in reducing the physiological effects of psychological stress induced under laboratory conditions in a group of healthy volunteers.[31] Valerian extract produced a significant decrease in systolic blood pressure responsivity, no significant reductions in diastolic blood pressure, and a decrease in the heart-rate reaction to mental stress.

Valerian may prove useful in relieving anxiety in patients with comorbid depression. In an open clinical trial, the combination of valerian with St. John's wort was found to improve symptoms more quickly than did St. John's wort monotherapy.[32] The combination therapy was well tolerated, and no significant side effects occurred.

Valerian was also shown to be effective in reducing anxiety in a double-blind clinical trial in 64 infertile women undergoing hysterosalpingography, indicating that valerian can be effective in situational anxiety.[33]

Menopausal Symptoms

Valerian may be helpful during menopause to help with both insomnia and hot flashes. In regard to the later, two controlled clinical trials have shown benefit.[34,35] In the first double-blind clinical trial, 76 menopausal women with the chief symptom of hot flashes were enrolled, with the treatment group receiving a 225-mg valerian capsule three times per day and the other group receiving a placebo, both for 8 weeks. After 4 and 8 weeks of treatment, the evaluation of results showed a meaningful difference between the valerian group and the placebo group. At week 4 and week 8 posttreatment, the valerian group had significantly less severe hot flashes (5.23 after 8 weeks) compared with the placebo group (9.86 after 8 weeks) as well as significantly fewer hot flashes compared with the placebo group, 4.83 versus 7.75, respectively.[33]

DOSAGE

As a mild sedative, valerian may be taken 30 to 45 minutes before bedtime. This timing of dosage has been verified by pharmacokinetic studies showing that the peak blood levels of valerenic acid occur within 1 to 2 hours after ingestion. Dosage recommendations are as follows:

- Dried root (or as tea): 1.5 to 3 g
- Tincture (1:5): 4 to 8 mL (1–2 tsp)
- Fluid extract (1:1): 2 to 4 mL (1/2–1 tsp)
- Solid (dry powdered) extract (4:1): 400 to 800 mg
- Valerian extract (1.0%–1.5% valtrate or 0.5% valerenic acid): 300 to 600 mg

For the rare patient with increased morning sleepiness, reducing the dosage will eliminate the problem. For the best results, dietary factors that disrupt sleep, such as caffeine and alcohol (see Chapter 187), should be eliminated.

TOXICITY

Valerian is generally regarded as safe and is approved for food use by the U.S. Food and Drug Administration. A major concern for any sedative or antianxiety medication is its potential to affect a person's ability to drive or operate potentially dangerous machinery. Valerian at a one-time 1600-mg dose did not affect standardized field sobriety testing (SFST) and driving simulator performance parameters in a double-blind study.[36] Another double-blind study evaluated the effect of a valerian–lemon balm preparation on psychomotor and mental performance tests.[37] No effect was found on reaction time, concentration, or attentiveness.

One case of valerian overdose has been reported in the literature.[27] The patient presented with mild symptoms, all of which disappeared within 24 hours after the patient had taken an overdose—approximately 20 times the recommended therapeutic dose of valerian. Another case history reports valerian-induced hepatotoxicity.[38]

DRUG INTERACTIONS

Although in vitro studies have demonstrated that valerian inhibits drug-metabolizing enzymes, at typical doses it is unlikely to produce clinically significant effects on the disposition of medications dependent on the CYP2D6 or CYP3A4 pathways of metabolism.[39] There is some concern that valerian may prolong thiopental- and pentobarbital-induced sleep—a concern based on animal data and indicating the need to avoid concurrent use of valerian and barbiturates.

Valerian was shown to significantly improve sleep and anxiety in HIV-positive patients taking the antiviral drug efavirenz.[40]

Viscum album (European Mistletoe)

Michael T. Murray, ND

OUTLINE

Viscum album L. (family: *Loranthaceae*)
Common names: European mistletoe, all-heal, birdlime, devil's fuge

GENERAL DESCRIPTION

Viscum album, or European mistletoe, is an evergreen semiparasitic plant found on the branches of deciduous trees in Europe and northern Asia. The roots of the plant penetrate through the bark into the wood of the host tree. The green branches are 1 to 2 ft long and form pendent bushes with leaves that are opposite, leathery, yellow-green, and narrowly obovate. Inconspicuous pale yellow or green flowers appear from March to May, the female developing into sticky white berries that ripen from September to November.[1]

Viscum is most commonly seen on old apple, ash, and hawthorn trees. Traditionally, mistletoe from oak has been the most widely used, although it does not grow as well on oak as on the previously mentioned trees (Fig. 124.1).

CHEMICAL COMPOSITION

V. album contains a variety of pharmacologically active substances, including alkaloids, polysaccharides, phenylpropanes, lignins, lectins, and viscotoxins.[2–10] Some specific compounds found in *Viscum* are as follows:

- A wide range of carbohydrates, including simple sugars as well as polysaccharides
- Phenolic compounds such as flavonoids, caffeic acid, syringin, and eleutherosides
- Sterols, including beta-sitosterol, stigmasterol, and triterpenes
- Various amino acids as well as vasoactive amines, including tyramine, phenylethylamine, and histamine
- Fatty acids such as linoleic, palmitic, and oleic acids

The alkaloids isolated from *Viscum* appear to be related to those found in the host plant.[3,4] For example, mistletoes growing on Solanaceae shrubs contain nicotine alkaloids like hyoscine, anabasine, and isopelletierine. Cardiac glycosides have been found in mistletoe growing on *Nerium oleander,* strychnine has been found in mistletoe growing on *Strychnos* species, and caffeine has been found in mistletoe growing on coffee plants.

Because pharmacologically active compounds appear to be concentrated within the mistletoe, different host trees providing diverse chemical constituents could be used for different therapeutic actions. Also of importance is the fact that the proteins/lectins are present only in aqueous extracts, indicating that their therapeutic activity would differ from that of the alcoholic/aqueous extracts. The alcoholic/aqueous extracts also demonstrate considerably less toxicity.

HISTORY AND FOLK USE

Mistletoe was held in great reverence by the Druids who, dressed in white robes, would search for the sacred plant. When some was discovered, a great ceremony would ensue, culminating in the mistletoe's separation from the oak tree with a golden knife. The Druids believed that mistletoe protected them from all evil and that the oaks on which it was seen growing were to be respected because of the wonderful cures that the priests were able to produce with it.[1]

Mistletoe's use has been recorded in the Middle East, Africa, India, and Japan, and it was mentioned as an anticancer drug by Pliny, Dioscorides, and Galen.[3] In 1720 an English physician, Sir John Colbatch, extolled the virtues of *Viscum* in a pamphlet titled *The Treatment of Epilepsy by Mistletoe.* For many years, mistletoe was used in the treatment of a variety of nervous system disorders, including convulsions, delirium, hysteria, neuralgia, and nervous debility.[1,3] It has been used in naturopathic medicine in the treatment of hypertension and vascular disorders of the uterus, bladder, and intestines.

Probably because of *Viscum's* potential toxicity, its use appears to have fallen into some disrepute shortly after Colbatch's work. For many years it was used only in external preparations for the treatment of dermatitis. Then, in 1906, a study demonstrating *Viscum*'s hypotensive effect in animals and humans was published. This paper appears to have restored its medical prestige, initially in France and eventually throughout Europe.[3]

Fig. 124.1 Viscum album habit.

PHARMACOLOGY

V. album exhibits diverse pharmacological actions. The herb and various extracts have demonstrated that it serves as follows:

- As a hypotensive
- As a vasodilator
- As a cardiac depressant
- As a sedative
- As an antispasmodic
- As an immunostimulator
- As an antineoplastic agent

Purified mistletoe lectins are, in general, not as active in experimental studies as are crude preparations.[11,12] Presumably, the crude preparations contain a number of compounds acting synergistically. It has also been proposed that alkaloid components are responsible for the maintenance of lectin structure and activity.[5] During isolation and purification procedures, alkaloid linkages are cleaved from the lectins, resulting in a loss of specificity for target molecules. Unfermented *Viscum* preparations typically demonstrate greater direct cytotoxicity to tumor cells owing to higher concentrations of the viscotoxin mistletoe lectin I (ML I).[13–15]

Cardiovascular Effects

Viscum has exhibited a variety of effects on the cardiovascular system.[3,16] In particular, *Viscum* has repeatedly demonstrated hypotensive action in animal studies. The mechanism of action for its hypotensive effect is still not entirely clear, and no recent investigations have been published. *Viscum* has been shown to inhibit the excitability of the vasomotor center in the medulla oblongata and to possess cholinomimetic activity.[16]

Viscum's hypotensive activity may depend on the form in which the mistletoe is administered and the host tree from which it was collected. Studies indicate that aqueous extracts are more effective; the highest hypotensive activity was demonstrated by a macerate of leaves of mistletoe parasitizing on willow and gathered in January.[16]

Viscum's nonprotein components—flavonoids, phenol carboxylic acids, phenylpropanes, and lignins—have been shown to possess hypotensive action. Alcoholic solutions (tinctures and fluid extracts) contain these compounds but not viscotoxins or lectins. As previously stated, however, aqueous extracts appear to be more effective.

Several *Viscum* preparations for hypertension are currently available in Europe. In fact, in Great Britain alone, more than 150 different mistletoe preparations are available.[3] These preparations typically have small amounts of *Viscum* in combination with other botanicals with hypotensive action, such as garlic, *Crataegus oxyacantha,* and *Tilia platyphyllos.*

Antineoplastic and Immunostimulatory Effects

Viscum preparations have been used clinically in Europe for the treatment of cancer since 1926, when Iscador, a fermented product made from the crude pressed juice, was introduced as an immunotherapeutic agent for cancer. This work was carried out under the direction of Rudolph Steiner. Since that time, numerous studies have shown that Iscador and other *Viscum* preparations and components are effective antineoplastic and immunostimulatory agents.[11–15,17–31]

Iscador and other fermented *Viscum* preparations differ from nonfermented extracts in their greater effectiveness and their lower toxicity.[17] Specifically, the major viscotoxin, ML I, is not found in Iscador.[18] It is thought that fermentation transforms ML I to its A and B chains, which have important immunological properties.[13] The A chain has mitogenic effects, and the B chain stimulates macrophages and the release of lymphokines. In addition, there is a rapid decrease of lectins during fermentation.

The pharmacological activity of Iscador has been shown to be due to its *Viscum* components rather than to other constituents, such as lactobacilli, which possess adjuvant activity. The lectins have clearly been demonstrated to be the *Viscum* components largely responsible for Iscador's adjuvant activity. Although unfermented plant juice has demonstrated tenfold-greater cytotoxicity to tumor cells than Iscador in vitro, fermented Iscador contains a great number of substances that may act synergistically. In vivo studies in mice have demonstrated Iscador to have greater adjuvant activity than purified mistletoe lectin and to be without secondary toxic effects.[19,20]

Viscum's adjuvant activity is demonstrable in both delayed-type hypersensitivity and antibody responses of mice to sheep red blood cells.[19,20] Like other adjuvants (e.g., bacille Calmette-Guérin, levamisole, muramyl dipeptide, bacterial and yeast components, etc.), Iscador is most effective when it is administered near the tumor, although systemic administration has also yielded positive results. Upon local administration, an inflammatory process ensues that promotes white blood cell (WBC) infiltration and encapsulation of the tumor.

The nonspecific host defense factors stimulated by *Viscum* include the following:

- Enhanced macrophage phagocytic and cytotoxic activity[17,20]
- Increased neutrophil production[17]
- Increased thymic weight and enhanced cortical thymocyte activity and proliferation[21,23]
- Enhanced natural killer (NK) cell activity[17,22,24,32]
- Increased antibody-dependent cell-mediated cytotoxicity[17,22]
- Inhibition of angiogenesis[33]

Iscador's effects on these immunological parameters have been confirmed in patients with cancer.[17,22]

Iscador's effect in stimulating the thymus gland has been demonstrated in several studies.[21,23] Its ability to induce hyperplasia of the thymic cortex and accelerate the regeneration of hematopoietic cells after x-irradiation is much greater than that of any other agent reported to date.[21] In addition, thymic lymphocytes became 29 times more responsive to concanavalin A as a result of Iscador administration.

In summary, *V. album* exhibits numerous cytotoxic, adjuvant, and immunostimulatory effects that indicate a therapeutic effect in human

cancer. These effects have been confirmed in vivo against murine tumors, Lewis lung carcinoma, colon adenocarcinoma 38, and C3H mammary adenocarcinoma 16/C.[4]

CLINICAL APPLICATIONS

Cancer

The clinical application with the most significant scientific documentation is the use of *Viscum* preparations as adjuncts in cancer therapy. In published studies, the route of administration of *Viscum* preparations used has been subcutaneous or intravenous. Therefore it is not known to what degree (if any) the effects noted for Iscador as well as other preparations and *Viscum* compounds can be achieved with oral administration, although one study has shown that an enteric-coated, specially prepared *Viscum* preparation led to the absorption of intact lectins.[34]

Early clinical investigations of Iscador were not well documented. Owing to the shortage of acceptable controlled clinical trials, the use of Iscador and other *Viscum* preparations for the treatment of cancer in Europe has remained controversial, although positive effects in the postoperative treatment of lung, breast, colon, and cervical carcinomas have been shown in several controlled studies.[25] The problem is that the methodological criteria in these studies are poor. Until their benefits are better documented, mistletoe preparations appear most useful as adjuncts to standard therapy.

The results of a prospective study indicate that Iscador is helpful in increasing the survival rate for various cancers.[35] The prospective long-term epidemiological study sought to determine whether Iscador treatment prolongs the survival time of patients with carcinoma of the colon, rectum, or stomach; breast carcinoma with or without axillary or remote metastases; or small cell or non–small cell bronchogenic carcinoma. A total of 10,226 patients with cancer were evaluated. Of these patients, 1668 had been treated with Iscador, and 8475 had taken neither Iscador nor any other mistletoe product (control patients). In the nonrandomized matched-pair study, the survival time of patients treated with Iscador was longer for all types of cancer studied. In the pool of 396 matched pairs, mean survival time in the Iscador groups (4.23 years) was roughly 40% longer than in the control groups (3.05 years).

Perhaps even more beneficial than Iscador is the new generation of mistletoe preparations standardized on ML I (e.g., Eurixor, Lektinol). This greater standardization offers significant advantages. ML I is a potent inducer of cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor. Its cytotoxic effects are also related to its ability to induce apoptosis (programmed cell death).[26]

In one study, the effect of Eurixor was examined in 40 patients with advanced carcinoma of the breast. Along with standard chemotherapy (vinblastine, epidoxorubicin, and cisplatin [VEC] regimen), 21 patients were assigned to receive mistletoe (treatment group), and 19 were given a placebo (control group).[27] After the fourth cycle of chemotherapy, the treatment group had statistically significantly higher leukocyte levels ($P < 0.001$) than the control group; the treatment group had an average WBC count of 3000/mm^3, and the control group had an average WBC count of 1000/mm^3. Furthermore, the parameters of quality of life and anxiety revealed significantly better values in the treatment group than in the control group. These results show that adjuvant treatment with mistletoe extracts, in this case Eurixor, is a valuable addition to standard chemotherapy for patients with advanced breast cancer. These results are important because advanced breast cancer carries a very poor prognosis. Similar results in better-designed studies have been shown with various *Viscum* preparations in advanced pancreatic, colon, and liver cancers.[28,36–41]

Detailed reviews of published studies with *Viscum* preparations indicate significant improvements in various quality-of-life parameters, such as coping, fatigue, sleep, exhaustion, energy, nausea, vomiting, appetite, depression, anxiety, ability to work, and emotional and functional well-being in general and, less consistently, in regard to pain, diarrhea, general performance, and side effects of conventional treatments.[42,43]

A study in ovarian cancer consisted of two randomized matched-pair substudies: The first substudy comprised 42 patients with ovarian cancer without distant metastases (Ovar) and 40 ovarian cancer patients with distant metastases (OvarRand). Patients were paired in random allocation to either Iscador or control. The second substudy comprised 150 patients with ovarian cancer without distant metastases (Ovar) and 124 ovarian cancer patients with distant metastases (OvarRand). Patients who had already received therapy with Iscador were matched by the same criteria to control patients. Increased survival rates with Iscador were significant in OvarRand but not in Ovar in both studies.[44]

One study in 220 patients with late-stage pancreatic cancer compared the overall survival of patients receiving an extract of *V. album* or no antineoplastic therapy. Patients with locally advanced or metastatic cancer of the pancreas were stratified according to a binary prognosis index, composed of tumor stage, age, and performance status, and were evenly randomized to subcutaneous injections of *V. album* extract or no antineoplastic therapy. The extract was administered in a dose-escalating manner from 0.01 mg up to 10 mg three times per week. Median overall survival was 4.8 for the group receiving the *Viscum* extract and 2.7 months for control patients (prognosis-adjusted hazard ratio [HR] = 0.49; $p < 0.0001$). Within the "good" prognosis subgroup, median overall survival was 6.6 versus 3.2 months, within the "poor" prognosis subgroup, it was 3.4 versus 2.0 months, respectively. These results showed a significant and clinically relevant prolongation of overall survival with the administration of *V. album* extract.[45]

In a study in 32 operated gastric cancer patients (stage Ib or II) treated with either 5-FU prodrug doxifluridine alone or in combination with *V. album* extract, those in the *Viscum* group demonstrated improvement in white blood counts, reduced reported bouts of diarrhea (7% vs. 50%), and improved quality-of-life scores.[46]

Presurgical treatment with *Viscum* preparations may help prevent the decreased NK cell activity associated with surgery. In a study of patients with colorectal cancer undergoing open tumor resection, patients were randomly assigned to either mistletoe infusion or no additional therapy. The NK cell activity of patients treated with mistletoe extract did not change significantly during the course of the study, whereas the control patients' NK cell activity decreased significantly after surgery (–44.4% at 24 hours).[47]

Immune Support

The immune-enhancing effects of *Viscum* preparations may extend to conditions beyond cancer. For example, Iscador was shown to reduce the rate of recurrent respiratory infections (RRIs) in children 5 to 14 years old living in areas exposed to the radioactive fallout from the Chernobyl nuclear reactor accident.[48] The dosage was two subcutaneous injections a week for 5 weeks. One year after a single-treatment course, the frequency of RRI relapses decreased by 75%. Furthermore, *V. album* therapy resulted in normalization of initial immune indices that were either below or above the normal ranges. This immunomodulatory effect was assessed by investigation of lymphocyte subsets, NK cell activity, phagocytic and oxidative activity of polymorphonuclear leukocytes, and antiviral activity of serum before and 1 week after treatment.

Clearly, additional investigations into the pharmacology of *V. album* are needed. Specifically, it must be determined whether the

effects noted both in vitro and in vivo in animals as well as in patients receiving injectable *Viscum* preparations can be attained with oral administration. In addition, greater clarification is needed to determine optimal *Viscum* preparations. What host tree should be selected for which condition? What is the optimal harvesting time? In what form should the *Viscum* be administered—crude herb, aqueous or alcoholic extract, fermented or nonfermented?

Viscum is undoubtedly one of the most complex botanicals; current data suggest that the future medicinal use of *V. album* looks promising.

DOSAGE

The standard historical dose of *V. album,* based on the *British Herbal Pharmacopoeia,*[49] is as follows:

- Dried leaves: 2 to 6 g (or by infusion) three times a day
- Tincture 1:5 (45% alcohol): 1 to 3 mL three times a day
- Fluid extract 1:1 (25% alcohol): 0.5 mL three times a day
- Dried aqueous extract 4:1: 100 to 250 mg three times a day

TOXICITY

V. album possesses significant toxicity. Historically, the berries have been regarded as being considerably more toxic than the leaves and stems despite the fact that they all contain similar toxic compounds. The berries are considered to be more toxic, probably because of the fatal poisonings of children who ingest the berries.

Lethal doses of *Viscum* lectins administered by various routes to mice produce the following two types of toxicity: (1) a typical type characterized by death after 3 to 4 days with marasmus-like symptoms and (2) an atypical type characterized by immediate death from respiratory paralysis.[23] In mice, the dose that is fatal to 50% of the subjects (LD_{50}) is 32 mg (dry weight) per kilogram of body weight of the plant juice administered intraperitoneally.[29]

The LD_{50} values of *V. album,* either orally administered or in extract form, have not yet been determined. As stated earlier, alcohol-based extracts contain virtually no *Viscum* proteins. This fact would imply significantly less toxicity with these preparations; however, it would also imply loss of activity because much of the pharmacology of *Viscum* relates to its protein content, especially its immune-enhancing activity.

The toxicity of Korean mistletoe, *Viscum album coloratum,* appears to be lower than that of European mistletoe.[30,31] This other species has also demonstrated anticancer effects, but they appear to be due to highly cytotoxic alkaloids rather than to lectins.[5,30] Studies comparing Korean *Viscum* extracts with European extracts as well as their alkaloid components have demonstrated that the Korean mistletoe has greater activity in inhibiting cancer cells. In addition, fresh Korean mistletoe extracts exhibited greater activity than fermented extracts.[5,30] Korean mistletoe may ultimately prove to be superior to European mistletoe.

DRUG INTERACTIONS

There is some theoretical concern that mistletoe's hypotensive effects might be additive with conventional antihypertensive drugs and that its immunostimulant effects could counter immunosuppressant drugs. However, there appear to be no clinical reports of such effects.

Vitamin A

Joseph Katzinger, ND, and *Michael T. Murray*, ND*

OUTLINE

INTRODUCTION

Vitamin A was the first fat-soluble vitamin to be recognized. Although identified as a necessary growth factor in 1913, it was not characterized chemically until 1930. The initial discovery of vitamin A was made almost simultaneously by two groups of research workers, McCollum and Davis at the University of Wisconsin and Osborne and Mendel at Yale University. They found that young animals fed a diet deficient in natural fats became very unhealthy, as evidenced by the inability to grow and poor immune function. These researchers also noted that the animals' eyes would become severely inflamed and infected with the restricted diet and that this condition could be quickly relieved by the addition to the diet of either butterfat or cod liver oil. Vitamin A was once known as the "antiinfective vitamin," and vitamin A status remains a major determinant of immune status.

Nomenclature

When isolated in its pure form, vitamin A is a pure, lipid-soluble yellow crystal with a condensed formula $C_{20}H_{29}OH$. Vitamin A is termed retinol, signifying that it is an alcohol that is intricately involved in the function of the retina of the eye. All-trans retinol is found in nature primarily as long-chain retinyl esters. The aldehyde form of all-trans retinol is commonly designated retinaldehyde or retinal, whereas the acidic form is termed retinoic acid. It has been suggested that retinol serves only as a precursor to these two active forms of vitamin A—retinal being primarily involved with vision and reproduction and retinoic acid being important in other somatic functions, such as growth and differentiation (Fig. 125.1).[1]

Synthetic derivatives of retinoic acid have been developed to treat many dermatological conditions and, more recently, certain forms of cancer. These compounds, however, are not without side effects.

Recommended Dietary Allowance

Vitamin A was originally measured in international units (IUs), with 1 IU being defined as 0.3 mg of crystalline all-trans retinol or 0.6 mg β-carotene. In 1967, an Expert Committee of the United Nations Food and Agriculture Organization and World Health Organization recommended that vitamin A activity be referred to in terms of retinol equivalents rather than in IU, with 1 mg of retinol being equivalent to 1 retinol equivalent (RE). The amount of β-carotene required for 1 RE is 6 mg, whereas the amount required for other provitamin A carotenoids is

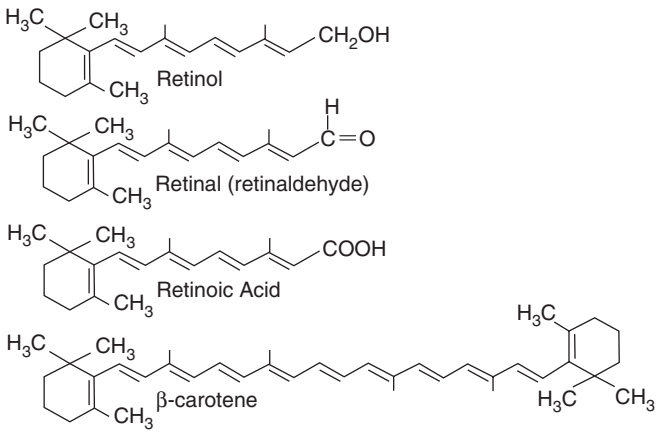

Fig. 125.1 Forms of vitamin A.

*Previous edition contributor

12 mg. In 1980, the Food and Nutrition Board of the National Research Council/National Academy of Sciences adopted this recommendation, and the 1980 recommended dietary allowance (RDA) for vitamin A is stated in milligrams and retinol equivalents; in 2001 the RDAs were revised to today's values (Table 125.1), which use μg RAE (retinol activity equivalent) instead of RE as the standard unit, with 1 μg RAE equivalent to 1 μg all-trans retinol. A distinction between dietary β-carotene and supplemental β-carotene was also made because the latter has much greater absorption as an oil. Thus the current accepted conversion is 1 μg RAE = 1 μg of all-trans retinol = 2 μg of supplemental all-trans β-carotene = 12 μg of dietary all-trans β-carotene = 24 μg of other dietary provitamin A carotenoids (see Fig. 125.2).[2]

Dietary Sources

The most concentrated sources of preformed vitamin A are liver, kidney, butter, whole milk, and fortified skim milk, whereas the leading sources of provitamin A are dark-green leafy vegetables (collards and spinach) and yellow-orange vegetables (carrots, sweet potatoes, yams, and squash) (Table 125.2). Ingestion of excessive amounts of liver—2.7 to 11 kg/week—has been reported to cause hypervitaminosis A.[4]

DEFICIENCY

Vitamin A deficiency may be due to inadequate dietary intake (primary deficiency) or to some secondary factor that interferes with the absorption, storage, or transportation of vitamin A. Some factors known to induce a vitamin A deficiency are as follows:

- Malabsorption due to bile acid or pancreatic insufficiency
- Protein-energy malnutrition
- Liver disease
- Zinc deficiency
- Abetalipoproteinemia
- Poor conversion of β-carotene to vitamin A

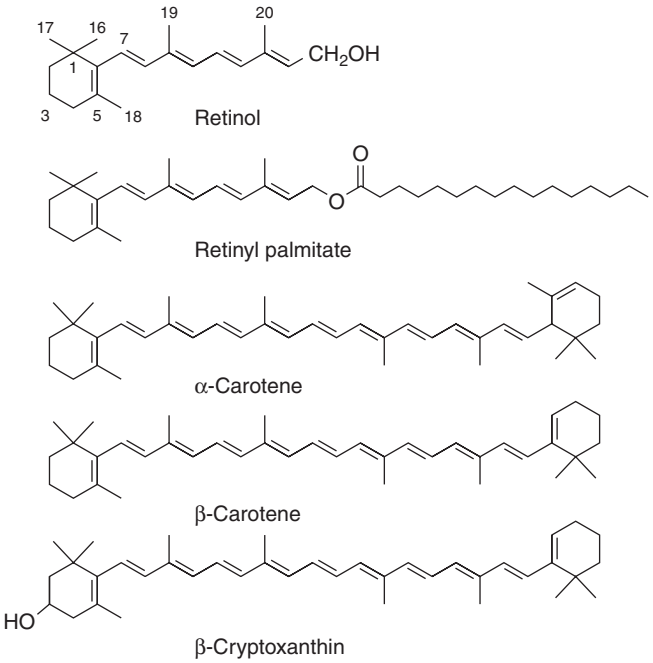

Fig. 125.2 Major forms of vitamin A. Preformed retinol is primarily found as retinyl palmitate in most animal livers, fortificants, and supplements. Of the approximately 50 provitamin A carotenoids in plants, the common ones include α-carotene, β-carotene, and β-cryptoxanthin. These forms of provitamin A carotenoids are often quantified in human serum. (From Tanumihardjo SA, Russell RM, Stephensen CB, et al. Biomarkers of nutrition for development (bond)-vitamin A review. J. Nutr. 2016;146:1816S–1848S. PMID: 27511929. Reproduced from a free access article, distributed under terms [http://www.nutrition.org/publications/guidelines-and-policies/license/].)

TABLE 125.1 Recommended Dietary Allowances

Life Stage Group	Retinol MCG/Day (Retinol Equivalents)	International Units (IU)
Infants (adequate intakes)		
0–6 months	400	1320
7–12 months	500	1500
Children		
1–3 years	300	1000
4–8 years	400	1320
Males		
9–13 years	600	2000
14–18 years	900	3000
19 to >70 years	900	3000
Females		
9–13 years	600	2000
14–18 years	700	2310
19 to >70 years	700	2310
Pregnancy		
<19 years	750	3750
19 to >50 years	770	3950
Lactation		
<19 years	1200	4000
19 to >50 years	1300	4300

TABLE 125.2 Food Sources of Vitamin A

Food	Portion Size	IU/Portion
Meats		
Beef liver, fried	100 g	50,375
Calf liver, cooked	100 g	26,872
Chicken liver, cooked	2 livers	25,760
Vegetables		
Sweet potatoes, baked	1 medium	14,600
Carrots, raw	1 large	11,000
Spinach, raw	100 g	8100
Carrots, cooked	½ cup	8000
Pumpkin, cooked	½ cup	8000
Spinach, cooked	½ cup	7300
Collard greens	½ cup	5400
Broccoli, cooked	½ cup	1900
Fruits		
Watermelon	1/16 melon	5310
Cantaloupe	¼ melon	3400
Apricots, dried	4 halves	2275
Apricots, raw	2–3 medium	2700
Nectarines, raw	1 medium	1650

Data from Selhorst JB, Waybright EA, Jennings S, et al. Liver lover's headache: pseudotumor cerebri and vitamin A intoxication. *JAMA*. 1984;252:3365.

Immune System Effects

Immune system abnormalities associated with a vitamin A deficiency include impaired ability to mount an effective antibody response, decreased levels of helper T cells, and alterations in the mucosal linings of the respiratory and gastrointestinal tracts. Vitamin A–deficient individuals are more susceptible to infectious diseases and have higher mortality rates. It appears that although a vitamin A deficiency may predispose an individual to an infection, vitamin A stores are also severely depleted during the course of an infection. Thus a vicious cycle ensues. Infectious conditions associated with vitamin A deficiency include measles, chickenpox, respiratory syncytial virus, acquired immunodeficiency syndrome, and pneumonia. Lower vitamin A levels have also been linked to asthma, at least in children, and may parallel pulmonary function in this population. Despite this association, supplementation has not yet shown to be of benefit.[5–7]

Other Effects

Prolonged vitamin A deficiency results in the characteristic signs of follicular hyperkeratosis (buildup of cellular debris in the hair follicles, giving the skin a goose-bump appearance, which occurs most often on the back of the upper arm), night blindness, and a higher rate of infection. As the condition worsens, the mucous membranes of the respiratory tract, gastrointestinal tract, and genitourinary tract also become affected, and the classic eye disease known as xerophthalmia due to vitamin A deficiency ensues. Even a mild vitamin A deficiency is associated with a significant rise in mortality. This association is extremely significant because vitamin A deficiency is particularly widespread in developing countries, especially in Asia, where as many as 10 million children are found to have xerophthalmia each year.[8] In 2009, the World Health Organization estimated that as many as 190 million preschool children and over 19 million pregnant women have a vitamin A deficiency, using serum retinol as a criterion.[9] The prevalence of vitamin A deficiency in developed countries is less recognized but may be more common than appreciated. For example, data from the U.S. National Health and Nutrition Examination Survey (NHANES) from 2003 to 2008 suggest that more than 75% of those age 19 to 50 have an intake below guidelines.[10]

Xerophthalmia

The term *xerophthalmia* is generally used to cover all the ocular manifestations of vitamin A deficiency. Blindness is one of the most serious consequences of vitamin A deficiency. Although it rarely occurs in the United States, it is the major preventable cause of blindness in Asia. The xerophthalmia of vitamin A deficiency is staged as shown in Table 125.3.

TABLE 125.3 Staging of the Xerophthalmias

Stage	Diagnosis	Signs and Symptoms
X0	Night blindness	Poor dark adaptation
X1A	Xerosis of conjunctiva	Dryness with "lackluster" appearance, thickening, wrinkling, and diffuse pigmentation of conjunctiva
X1B	Biot spots	Usually triangular collections of desquamated, keratinized epithelial cells and mucus
X2	Xerosis of cornea	Dryness of cornea, leading to keratinization and a hazy, milky appearance
X3	Keratomalacia	Ulceration, distortion, and softening of the cornea with eventual perforation and prolapse and infection of the iris

In an effort to prevent vitamin A deficiency in underdeveloped countries, large prophylactic doses (200,000 IU) are given by the World Health Organization to children every 6 months.

Determination of Deficiency

The rapid dark adaptation test is perhaps the most sensitive of the currently available tests designed to determine vitamin A deficiency. Measurement of serum retinol levels is usually not useful because they may not drop until marked deficiency occurs. Retinol isotope dilution is the most sensitive test to measure vitamin A status, and although technically difficult to perform, it measures total body stores ranging from deficiency to hypervitaminosis. The MRDR test is less demanding to perform, and although more accurate than serum retinol levels, it cannot define vitamin A status above adequacy.[3] Deficiency in the United States and other developed countries is usually secondary to malabsorption, liver disease, or proteinuria.

METABOLISM

Absorption

A variety of factors are known to influence the absorptive efficiency of vitamin A and carotenoids. Although retinol does not require bile acids to facilitate absorption, carotenoids do. Other factors that affect vitamin A and carotenoid absorption are as follows:

- The presence of fat, protein, and antioxidants in food
- The presence of bile and a normal complement of pancreatic enzymes in the intestinal lumen
- The integrity of the mucosal cells

The absorptive efficiency of dietary vitamin A is usually quite high (80%–90%), with only a slight reduction in efficiency at high doses. In contrast, dietary β-carotene's absorptive efficiency is much lower (approximately 10%), and it diminishes rapidly with increasing dosage. Carotene supplements are better absorbed than the carotenes from foods (β-carotene has a roughly sixfold higher absorption as a supplement vs. dietary source.)[11] Both retinyl palmitate and β-carotene are transferred to lipid droplets and mixed micelles; although β-carotene is unaltered at this stage, retinyl palmitate is hydrolyzed to retinol by enzymes that include pancreatic lipase (encoded by PNLIP; Fig. 125.3).

Transformation in the Intestinal Mucosa

The majority of absorbed retinol is esterified with palmitic acid or another free fatty acid within the intestinal mucosal cells. To cross into the cytoplasm of the enterocyte, it is currently speculated that β-carotene's uptake is facilitated by scavenger-receptor class B-type I (SR-BI) and CD36 molecule, although this mechanism is not well established. SR-BI also facilitates cholesterol, vitamin E, and vitamin K uptake.

A number of additional enzymes are thought to be involved in the metabolism, transport, and ultimately the incorporation (along with triglycerides, phospholipids, and cholesterol esters) into chylomicra, including cellular retinol-binding protein type II (CRBPII) and β-carotene oxygenase 1 (BCO1), the primary enzyme involved in β-carotene cleavage (Fig. 125.4). Each chylomicron is transported through the lymphatic channels into the general circulation and eventually removed from the circulation by the liver.

Transport, Storage, and Excretion

Upon reaching the liver, vitamin A is stored primarily in special perisinusoidal lipocytes (Ito cells), which store 70% to 90% of liver vitamin A; the hepatocytes contain only a minor fraction of the total vitamin A stored in the liver. Although small amounts of vitamin A are found in most tissues (Table 125.4), more than 70% of the total body vitamin A content is stored in the liver.[12] It is stored as a lipoglycoprotein complex

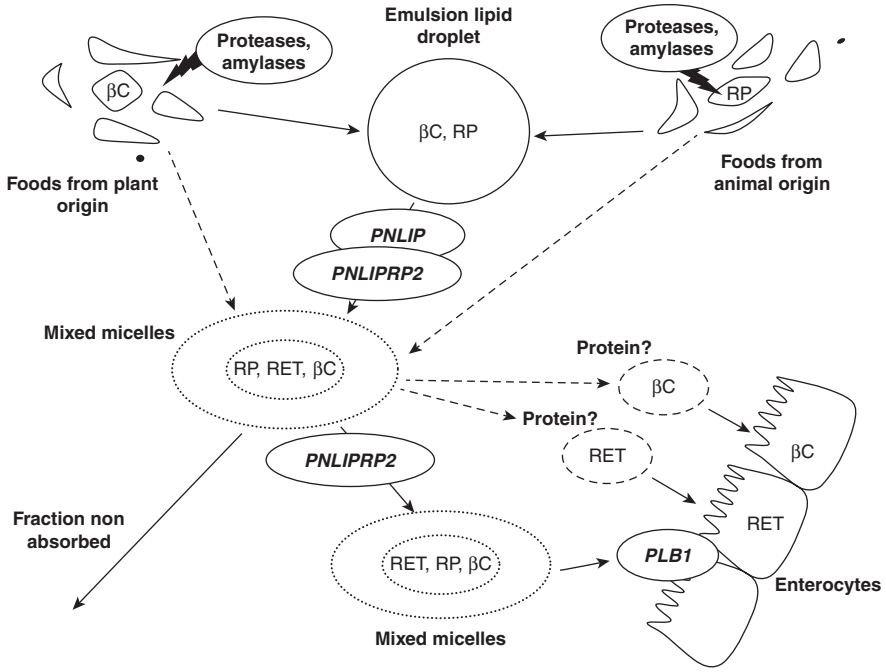

Fig. 125.3 Vitamin A metabolism in upper gastrointestinal tract. Proteins are involved, or hypothesized to be involved, in vitamin A (VA) metabolism within the lumen of the upper gastrointestinal tract. *βC,* β-carotene and all other provitamin A carotenoids; *PLB1,* phospholipase B; *PNLIP,* pancreatic lipase; *PNLIPRP2,* pancreatic lipase-related protein 2; *RET,* retinol; *RP,* retinyl palmitate and all other retinyl esters. Proteins followed by a question mark have been hypothesized to be involved because RET and βC are not soluble in water, and thus nonmicellarized VA is assumed to be associated with proteins. A dotted arrow means the pathway is suspected to exist, but there is no evidence thereof yet.[13] (From Borel P, Desmarchelier C. Genetic variations associated with vitamin A status and vitamin A Bioavailability. *Nutrients.* 2017;9(3):E246. PMID: 28282870 Reproduced from an open access article distributed under the terms and conditions of the Creative Commons Attribution (CC BY) license [http://creativecommons.org/licenses/by/4.0/].)

consisting of 96% retinyl esters and 4% unesterified retinol. At least two lipases are necessary for the mobilization of retinyl ester stores, adipose triglyceride lipase (ATGL) and patatin-like phospholipase domain-containing 3 (PNPLA3) protein. The retinyl esters are hydrolyzed by a tightly bound retinyl ester hydrolase, which transfers the released all-trans retinol to intracellular retinol-binding protein (RBP), which in turn binds to transthyretin (TTR) (Fig. 125.5).[13] The bound retinol is then processed through the Golgi apparatus and secreted into the plasma, where it forms a reversible 1:1 molar complex with prealbumin.[1,14]

It is worth mentioning that a polymorphism in one of the lipases just mentioned, PNPLA3, has emerged as a robust link between an apparent vitamin A deficiency and nonalcoholic fatty liver disease (NAFLD). Although many details regarding the precise role of this enzyme are still unknown, it appears that the I148M variant (rs738409, G allele) has limited lipase activity, leading to lower circulating retinol levels, particularly among overweight individuals. Despite an apparent vitamin A deficiency (as measured by serum retinol), hepatic stellate cell retention of retinol is increased, and along with increased production of triglycerides, this appears to drive the pathogenesis of NAFLD, as well as progression to steatohepatitis (NASH) and cancer.[15] Furthermore, the at-risk allele has been linked to both NASH as well as low bone mineral density among adolescents and may be a causal factor.[16]

Adequate dietary protein, iron, and zinc are necessary for proper retinol mobilization. The half-lives of RBP and prealbumin are less than 12 hours, making them particularly likely to be deficient during protein-calorie malnutrition or other situations in which protein metabolism is abnormal. A zinc, iron, or vitamin E deficiency also severely impairs vitamin A metabolism because these nutrients function synergistically in many physiological processes of vitamin A metabolism (absorption, transport, and mobilization in particular).[17,18]

Retinol is transferred into the cell after RBP binds to a cell-surface receptor. The retinol is then quickly bound by cellular retinol-binding protein (CRBP) in the cell cytosol.

Retinoic acid is metabolized differently from retinol. It is absorbed through the portal system and transported in the plasma bound to albumin. It does not accumulate in the liver or other tissues in any appreciable amounts. It is metabolized quite rapidly to more polar oxygenated compounds. Intracellularly, it is bound to the cellular retinoic acid–binding protein.

Vitamin A metabolites are excreted mainly through the feces (via the bile) and the urine. During periods of deficiency, there appears to be an adaptation in utilization, as evidenced by a reduction in the rate of vitamin A catabolism.[1,14] Indeed, blood levels of retinol are tightly regulated, with fasting concentrations ranging from 2 to 4 μM in adults).[12]

Conversion of Beta-Carotene to Vitamin A

Emerging research is revealing genomic variations that result in impaired conversion of β-carotene to vitamin A are surprisingly common. Single-nucleotide polymorphisms have been identified that result in decreased activity of 15,15′-monooxygenase, the key enzyme responsible for the conversion of β-carotene to retinol. The R267S (rs12934922) and A379V (rs7501331) variants are common, with frequencies in the population of 42% and 24%, respectively. Of these two variants, the latter appears to have a greater effect; those with at least one copy of the less common allele have a 32% drop in activity (presumably more among homozygotes). Those with both 267S and 379V have a 57% reduction in

TABLE 125.4 Distribution of Vitamin A in Some Human Tissues (mcg/kg)

Tissue	Vitamin A
Adrenal gland	10.4 ± 7.1
Liver	149 ± 132
Testis	1.14 ± 1.23
Fat	1.46 ± 1.55
Pancreas	0.52 ± 0.28
Spleen	0.89 ± 0.88
Lung	0.91 ± 1.89
Thyroid	0.43 ± 0.33

conversion rate. Those with these variants have increased blood levels of β-carotene and decreased blood levels of vitamin A.[19]

This may be especially concerning among groups with a low intake of preformed vitamin A, such as vegans. A review of dietary intake among Western industrialized nations found that approximately 35% of vitamin A intake is via carotenoids, although individuals who consume only one component (preformed vitamin A, or carotenoids alone) are unlikely to reach a recommended intake, a concern exacerbated by poor conversion.[20]

PHYSIOLOGICAL ROLES OF VITAMIN A

Vision

The best-understood physiological role of vitamin A is its effects on the visual system. The human retina has four kinds of vitamin A–containing photopigments. Rhodopsin, maximum absorption at 498 nm, is present in the rods. The three iodopsins, as follows, are in the cones:

- Blue cones (maximum absorption 420 nm)
- Green cones (maximum absorption 534 nm)
- Red cones (maximum absorption 563 nm)

The vitamin A form found in these pigments is the 11-cis isomer of vitamin A aldehyde (retinal). When a photon of light strikes the dark-adapted retina, the 11-cis configuration is converted to the all-trans form of the retinaldehyde and split from the rhodopsin molecule to yield opsin and all-trans retinol. This leads to a change in membrane potential and subsequent visual excitation. During light adaptation, because the visual processes largely depend on the cone cells, the released all-trans retinal or retinol from the rod cells is transported to pigment epithelial cells and stored as retinyl palmitate. During dark adaptation, these processes are reversed, and the retinal is isomerized to the 11-cis form. The rod cells are particularly sensitive to vitamin A deficiency, so night blindness or poor dark adaptation is an early consequence of vitamin A deficiency. This sensitivity may have clinical significance in older adults with normal retinal health or early age-related maculopathy (ARM). In a double-blind, placebo-controlled experiment, 104 adults 50 years of age or older whose fundic photographs for the eye fell within steps 1 to 9 of the Age-Related Eye Disease Study Grading System were randomly assigned to a 30-day course of 50,000 IU oral retinol or a placebo. At 30 days, the retinol intervention group had significantly larger (i.e., steeper) rod slopes, indicating faster recovery of sensitivity, than did the placebo group. It is believed that the structural changes in the retinal pigment epithelium and Bruch's membrane in aging and early ARM cause a localized vitamin A deficiency.[14] Despite this finding, the link between intake of vitamin A (as well as β-carotene) and macular drusen (a

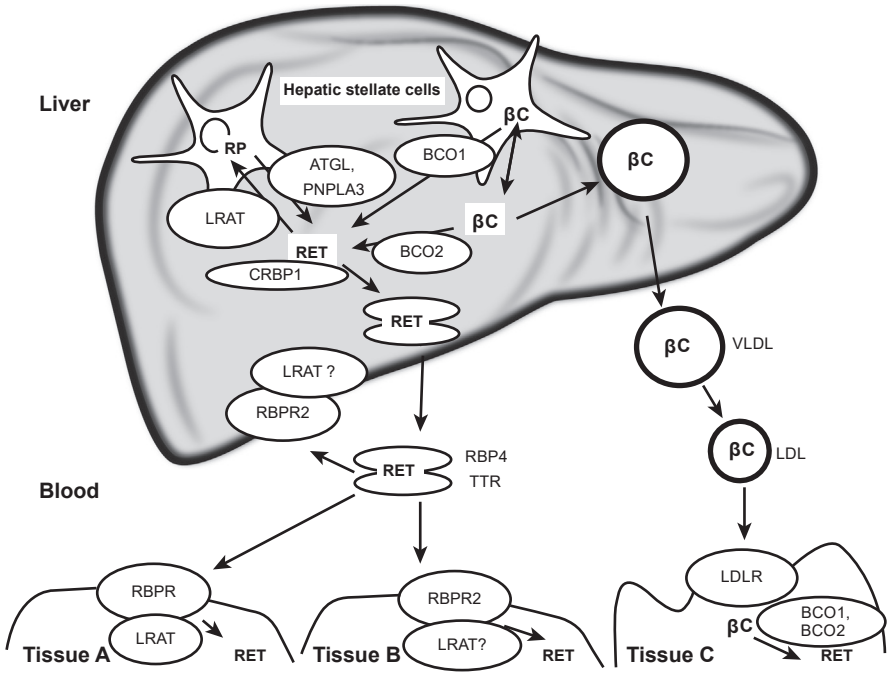

Fig. 125.5 Proteins involved in the liver metabolism of vitamin A. *ATGL,* adipose triglyceride lipase; *βC,* β-carotene and all other provitamin A carotenoids; *BCO1,* β-carotene oxygenase 1; *BCO2,* β-carotene oxygenase 2; *CD36,* cluster determinant 36; *CRBPI,* cellular retinol binding protein I; *LDLR,* LDL receptor; *LRAT,* lecithin retinol acyltransferase; *PNPLA3,* patatin-like phospholipase domain-containing 3; *RBPR2,* RBP4 receptor-2; *RBP4,* serum retinol-binding protein; *RBPR,* RBP receptor (encoded by STRA6); *RET,* retinol; *RP,* retinyl palmitate and all other retinyl esters; *TTR,* transthyretin. The liver is the hub of vitamin A metabolism: it is the main organ that stores VA and distributes it to the peripheral tissues. VA reaches the liver mainly as retinyl esters, mainly RP, and provitamin A carotenoids, mainly βC, incorporated in chylomicrons after VA absorption. VA is then mostly stored in hepatic stellate cells. This figure shows the main proteins involved in the mobilization of the liver stores of VA and in the distribution of liver VA to peripheral tissues.[13] (From Borel P, Desmarchelier C. Genetic variations associated with vitamin A status and vitamin A Bioavailability. *Nutrients.* 2017;9(3):E246. PMID: 28282870 Reproduced from an open access article distributed under the terms and conditions of the Creative Commons Attribution (CC BY) license [http://creativecommons.org/licenses/by/4.0/].)

precursor for degeneration) is still in question. Recent studies have pointed to an increase in risk for drusen with a higher dietary intake of preformed vitamin A in those with a genetic predisposition, possibly due to an increase in retinol-based toxic waste products and/or lipofuscin.[21]

Growth and Development

Vitamin A is believed to affect growth and development through its necessary role in the synthesis of many glycoproteins (e.g., mucus), some of which may control cellular differentiation, and by its function as CRBP in controlling gene expression.[1]

The adhesion between cells is apparently related to glycoprotein synthesis, which is markedly depressed in vitamin A deficiency. Consequently, there is a loss of normal stimuli for cellular growth and differentiation during deficiency. CRBP is transferred directly into the nucleus and may function much like some of the steroid hormones. The effects of a vitamin A deficiency most readily seen at the cellular level are in those differentiating tissues that have a rapid turnover rate—epithelial cells of the oral cavity, respiratory tract, urinary tract, and ducts of the secretory glands.[1]

Development and Maintenance of Epithelial Tissue

The role of vitamin A and carotenoids in the development and maintenance of epithelial tissue cannot be overstated. Vitamin A status determines whether mucin or keratin is synthesized in epidermal cells—the presence of adequate vitamin A results in mucin production, whereas a lack leads to hyperkeratinization of the skin, cornea, upper respiratory tract, and genitourinary tract. Mucopolysaccharide synthesis also appears to depend on adequate vitamin A status.[1,22]

Reproduction

The requirement of vitamin A for reproductive functions in higher animals has been known since 1922. Beta-carotene has also been reported to have a specific effect in fertility distinct from its role as a precursor to vitamin A.[23–25] In bovine nutritional studies, cows fed β-carotene–deficient diets exhibited delayed ovulation and an increase in the number of follicular and luteal cysts.[23,25] The corpus luteum has the highest concentration of β-carotene of any organ measured.[25] The carotene cleavage activity changes with the ovulation cycle, with the highest activity occurring during the midovulation stage. It has been speculated that a proper ratio of carotene to retinol must be maintained to ensure proper functioning of the corpus luteum.

The corpus luteum produces progesterone; therefore inadequate corpus luteum function could have significant deleterious effects. Inadequate corpus luteum secretory function is one of the characteristic features of infertile and/or irregular menstrual cycles.[26] Furthermore, an increased estrogen/progesterone ratio has been implicated in a variety of clinical conditions, including ovarian cysts, premenstrual tension syndrome, fibrocystic breast disease, and breast cancer.[27] Because supplemental β-carotene given to cows significantly reduced

the incidence of ovarian cysts (42% in the control group vs. 3% in the β-carotene group), it may have a similar effect in humans.[24,25] Another bovine condition that has benefited from higher levels of dietary β-carotene is cystic mastitis.[26] It appears that farmers have a greater appreciation of β-carotene than many nutritionists. Of course, there are significant financial reasons for this because the annual monetary loss from bovine mastitis in the United States has been estimated to be at least $1.5 to $2 billion, and ovarian cysts represent the major cause of infertility in cattle.

Immune System

Vitamin A is absolutely essential to proper immune function. Vitamin A plays an essential role in maintaining the epithelial and mucosal surfaces and their secretions. These parts of the immune system constitute a primary nonspecific host defense mechanism. Furthermore, vitamin A has been shown to stimulate and/or enhance numerous immune processes, including induction of antitumor activity, enhancement of white blood cell function, and an increased antibody response.[28] These effects are not due simply to a reversal of vitamin A deficiency because many are further enhanced by (supposedly) excessive amounts of vitamin A. Retinol has also demonstrated significant antiviral activity and has prevented the immunosuppression induced by glucocorticoids, severe burns, and surgery. Some of these effects are probably related to vitamin A's ability to prevent stress-induced thymic involution and promote thymic growth. The carotenes, which are better antioxidants, may turn out to be even more effective in protecting the thymus gland than vitamin A because the thymus gland is particularly susceptible to free radical and oxidative damage.

CLINICAL APPLICATIONS

Adequate tissue vitamin A levels are vital for optimal health. In addition, this nutrient can be used beyond its "physiological" role in the treatment of various conditions. Supplemental vitamin A is used primarily to enhance the immune system in viral illnesses and to treat numerous skin disorders.

Natural vitamin A is available as either retinol or retinyl-palmitate. Absorption may be improved via micellization or emulsification. Micellization is the process of making the fat-soluble vitamin A into very small droplets (micelles) so that the material is dispersed in water. Emulsification is the process of suspending vitamin A in a colloidal mixture with another chemical (e.g., lecithin) so that it can mix with water. Despite manufacturers' claims, it is important to remember that regular vitamin A is absorbed at a rate of 80% to 90%.

Infections

As discussed previously, vitamin A is absolutely critical to a healthy, functioning immune system. Vitamin A–deficient individuals are more susceptible to infectious diseases in general but especially parasitical and viral infections. Although vitamin A deficiency may predispose an individual to an infection, vitamin A stores are severely depleted during an infection.

Parasitical Infections

Vitamin A is critical not only to immune function but also to the integrity and function of the intestinal barrier. Hence vitamin A deficiency may be a predisposing factor for intestinal parasitical infections. In one study evaluating the effects of retinol on intestinal barrier function, growth, total parasites, and *Giardia* species infections in children in northeastern Brazil, 79 children received vitamin A 100,000 to 200,000 IU ($n = 39$) or placebo ($n = 40$) at enrollment and then again at 4 and 8 months; they were followed for 36 months. Total intestinal parasitical, specifically new, infections were significantly lower in the vitamin A group compared with the control group; this outcome was accounted for entirely by significantly fewer new *Giardia* infections in the vitamin A group, indicating that adequate vitamin A stores may help prevent *Giardia* infections.[29]

In another study, the effect of vitamin A supplementation on the overall incidence of diarrheal disease and respiratory tract infections in children was evaluated in 188 children, aged 6 to 15 months, from periurban marginalized communities of Mexico City. The children were assigned to receive vitamin A (below 12 months of age, 20,000 IU retinol; at or above 12 months, 45,000 IU retinol) or a placebo every 2 months and were followed for up to 15 months. Vitamin A supplementation had no significant effect on the risk of overall diarrheal disease but reduced mild watery diarrhea (incidence rate ratio [RR] 0.69) and cough with fever (RR, 0.69). Vitamin A supplementation also decreased diarrheal disease during the summer (RR, 0.74), among nonstunted children (RR, 0.69) and among children from higher socioeconomic level households.[30]

Measles

Vitamin A deficiency is a major problem in many developing countries. A number of well-designed studies have confirmed an effect first noted in 1932: vitamin A supplementation can significantly reduce infant mortality due to measles by at least 50%. Typically, the dosage of vitamin A in double-blind studies has been 200,000 to 400,000 IU administered only once or twice to replenish body stores.[31,32] However, the benefit of vitamin A supplementation in the treatment of measles is not limited to developing countries. A study of well-nourished children in Long Beach, California, suffering from measles indicated that 50% were deficient in vitamin A.[33] This finding supports the use of vitamin A supplementation even in the United States.

Infants With Respiratory Syncytial Virus Infections

Wide-scale immunization programs have reduced the risk of measles in children. However, vitamin A therapy appears appropriate for other childhood viral illnesses as well. One of the more common viruses is respiratory syncytial virus (RSV), a common cause of severe respiratory disease in young children. Studies have shown that children with RSV have low serum levels of vitamin A. Furthermore, the lower the vitamin A level, the greater the severity of the disease, similar to the relation shown in measles. Because vitamin A supplementation diminishes the morbidity and death caused by measles, a group of researchers decided to determine vitamin A's safety and absorption pattern in RSV as a first step in assessing its therapeutic effectiveness.[34]

Twenty-one children with a mean age of 2.3 months (range 1–6 months) with mild RSV infection were treated with 12,500 to 25,000 IU of oral micellized vitamin A. Baseline vitamin A levels were shown to be low; however, within 6 hours of administration of 25,000 IU but not 12,500 IU of vitamin A, normal levels were reestablished. Despite their young age, none of the children experienced any obvious signs or symptoms of vitamin A toxicity. Although the study was not designed as a therapeutic trial, the subjects receiving vitamin A had shorter hospital stays than children with a similar severity of illness who were not enrolled in the study.

Although vitamin A supplementation is an attractive treatment of RSV infections because of its low cost, wide availability, and ease of administration, placebo-controlled trials have suggested that it may be of value only in the most severe cases. A placebo-controlled study of 180 children in Chile with RSV provided 50,000 to 200,000 IU of retinyl palmitate (according to age) within 2 days of admission.[35] Supplementation resulted in no significant benefit except for those

children suffering from hypoxemia. These children experienced substantial benefit, consisting of a more rapid resolution of tachypnea and shortening of their hospital stay from 9.3 to 5.5 days. Similar results were seen in a study involving hospitalized pediatric patients with nonspecific upper respiratory infections.[36]

Acquired Immunodeficiency Syndrome

Patients with acquired immunodeficiency syndrome (AIDS) may also benefit from vitamin A supplementation. One study showed that a vitamin A deficiency is quite common during human immunodeficiency virus (HIV) infection and that vitamin A deficiency is clearly associated with a decreased level of circulating helper T cells, one of the hallmarks of AIDS.[37]

Analysis of vitamin A levels, helper T cells, and other blood parameters in individuals with HIV indicated that more than 15% had low serum vitamin A levels. Helper T-cell levels were much lower in patients with HIV infection whose vitamin A levels were low than in those who had normal levels of vitamin A. Vitamin A deficiency was also shown to be associated with a higher rate of mortality due to HIV.

Increasing β-carotene may be the preferred form of vitamin A for supplementation in patients with HIV because retinoic acid, the active form of vitamin A, may actually increase HIV replication in humans. Low β-carotene levels are common in AIDS, presumably as a result of fat malabsorption. Low β-carotene levels are associated with greater impairment of immune function.[38]

Skin Disorders

The use of high-dose vitamin A therapy for acne and other skin disorders was introduced in dermatology in the late 1930s. It is still used by a few dermatologists, although this type of therapy is not as popular as before the advent of synthetic retinoids. Vitamin A therapy has been shown to be quite effective in treating skin conditions associated with excessive formation of keratin (hyperkeratosis), a skin protein that can clog the pores of the skin to produce a "goose bump" effect. Examples of some skin conditions associated with hyperkeratosis include acne, psoriasis, ichthyosis, lichen planus, Darier's disease, palmoplantar keratoderma, and pityriasis rubra pilaris. The dosages of vitamin A used to treat these conditions have typically been quite high (300,000–500,000 IU/day for 5–6 months in the treatment of acne; 1–3.5 million IU/day for 1–2 weeks for the other conditions).[39–42] The use of these high dosages usually results in the development of significant toxicity (see later discussion). Although there is some evidence that carotenes may be more useful and less toxic in some of these conditions, the pharmacological activity responsible for the effects of vitamin A in hyperkeratosis is believed to occur when serum retinol levels exceed serum RBP capacity, causing destabilization of membranes and destruction of the keratin-producing cells.[38]

In monitoring for vitamin A toxicity, laboratory tests appear unreliable until obvious toxicity symptoms are apparent. The first significant toxic symptom is usually headache, followed by fatigue, emotional instability, and muscle and joint pain. Chapped lips (cheilitis) and dry skin (xerosis) generally occur in the majority of patients, particularly in dry weather. Because high doses of vitamin A during pregnancy can cause birth defects, women of childbearing age should use effective birth control during vitamin A treatment and for at least 1 month after discontinuation.

High doses of vitamin A may not be necessary if other nutritional factors, like zinc and vitamin E, are included. These nutrients work with vitamin A in promoting healthy skin. A safe and effective recommendation for vitamin A in the treatment of acne is less than 25,000 IU/day.

Dry Eyes

Dry-eye disorders are a complex group of diseases characterized by a localized water deficiency in the tear ducts, a mucin deficiency, or a combination of the two. Despite the diversity of underlying causes, the changes in the conjunctiva of the eye are similar in all cases—loss of goblet cells (mucin-producing cells); abnormal enlargement of nongoblet epithelial cells; and increases in cellular layers, keratin deposition and stratification, and keratinization.

Apart from topical vitamin A therapy, all other nonsurgical therapies for dry eye (i.e., the frequent application of artificial tears, lubricants, or slow-releasing polymers and the therapeutic use of soft contact lenses) are not directed toward reversing the underlying process but, rather, toward alleviating the symptoms.

The hypothesis that a localized vitamin A deficiency in the lining of the outer eye may be responsible for dry eye, based on vitamin A's vital role in epithelial tissue, seems obvious. Clinical studies featuring commercial vitamin A eyedrops (Viva-Drops, Vision Pharmaceuticals, vivadrops.com, Mitchell, South Dakota) have yielded impressive clinical results in the treatment of dry eyes.[43,44]

Emerging Potential Applications

It has long been recognized that both iodine and vitamin A deficiencies contribute to hypothyroidism, and their combined use may be more effective than either alone.[45] A recent clinical trial conducted among premenopausal women suggests that retinyl palmitate (25,000 IU/day) may reduce the risk of subclinical hypothyroidism—significant increases in T3 and decreases in thyroid-stimulating hormone (TSH) were found compared with placebo. More clinical data are needed before broad recommendations can be made, but this suggests a potential for supplementation even without documented deficiency.

Neurodegenerative diseases, including Alzheimer's disease and multiple sclerosis, may prove to be valid applications of vitamin A therapy. One recent study found that a marginal vitamin A deficiency is more than twice as common as a vitamin A deficiency among the elderly, with lower levels associated with greater cognitive decline, possibly by stimulating Aβ production and neuritic plaque formation.[46] Evidence also indicates that patients with multiple sclerosis have lower plasma levels of vitamin A, which may lead to impaired immune tolerance. Clinical trials (25,000 IU per day) with retinyl palmitate have shown improvement in the balance of Th1 and Th2 cells, as well as improvements in fatigue and depression.[47,48]

DOSAGE

Dosage ranges for vitamin A reflect the intent of use. For general health purposes, a dosage of 5000 IU for men and 2500 IU for women appears reasonable. During an acute viral infection, a single oral dosage of 50,000 IU for 1 or 2 days appears to be safe even in infants (note that women who might be pregnant must not use vitamin A supplements; β-carotene, however, is fine). For the treatment of acne and hyperkeratotic skin disorders, high-dose therapy may be useful but should be monitored closely by a physician.

TOXICITY

Vitamin A supplementation must be avoided during pregnancy because large doses have been shown to be teratogenic. Unfortunately, safe dosages for pregnant women have not yet been determined, although combined human and animal data suggest that 30,000 IU/day should be considered safe.[49] Nonetheless, women who may become pregnant should keep their supplemental vitamin A levels below 5000 IU or, better yet, switch to carotenes.[50] (Emerging

research is showing that 20%–30% of the population is unable to convert β-carotene to vitamin A. The only way to know is by measuring blood levels.) Excess dietary intake of vitamin A has been associated with birth defects in humans in fewer than 20 reported cases over the past 30 years.[51] Acute toxicity with vitamin A, which is most often seen in children as a result of the accidental ingestion of a single large dose of vitamin A (100,000–300,000 IU), manifests as follows:

- Raised intracranial pressure with vomiting
- Headache
- Joint pain
- Stupor
- Occasional papilledema

Symptoms rapidly subside upon withdrawal of the vitamin, and complete recovery always ensues.

Vitamin A toxicity may occur in adults who have taken more than 50,000 IU/day for several years. Smaller daily doses may produce toxicity symptoms if there are defects in the storage and transport of vitamin A, as occurs in cirrhosis of the liver, hepatitis, or protein-calorie malnutrition as well as in children and adolescents.[52,53] Signs of vitamin A toxicity generally include the following:

- Dry, fissured skin
- Brittle nails
- Alopecia
- Gingivitis
- Cheilosis
- Anorexia
- Irritability
- Fatigue
- Nausea

Serum levels of vitamin A between 250 and 6600 IU/dL are typical of toxicity. Prolonged, severe hypervitaminosis A leads to bone fragility and thickening of the long bones.

Toxicity is typically encountered during high-dose vitamin A therapy for various skin conditions. Although dosages smaller than 300,000 IU/day for a few months rarely cause toxicity symptoms, early recognition is still very important. Cheilitis (chapped lips) and xerosis (dry skin) generally appear in the majority of patients, particularly in dry weather. The first significant toxicity symptom is usually headache, followed by fatigue, emotional lability, and muscle/joint pain. Laboratory tests are of little value in monitoring toxicity because serum vitamin A levels correlate poorly with toxicity, and values of serum glutamic-oxaloacetic transaminase and serum glutamate pyruvate transaminase are elevated only in symptomatic patients.[38]

Prostate cancer risk may also be an area for toxicity concern. Serum retinol was recently associated with both total (odds ratio [OR] 1.3) and high-grade prostate cancer risk (OR 1.74) in the large nested case-control Prostate Cancer Prevention Trial. The increase in risk appeared to be limited to men with a for-cause biopsy and those who reported supplement use, suggesting that supplemental vitamin A may be more of a risk factor than dietary sources.[54] This is in agreement with one of the largest prospective studies to date, the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study, as well as a large pooled analysis of nearly 11,000 cases, both of which found associations between serum retinol and prostate cancer risk, with either no effect or a protective association with carotenoids such as lycopene and β-carotene.[55,56]

DRUG INTERACTIONS

Vitamin E and zinc are particularly important to the proper function of vitamin A. A deficiency of zinc, vitamin C, protein, or thyroid hormone will impair the conversion of provitamin A carotenes to vitamin A.

Excessive vitamin A intake can inhibit vitamin D–mediated calcium absorption, accelerate bone loss, and inhibit the formation of new bone.[57,58] All of these actions may raise the risk of osteoporosis and hip fracture. In one prospective study, a vitamin A intake greater than 5000 IU/day, compared with a lower intake, was associated with a reduction in bone mineral density that approximately doubled the risk of hip fracture.[59] However, a recent long-term study that enrolled 663 men and 335 women taking either retinol (7.5 mg RE/d) or beta-carotene (30 mg/d) found no increase in risk for osteoporotic fracture, suggesting this relationship needs more data, although compelling evidence suggests that only in the context of vitamin D deficiency does vitamin A pose a risk for osteoporosis.[60,61]

Studies have demonstrated a link between exposure to toxic chemicals and vitamin A nutrition. Administration of compounds such as polybrominated biphenyls, dioxin, and other toxic chemicals to rats leads to a decrease in the hepatic content of vitamin A. Concurrent administration of vitamin A and the xenobiotics partially prevents the symptoms of toxicity. Exposure to these compounds results in an increased vitamin A requirement because of the enhanced degradation of vitamin A in the liver.[62,63]

Vitamin K

Cristiana I. Paul, MS Nutrition

OUTLINE

INTRODUCTION

When vitamin K_1 was discovered, it was believed to have only the one role of supporting coagulation, hence the name K, from the German word *Koagulation*. Research from more than two decades has uncovered numerous functions for vitamin K beyond that of clotting. We have also become aware of different forms of vitamin K, while the vitamin K_2 family emerges with distinct cellular effects from vitamin K_1. It seems that nature has evolved a very complex system of vitamin K forms that work together to support various physiological functions for successful survival and reproduction even when its food sources are scarce.

Most importantly, current knowledge of the newly discovered functions of vitamin K is causing a paradigm shift in defining optimal vitamin K intake for supporting many critical aspects of health. In addition, vitamin K's roles in human physiology opens exciting opportunities to intervene with the therapeutic vitamin K doses for the management and potentially reversal of many common health conditions.

FORMS, SOURCES, ABSORPTION, AND METABOLISM

The currently known forms of vitamin K can be grouped in three categories: vitamin K_1 (one type), vitamin K_2 (14 types), and vitamin K_3 (one type) (Fig. 126.1). Vitamins K_1 and K_2 are fat-soluble, whereas vitamin K_3 is water-soluble.[1] Based on current Reference Daily Intake (RDI), only vitamin K_1 is recognized as a true vitamin, essential for human and animal well-being. Vitamins K_2 and K_3 can be derived as metabolites of vitamin K_1 in various tissues or the gastrointestinal tract in animals or humans. However, there may be many clinical situations that can benefit from supplementation with vitamin K_2 (from diet and/or supplements) or from the intravenous administration of vitamin K_3. Oral vitamin K_3 is used only in animal nutrition; for humans, it is currently allowed only for research purposes.[2]

The structures of vitamins K_1, K_2, and K_3 are similar in regard to their core molecule, called menadione (or 2-methyl-1,4-naphtoquinone). Vitamin K_3 is simply composed of the core molecule menadione (see Fig. 126.1C), whereas vitamins K_1 and K_2 contain the core molecule menadione plus specific side chains that distinguish them as follows[3]:

- In addition to the menadione core, vitamin K_1 contains a side chain of one unsaturated isopentenyl unit and three saturated isopentyl units (see Fig. 126.1A).
- In addition to the menadione core, each member of the vitamin K_2 family contains a side chain of specific length, anywhere from 1 to 14 repeats of unsaturated isopentenyl units (see Fig. 126.1B). The length of the side chain determines the name of each type of vitamin K_2 as follows: MK-1 (with 1 unit), MK-2 (with 2 units), and so on, through MK-14 (with 14 units). In this review, a K_2 designation is added in front of their names, as follows: K_2 (MK-1), K_2 (MK-2 through MK-14) to avoid confusion with vitamins K_1 and K_3.

On average, it is estimated that 80% to 90% of dietary vitamin K intake is typically derived from vitamin K_1, with the rest coming from various types of vitamin K_2.[4]

Vitamin K_1

Vitamin K_1, also called phylloquinone or phytomenadione, is synthesized only by plants or algae, where it is bound in the thykaloid membranes of chloroplasts and participates in the electron transport chain of photosynthesis. Vitamin K_1 occurs in significant amounts (50–800

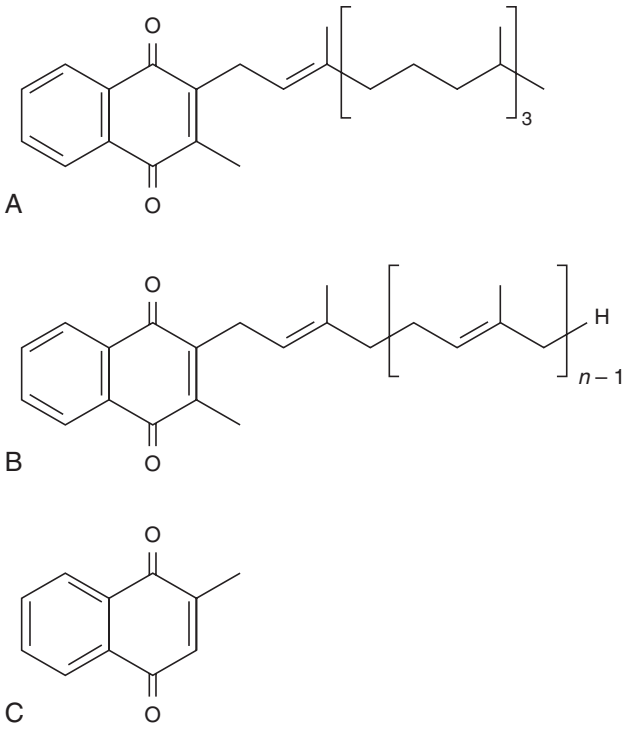

Fig. 126.1 (A) Vitamin K_1, also called phylloquinone or phytomenadione. (B) Vitamin K_2 family, K_2 (MKn) n = 1 to 14, also called menaquinones. Menaquinones have side chains composed of a varying number of isoprenoid residues. (C) Vitamin K_3, menadione.

mcg/100 g food) in certain vegetables, vegetable oils, seeds, algae, and in small amounts (<50 mcg/100 g food) in the rest of the vegetable and animal foods, as listed in Fig. 126.2. Table 126.1 lists the typical yield of vitamin K_1 in common measures of select vegetables, which are the most significant sources of vitamin K_1 of all vegetable foods.

Vitamin K_1 is also available for oral or intramuscular injection to correct clotting deficiency in newborns or to compensate for anticoagulant overdose in adults. Studies are conflicting in regard to the concern that vitamin K_1 injection may increase the risk of various cancers, including leukemia in infants. Recent research seems to have established that the risk was related to the route of administration, specifically to injection and not via the oral route. Also, the safest and most reliable way to increase vitamin K_1 in the unborn fetus and reduce the risk of bleeding after birth seems to be by increasing the mother's vitamin K status, as some studies suggest.[5]

Vitamin K_1 Absorption

Absorption of vitamin K_1 varies considerably depending on its source. When it is delivered in a vegetable, its bioavailability is low (3%–10%) because it is trapped in the chloroplast.[6] Cooking and/or mechanical processing (blending, juicing) of the vegetables or pressing the oil out of the vegetable seeds (such as sunflower seeds) increases the vitamin's bioavailability and absorption up to as much as 50% compared with the raw vegetable.[7]

By adding dietary fat to the vitamin K_1-containing food, absorption of the vitamin can be doubled; it may then reach 10% to 15%.[8] Following is a summary of estimated vitamin K_1 absorption values, obtained by comparing a number of studies[9–17]:

- Absorption from raw vegetables (such as spinach or broccoli): 3% to 5%; some suggest as high as 10%
- Absorption from cooked vegetables without fat: some have found no difference compared with raw vegetables
- Absorption from cooked vegetables with fat: approximately 2.5 times the absorption from raw vegetables
- Absorption from vitamin K_1 dissolved in vegetable oil: approximately 50% to 80%
- Absorption from a synthetic vitamin K_1 supplement: approximately 10% (if mixed in a capsule with 85% cellulose) and approximately 80% (if mixed in an emulsion containing lecithin and a bile acid)

Exposure to ultraviolet (UV) light inactivates vitamin K. When oils containing vitamin K_1 are hydrogenated (during industrial processing, cooking, frying, or baking), a big percentage (40%–50%) of the vitamin K_1 content is also hydrogenated. Studies have shown that hydrogenated vitamin K_1 has very little biological activity.[18] It is important to note that a large section of the population derives a majority of its vitamin K_1 from vegetable oils as opposed to vegetables, so the effect of vitamin K inactivation by hydrogenation may have an important effect on common deficiencies of vitamin K, which may be higher than estimated from just vitamin K_1 intake surveys.

Vitamin K_1 Transport, Metabolism, and Distribution in Human Tissues

Once ingested, vitamin K_1 can be metabolized through various routes in the body (see Fig. 126.2).

Vitamin K_1 is transported initially in the chylomicrons through lymph and blood to the liver and other tissues. Once taken up by various tissues, vitamin K_1 may be stored and utilized unchanged, while part of it may be converted to K_2 (MK-4). For unclear reasons, the steady-state ratio of K_1/K_2 (MK-4) stored in each tissue varies based on tissue type and from individual to individual. See Fig. 126.2 for a list of these ratios in various tissues and organs derived from an animal study.[19]

One study estimates that 5% to 25% of the absorbed vitamin K_1, the same as various K_2 forms, is converted to K_3 in the intestinal cells.[20] Various cells in the body may take up vitamin K_3 and convert it to vitamin K_2 (MK-4). A portion of vitamin K_3 is converted to K_2 (MK-4) in each tissue.[21]

The unabsorbed fraction of vitamin K_1 is metabolized by certain types of gastrointestinal bacteria (*Bacteroides, Escherichia coli,* and *Propionibacterium*) and converted into vitamin K_3 or into vitamin K_2 (MK-n, n = 1–14), the most predominant forms being the longer-chains MK-7, 8, 9, 10, and 11.

As a result of uptake in all the metabolic pathways described previously, vitamin K_1 intake can lead to an increase of various forms of vitamin K in the body, as follows: vitamin K_1 in serum and tissues/organs, vitamin K_3 especially in the serum, vitamin K_2 (MK-4) in tissues/organs, and long-chain K_2s are typically stored in the liver.

One study looked at the vitamin K stored in the rat brain in response to supplementation with either vitamin K_1 or vitamin K_2 (MK-4).[20] Contrary to what was expected, the results showed that supplementation with vitamin K_1 was able to increase the brain content of K_2 (MK-4) more than direct supplementation with vitamin K_2 (MK-4).

Vitamin K_2 (Menaquinones K_2 (MK-1) Through K_2 (MK-14)

Food sources, metabolism. Vitamin K_2 is not considered a vitamin in the true sense because theoretically it is not an essential nutrient. This is because animal and human tissues synthesize vitamin $K_{2\ (MK-4)}$ from the vitamin K_1 ingested, and intestinal bacteria can synthesize various long-chain K_2s from it as well. Although there is an overlap in their carboxylating function, it is not clear whether any of the vitamin K_2 forms can perform all the functions that vitamin K_1 exerts, and there is no proof that they can convert into vitamin K_1.

Vitamin K_2 can be viewed as a metabolite of vitamin K_1 inside human/animal tissues, but some researchers are calling it "the active form of vitamin K_1." Consequently, vitamin K_2 may be conditionally essential for certain individuals owing to their genotypes, aging, and metabolic or disease conditions where the conversion of vitamin K_1 to K_2 is inadequate.

Like the essential role of vitamin K_1 in the energy production (photosynthesis) of plants or algae, vitamin K_2 is an obligatory component of the

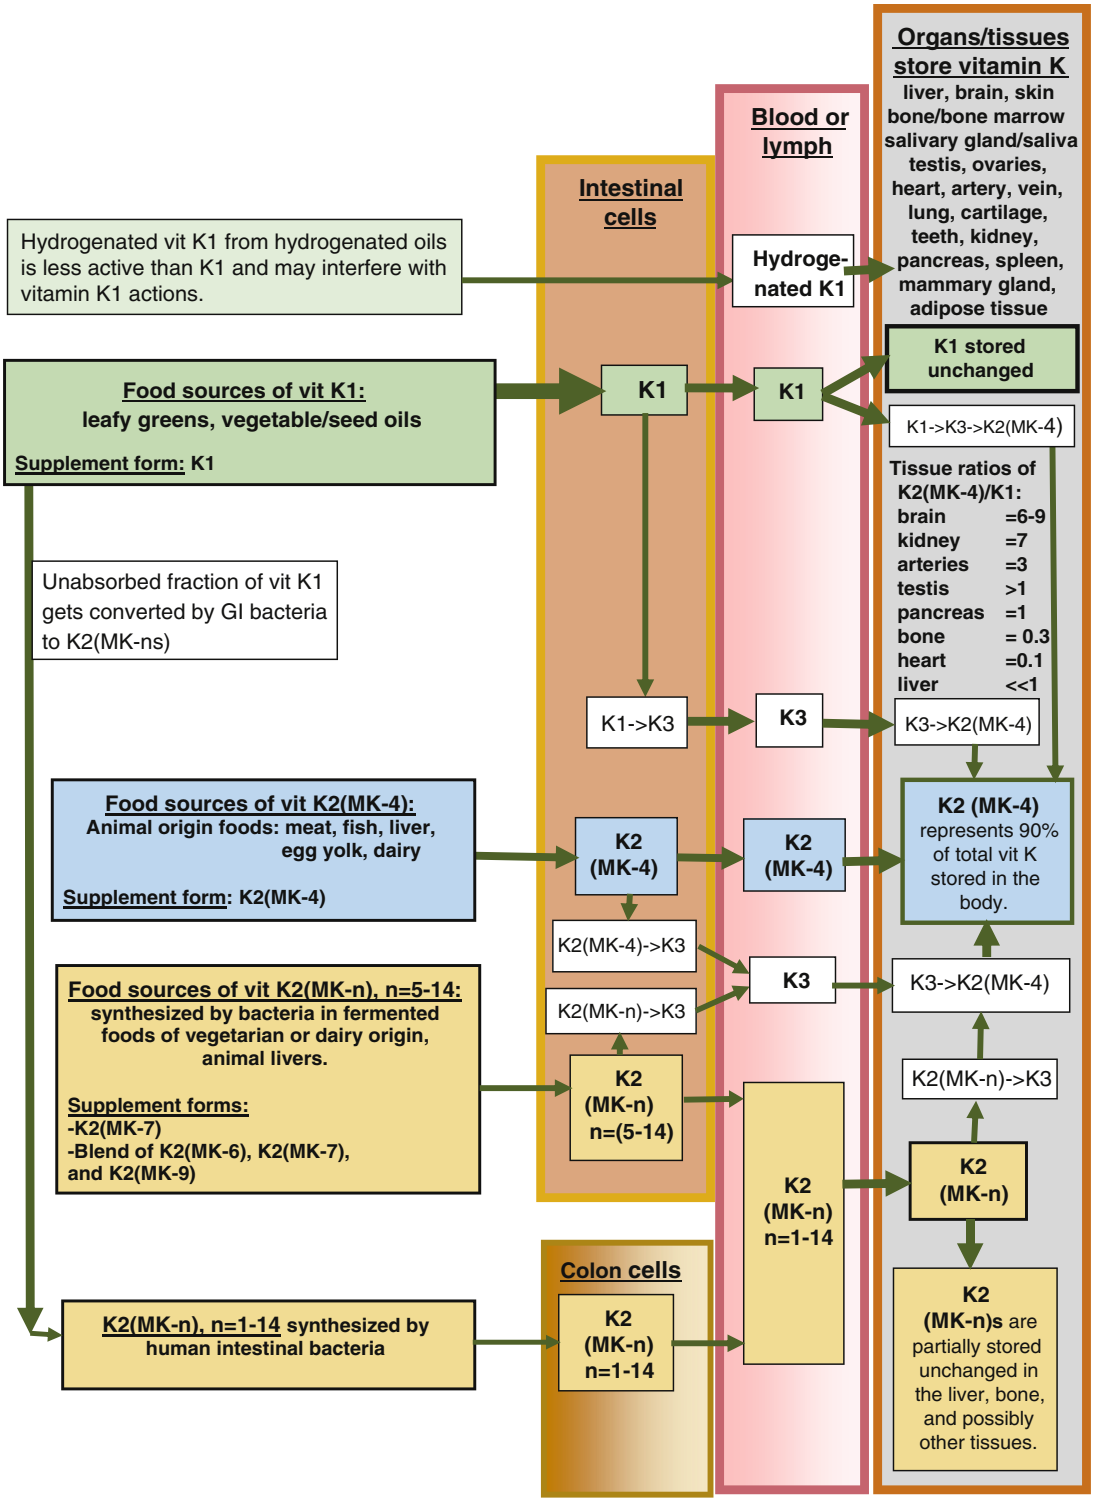

Fig. 126.2 Vitamin K forms, sources, absorption, conversions, transport, and distribution in the blood and organs.

electron transfer pathway in the mitochondria of certain bacteria, analogous to the role of the quinone coenzyme Q10 in animal mitochondria.[22]

Vitamin K_1 Conversion to Vitamin K_2 (MK-4): Tissue Distribution of Vitamin K_1 Versus Vitamin K_2 (MK-n), n = 1 to 14

Vitamin K_2 (MK-4) is the most prevalent form of vitamin K in human and animal tissues, at about 90% of total vitamin K stored, with the remainder as mostly vitamin K_1 and small amounts of long-chain K_2 (MK-n)s (n = 7–11).

The distribution of K_1 versus K_2 in tissues/organs was found to vary widely in an animal study, as shown in Fig. 126.2. The ratio of K_1/K_2 (MK-4) stored varies based on relative and absolute intakes of various forms of vitamin K.

Many studies have shown that various long-chain K_2 (MK-n)s are converted to K_2 (MK-4) in all tissues with the exception of the liver. For example, dietary supplementation of rats with a dose of K_2 (MK-7), equivalent to approximately 90 mcg in humans, was shown to result in a significant increase of K_2 (MK-4) in bone, whereas no

TABLE 126.1 Foods With High Vitamin K_1 Content

Food	Weight (g)	Measure	Amount of K_1 (mcg)
Kale, cooked and drained	130	1 cup	1062
Collards, cooked and drained	170	1 cup	1059
Spinach, cooked and drained	180	1 cup	889
Beets, cooked and drained	144	1 cup	697
Broccoli, cooked drained	156	1 cup	220
Brussels, cooked and drained	156	1 cup	219
Onions, raw	100	1 cup	207
Parsley, raw	10	10 sprigs	164
Cabbage, cooked drained	150	1 cup	163
Spinach, raw	30	1 cup	145
Asparagus, cooked and drained	180	1 cup	144
Lettuce, iceberg	129	1 head	129
Broccoli, raw	88	1 cup	89
Cabbage, raw	70	2 cups	53
Cucumber, raw	301	1 large	49

Data from USDA National Nutrient Database for Standard Reference, Release 17. Content of Selected Foods per Common Vitamin K (phylloquinone) Measure, sorted by nutrient content, http://www.nal.usda.gov/fnic/foodcomp/Data/SR17/wtrank/sr17w430.pdf. Accessed February 13, 2012.

MK-7 was detected in the bone.[23] However, another animal study reported that a fraction of supplemented K_2 (MK-7) is deposited as such in bone. However, this rat study used a dose equivalent to a human dose of 85 mg of K_2 (MK-7), which does not translate into practical applications.[86]

A substantial amount of long-chain K_2 [MK-n]s, n = 7 to 11 is stored in the liver unchanged, and this organ has a distinct distribution of vitamin K compared with all other tissues: that is, 90% long-chain menaquinones (K_2 [MK-n]s, n = 8–11) and 10% vitamin K_1. This may be because the liver is the first organ to have access to the vitamin K_2 synthesized by the intestinal bacteria, which is absorbed through the lower ileum. This preferential sequestering of MK-ns in the liver is hypothesized to be an evolutionary adaptation for securing a low-turnover vitamin K pool to support clotting needs and protect against the dietary variability of vitamin K_1 or K_2 (MK-4).

Dietary Sources of Various Forms of Vitamin K_2

Dietary sources of various forms of vitamin K_2 (various menaquinones) include animal meats and dairy as well as fermented foods of animal or vegetable origin, as follows:

Animal foods. Meats (2–3 mcg/100 g), egg yolk (10 mcg/one egg), and milk. These sources preferentially provide the K_2 (MK-4) form along with similar amounts of vitamin K_1. Table 126.2 contains a listing of the vitamin K_2 content of various foods. Table 126.2 lists the vitamin K_2 content of select foods from three studies in the United States, Holland, and Japan.[25]

The content of vitamins K_1 and K_2 in human milk depends on the mother's intake of these vitamins.[26] The same may be true for cow's milk and other animal milks. Similarly, the vitamin K content of animal tissues may be lower for animals fed mostly corn versus those that

Data from Kamao M, Suhara Y, Tsugawa N, et al. Vitamin K content of foods and dietary vitamin K intake in Japanese young women. *J Nutr Sci Vitaminol (Tokyo).* 2007;53(6):464–470; Elder SJ, Haytowitz DB, Howe J, Peterson JW, Booth SL. Vitamin K contents of meat, dairy, and fast food in the U.S. diet. *J Agric Food Chem.* 2006;54(2):463–467; Schurgers LJ, Vermeer C. Determination of phylloquinone and menaquinones in food. Effect of food matrix on circulating vitamin K concentrations. *Haemostasis.* 2000;30(6):298–307.

are exclusively grass-fed, although no studies have measured this. The vitamin K_2 content of animal-derived food may be higher when they are supplemented with vitamin K_3 (a common practice). Because vitamin K_3 supplementation has proved detrimental for humans, it may be of questionable safety for animals. Also, continuous antibiotic treatment of the animals (to enhance growth) may impair their intestinal bacterial production of vitamin K_2.

Fermented foods (animal or vegetable). Various forms of vitamin K_2 are produced by certain bacteria, ranging from K_2 (MK-4) to K_2 (MK-12) (see Table 126.2):

1. Animal origin: cheese and other fermented milk products (yogurt, kefir, buttermilk, sour cream) provide vitamin K_2 forms mostly as K_2 (MK-8) and K_2 (MK-9).
2. Vegetable origin: natto, sauerkraut, kimchi. For example, the bacteria specific to natto (a fermented mix of soybeans and rice) will provide vitamin K_2 mostly in the K_2 (MK-7) form; bacteria in foods like sauerkraut (pickled cabbage) provide vitamin K_2 in a wide variety of forms, such as K_2 (MK-5) through K_2 (MK-9).

Vitamin K_2 Produced by Human Intestinal Bacteria

Certain bacteria residing in the human intestinal tract convert the ingested vitamin K_1 or other dietary components (such as alpha-ketoglutarate) to various forms of vitamin K_2 (MK-n). The types of bacteria that have this property are mostly gram-negative, such as *Bacteroides fragilis, Propionibacterium,* and particular strains of *E. coli* (normal gastrointestinal resident strain, not necessarily pathogenic). Certain strains of *Lactobacillus* were also found to produce vitamin K_2, although these are not the commonly known strains of *Lactobacillus* or probiotics used in supplements or found in yogurt. Vitamin K produced by the gut bacteria may represent a significant portion of the total vitamin K_2 acquired by some people if their vitamin K status is marginal.[27]

Vitamin K_2 Absorption and Transport

Very few studies have evaluated the absorption of various forms of vitamin K_2.[28] One study found that absorption of K_2 (MK-4) was 16%, 21%, 44%, and 44% with meals containing 8 g, 20 g, 35 g, and 45 g fat, respectively. One study administered K_2 (MK-7) from a natto extract and claimed to have obtained "almost complete" absorption, whereas the absorption of K_2 (MK-7) derived from a supplement was 78% of that from natto.

Vitamins K_2 (MK-4) and K_2 (MK-7) are believed to be partially cleaved (around 5%–25%) in the intestinal wall to form vitamin K_3, which was found in the urine 2 to 3 hours after ingestion of these vitamers.

Plasma half-life of a one-time administration of K_2 (MK-4) is around 1 to 2 hours, whereas that of K_2 (MK-7) is around 2 days. Some hypothesize that K_2 (MK-4) is taken up by the tissues a lot faster because it is the preferred storage form of vitamin K_2. However, after 4 weeks of supplementation with 1.5 mg K_2 (MK-4), for example, fasting plasma levels of K_2 (MK-4) increased from 0.2 ng/mL to 1.5 ng/mL.[184]

Table 126.3 shows the average intakes of various forms of vitamin K from an epidemiological study in a Dutch population. The particularly high contributions from MK-9 and MK-8 are known to be a result of cheese consumption, whereas MK-4 is derived mostly from meat and eggs.

Supplement Forms and Doses Available

Vitamin K_2 is currently available as a supplement in three forms:

1. Vitamin K_2 (MK-4) (menaquinone-4 or menatrenone), which is provided in a synthetic version. It is typically available in doses in

TABLE 126.3 Average Intake of Various Forms of Vitamin K in a Dutch Population (All Values in µg/day)

			VITAMIN K_2 FORMS					
	K_1	Total K_2	MK-9	MK-4	MK-8	MK-7	MK-5	MK-6
Mean	211.7	29.1	14.7	7.1	6.0	0.4	0.3	0.3

Upper end	991.1	128	81.9	28.2	32.8	2.2	2.1	1.5

Data from Gast GC, de Roos NM, Sluijs I, et al. A high menaquinone intake reduces the incidence of coronary heart disease. *Nutr Metab Cardiovasc Dis*. 2009;19(7):504–510. Epub 2009 Jan 28.

the range of 40 to 50 mcg, 1 mg, 15 mg, or 45 mg in stand-alone vitamin K formulas, vitamin D combination with vitamin K formulas, or bone-specific formulas. It is also available as a prescription medication in Japan, called Glakay, in 15-mg doses (with the indication of three times daily).[29]

2. Vitamin K_2 (menaquinone-7, MK-7) is available either in a synthetic version or as a product of fermentation. It can, of course, be ingested with the natto food itself, which provides an average of 1000 mcg/100 g serving. The average vitamin K_2 intake found in young Japanese women was 61.7 mcg. From this, K_2 (MK-7) typically represents 57.4 mcg owing to the common consumption of natto.
3. A blend of three menaquinones (MK-6, MK-7, MK-9), a product of fermentation. This particular mix is meant to better mimic a natural dietary mix of menaquinones.

Vitamin K_3 (Menadione)

Occurrence, Properties, and Special Considerations for Animal and Human Consumption

Vitamin K_3 (menadione) has not been observed to occur in natural foods in any significant amount. It is believed to be formed inside intestinal cells and possibly other tissues and organs of humans and animals and can be found in the plasma and urine 2 to 3 hours after ingestion of either vitamin K_1, K_2 (MK-4), or K_2 (MK-7). Certain intestinal bacteria can convert the ingested vitamin K_1 to K_3 or de novo synthesize vitamin K_3 from compounds such as alpha-keto-glutarate.

Vitamin K_3 is not a vitamin in the true sense; initially it was synthesized to be used as an oral provitamin K compound, most likely because of its conversion to vitamin K_2 (MK-4) in human and animal tissues.

Vitamin K_3 may have been chosen as a supplement because it is a much simpler molecule to synthesize than vitamins K_1 or K_2; thus it was less expensive to produce. However, oral consumption of vitamin K_3 was banned in humans when various side effects were noticed, such as increased red blood cell lysis, excessive oxidative stress, and nonspecific binding of thiols from large and small molecules in the blood.

However, the cytotoxic effects of vitamin K_3 were recognized as useful in support of cancer treatment, alone or in addition to chemotherapy, and K_3 has been used in the oral and intravenous forms (discussed later) in research studies involving humans. Vitamin K_3 is not currently available as a drug or supplement for human use.

It is important to keep in mind that serum vitamin K_3 can rise significantly as a result of ingesting supraphysiological doses of vitamins K_1 or K_2 (above 1 mg), especially if given in one bolus. (This concern is discussed under "Potential Side Effects of High Doses of Vitamins K_1, K_2, and K_3").

Animal nutrition. Certain animal feeding practices include synthetic vitamin K_3 as a supplement, probably because animals fed corn instead of grass receive little natural vitamin K_1. Vitamin K_3 is chosen because it costs significantly less than it would to add vitamin K_1 or incorporate foods naturally high in vitamin K_1, such as grass. No studies have reported the content of vitamin K_3 in animal foods from animals supplemented with vitamin K_3, and very few have reported the tissue content of vitamin K_2 (MK-4) in these animals. There is at least a theoretical concern that these foods may contain abnormally high levels of vitamin K_3 owing to incomplete conversion to the normally occurring K_2 (MK-4). It is not clear whether organic meats come from animals fed vitamin K_3, because they get plenty of vitamin K_1 from the grass.

PHYSIOLOGICAL ROLES OF VITAMIN K: EFFECTS OF NORMAL TO SUPRAPHYSIOLOGICAL DOSES

Mechanisms of Action of Vitamins K_1 and K_2

Aside from blood clotting support, new research is revealing numerous roles for vitamin K in many tissues and organs through a variety of mechanisms.

Vitamin K's actions in human physiology are very complex:

1. Posttranslational modification (through carboxylation) of a number of functional proteins, called vitamin K-dependent proteins (VDKs)
2. Modulation of inflammation through downregulation of cytokine IL-6 and prostaglandin E2 (PGE_2) (by inhibiting COX-2)
3. Downregulation of cell signaling proteins (produced downstream of mevalonate and 3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA]), which affect cell differentiation, proliferation, or apoptosis
4. Neurological effects through modulation of galactocerebroside sulfotransferase enzyme
5. Genetic expression modulation. K_2 (MK-4) stimulates the steroid and xenobiotic receptor, which upregulates expression of bone blastic proteins and collagen.
6. Anticancer effects

Vitamin K activates a variety of VKDs throughout the body by carboxylating a specific number of the glutamatic acid residues they contain, which become, as a result, gamma-carboxyglutamate residues, also called Gla. One molecule of vitamin K_1 or K_2 can be recycled many times, so it is used multiple times to produce Gla residues before it is metabolized for elimination (Fig. 126.3).

Once carboxylated, these residues can bind calcium or interact with cell membranes more efficiently. The more glutamate residues are carboxylated on a VKD protein, the better its functionality. Ultimately, the more vitamin K is available in the body, the higher the percentage of fully carboxylated VKDs will be.

Until now, the AI (adequate intake) for vitamin K has been defined as the amount needed to completely carboxylate prothrombin. With the discovery of new roles for various VKDs throughout the body, many researchers are now proposing redefining the AI at a level where all VKDs in the body are 100% carboxylated. A review by

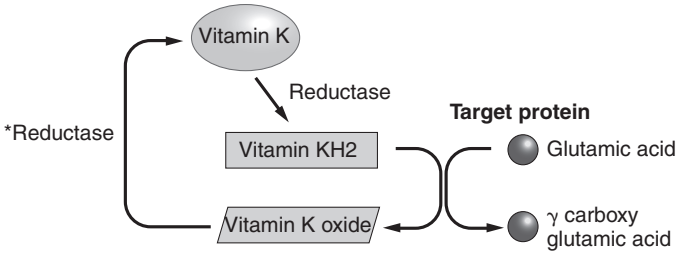

Fig. 126.3 Vitamin K recycling and carboxylation reactions. (From Bowen RA. Vitamin K. http://www.vivo.colostate.edu/hbooks/pathphys/misc_topics/vitamink.html. Accessed May 29, 2012.)

McCann and Ames points out that vitamin K affinity varies greatly for each type of VKD, which may influence the order in which VKDs are carboxylated. Most likely, this is done in an order of physiological priority, selected by evolutionary pressure for survival.[30] For example, clotting may have the highest priority in utilizing most of the vitamin K ingested when intake is around or below 100 mcg/day. In this situation, most of the other VKDs in the body will tend to be inadequately carboxylated and so have poor functionality. Unfortunately, there are no tests to verify the carboxylation of all the known VKDs except for the three that will be discussed (protein induced by vitamin K antagonist-II [PIVKA II], osteocalcin, and matrix GLA protein [MGP]). Important cofactors affecting the rate of carboxylation of VKDs are manganese and vitamin B_6, specifically pyridoxal-5-phosphate. Deficiency of these cofactors, as well as that of estrogen and thyroid hormone may downregulate carboxylation, whereas supplementation with pyridoxal-5-phosphate was shown in vitro to upregulate it twofold.

Osteocalcin is a protein produced by osteoblasts (bone-building cells) that transports calcium inside the bone for fixating it in the hydroxyapatite structure, thus supporting bone mineralization. Vitamin K has been shown to stimulate osteoblasts to increase their production of osteocalcin and collagen type I, both important components of the bone structure. Increased levels of osteocalcin are able to better support bone remodeling and thus improve bone architecture, which translates into better bone elasticity and thus reduced risk of fracture.[31–33]

Osteodentin (tooth dentin) is responsible for tooth mineralization, similar to osteocalcin's role in the bone.[34] Note that the salivary gland concentrates a significant amount of vitamin K, which may have a role in supporting oral health. Vitamin K is known to affect certain bacteria by participating as a cofactor in their energy production (similar to coenzyme Q10 in animal mitochondria). If it is in fact proved that salivary glands secrete vitamin K, this would affect oral bacteria; one researcher has stated that excess vitamin K may exacerbate periodontal disease.[35]

Nephrocalcin is found in kidney tissue and is believed to support calcium ion solubilization and inhibit crystal nucleation, thus reducing the risk of kidney stones.

Matrix Gla protein, or MGP, is found in many soft tissues, where it has at least one identified role, that of rejecting calcium deposition. Specifically, it is found in the skin and in the walls of arteries and veins, where it prevents the calcification of elastin fibers, thus reducing the risk of elasticity loss in these tissues. It is also found incorporated with underlying ground substance of the skin and cartilage (associated with chondrocytes), where it seems to play a role in the synthesis of glycosaminoglycans.[36] MGPs have also been identified in testes and sperm; their role there is not clear, but vitamin K deficiency has been shown to reduce testosterone production and sperm motility. One study that looked at primary prostate cancer cells versus metastatic cells found that "loss of MGP expression may be associated with tumor progression and metastasis."[37]

Note here the important roles of vitamins D and A in some of these VKDs:

- The active form of vitamin D (1,25[OH]D3) stimulates the synthesis of osteocalcin and MGP.[38]
- Vitamin A (retinoic acid) stimulates the synthesis of osteocalcin but inhibits that of MGP.[39]

Consequently, vitamins K, D, and A work in concert and have interdependent actions. Thus for vitamin K to fully realize its potential benefits, the status of vitamins D and A must be optimized so that VKDs are expressed adequately. It has also been established that the genetic effects of 1,25(OH)D3 are mediated by vitamin A through its nuclear receptor, which exerts a permissive activation on the vitamin D nuclear receptor.[40]

GAS-6 protein (growth arrest-specific gene 6) is believed to play a role in platelet aggregation, cell growth, and apoptosis and has been shown to support the survival of cells in tissues such as arterial muscle, eye lens epithelium, brain, and possibly others. It is also involved in supporting adequate innate immunity (natural killer [NK] cells) and reducing the risk or severity of autoimmune cellular events.[41]

Modulation of Inflammation by Downregulation of Inflammatory Cytokines

Vitamin K may reduce inflammation by downregulating of interleukin-6 (IL-6) and PGE_2 as follows:

- Metabolites of vitamin K, the 5- and 7-carbon carboxylic acid catabolites of vitamins K_1 or K_2 (MK-4 or MK-7), inhibit the release of IL-6. This was shown specifically for osteoblasts.[42]
- Vitamin K_2 (MK-4) has been shown to reduce the production of PGE_2 by direct inhibition of the COX-2 enzyme.[43]

These actions of vitamin K may reduce the activity of any inflammatory/autoimmune diseases that are exacerbated by PGE_2 and IL-6.[44] In osteoporosis, IL-6 and PGE_2 have been shown to enhance bone resorption through activation of the RANKL receptor, which in turn upregulates osteoclast differentiation.[45] This mechanism is considered one of the targets of treatment with high doses of K_2 (MK-4) in reducing and reversing bone loss. Vitamin K_2 has also been shown to reduce the activity of rheumatoid arthritis by inhibiting the proliferation of the rheumatoid synovial cells.[46] A correlation has been found between vitamin K status (plasma vitamin K_1) and osteoarthritic disease activity in the hands and knees.[47] In the Framingham study, plasma vitamin K_1 was shown to inversely correlate with C-reactive protein (CRP), a marker of inflammation.

An elevated PGE_2 should also be corrected by addressing the arachidonic acid/eicosapentaenoic acid (AA/EPA) ratio. This, in effect, modulates the substrates of the COX2 enzyme and would have an additional effect on PGE_2 production when added to the effect of vitamin K_2 (MK-4) of inhibiting COX2. One study states the effect of the AA/EPA ratio on another inflammatory intermediate as follows: "nuclear factor κB is activated by arachidonic acid but not by eicosapentaenoic acid."[48]

Downregulation of Cell-Signaling Proteins (Produced Downstream of Mevalonate and HMG-CoA) Affecting Cell Differentiation and Apoptosis

Vitamin K_2 (MK-4) is believed to have an inhibitory effect in pathways downstream of mevalonate, the same pathways where statins and bisphophonates are believed to inhibit key enzymes (HMG-CoA reductase and protein farnesyl transferase, respectively). However, the actions of K_2 (MK-4) are not the same as those of pharmaceutical

drugs, which have a direct enzyme inhibitory action. Instead, K_2 (MK-4) seems to work through a feedback inhibition effect on the mevalonate pathway by "mimicking" one of its downstream metabolites, the molecule geranylgeranyl pyrophosphate.[49,50] This mimicry occurs by means of the side chain of vitamin K_2 (MK-4), which is the molecule. This may be why K_2 (MK-4) has distinct effects compared with those of other forms of vitamins K_2 or K_1.

The inhibition of the mevalonate pathway has multiple effects on human physiology besides cholesterol inhibition because it also downregulates the synthesis of various geranylgeranylated proteins (rho, rab, rac) involved in cell proliferation, cell death, and survival, inflammation, and immune response.[51] Consequently when vitamin K_2 (MK-4) is supplied orally in large doses (many studies have used 45 mg and even 90 mg,[52] which are in the supraphysiological range), it exerts a "mass action" characterized by some researchers as "pharmacological" in nature.

K_2 (MK-4) has been used as a drug in Japan and as a therapeutic nutrient in the United States for the prevention or reversal of osteoporosis, prevention or reversal of cardiovascular calcification, cancer prevention, and treatment support.

In conclusion, vitamin K as K_1 or K_2 has a plethora of actions and specific benefits for health maintenance and disease prevention or treatment.

Bone Health and Therapeutic Interventions for Osteoporosis

The composition of bone is relevant for determining the nutrients needed to maintain its physical structure and those required for the biochemical processes that support this structure: 70% of bone mass is represented by minerals (mostly calcium and phosphorus along with magnesium and silicon) with the rest being composed of 20% organic matter and 10% water. Organic matter is in turn composed of cells and proteins, of which collagen represents 80% to 90%.[53] Collagen fibrils connect bone mineral crystals of calcium and phosphate (Fig. 126.4) and contribute to bone elasticity, strength, and overall quality, which are important determinants of fracture risk (FR).[54]

Bones undergo continuous remodeling by two opposing processes: (1) bone breakdown (or bone resorption) by osteoclast cells and (2) bone building by osteoblast cells. Vitamins K_1 and/or K_2 are stored in bone, partially in the same form as ingested, and partially after being converted to K_2 (MK-4). One animal study revealed a proportion of 10% K_1 and 90% K_2 (MK-4) stored in bone when only vitamin K_1 was ingested.[24] Regarding MK-7, reports are conflicting, with some stating that no MK-7 is detected in bone after MK-7 supplementation[23] probably due to conversion to MK-4, whereas others state that some of it ends up as such in bone. It is not clear what determines the relative distribution of vitamin K forms stored, but it is likely influenced by the absolute and relative amounts of vitamin K forms ingested and the duration of this exposure. The type and amount of vitamin K stored in bones is likely an important determinant of its clinical effects and should factor in choosing various vitamin K forms, alone or in combination, for clinical applications in future studies.

Vitamins K_1 and K_2 modulate bone metabolism as follows:

1. Vitamins K_1 and K_2 participate as cofactors in the activation (by carboxylation) of osteocalcin, which enables binding of calcium and its proper deposition in the bone matrix. Other VKDs have been detected in bone and are believed to have functional roles, not well clarified yet.

Intervention studies and large population assessments revealed that a significant percentage of osteocalcin is uncarboxylated (uncarboxylated osteocalcin, or ucOc) in humans of all ages. See Tables 126.4 to 126.7, which list baseline percentage ucOC in study subjects in the range of 2.6% to 65%.

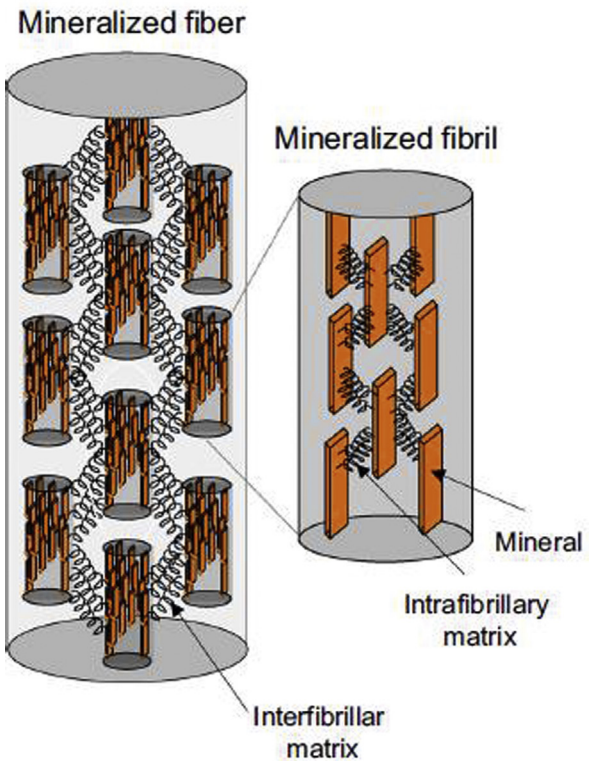

Fig. 126.4 Bone components: collagen fibrils connected to minerals providing a structural scaffold with resilience and elastic properties.

2. Vitamin K_2 (MK-4) is unique among the vitamin K_2 family of compounds because the ligand it contains, geranylgeranyl (GG), is similar to one intermediate of the cholesterol synthesis pathway, geranylgeranyl diphosphate (GGDP). GG it is believed to have inhibitory actions downstream of mevalonate and HMG-CoA, on various metabolites, including synthesis of cholesterol, inflammatory and proproliferatory compounds, thus reducing osteoclast proliferation.[49,55,56]
3. Vitamin K_2 (MK-4) stimulates synthesis of the bone blastic proteins osteoprotegerin and osteopontin.[57]
4. In vitro studies with vitamin K_2 (MK-4) have shown it to increase osteoblast production of osteocalcin and collagen type I, via steroid and xenobiotic receptor activation.[58,59] This increase in collagen production may, at least partially, explain why vitamin K_2 improves bone strength and FR even when BMD is not improved, because collagen represents 80% to 90% of the organic mass of bone.[60–62]

Although MK-7 was also shown to activate the steroid and xenobiotic receptor (SXR) in vitro, there is no exact overlap of its actions with those of MK-4, as a result of distinct effects on other genes.[63] Because MK-7 converts to MK-4 (partially or entirely) in human physiology, it is not clear what the difference would be between the genetic effects of oral administration of these two different forms of vitamin K_2, as no studies have investigated them side by side.

5. Vitamin K_2 (MK-4) was shown to reduce osteoblast apoptosis in in vitro studies.[64]
6. Vitamin K_2, as MK-4 and MK-7, demonstrated an inhibitory effect on RANKL-induced osteoclast differentiation and bone resorption in in vitro studies, whereas MK-4 exhibited a significantly greater efficiency compared with MK-7.[65]
7. Vitamin K_2 (MK-4) reduces osteoclast production from bone marrow cells[66] and induces osteoclast apoptosis, which in effect reduces the total number of osteoclasts. These metabolic effects are achieved

through vitamin K_2's ability to downregulate inflammation (IL-6, PGE_2) and cell proliferation while increasing apoptosis (through the geranylated proteins produced in the mevalonate pathway).[67] This is especially beneficial when osteoclastic activity is elevated, as is often the case in menopause/andropause, likely as a result of estrogen or testosterone insufficiencies.

In conclusion, both K_1 and K_2 (as MK-4 or MK-7) forms can directly carboxylate osteocalcin as such. MK-4 (whether supplemented as such or derived from K_1 or MK-7) induces mechanisms that reduce bone resorption and increase collagen and osteocalcin content of bone. The MK-7 form exerts some but not all the effects of MK-4. This may be because of the unique ligand, GG, contained in MK-4, and its pharmacokinetics, which may explain its unique benefits.[49,55]

Optimal Dose of Vitamin K_1 and/or K_2 for Complete Activation (Carboxylation) of Osteocalcin

Table 126.4 lists studies that investigated the relationship between the level of vitamin K_1 and/or K_2 ingested from a supplement plus from the diet and the level achieved for percentage of ucOc. Tables 126.5 to 126.7 list additional studies that show the change in percentage of ucOc from various interventions with vitamin K_1 or K_2, aimed at evaluating effects on bone density, bone strength, FR, and bone turnover markers. The combined evidence from these studies shows the following:

- With respect to vitamin K_1 interventions, a dose as high as 1 mg is necessary to maximize carboxylation of Oc, which is reflected by minimizing the percentage of ucOc (% ucOc = ucOc/Total Oc) to values such as: 1.9%[25] or 0.54% (close to the detection limit).[68] A dose of 0.5 mg K_1 was able to lower ucOc down to 2.5% in one study,[25] but others showed less lowering, such as 21.1%[69] or 17.4% (males) and 24.1% (females).[70] The discrepancy between studies may be a result of testing methods, and possibly other characteristics, such as different baseline percentage ucOC.
- With respect to vitamin K_2 (MK-4), a dose of 45 mg lowered % ucOc to approximately 4.5%[65] or 5%,[71] whereas a 1.5 mg dose of MK-4 lowered it only to 22% or 14.3%.[72]
- With respect to vitamin K_2 (MK-7), doses of 0.36 mg or 0.375 mg lowered % ucOc to 10%[73,74] or 9%,[75] respectively. A dose of 0.18 mg MK-7 lowered % ucOc down to 24%,[76] whereas a dose of 0.045 mg of K_2 (MK-7) reported a drop in % ucOc from 48% to 38%.[77]

The subjects in the intervention studies that used K_1 or K_2 (MK-4 or MK-7) as a supplement were also ingesting K_1 from their regular diets. These values are specified in Tables 126.4 to 126.7, based on what was reported in each study or an average intake of K_1 from the country where the study took place.

Discussion of results from interventions with various forms of vitamin K are grouped as follows by vitamin K_1, K_2 (MK-4), and K_2 (MK-7) forms because they have different pharmacokinetics and tissue deposition.

Interventions With Vitamin K_1 Alone or in Comparison With K_2 (MK-4 and MK-7)

Table 126.5 lists the most relevant interventions with vitamin K_1 to date, with the majority assessing bone mineral density (BMD), one evaluating FR, and a few of them looking at markers of bone formation and breakdown. The treatment doses of vitamin K_1 used in these studies range from 0.1 mg to 1.0 mg. Some authors claimed to have chosen the K_1 dose from a range of 0.1 mg to 0.5 mg, determined to be equivalent to what may be derived from dietary intake. However, an intake of 1 mg/day is achievable if one ingests a considerable amount of leafy greens or possibly their juices. Within a dietary range of 0.1 mg to 1.0 mg of K_1 intake, this vitamin is expected to exert its effects within normal physiological function based on evolutionary adaptation[78]; thus we will refer to these as "physiological" doses, with higher ones considered "supraphysiological." It is not clear why K_1 doses lower than 1 mg were chosen in any of these studies published after 2002, because at that time, a study demonstrated this to be the dose needed for complete carboxylation of osteocalcin.[79] This likely maximizes the bone building effects of treatments with vitamin K_1 combined with calcium and vitamin D. In the following section is a discussion of results obtained from the studies presented in Table 126.5, which used doses of vitamin K_1 in a physiological range (0.1–1 mg) for women in menopause.

Effects of Vitamin K_1 Supplementation in the Range of 0.1 mg to 1 mg on Bone Mineral Density

Only one study reported increases in whole body BMD of 1.3% and lumbar spine BMD of 1.6% in the group treated with 0.1 mg K_1 (plus 0.11 mg K_1 from the diet), which is the lowest dose used among all listed studies.[80] These interventions included approximately 1000 mg of calcium (from diet + supplementation) and 400 mg magnesium (from diet), highest among all listed studies. The study setting was in Greece, where the diet was most likely of a Mediterranean type. It was the only study that imposed a certain amount of daily physical activity, which was monitored by a pedometer. Bioavailability of K_1 may have been enhanced by delivery in dairy products (milk or yogurt). Only one other study, using a 0.2 mg dose of vitamin K_1, showed an increase in BMD, and only at the ultradistal radius, of 6.2 mg/cm,[81] whereas the control group showed a decline in BMD. This study also included a high calcium intake of 1000 mg, similar to the study discussed previously. Other studies listed in Table 126.5 did not achieve increases in BMD despite using higher doses of vitamin K_1 (0.5–1 mg). They reported either a slower or similar BMD decline compared with the control groups. One explanation could be that all these studies incorporated insufficient calcium intake, in the range of 500 to 700 mg. In addition, for all studies listed, the vitamin D status, as reported by serum 25(OH)D3, was typically near the lower limit of the normal reference range. This was not optimal, by US standards, but not surprising because the amounts of vitamin D given in supplement form were: 0, 320, 400, and 600 IUs, with no significant sun exposure.

Effects of Supplementation With 0.1 mg to 1 mg Vitamin K_1 on Markers of Bone Metabolism

Urinary D-Pyd decreased by 22% in the group treated with 0.1 mg K_1 for 1 year.[80] The other study that measured markers of bone breakdown found no significant changes.[82] Unfortunately, none of the vitamin K_1 studies that supplemented with physiological doses reported FR.

Effects of Supplementation With 5 mg and 10 mg Vitamin K_1 on Bone Mineral Density, Fracture Rate, and Markers of Bone Metabolism

Table 126.5 lists a few studies that used supraphysiological doses of vitamin K_1 at 5 mg and 10 mg. The rationale for these doses was not explained by the authors, but it was possibly under the assumption that they would have more pronounced effects on bone metabolism, possibly by increasing conversion of vitamin K_1 to K_2 (MK-4) and their stimulatory effects on bone metabolic pathways. The resulting increase in vitamin K_2 (MK-4) stored in bone would be expected to reduce inflammation and osteoclast activity and cause osteoclast apoptosis, possibly similar to supplementing directly with high doses of K_2 (MK-4). The study that used a dose of 5 mg in conjunction with 1500 mg calcium for postmenopausal women found a 50% reduction in FR after 2 years, whereas the BMD decline was the same as in the control group at −1.28%. Two studies used a dose of 10 mg K_1 in young athletes, some with amenorrhea, who had similar hormone levels to those

TABLE 126.4 Summary of Studies Using Interventions With K_1, MK-4, or MK-7 to Assess Changes in Osteocalcin Carboxylation

Reference	Length	Age, Gender	Vit K Supplement	Vit K from Diet	Baseline % ucOc	Final% ucOc	Final UcOc	Comments
Binkley[79] 2002, USA	2 wks	25 yrs, females	0.25 mg K_1	0.08 mg K_1	7.9%	ns.[a]		Maximal carboxylation of Oc may be achieved with a supplement of ≥1 mg K_1 BMI = 26
			0.37 mg K_1	0.12 mg K_1	6.5%	ns.[ab]		
			0.5 mg K_1	0.09 mg K_1	8.7%	2.5%		
			1 mg K_1	0.08 mg K_1	8.3%	1.9%[b]		
Koitaya[184] 2009, Japan	4 wks	53–65 yrs, females in menopause	1.5 mg MK-4	0.22 mg K_1	Approx. 43%	Approx. 22%		Plasma MK-4 raised from 0.2 to 1.5 ng/mL
			Placebo	0.31 mg K_1	No significant change			
Nakamura[72]2014, Japan	1 wk	25 yrs males	Placebo	0.07 mg K_1	21%	21%	-	A dose ≥ 0.6 mg MK-4 dose is needed to reduce total ucOc level below the cut-off value of 4.5 ng/mL, which was assessed to be relevant for increased fracture risk.[72] Average PT-INR was maintained in the normal range. Plasma MK-4 raised from 0.14 to 0.58 ng/mL
			0.3 mg MK-4	0.09 mg K_1	21%	24%	6.8 ng/mL	
			0.6 mg MK-4	0.05 mg K_1	21%	15.9%	4.8 ng/mL	
			0.9 mg MK-4	0.02 mg K_1	21%	11.5%	2.9 ng/mL	
			1.5 mg MK-4	0.02 mg K_1	21%	14.3%	3.9 ng/mL	
Dalmeijer[189]2012, Holland	12 wks, n = 60	40–65 yrs	0.18 mg MK-7	0.18 mg K_1, 0.02 mg K_2	32%	13%		dp-ucMGP was reduced from 401 to 276 pmol/L, by 31%
			0.36 mg MK-7	0.19, mg K_1 0.02 mg K_2	30%	10%		dp-ucMGP was reduced from 391 to 209 pmol/L, by 46%

[a]There was no statistical difference from baseline
[b]This value is said to be close to the detection limit.

TABLE 126.5 Summary of Studies Using Interventions With K_1 or K_1 Versus K_2

Reference	Length	Age, Gender	Vit K Supplement	Vit K From Diet	Vit D	Minerals (Ca, Mg, Zn)	Baseline %ucOc	Final %ucOc	BMD, BMC, Fracture Rate, Bone Strength, Markers of Bone Turnover	Comments
Braam[68] 2003, Holland	3 yrs	50–60 yrs, fem	1 mg K_1	Approx. 0.21 mg[a] K_1 0.03 mg[a] K_2	320 IU	500 mg Ca, 150 mg Mg, 10 mg Zn	3%	0.54%	ΔBMD = –3.8%	Study sponsored by Novartis, which is a maker of a bisphosphonate, thus presenting a potential conflict of interest. The study concludes: nutritional interventions are not as effective at increasing or preventing BMD decline as bisphosphonates do.
			Placebo		320 IU	500 mg Ca, 150 mg Mg, 10 mg Zn	2.6%	2.5%	ΔBMD = –5.1%	
			Placebo		-	-	2.8%	2.8%	ΔBMD = –5.5%	
Bolton-Smith[81] 2007, UK	2 yrs	67 yrs, fem	0.2 mg K_1	0.08 mg K_1	600 IU	1000 mg Ca	50.0%	23.0%	ΔBMD (ultra distal radius) = +6.2 mg/cm ΔBMD (mid distal radius) = –16.9 mg/cm,	Serum vitamin K_1 increased from 0.22 to 0.55 μg/L. Plasma 25(OH)D3 range = 24.7–28.3 μg/L. It took 6 mo for ucOc to attain at the final lower value of ucOc of 23%. BMI = 26.
			Placebo		600 IU	1000 mg Ca			ΔBMD (mid distal radius) = –16.6 mg/cm	
			0.2 mg K_1		-	-	48.0%	25.2%	ΔBMD (mid distal radius) = –18.6 mg/cm	
			Placebo	-	-	-			ΔBMD (mid distal radius) = –20.4 mg/cm	
Cheung[129] 2008, Canada	2 yrs	59 yrs, fem	5 mg K_1	Approx. 0.12 mg[a] K_1	800 IU	1500 mg Ca	44.8%	23.8%	RR of fracture was reduced by 50%. ΔBMD = –1.28%, and not statistically different from placebo.	The K_1 dose of 5 mg did not lower % ucOc similar to other studies to less than 3%. Serum vitamin K_1 increased approx. 10 times from 1.8 nmol/L to 22.6 nmol/L.
			Placebo		-	-	46.8%	No change	ΔBMD = –1.22%	
Ned[82] 2007, Holland	6 wks	62 yrs, fem	0.2 K_1	0.18 mg K_1, 0.03 mg[a] K_2	400 IU	700 mg Ca (from diet)	Not reported	24%	No significant change in bone turnover marker serum bone alkaline phosphatase or urinary markers of bone resorption: NTX (N-telopeptide), pyridinoline and deoxypyridinoline.	Final serum vitamin K_1 attained the following levels: 2.4 nmol/L, 3 nmol/L, 4.7 nmol/L, I for K_1 intake of 0.18 mg, 0.38 mg, 0.67 mg, respectively. Average dietary phosphorus was 961 mg/day. BMI = 26.
			0.5 K_1		400 IU			13%		
			Placebo		400 IU			43%		
Booth[70] 2008, US	3 yrs	60–80 yrs, fem	0.5 mg K_1, effervescent tablet	Approx. 0.12 mg[a] K_1	400 IU	600 mg Ca	35.9% (M) 42.8% (F)	17.4% (M) 24.1% (F)	ΔBMD = –0.9% in males, ΔBMD = –1.8% in females	Serum K_1 (nmol/L) increased from 1.4 (M), 1.1 (F) to 1.4 (M), 2.3 (F), which is not as high as in other studies after supplementation with vit K_1 = 0.5 mg. Plasma 25(OH)D3 range: 20.8–24.3 and 25–26.5 (μg/L).
			Placebo				39.1% (M) 41.6% (F)	40.7% (M) 44.7% (F)	BMD loss was not statistically different compared with the vit K_1 group	
Shea[69] 2008, US	3 yrs	60–81 yrs, fem	0.5 mg K_1	Approx. 0.12 mg[a] K_1	400 IU	600 mg Ca plus a multivitamin	40.1%	21.1%	No change in BMD in both groups. No BMD decline in the placebo group is an unexpected finding. No change in inflammatory cytokines.	36% of subjects were on statins, which are known to impair conversion of vitamin K_1 to K_2, but may help reduce bone loss. Plasma 25(OH)D3 was not assessed. BMI = 27.2–28.4
			Placebo				40.8%	42.8%

TABLE 126.6 Summary of Studies Using Interventions With MK-7

Reference	Length	Age, Gender	Vit K Supplement	Vit K From Diet	Vit D	Minerals (Ca, Mg, Zn)	Baseline %ucOc	Final %ucOc	BMD, BMC, Fracture Rate, Bone Strength, Markers of Bone Turnover	Comments
Emaus[74] 2010, Norway	1 yr, n = 354	50–60 yrs, fem meno-pausal	0.36 mg MK-7 placebo	Approx. 0.21 mg[a] K_1 0.03 mg[a] K_2	- -	- -	23% 24%	10% 20%	No significant difference in BMD decline between treatment and placebo groups.	The subjects were an avg. of 3.6 yrs post menopause onset. Some authors claim that interventions to reverse bone loss are likely more successful when implemented before significant drops in estrogen/progesterone levels, due to loss of trabecular networks. BMI = 24.5.
Knapen[76] 2013, Holland	3 yrs, n = 244	55–65 yrs, fem meno-pausal	0.18 mg MK-7 Placebo	Approx. 0.21 mg[a] K_1 0.03 mg[a] K_2	- -	- -	40% 39%	24% 39%	BMD and BMC declined less in the MK-7 group compared with the placebo group at the spine and femoral neck but not at the hip. The "impact strength index," declined less in the MK-7 group compared with placebo, while there was not statistical difference for the other two bone strength indices between the two groups. Vertebral height (in the lower thoracic region) was reduced less in the treatment group.	Study supported and vitamin K_2 provided by Nattopharma. BMI >30. Plasma 25(OH)D3 range: 29.8–30.8 (ng/mL). One vertebral fracture occurred in the treatment group and six in the placebo group, but these results could not be given statistical significance.
Ronn[85] 2017, Den-mark	1 yr, n = 149	60–80 yrs, fem meno-pausal	0.375 mg MK-7	Approx. 0.21 mg[a] K_1 0.03 mg[a] K_2	1520 IU	800 mg	25%	9%	The BMD decline was small but with no significant difference between groups. In the tibia, markers of bone quality/ microarchitecture (trabecular numbers, spaces and thickness) were unchanged in the MK-7 group while changing unfavorably in the placebo group. There was a small significant increase in bone formation marker BAP (Bone Alkaline Phosphatase)	Study supported by Orkla Health, which provided the vit K_2, Ca, and vit D. T-score at baseline > –2.5 and < –1, 25(OH)D3 range: 88–86 nmol/L, 16.9–17.5 years since menopause.

[a]Based on average intake of K_1 in the geographical region where the study took place.
Reference range by a US commercial laboratory for serum K_1: 0.08–1.16 µg/L or 0.17–2.6 nmol/L. It is influenced by plasma triglycerides and various genetic polymorphisms.
Reference range by a US commercial laboratory for serum 25(OH)D3: 30–100 µg/L (ng/mL) or 74.9–249 nmol/L. It is influenced by various genetic polymorphisms.

TABLE 126.7 Summary of a Few Selected Studies Using Interventions With MK-4

Reference	Length	Age, Gender	Vit K Supplement	Vit K From Diet	Vit D	Minerals (Ca, Mg, Zn)	Baseline %ucOc	Final %ucOc	BMD, BMC, Fracture Rate, Bone Strength, Markers of Bone Turnover	Comments
Koitaya[186] 2014, Japan	1 yr, n = 50	50–60 yrs, fem meno.	1.5 mg MK-4	0.17 mg K_1, 0.06 mg[a] K_2	Approx. 312 IU	Approx. 467 mg Ca, 272 mg Mg	24%	14%	No decline in forearm BMD	Plasma pentosidine (a marker of non-enzymatic collagen cross-linking) decreased significantly. This may be attributed to antioxidant activity of MK-4. Plasma MK-4 increased from 0.1 to 0.29 ng/mL. Plasma 25(OH)D3 range: 19.4–20.5 ng/mL
			Placebo	0.18 mg K_1, 0.06 mg[a] K_2	Approx. 336 IU	Approx. 508 mg Ca, 266 mg Mg	22%	24%	Decline in forearm BMD was –2.4%	
Knape[71]n 2007, Holland	3 yrs	55–75 yrs, meno.	45 mg MK-4 (15 mg 3x/day)	Approx. 0.21 mg[a] K_1	-	Approx. 870 mg from diet	25%	5%	Femoral neck width and its BMC increased in the MK-4 group relative to placebo. The overall BMC declined, but at a lower rate than placebo. BMD of femoral neck and of total hip declined the same as in placebo group. One of three indices of hip bone strength was maintained in the MK-4 group but declined in placebo group, whereas the other two declined much less than in the placebo group.	Study was sponsored by Eisai, a pharmaceutical manufacturer of Glakay (15 mg MK-4). Plasma 25(OH)D3 range: 67–72.3 [nmol/l].
			Placebo	0.03 mg[a] K_2	-	Approx. 811 mg from diet	30%	Not statistically different from baseline		
Ushiro-yama[90] 2002, Japan	2 yrs	Meno.	45 mg MK-4	Approx. 0.15 mg[a] K_1	1 μg 1-α OH-D3	Guidelines to eat dairy	Not reported		ΔBMD = +4.92%	1 μg 1-α OH-D3 is the active form of vitamin D_3, a prescription medication in Japan. Authors state that vitamin D_3 supplements were not available in Japan at the time when many studies with Glakay (45 mg MK-4) were performed.
			45 mg MK-4	0.06 mg[a] K_2	-		Not reported		No significant decline in BMD	
			Placebo		1 μg 1-α OH-D3		Not reported		No significant decline in BMD	
			Placebo		-		Not reported		BMD declined	

of postmenopausal women, as a result of intense training and/or low body fat. One of the studies found no effect on BMD in the groups supplemented with 10 mg vitamin K_1 compared with controls,[83] whereas the other study reported improved markers of bone formation and resorption after 1 month of supplementing with 10 mg vitamin K_1.[84]

Interventions With Vitamin K_2 (MK-7)

Table 126.6 lists three of the only four human trials with K_2 (MK-7) interventions available, which used doses of 0.18 mg, 0.36 mg, and 0.375 mg. The fourth study used a dose of 0.1 mg K_2 (MK-7) in a side-by-side comparison with 0.1 mg K_1, see details in Table 126.5.[80]

These K_2 (MK-7) doses can be considered nutritionally equivalent to a fraction of a serving of natto, which provides approximately 400 mcg K_2 (MK-7)/serving. These doses are higher than average consumption of K_2 (MK-7) in Japanese and Western diets, reported at 57.4 mcg or 7 mcg MK-7, respectively. To put this in perspective, total consumption of all forms of K_2 averages 61.7 mcg and 29.1 mcg in Japanese and Western diets, respectively.

All three listed studies were done in Northern Europe, where average vitamin K_1 intake was reported at 0.21 mg, which counts toward the total vitamin K intervention. Vitamin D and calcium were supplemented in only two of these studies.[80,85]

Effects of MK-7 on Bone Mineral Density and Bone Mineral Content

Studies which used supplemental doses of 0.36 mg[74] and 0.375 mg[85] K_2 (MK-7) reported no difference in BMD decline compared with placebo, whereas the study, using the dose of 0.18 mg K_2 (MK-7), reported a slower decline in total BMD and bone mineral content (BMC) compared with control at the spine and femoral neck but not at total hip.[76] The study that used 0.1 mg K_2 (MK-7) (plus 0.14 mg K_1 from diet) noted an increase in total BMD of 1.3%, and of 0.6% for BMD of the lumbar spine.[80] This study reported the same benefit on total BMD for the vitamin K_1 intervention with 0.1 mg (plus 0.14 mg K_1 from diet) but better improvement of BMD at the lumber spine of 1.6% with the vitamin K_1 intervention. The reason why this study achieved better improvement in BMD compared to all other interventions with K_1 or K_2 (MK-7), may be a result of better bioavailability of vitamin K_2 (MK-7) and that of vitamin K_1 administered in dairy; higher calcium, magnesium, and vitamin D intake; enforcement of exercise; and a Mediterranean diet.

Effects of MK-7 on Bone Strength, Bone Quality

The study that used the 0.18 mg K_2 (MK-7) dose for 3 years reported that one out of three bone strength indices declined less in the treatment compared with placebo group, whereas the other two declined to the same degree as placebo. Also, loss of height for a few lower thoracic region vertebrae was less pronounced in the 0.18 g MK-7 group.[76] The study that used the 0.375 mg K_2 (MK-7) dose for 1 year reported that markers of bone quality (such as trabecular numbers, average thickness and spaces) were unchanged in the treatment group, while being changed unfavorably in the control group.[85]

Effects of MK-7 on Markers of Bone Metabolism

A small but significant increase in the bone formation marker bone alkaline phosphatase was reported for the treatment group with 0.375 mg K_2 (MK-7), after 1 year.[85] Urinary D-Pyd decreased by 21% in the group treated with 0.1 mg K_2 (MK-7) for 1 year.[80]

Effects of MK-7 on Raising Bone Content of Vitamin K

One animal study compared the effects of supplementing ovariectomized rats with equimolar doses of K_2 (MK-7) and K_2 (MK-4) for 6 weeks, on changes in bone content of various forms of vitamin K.[86] This study showed that supplementation with an equivalent human dose of 57 mg of K_2 (MK-4) was more efficient than an equimolar human dose of 85 mg of K_2 (MK-7) at raising bone content of vitamin K, as illustrated by the following posttreatment levels:

- After the K_2 (MK-4) intervention, bone levels were: 62.4 nmol/L MK-4
- After the K_2 (MK-7) intervention, bone levels were: 16.7 nmol/L MK-7+1 nmol/L MK-4

Interventions With Vitamin K_2 (MK-4) With Doses in the Supraphysiological Range

Average dietary consumption of K_2 (MK-4) in Western diets was estimated at 7.1 mcg (2.1–28 mcg), whereas that of all forms of K_2 was 29.1 mcg (0.1–128 mcg). Knowing that a large proportion of vitamin K_1 converts to K_2 (MK-4) in human physiology, a dose as high as 1 mg MK-4 may still be considered within physiological range. Such doses were investigated only for their effect on carboxylation of Oc[72] (see Table 126.4). The results show that MK-4 is not as efficient at caboxylating Oc as K_1, because a dose of MK-4 of 0.9 mg was only able to lower it to 11.9% ucOc. On the other hand, all interventions designed with bone health outcomes documented so far used supraphysiological doses of K_2 (MK-4), (e.g., 45 mg). Most of these studies were done in Japan in the form of a pharmaceutical drug called Glakay, intended for menopausal or cortisone-induced osteoporosis. It is claimed that this dose was selected after lower doses of K_2 (MK-4) were studied (unpublished data) and did not perform as well. This dose is likely intended to enhance vitamin K_2 (MK-4) storage in bone and exert intense stimulation on bone biochemical pathways (Fig. 126.5).

A recent study investigated a much lower dose of K_2 (MK-4) of 1.5 mg/day in menopausal women and reported no change in forearm BDM, whereas in the control group there was a 2.4% decline in BMD (see data in Table 126.7).

Treatment with 45 mg MK-4 (15 mg 3x/day) has been reported in many studies to reduce FR significantly, even when BMD was not affected.[32,87] Examples of such FR reduction are: 77% for hip, 60% for vertebral, and 81% for nonvertebral types.[32]

A meta-analysis study concludes: "high dose vitamin K_2 (MK-4) improved indices of bone strength in the femoral neck and reduced incidence of clinical fractures," and "bone strength is a reflection of both bone mass and bone quality independent of the BMD."[87] Two meta-analysis studies concluded that the overall effect of vitamin K_2 (MK-4) on BMD was modest and only at the lumbar spine and not femoral neck.[88,89] However, it is important to note that only a few of these studies used the pharmaceutical form of vitamin D 1,25 (OH) D3, which may have had some of the benefits seen when raising vitamin D status with 25(OH)D3. The data from one of these studies are presented in Table 126.7 and show that treatment of menopausal women with 1,25 (OH)D3 alone, or K_2 (MK-4) alone, could only stall the BMD decline, but the combination of these treatments was able to produce an increase in BMD of 4.92% after 2 years.[90]

A Glakay 1996 postmarketing population survey done in Japan of 4000 people taking the same dosage of 45 mg/day of K_2 (MK-4) did not measure BMD and showed no effect on overall FR; however, a subgroup that had at least five fractures at baseline did show a fracture reduction of about 40%.[91] These disappointing results may be due to a likely suboptimal vitamin D status in the Japanese patients taking Glakay and likely lack of guidelines to supplement with calcium and vitamin D, or to increase sun exposure.

It is interesting that two studies conducted in Holland and the United States, where the investigators used the same K_2 (MK-4) material from Japan (Glakay), obtained no effect on BMD (see data in Tables 126.7[71] and 126.5[92]), but this may also be explained by low vitamin D status.

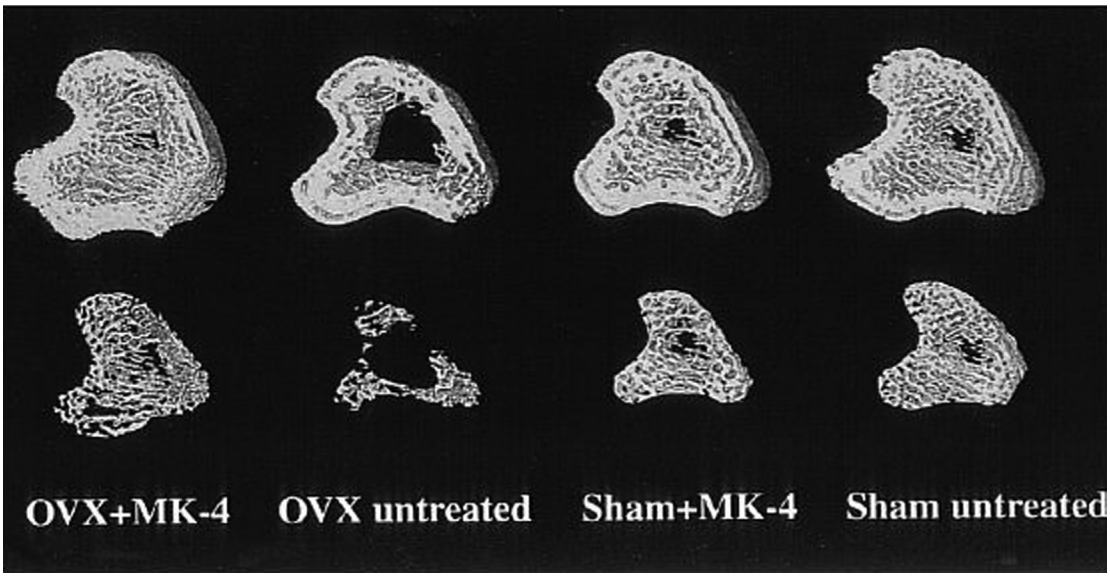

Fig. 126.5 Rat bone specimens after the removal of the cortex. Treatment with 30 mg/kg body weight of vitamin K_2 (MK-4), for 8 weeks, prevented OVX-induced cancellous bone loss. *OVX*, Ovariectomy; *Sham*, sham operation; *MK-4*, vitamin K_2 (MK-4).[183]

However, the Dutch study found other positive changes in markers of bone quality, such as increased femoral neck width and BMC, even though BMD of the femoral neck and of total hip declined the same as with placebo. One of three indices of hip bone strength was maintained in the K_2 (MK-4) group but declined in the placebo group, whereas the other two indices declined less than in the placebo group.

Interventions for osteoporosis are especially needed for women with insufficient estrogen resulting from menopause, ovariectomy,[93] anorexia, or excess exercise. When estrogen levels drop dramatically, it promotes the following changes: (1) elevated osteoclast cell activity, (2) higher ucOc levels (probably caused by reduced carboxylation efficiency needed for Oc carboxylation), (3) increased cortisol levels,[94] and (4) decreased whole body collagen synthesis, which is relevant for bone collagen.[95]

One Japanese study has compared the bone loss in three groups of menopausal women with that of women on placebo: group 1 took 45 mg of K_2 (MK-4) alone, group 2 took vitamin D in a drug form (active vitamin 1,25(OH)D3) alone, and group 3 took hormone replacement therapy (HRT) in the form of conjugated equine estrogen mix (CEE) 0.625 mg/day together with progestin (2.5 mg/day).[96] After a year, the groups had the following changes in BMD: +0.23% for group 1 (with K_2(MK-4)), −0.47% for group 2 (with D3), +4% for group 3 (with HRT), and −2.87 for placebo. Only the result for group 3 was statistically significant in differing from placebo. The results of this study suggest that vitamin K_2 (MK-4) at 45 mg/day may at least forestall the bone loss typical of menopause. Had these investigators combined vitamin K treatment with adequate vitamin D and minerals, the results might have become significant, with a potentially larger increase in BMD. Also, it should be noted that this study used equine HRT. No studies have looked at the effects of vitamin K_2 treatment in comparison with—or ideally, in conjunction with—bioidentical HRT (BHRT), which for numerous reasons is superior, safer, and more effective than equine-based HRT. Combining vitamin K_2 and BHRT treatment is likely to produce better results, not only in terms of bone, but in effects on overall health.

Similarly, one study showed that for men with low testosterone due to leuprolide treatment (for prostate cancer), a daily treatment of 45 mg of vitamin K_2 (MK-4) was able to reduce the expected decrease in BMD.[43] It is conceivable that the same treatment may be helpful for other low testosterone states as well.

Corticosteroids have been shown to downregulate Oc expression, but vitamin K_2 (MK-4) supplementation at 45 mg was able to partially mitigate this effect.

How Does K_2 (MK-4) Compare With Bisphosphonate Actions and Does It Make Sense to Combine Them?

One Japanese study showed that combining K_2 (MK-4) supplementation with bisphosphonate (BP) treatment showed an additive and synergistic effect, probably because of the complementary actions exerted by vitamin K_2 (MK-4) in addition to osteoclast apoptosis, which is the sole mechanism of typical BPs.[97,98] Another study showed that vitamin K_2 (MK-4) improved the effect of the BP in reducing FR significantly (slightly more than 50%) but had only a modest effect in improving BMD. Overall, BPs seem to have a much stronger effect in increasing BMD than K_2 (MK-4). However, some BPs seem to produce an increase in certain types of FR after long-term use.[99] Also, as discussed in Chapter 203, Osteoporosis, although bisphosphonates increase BMD short term, such bones are less remodeled and seem to be less elastic and more brittle, and therefore, with time, tend to become more vulnerable to fracture. Another reason to add K_2 (MK-4) to BP treatment is because of the fact that BPs, like statins, inhibit formation of metabolites of mevalonate-derived pathways (downstream from HMG-CoA). One of these metabolites is geranylgeranyl, which is used in the conversion of all forms of vitamin K to K_2 (MK-4). Thus because some of the benefits of taking K_1 and K_2 (MK-7) are derived from their partial conversion to K_2 (MK-4), it is especially important to incorporate K_2 (MK-4) with vitamin K supplementation for patients taking BPs or statins.

The Potential Reasons for Some of the Disappointing and Conflicting Results Among Vitamin K Studies May Be Explained by Some of the Following:

1. Duration of some studies was not long enough, such as 6 weeks or 1 year, to allow for statistically significant changes to occur.
2. Insufficient doses of vitamin K_1 and/or K_2, derived from diet plus supplementation, in most intervention studies compared with levels that would likely achieve complete carboxylation (activation) of Oc.

3. Insufficient doses of the nutrients essential to the specific actions of vitamin K on bone (such as vitamin D and calcium) as well as those addressing other aspects of bone metabolism, such as magnesium, zinc, manganese, vitamin B_6, vitamin A, and omega-3 fatty acids.
4. Vitamin K is a fat-soluble ingredient that is best delivered with fat and emulsifiers. The formulations given in different studies may have had different absorption rates as a result of delivery medium (capsule vs. soft gel, emulsifiers, mixed in dairy or delivered as an effervescent tablet to be dissolved in water, etc.).[100] Also, different forms of calcium have vastly different absorption rates.
5. The common diagnostic technique to measure BMD used in studies of vitamin K is not as sensitive in detecting the specific actions of vitamin K on bone as are other types of evaluations of bone health and bone quality, such as BU (bone ultrasound test of the heel), BMC, BG (bone geometry or size of various bone components, including height changes), or BS (bone strength, calculated from BMD, BG, height, and weight). By the nature of the measurement, BMD is thought to be unable to "give the complete picture" of bone status because it cannot distinguish architectural aspects of the bone quality, which involve its collagen scaffold.[101] This in turn determines its elasticity and strength, which are all important predictors of FR. This explains why vitamin K_1 and K_2 supplementation was shown to improve bone quality even in studies where BMD did not change as expected.[60,71,102,103]

Researchers estimate that vitamin K status, as assessed by plasma undercarboxylated Oc (ucOc), may correlate better with BU and FR than BMD.[104] Bone heel BU was found to have an accuracy and ability to discriminate osteoporotic patients similar to lumbar spine BMD (by dual-emission x-ray absorptiometry, or DEXA), with potentially better prediction for FR. Consequently, it may be useful to do a BU measurement (in addition to or instead of DEXA) in assessing the effects of vitamin K interventions in clinical practice. One study found that "ultrasound parameters were still significant independent predictors of vertebral fracture even after adjusting for BMD."[105] The BU test may give additional information to the BMD test, especially for patients who, for example, have increased their BMD after many years of bisphosphonate therapy (which reduces bone remodeling severely owing to its main mechanism of action of inducing osteoclast apoptosis).

Potential Synergistic Action Between Vitamin K_2 (MK-4) and Supplemented Hydrolyzed Collagen Protein

As mentioned previously, vitamin K_2 (MK-4) was demonstrated to stimulate the synthesis of bone collagen, which represents the scaffold that holds the mineral crystals in an elastic, resilient architecture. Dietary collagen protein has a very similar amino acid composition to human collagens, which represent 25% to 30% of total body protein, and 16% to 18% of bone mass. On the other hand, dietary collagen protein is unique, with a very distinct amino acid composition compared with all other food proteins, as a result of the very high proportion of glycine, proline, and hydroxyproline.

A few recent human studies have shown that supplementing with 5 g or 10 g of hydrolyzed collagen in postmenopausal women for 1 year has resulted in increases in BMD of 6.4% in the femoral neck and 5.5% in the spine[106] or 79% reduction of FR.[107] In vitro studies have demonstrated that collagen peptides stimulate bone collagen synthesis while also providing collagen amino acids inside cells,[108] thus we hypothesize on a potential synergy between vitamin K_2 (MK-4) and hydrolyzed collagen supplementation.

The Synergy and Necessity of Combining Vitamins K and D

Vitamin D is known to enhance Oc expression, which many be synergistic with the same action by vitamin K_2. Vitamin D increases calcium absorption in the gut, whereas vitamin K was shown to enhance calcium reabsorption in the kidneys. In vitro studies show that the most active form of vitamin D (1,25[OH]D3) enhances the effect of vitamin K_2 on Oc.[109] Thus vitamin D in conjunction with adequate calcium intake has potential to magnify the effects of vitamin K on calcium metabolism.[110] As discussed earlier, none of the studies employing vitamin K_1 or K_2 supplementation optimized the vitamin D status (as assessed by plasma 25[OH]D3) with sun exposure or vitamin D supplementation, compared with midrange values within laboratory reference ranges in the United States. Unfortunately, the doses necessary to achieve this, such as 2000 to 5000 IU of vitamin D_3 per day (depending on sun exposure), are still considered above the commonly accepted UL (upper tolerable limit). Plasma levels of 25(OH) D3 in vitamin K studies discussed here were close to the bottom of the reference range as a result of use of doses of vitamin D in the range of 200 to 1500 IU. Interestingly, the studies that administered 45 mg K_2 (MK-4) in conjunction with the active form of vitamin D (1,25(OH) D3) reported some of the best benefits on BMD among similar interventions with vitamin K.

Important Complementary Interventions to Increase Vitamin K Supplementation Efficacy

Adequate vitamin K intake from food and/or supplements or therapeutic high-dose supplementation may achieve the best results if it is coordinated with:

- Optimal vitamin D and vitamin A status.[111] Hypervitaminosis A has been shown to cause an excessive increase in bone turnover and to reduce bone quality.[112]
- Adequate intake of well absorbed minerals (Ca, Mg, Zn, boron), vitamin B_6, and vitamin C[113] and consider supplementation with 5 to 10 g of optimally hydrolyzed collagen protein.
- Optimal omega-3/omega-6 and EPA/AA (arachidonic acid) balance (to prevent excessive PGE_2 formation)[114]
- Proper acid/alkaline balance (possibly by monitoring urine pH) through dietary balance, optimal minerals, and potassium intake[115]
- Optimal levels of hormones (estrogen, progesterone, testosterone, DHEA, growth hormone, cortisol, thyroid)[116] as appropriate based on age and risk/benefit assessment.

Conclusions: What Is the Best Approach to Optimizing Status of Vitamin K in Support of Bone Health?

Some of the intervention studies discussed here, for each form of vitamin K, show promising results, although few proved to completely reverse all aspects of osteoporosis progression. Most studies did not report a restoration to healthy levels for BMD, BMC, or other indices of bone strength or bone quality, nor did they report normalization in markers of bone turnover. At best, many studies showed a slower decline or no decline in the previously-mentioned markers in menopausal women with established osteoporosis, whereas some reported significant reduction in FR for the high-dose treatment with 45 mg K_2 (MK-4) or 5 mg K_1. However, it seems that there is great potential in a therapy that combines all known bone beneficial nutrients, in bioavailable forms and adequate doses (from diet, supplements, and sun), along with optimizing vitamin K status. All forms of vitamin K seemed to show some benefit, whether at physiological or supraphysiological doses and the question arises, when is supplementation warranted in addition to diet, with what doses, which forms, and alone or in combination? Nutritional bone support should be tailored based on age and gender, but the available data are mostly from studies involving women in menopause.

A foundational recommendation for any age or gender is to derive as much vitamin K_1 from an abundant intake of leafy greens

or their juices (which are also alkalinizing) and healthy oils, such as olive oil. Human physiology is evolutionarily adapted to an intake of vitamin K_1 as high as 1 mg/day.[78] This level of intake happens to also support almost complete carboxylation of Oc, as discussed earlier. However, it is not practical to believe that most individuals will achieve this goal by adjusting their diet, because average intakes have been reported at 0.12 mg in the United States and 0.21 mg in Europe. Thus supplementation with K_1 and/or K_2 may be warranted for a large proportion of these populations. The question is, which forms and doses of vitamin K should be supplemented based on bone health goals and clinical status? A practical approach takes into consideration efficacy proven in clinical trials, pharmacokinetics, and the relative cost of the forms, given that on a per milligram basis the MK-7 ingredient is 10 times more expensive than MK-4, which in turn is 10 times more expensive than K_1. If cost is the primary concern, the actual clinical dosages prescribed should be used to determine actual relative costs.

Recommendation for Young Individuals

Optimizing vitamin K status with vitamin K_1 from diet plus vitamin K_1 supplements may be sufficient for men and women during development and reproductive age, with the goal of achieving peak bone mass and maintaining it until significant age-related decline in hormones occurs. In this case supplementing with K_1, at the level of 0.5 mg to 1 mg, depending on one's diet, may support complete carboxylation of Oc (possibly also that of MGP, discussed in the next section). At this level, a portion of vitamin K_1 is expected to convert to K_2 (MK-4) before, as well as after it is deposited in bone and other tissues. For individuals that take statins or bisphosphonates, it makes sense to supplement with additional K_2 (MK-4) above this amount, because these pharmaceuticals impair conversion of K_1 to K_2 (MK-4).

Recommendation for Older Individuals, Especially Women in Peri- and Established Menopause or Men With Lower Than Optimal Testosterone Levels

Additional vitamin K_2 may be needed to possibly compensate for poor vitamin K_1 to K_2 (MK-4) conversion and take advantage of intensive metabolic signaling that only vitamin K_2 can exert. The question is which form and doses of vitamin K_2 should be chosen to reverse bone loss or stall its decline, if peak bone mass was optimal. The best evidence currently available is for the high-dose K_2 (MK-4) at 45 mg/day (15 mg 3x/day) to reduce FR and increase BMD in menopausal women or men with low testosterone, especially in studies where vitamin D status was improved. This author believes current evidence does not support recommending supplementation with the MK-7 form of vitamin K_2 over the MK-4 for the following reasons.

Studies with nutritional doses of MK-7 are few, and although they have shown some benefits, the majority did not prove the ability to stall or reverse a decline in BMD or all markers of bone strength in menopausal subjects. None of the studies obtained a statistically significant effect on FR. The one study that reported a benefit for BMD, at a dose of 0.1 mg K_2 (MK-7), showed that the same result was obtained from an equivalent dose of K_1. One animal study showed that supplementation with K_2 (MK-4) was more efficient than with K_2 (MK-7) on raising bone content of vitamin K_2 (MK-4) and total vitamin K_2.[86] Unfortunately, there are no human studies comparing the effects on bone between K_2 (MK-7) and K_2 (MK-4).

In conclusion, for older individuals that need intensive bone support, it makes sense to supplement with vitamin K_1 at the level of 0.5 to 1.0 mg, or as high as 5 mg K_1, depending on one's diet, and an additional 45 mg K_2 (MK-4) (15 mg 3x/day). It is conceivable that less MK-4 may be just as effective in a setting where at least 1 mg K_1 is provided from diet plus supplements.

Dental Bone Support

Vitamin K status may be essential for oral health because it supports the activation of Oc and osteodentin, two functional proteins involved in tooth mineralization and dental bone metabolism. In addition, salivary glands have a high content of vitamin K, which suggests additional roles for it in oral health.

Cardiovascular Health

Vitamin K influences many aspects of cardiovascular physiology: blood clotting, calcification of tissues critical to cardiovascular function, arterial elasticity, inflammation, and oxidative stress.

Vitamin K is an important cofactor necessary for the physiological process of inhibiting inappropriate calcification of soft tissues that are not normally calcified, such as arterial/venous vessel walls, heart valves, skin (elastin/collagen fibers), cartilage (other than the normal growth-related mineralization), and kidney tissues.[117] Vitamin K mediates this defensive action by carboxylation of various VKDs, such as MGP and GAS-6, which enhances their ability to bind calcium and prevent deposition in tissues where it has pathological effects.

MGP, which contains five GLA residues, must be completely carboxylated and phosphorylated to maximize calcium binding. The levels of plasma dephosphorylated-uncarboxylated MGP (dp-ucMGP), a fraction of MGP, have been found to be a marker of arterial or other types of soft tissue calcification.[118,119]

The types of calcification that occur in the arterial wall can be grouped based on their location, but vitamin K status and vitamin K interventions may affect each type of calcification differently. Data in Table 126.8 summarize results from relevant interventions with various forms of vitamin K for cardiovascular pathologies.

Intimal Calcification

Intimal calcification occurs within the atherosclerotic plaque, adjacent to the intima layer of arteries, and is always associated with atherosclerotic disease. The question is whether optimizing vitamin K status or using high-dose vitamin K interventions may help prevent or reduce the rate of intimal plaque formation and calcification, in conjunction with established interventions that address classical cardiovascular risk factors.

One animal study, with rabbits, showed that supplementation with very high doses of vitamin K_2 (MK-4) (1, 10, or 100 mg/kg body weight) suppressed progression of arterial plaque, reduced intimal thickening, pulmonary atherosclerosis, total cholesterol, and lipid peroxidation while not promoting coagulative tendencies.[120] In vitro studies with vitamin K have revealed various mechanisms that may mitigate processes involved in atherosclerotic plaque formation and rupture: enhanced mitochondrial function, vitamin K_2 (MK-4) reduces inflammation, as evidenced by lowering PGE_2, and both vitamins K_1 and K_2 (MK-4) were shown to have antioxidant activity.[121]

Unfortunately, no human studies have been done with vitamin K to investigate the previously mentioned CVD-related outcomes.

Medial Calcification (or Monckeberg's Arteriosclerosis)

Medial calcification occurs within the middle layer of the arterial wall, surrounding elastin/collagen fibers, and within transformed vascular smooth muscle cells, as well as within the heart valves and vein walls. Unlike intimal calcification, this type of calcification is not necessarily associated with cardiovascular plaque pathology. It seems so common that one study found it present in 95% of men and women

TABLE 126.8 Results of Intervention With Three Vitamin K Forms on Markers of Cardiovascular Health

	Study Results With K_1	Study Results With K_2 (MK-4)	Study Results With K_2 (MK-7)
Effects on Arterial Stiffness or Other CVD Health Markers	(1 mg K_1 or placebo) + (500 mg Ca, 320 IU D3, 10 mg Zn, 150 mg Mg) and placebo alone (3 yrs, women age 50–60). Results: the placebo and 1 mg + minerals group had no changes in carotid elasticity. The placebo and "minerals only" group had 6.3% and 13% increases in pulse pressure and young modulus and 8.8% and 8.6% decreases in arterial compliance coefficient and distensibility coefficient[187]	(45 mg K_2 (MK-4) and no placebo) (1 yr, males/fem, avg. age = 69 yrs). Results: reduced arterial stiffness by 16% in subjects deficient in vitamin K. Statin use: 58%. Vit D and Ca, which contribute to medial calcification and stiffness, were not supplemented or assessed in this study[142]	(0.18 mg K_2 (MK-7) or placebo) (3 yrs, postmenopausal, avg. age 59 yrs). Results: reduced index of arterial stiffness (AT) by 6% in a subgroup with high baseline AT. Statin use: 11%. Vit D and Ca, which contribute to CAC and stiffness, were not supplemented or assessed[143]
		(1, 10, 100 mg K_2 (MK-4)/kg BW or control), (rabbits, 10 wks). Results: all interventions reduced cholesterol deposition in aorta, lipid peroxidation and total cholesterol[120]	(0.1 mg K_2 (MK-7) or placebo), (6 mo., males/fem, avg. age = 76 yrs). Results: No changes in endothelial function, vascular elasticity, or other CVD health markers. Statin use: 26%[144]
Effects on Coronary Artery Calcification (CAC)	(2 mg K_1 or placebo) (1 yrs, males, females, avg. age 69.3 yrs). Results: reduced progression of CAC by 45%. Statin use: 71%[139]	45 mg K_2 (MK-4) and no placebo) (1 yr, males/fem, avg. age 69 yrs). Results: treatment did not reduce CAC. Vit D and Ca, which contribute to medial calcification and stiffness, were not supplemented or assessed in this study[142]	Effects of K_2 (MK-7) on CAC in humans or animals with chronic kidney disease (CKD) are not included in this table, because the physiology of CKD is altered significantly from normal physiology
	(0.5 mg K_1 or placebo) + 600 mg Ca + 400 IU vit D multivitamin (3 yrs, men/women, avg. age = 56–62). Results: 6% less progression of CAC than in the control group. Statin use: 25%[139]		
	0.1 mg or 2 mg K_1/day (in rats, 6 wks). Results: the dose of 2 mg K_1/day, equivalent to 8 mg/kg body weight in rats,[a] reduced CAC by 50% and improved arterial distensibility. CAC resulted from treatment with anticoagulant warfarin[141]	0.1 mg or 2 mg K_2 (MK-4)/day (in rats, 6 wks). Results: the dose of 2 mg K_2 (MK-4)/day, equivalent to 8 mg/kg body weight in rats,[a] reduced CAC by 50% and improved arterial distensibility. CAC resulted from treatment with anticoagulant warfarin[141]	(0.36 mg K_2(MK-7) or placebo) (6 mo., 69 yrs, male/fem with type 2 diabetes, CVD). Results: compared to placebo, treatment with K_2(MK-7) did not slow down the progression of arterial calcification, which measured 10% higher after 6 mo. compared to baseline. dp-ucMGP decreased by –33% (from 613 to 408 pmol/L).[190]
Effects on dp-ucMGP Changes (Human Studies)	0.5 mg K_1 decreased dp-ucMGP by –80%, from 485 to 97 pmol/L. dp-ucMGP levels were not associated with CAC[188]	No studies available for effects of K_2 (MK-4) on dp-ucMGP	0.1 mg K_2 (MK-7) decreased dp-ucMGP by –16%, 789 down to 668 pmol/L[144]
			0.18 mg K_2 (MK-7) decreased dp-ucMGP by –31%, 401 down to 294 pmol/L[189] –50%, to 256 pmol/L[143]
	2 mg K_1 decreased dp-ucMGP by –45%, from 432 to 243 pmol/L[140]		0.36 mg K_2 (MK-7) decreased dp-ucMGP by –46%, 391 down to 209 pmol/L[189] –56%, 389 down to 171 pmol/L[145]

dp-ucMGP; Desphospho-uncarboxylated matrix Gla-protein.
[a]The human equivalent dose of the rat dose of 8 mg/kg body weight can be calculated as follows: 8 mg/kg body weight of the rat × 0.162 = 1.296 mg/kg body weight of the human. This translates into 64.8 mg for a 50 kg human.

at autopsy.[122] It seems to progress slowly with aging and may be an important component of the age-associated increase in coronary artery calcification (CAC).

Suboptimal vitamin K status cannot support maximal carboxylation of MGP, leaving it incompletely functional, and results in the following pathological phenomena:

1. Calcium deposition around the elastin/collagen fibers inside the arterial wall, which causes them to lose elasticity. This, in turn, will lead to reduced arterial compliance and increased risk of essential hypertension. Incidentally, the same phenomenon occurs in the skin elastin/collagen fibers, which may be one reason why skin elasticity decreases with aging.
2. A fraction of vascular smooth muscle cells belonging to the medial arterial wall change phenotypically to bone marrow type cells, which express osteocalcin. This in turn promotes calcium retention in the arteries.[123–125]
3. Calcium deposition in the walls and valves of veins and heart valves leads to dysfunctional changes in these cardiovascular tissues and impaired return circulation to and from the heart.

In vitro studies have shown that vitamin K_2 was shown to stimulate collagen and elastin synthesis.[58,59] This implies that vitamin K deficiency may reduce collagen and elastin turnover and renewal, which may contribute to loss of elasticity in many tissues that rely on it for their function.

Evidence From Epidemiological Studies for Relationships Between Vitamin K_1 and/or K_2 Intake and Cardiovascular Disease

Some epidemiological studies found correlations between intake of vitamin K_1 or K_2 and cardiovascular disease (CVD)-related outcomes. The study performed in the United States (Nurses' Health Study) found that the highest (300 mcg) versus lowest (87 mcg) quintile of vitamin K_1 intake had a multivariate relative risk (RR) of CVD events of 0.84, after data were adjusted for a number of dietary factors relevant to CVD.[82] The PREDIMED (Prevención con Dieta Mediterránea) study found that baseline vitamin K_1 intake was inversely associated with all-cause mortality (hazard ratio [HR] = 0.64), while individuals who increased their intake of dietary vitamin K_1, over the study period, had a RR = 0.52 of cardiovascular mortality, while no association was observed between changes in vitamin K_2 intake and CVD mortality.[126]

One study with postmenopausal women found a significant difference for total vitamin K intake between subjects with CAC (243.6 mcg) versus those without CAC (189.9 mcg).[127]

In contrast, an epidemiological study performed in Dutch subjects (the Rotterdam study) found no correlation between CVD mortality or CAC with vitamin K_1 intake. Instead, this study reported a RR of CVD mortality of 0.73 for the upper tertile of dietary vitamin K_2 intake (average of 40.9 mcg) compared with the lower tertile (average 15.1 mcg).[73] Dietary vitamin K_2 composition was represented in majority by MK-9 (14.7 mcg) and MK-8 (6 mcg), both derived mostly from cheese, and MK-4 (7.1 mcg), derived mostly from meats and eggs. MK-7 content was only 0.4 mcg. However, it is unlikely that an intake of 40.9 mcg K_2 explains the risk reduction of CVD mortality and arterial calcification, because much higher levels of vitamin K (360–500 mcg) are necessary to achieve significant carboxylation of MGP (see data in Table 126.8). No study to date has shown that supplementation with small doses of vitamin K_2 can produce such benefits. For example, a study that supplemented subjects with 100 mcg K_2 (MK-7) for 6 months did not report any improvements in CVD-related outcomes. In addition, the effects of vitamin K_2 intake cannot be interpreted in isolation from concurrent vitamin K_1 intake because their effects are additive for carboxylation of MGP and other VKDs. In the Rotterdam study, the upper tertile of vitamin K_1 intake was 311 mcg. It would have been useful if the authors had investigated the correlations involving total vitamin K intake (K_1+K_2).

The conflicting reports on correlations with vitamin K_1 and/or K_2 may be caused by associated patterns of food intake that have CVD benefits.[70,128] For example, vitamin K_1 is associated with intake of leafy greens and vegetable oils, and long-chain menaquinones are primarily provided by fermented foods (dairy or vegetarian origin), which may also be a source of probiotics. Thus the relationship between vitamin K and CVD pathologies is not likely to be revealed in correlation studies because average intakes of K_1 are in the range of 100 to 200 mcg and for K_2 around 29 mcg in Western countries, which are too low to support adequate carboxylation of MGP (as depicted in Table 126.8) or have other therapeutic effects specific to vitamin K_2. Intervention studies have used much higher doses of vitamin K_1 or K_2 to test CVD outcomes, as discussed later.

Vitamin K Interactions With Vitamins/Hormones Affecting Matrix Gla Protein Expression and Carboxylation

A 68% reduction in MGP expression was associated with a 33% increase in arterial calcium content.[129] Vitamin A and thyroid supplements are both modulators of MGP expression. Excess vitamin A has been shown to increase the risk of arterial calcification, which may be related to the fact that it downregulates MGP expression. Similarly, the thyroid hormone T3 is essential in supporting adequate expression of MGP, and it has been shown that MGP expression is reduced in hypothyroidism. Estrogen deficiency reduces carboxylation efficiency of VKD proteins. Vitamin B_6 and manganese are cofactors for the carboxylation reaction, whereas excess vitamin E (specifically alpha-tocopherol) has been shown to interfere with vitamin K recycling (similar to warfarin), thus reducing its ability to carboxylate VKDs.[130] Other interactions between vitamin E and K are discussed under "Vitamin K Interactions."

In the setting of vitamin K deficiency, adequate intake of vitamin D and calcium promotes calcification of soft tissues and, as a result, an increase in arterial stiffness. Fortunately, one human study showed that the addition of 1 mg K_1 to the supplementation of calcium and vitamin D (plus zinc and magnesium) completely prevented an arterial stiffness increase, as observed in the control group that was supplemented only with calcium and vitamin D (plus zinc and magnesium), see detailed data in Table 126.8.[131] [JP. Yet another example of the problem with researching nutrients using an isolation study like a drug, rather than as part of a complex matrix requiring multiple nutritional factors to function properly.]

What Is the Potential of Preventing or Reversing Arterial Calcification With Vitamin K Supplementation?

Table 126.8 presents results from intervention studies aimed at either evaluating effects on CAC or arterial stiffness. The CAC scores represent the sum of intimal and medial calcium content.

An animal study showed that upon vitamin K_1 supplementation, the conversion to K_2 (MK-4) resulted in an arterial tissue deposition pattern of 75% K_2 (MK-4) with the rest of 25% as vitamin K_1, suggesting extensive systemic and local conversion of K_1 to K_2. Thus K_2 (MK-4) seems to be the preferred form in this tissue.

Vitamin K_2 (MK-4) is unique among the vitamin K_2 family of compounds because the ligand it contains, geranylgeranyl (GG), is similar to one intermediate of the cholesterol synthesis pathway (downstream of mevalonate and HMG-CoA). There, GG is believed to have inhibitory actions on various metabolites, including cholesterol, inflammatory compounds and, as mentioned earlier, on osteoclast proliferation.[49,55,56]

The conversion of vitamin K_1 to K_2 (MK-4) seems crucial for vitamin K to exert its role in preventing arterial calcification. This was demonstrated by one study that gave warfarin plus either K_1 (WK_1) or K_2 (WK_2) to rats, knowing that warfarin blocks K_1 to K_2 (MK-4) conversion.[55] The doses of vitamin K_1 and K_2 were 1.5 mg/g diet, devised to be high enough to compensate for the arterial calcification effect of warfarin at 3 mg/g diet. Vitamin K_2 prevented calcification in the WK_2 group, whereas an equal dose of K_1 did not. This study was not designed to explore the possible benefits of giving vitamin K along with warfarin because the dose used canceled any anticoagulant effects from warfarin, but it proved the point that vitamin K_1 must be converted to vitamin K_2 to prevent arterial calcification.[132] This is why it is important to keep in mind that statins impair the conversion of vitamin K_1 to K_2 (MK-4) by reducing the availability of GG ligand necessary to form K_2 (MK-4) from the vitamin K_3 intermediate (generated from K_1). The conversion of other menaquinones, such as K_2 (MK-7) to K_2 (MK-4), may be impaired as well, because they too convert to the vitamin K_3 intermediate.[133] In addition, some studies claim that a fraction of K_2 (MK-4) converts to K_3 during gut absorption and then is converted back to K_2 (MK-4) inside various tissues.[24,134–138]

For this reason, the percentage of subjects using statins has been noted in Table 126.8, to emphasize the potential influence of impaired conversions of various vitamin K forms to K_2 (MK-4) on the reported results.

Statins have shown some potential in retarding intimal and/or medial calcification, possibly by reducing inflammation and low-density lipoprotein load, but no studies have shown potential to reverse established calcifications.

Two human studies showed that supplementation with 0.5 mg or 2 mg of vitamin K_1 (for 3 or 2 years, respectively) could slow the CAC progression by 6%[139] or 45%,[140] respectively. The corresponding reductions of dp-ucMGP were −80% and −45%, respectively. It is not clear why the authors chose the 0.5 mg dose of K_1 because doses higher or equal to 1 mg were demonstrated to support almost complete carboxylation of Oc, which were shown to correlate with the degree of MGP carboxylation.[79]

The potential to reverse already established CAC of the medial layer has been demonstrated in a rat study from 2007 and such reversal has yet to be reproduced in humans.[141] In the first part of the study, rats were in a protocol designed to cause them to develop arterial calcification by treatment with warfarin, which causes a state of severe vitamin K deficiency. In the second part of the study, the hypothesis tested was whether a low-dose or high-dose vitamin K_1 or K_2 (MK-4) (0.1 mg or 2 mg/day) could reverse this calcification.

Warfarin was discontinued when the desired calcification level had been achieved. Vitamin K_1 or K_2 (MK-4) supplementation was given right after warfarin treatment was stopped. Both treatments of 6 weeks with 2 mg/day of vitamin K_1 and 2 mg/day or vitamin K_2 (MK-4) were able to reduce the baseline calcification by 37%. The lower dose of 0.1 mg/day of either K_1 or K_2 did not achieve the same; in fact, arterial calcification progressed in this group in spite of the fact that warfarin had been discontinued. The calcification reversal observed in this study is impressive, and the dose of 2 mg/day may be translated into an equivalent human dose as follows: 8 mg/kg body weight(rat)*0.16 = 1.28 mg/kg body weight (human) or 64 mg for a 50 kg person. This dose obviously falls in a supraphysiological range. Unfortunately, the animal study previously discussed did not test any intermediate doses between 2 mg and 0.1 mg/day for the same outcome.

One human study has investigated effects of supraphysiological doses of vitamin K_2 (MK-4) at 45 mg on CAC and arterial stiffness for 1 year.[142] No effect was observed on CAC progression, but arterial stiffness declined by 16% in a subgroup that was vitamin K deficient at baseline, as assessed by PIVKA-2.[142] Unfortunately, this study did not report the change in levels of dp-ucMGP, and no other studies did so either.

Supplementation with vitamin K_2 (MK-7) was investigated for effects on arterial stiffness[143,144] and other markers of CVD health.[144] Supplementation with 0.1 mg K_2 (MK-7), given for 6 months, produced no significant CVD-related improvements,[144] and the reduction obtained in levels of dp-ucMGP was only −16%, which may explain the lack of benefits observed. Supplementation with 0.18 mg vitamin K_2 (MK-7) for 3 years resulted in a 6% reduction of arterial stiffness in a subgroup that had elevated arterial stiffness at baseline, and obtained a 50% reduction in levels of dp-ucMGP.[143] Results from other studies are listed in Table 126.8, where reductions of 46%[143] and 56%[145] were obtained for the highest dose tested of 0.36 mg vitamin K_2 (MK-7).

In conclusion, the best reduction in dp-ucMGP levels was obtained at −80% by the intervention with 0.5 mg vitamin K_1, to a level of 97 pmol/L.[145] It is important to note that although the studies done with 45 mg vitamin K_2 (MK-4) and 0.18 mg vitamin K_2 (MK-7) showed a reduction in arterial stiffness, they did not supplement with calcium and vitamin D, which have been proven necessary for bone health. Thus these results cannot be compared with those obtained with 1 mg vitamin K_1, which showed a prevention of arterial stiffness increase in those supplemented with calcium and vitamin D.

Supplementing humans with 0.36 mg/day of K_2 (MK-7) did not slow down CAC progression (see Table 126.8).[190]

The benefits of all three forms of vitamin K on arterial elasticity may be caused in part by the reduction of arterial calcium deposition, and also by the demonstrated ability of vitamin K_2 to stimulate collagen and elastin synthesis.[58,59] This is especially needed in menopause when collagen and elastin synthesis is reduced as a result of estrogen deficiency.[95]

What May Be the Most Efficacious Intervention With Vitamin K Supplements to Prevent or Benefit Cardiovascular Disease?

A preventive approach to CVD is to maintain *an optimal vitamin K status* throughout life, which would likely prevent/retard age-related increases in arterial medial calcification and stiffness. In fact, the term *age-related calcification* may be replaced with *vitamin K deficiency-related calcification* and treated as a reversible condition.

The question is what would be the most effective doses and forms of vitamin K for therapeutic interventions for those with established CVD and CAC? Current commercially available forms of vitamin K are: K_1, K_2 (MK-4), K_2 (MK-7) and/or a mix of long-chain menaquinones (MK-6,-7,-9), but K_2 (MK-4) and long menaquinones are 10 times and 100 times more expensive than K_1 per microgram, whereas there are no side by side comparisons on relative efficacy for CVD.

As discussed in the previous section, human interventions with vitamin K_1 seem to provide good evidence for reducing CAC progression and maintaining arterial elasticity. In spite of promising results from animal studies that showed that supraphysiological doses of K_1 and K_2 (MK-4) can reverse vitamin K deficiency-induced CAC, one human study with K_2 (MK-4) reported no changes in CAC progression, whereas the rest did not assess it. Interventions with K_2 (MK-4) or K_2 (MK-7) reported reduced arterial stiffness by 16% and 6%, respectively, but it is not clear if they would completely prevent an increase in arterial stiffness when supplemented along with adequate amounts of calcium and vitamin D, as proven by vitamin K_1 supplementation.

Because vitamin K_1 interventions did not completely stall or reverse CAC, and the role of K_2 (MK-4) is established to be critical in this process, it is possible that a combination of vitamin K_1 and K_2 may provide a synergistic and more efficacious intervention than vitamin K_1 alone, especially for older individuals. For patients who take statins, supplementation with large doses of K_2 (MK-4) is warranted, because these medications impair conversion of K_1 to K_2 (MK-4) by reducing synthesis of geranylgeraniol.

As discussed in the osteoporosis section, average intake of vitamin K_1 is low in Western and Asian populations and it is not practical to believe that most individuals would change their diet enough to raise it to a physiologically replete level (close to 1 mg/day). Thus in most cases, it makes sense to suggest supplementing with 1 mg vitamin K_1, as a foundation for optimizing vitamin K status. Human physiology has likely adapted through evolution to an intake close to 1 mg K_1,[78] and relatively small amounts of additional MK-4 and long-chain menaquinones, probably around 0.05 mg (based on average intake in Holland). Supplementing with at least 1 mg K_1 is important for maintaining arterial elasticity, especially females, who need to ingest adequate amounts of calcium (from diet + supplements) and vitamin D.

The question is which form(s) of vitamin K_2 should be added to a foundational amount of K_1, and in what therapeutic doses, to improve the odds of stalling or reversing CAC and arterial stiffness?

There are no side-by-side comparison studies available for treatments with K_2 (MK-4) and K_2 (MK-7) that evaluated CVD outcomes or the types and amounts of vitamin K stored in arterial tissue. The

effects of treatments with 45 mg K_2 (MK-4) on reducing arterial stiffness were stronger than those with 0.18 mg K_2 (MK-7). Thus based on current data, it makes sense to choose supplementation with K_2 (MK-4) over that with K_2 (MK-7), especially because K_2 (MK-7) likely derives all its benefits from its conversion to K_2 (MK-4).

Future studies should investigate the effects of combinations of a foundational amount of K_1 (e.g., 1 mg) plus various amounts and forms of vitamin K_2 on CAC- and CVD-related benefits.

Are There Benefits From Adding Vitamin K_1 or K_2 to Anticoagulant Treatments Such as Warfarin?

Anticoagulant therapy induces an extreme state of vitamin K deficiency, and studies have shown that it may increase arterial calcification by twofold to eightfold as well as increasing aortic pulse pressure and heart valve calcification.[141]

Patients on anticoagulant treatment are told to minimize intake of vitamin K-containing foods, such as green leafy vegetables. Most patients end up not eating enough vegetables in fear of counteracting their anticoagulant therapy. This is unfortunate, because they would be obviously missing important benefits. Some studies have proposed and demonstrated that supplementing with vitamin K_1 doses in the range of 0.1 to 5 mg, during anticoagulant therapy, may help minimize the need for adjusting the dose of the anticoagulant in response to dietary variations of vitamin K.[146,147] One shortcoming of using vitamin K_1 in this scenario is that warfarin blocks the conversion of vitamin K_1 to K_2, which eliminates many of its benefits, especially in the extrahepatic tissues.

This strategy could potentially be implemented with vitamin K_2 (MK-4) in addition to vitamin K_1, although no studies have explored this yet. The advantages of using additional vitamin K_2 would be as follows: (1) it would bypass the warfarin block on vitamin K_1 to K_2 (MK-4) conversion and (2) a fraction of the ingested vitamin K_2 (MK-4) is absorbed intact and can reach arteries (and other peripheral tissue such as bone), where it may partially compensate for the undesirable effects of the anticoagulant, such as tissue calcifications (in arteries, veins, and heart valves).

Will Therapeutic Doses of Vitamin K Increase Clotting and Thrombosis Excessively?

As discussed in detail, in the last section titled "Safety", vitamin K doses higher than those needed to fully carboxylate VKDs involved in clotting have not been shown to further increase clotting and thrombosis tendencies beyond normal physiological function.

Effects on Cancer of Vitamins K_1, K_2, and K_3

Epidemiological, interventional, and in vitro studies provide evidence that vitamin K plays a role in reducing the incidence and progression of cancer. The three different forms of vitamin K each seem to manifest distinct activities in vitro against cancer cells. Vitamin K_3 has been found to have the highest anticancer activity through multiple mechanisms, followed by vitamin K_2, whereas vitamin K_1 had the weakest effect. Vitamin K_3 was shown in vitro and in vivo to induce oxidative stress, generate hydrogen peroxide, and deplete glutathione, unlike vitamins K_1 and K_2. In fact, some studies showed an antioxidant activity for the latter.[148]

Most likely the human body derives a significant amount of vitamin K_3 from cleaving the side chains of vitamin K_1 or K_2, especially when these agents are ingested in supraphysiological doses. One study found that urinary excretion of vitamin K_3 was significant 2 to 3 hours after vitamin K_1 ingestion, but plasma vitamin K_3 was not measured.[20] It was also estimated that the percentages of vitamin K_1 or K_2 (MK-4) or K_2 (MK-7) to K_3 conversion are around 5% to 25%. This is believed to occur in the intestinal cells and other extrahepatic tissues, possibly also in the liver. Any effect of oral vitamin K_1 on cancer could be attributed to its direct actions and its partial conversion to K_3 and K_2. Similarly, any effect on cancer from oral vitamin K_2 could be attributed to its direct actions and its partial conversion to K_3.

Vitamin K_3 is cytotoxic to cancer cells through oxidative effects and various other mechanisms of action. In vitro studies with vitamin K_3 have shown an inhibitory effect against breast, endometrial, urological, and prostate cancer as well as leukemia and squamous cell carcinoma.[2] Unfortunately, K_3 is also toxic to normal cells, especially red blood cells, which is why it is no longer used as a provitamin in humans. This profile would most likely qualify vitamin K_3 as a chemotherapeutic agent, but because it is not a patentable molecule, there are not enough studies to achieve U.S. Food and Drug Administration (FDA) evaluation. Currently, vitamin K_3 is only allowed to be used for research purposes in humans; in animals, it is used as a vitamin K precursor to vitamin K_2.

Many studies have observed a synergistic benefit from combining vitamin K_3 with vitamin C (in the intravenous and oral forms) for reducing the rise of prostate-specific antigen in prostate cancer patients[149] and also with all-transretinoic acid (ATRA) for the treatment of leukemia.[2] Vitamin K_3 has also been shown to inhibit DNA polymerase and angiogenesis[150] and to act as a radiation sensitizer.

Oral and intravenous vitamin K_3 has been used in studies for the treatment of various cancers (leukemia, lung, prostate, and bladder) with and without chemotherapy; such treatment has resulted in improved survival and reduced cancer growth but not complete cures.[2]

One epidemiological study of a Dutch population found a reduced risk of overall cancer incidence and mortality by 14% and 28%, respectively, for the upper quintiles of vitamin K_2 intake, whereas no correlation was found with the intake of vitamin K_1.[151] The risk reduction was most pronounced for lung and prostate cancer. These results are strikingly similar to the correlations found for vitamin K_2 intake and reduced risk of cardiovascular calcification in the Dutch epidemiological studies. Considering that the average intake of vitamin K_2 in the population studied is in the range of 26 mcg (first quintile) to 42 mcg (fourth quintile), the results are surprising and warrant future interventional studies with doses of vitamin K_2 (MK-4) in that range and above.

Vitamin K_1 and Cancer

Very few studies have investigated the effects of oral supplementation with vitamin K_1 on cancer but those that have been done include the following:

1. Oral supplementation with 5 mg of vitamin K_1 for 4 years, along with 800 IU of vitamin D_3 and 1500 mg of calcium, resulting in an approximate 75% reduction in all types of cancer in postmenopausal women. This was a randomized controlled trial designed to observe the effect of vitamin K_1 plus vitamin D and calcium on bone density; the cancer findings were incidental.[104]
2. A number of Phase I/Phase II trials investigated the effect of oral supplementation with 40 mg (20 mg twice daily) of vitamin K_1 in patients with hepatocellular carcinoma. All studies found improved survival rates, temporary disease stabilization, and reduced tumor growth and invasion.[2]
3. A recent study used both an oral dose of 40 mg/day of vitamin K_1 in one group and incremental intravenous doses of vitamin K_1 (from 40 mg to 1000 mg) in small groups of patients with unresectable hepatocellular carcinoma and distant metastases. All doses, oral and intravenous, were tolerated without toxicity. A small percentage of patients, 3 out of the group of 23 who received oral vitamin K_1 and 3 out of the group of 27 who received intravenous vitamin

K_1, had tumor shrinkage, and 16 of each group had tumor stabilization (according to computed tomography). Also, 3 and 6 patients of the oral and intravenous groups, respectively, had a reduction in the tumor marker alfa fetoprotein (AFP).[152] In vitro testing of tumor cells extracted from the subjects in this study has shown that vitamin K_1 induced an inhibition of cell growth through "phosphorylation of JNK and c-Jun and caspase-mediated apoptosis." Even though the authors were aware of the evidence for the efficacy of vitamin K_2 (MK-4) in this type of cancer, they stated that they chose vitamin K_1 instead because "it is the only form of vitamin K available clinically in the US." Also, the study authors stated that the dose of 40 mg was chosen based on "how many tablets of the drug Mephyton (5 mg K_1) were the patients willing to swallow comfortably."

Vitamin K_2 and Cancer

In vitro studies have identified an anticancer activity for vitamin K_2 against liver, colon, leukemia, lung, stomach, lymphocyte, osteosarcoma, epidermoid, glioma, hepatoma, and breast cancer cell lines. Some of the anticancer mechanisms that have been identified for vitamin K_2 are induction of apoptosis, cell cycle arrest (at G1/S transition), cell differentiation, reduction of cell proliferation and angiogenesis (resulting from inhibition of COX2), inhibition of signaling for tumor growth, and activation of the PXR genes. Many of these actions are not shared by vitamin K_1, which may be because of vitamin K_2's specific side chain, the molecule geranylgeranyl.

Interventions with oral doses of 20 to 135 mg (but most frequently with 15 mg three times daily) of vitamin K_2 (MK-4) have led to improved survival rates for hepatocellular carcinoma, with a slower progression and reduced recurrence rates (especially when patients were infected with the hepatitis C virus).[153] The combination of vitamin K_2 (MK-4) treatment with an angiotensin-converting enzyme inhibitor decreased the recurrence of hepatocellular carcinoma.

Because none of the studies employing high doses of vitamin K_1 or K_2 investigated any lower doses of vitamin K, such as 1 mg or any dose in between 1 and 40 mg of vitamin K_1 or 1 and 45 mg of vitamin K_2 (MK-4), the minimum dose that would achieve the same effect is not clear, nor, most importantly, is it known at what point no further benefit can be achieved by increasing the dose.

Some promising responses have been obtained from using high doses of vitamin K_2 (MK-4) (45 mg) for patients with leukemia or myelodysplastic syndrome, with an improvement of anemia and thrombocytopenia and sometimes complete remission.[154] The effect was even more pronounced for the group who were also given vitamin D_3.

Vitamin K status, measured by the percent uncarboxylated osteocalcin in serum, was found to correlate with advanced-stage and high-grade prostate cancer.[155] As discussed later, this biomarker of vitamin K status can be considered a marker not only for bone health but also for risk prediction for other conditions where vitamin K plays an important role.

In using vitamin K supplementation for general health and for cancer therapy, it is important to keep in mind that, in advanced stages of certain cancers, thrombosis is abnormally activated. This is mediated through unclear mechanisms that may be unique to each cancer's strategy to promote its survival and metastasis. Upregulation of clotting factors and other VKDs, as mentioned, may have an important role in this pathological process. McCann et al. point out that in some specific cancer cases, warfarin treatment has been shown to improve survival rates.[30]

In utilizing vitamin K for cancer risk reduction or treatment, the patient should be evaluated first for coagulation/thrombosis status to make sure that he or she is not in a state where the cancer process is upregulating that status.

In addition, for therapeutic effects, the vitamin K_2 (MK-4) form may be a better choice than vitamin K_1 in implementing a therapy with supraphysiological doses. The dose in the vicinity of 45 mg has a good safety record and the most evidence for efficacy. High doses of vitamin K_2 (MK-4) were found not to increase clotting or platelet aggregation while actually reducing thrombotic tendencies. On the contrary, vitamin K_1 was shown to increase thrombotic tendencies at very high doses. This and the fact that the overall efficacy of vitamin K_1 against cancer is weaker compared with K_2 (MK-4) make vitamin K_2 (MK-4) the overall better candidate for therapeutic doses in cancer treatment and prevention in high-risk patients.

Effects on Various Other Conditions: Insulin, Kidney Stones, Skin Elasticity, Cystic Fibrosis, Brain Protection, Hemorrhage, Joint Health, and Inflammation After Laser Therapy

The optimization of vitamin K status with diet and/or supplements, as well as therapeutic doses of these two vitamers, may have many additional benefits to those previously discussed. These additional effects can be inferred from the presence of VKDs in many tissues, even though all their roles have not been precisely identified. In addition, observing vitamin K deficiency states or inducing them in laboratory experiments for various tissues has provided many clues on vitamin K's potential to alleviate various pathological processes.

Vitamin K has a complex role in the clotting processes supporting both the coagulation and anticoagulation/balancing pathways. Its deficiency may lead to increased risk of hemorrhage in various conditions: excessive menstrual, gum, or nose bleeding and increased risk of hemorrhage in infants born and breastfed by vitamin K-deficient mothers.[156,157]

Vitamin K deficiency may have many other consequences:

1. Improper cartilage maturation as a result of excessive growth plate mineralization[158]
2. Accelerated age-related degeneration of the intervertebral discs (increased calcified/uncalcified cartilage ratio)[159]
3. Reduced glucosamine and glycosaminoglycan synthesis, which affects the health of many tissues in the body: joint cartilage, tendons, ligaments, the dermal layer of the skin, the lining of the gastrointestinal tract, as well as the walls of the and blood vessel and veins[36]
4. Suboptimal skin health, elasticity, and overall appearance caused by the following consequences of vitamin K deficiency:
   - Increased skin collagen breakdown
   - Risk of calcification of the elastin fibers, which are a major determinant of skin elasticity
   - Thinning of the skin ground substance layer. MGPs are found in the dermis, and control collagen expression as well as glycosaminoglycan biosynthesis (collagen and glycosaminoglycans are both components of the supporting structure of the dermis).
5. Impaired insulin secretion and increased insulin resistance[160]
6. Increased risk of kidney stone formation[161]
7. In animal studies (rats), vitamin K deficiency was shown to cause suboptimal energy production, a 10% reduction in muscle creatine kinase, and a 20% reduction in the alkaline phosphatase of the intestinal mucosa, which may be caused by structural mitochondrial alterations[162]
8. Inadequate antioxidant protection of the brain
9. Increased severity of cystic fibrosis. Supplementation with 1 mg of vitamin K_1 was shown to be useful in compensating for the carboxylation defects that are characteristic of cystic fibrosis[163]
10. Reduced testosterone production[164]

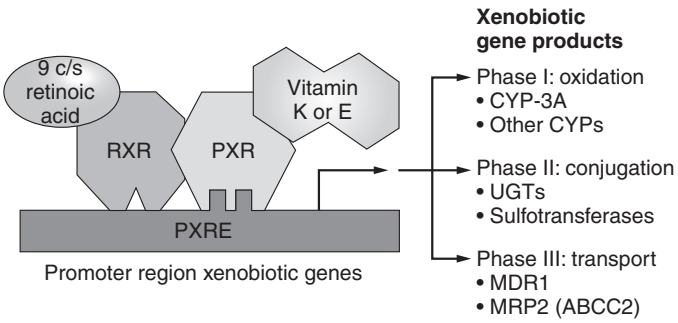

Fig. 126.6 Xenobiotic receptor activation by vitamin E or vitamin K. (From Traber MG, Frei B, Beckman JS. Vitamin E revisited: do new data validate benefits for chronic disease prevention? *Curr Opin Lipidol.* 2008;19[1]:30–38. Review.)

Other observed benefits: Topical application of vitamin K_1 was shown to reduce laser treatment-induced redness (inflammation).[165] As described, it would seem that a topical cream containing vitamin K might influence skin physiology positively.

INTERACTIONS WITH OTHER VITAMINS

Interactions With Vitamins E, A, and D

These interactions and synergistic effects of vitamin K with vitamin D and vitamin A were discussed previously regarding their influence on the expression of VKDs: osteocalcin and MGP.

Vitamin E May Interfere With Vitamin K Metabolism When Administered in Very High Doses

Supplementation with high doses of vitamin E, such as 800 to 1200 IU of alpha-tocopherol, has been shown to impair blood clotting by interfering with the vitamin K-dependent carboxylation of prothrombin.[130] This is thought to be mediated by a metabolite of oxidized vitamin E called tocopheryl quinone. Another study in rats suggested that high doses of vitamin E may impair the conversion of vitamin K_1 to K_2.[166] This is thought to be a result of the competition that can occur between vitamin K_1 and excess vitamin E for a specific cytochrome P450 enzyme responsible for the first step in the conversion of vitamin K_1 to K_2.

Reviews also point out that excessive doses of vitamin E may upregulate the expression of metabolizing enzymes responsible for both vitamin E and vitamin K clearance.[166] The reverse may be also true when supraphysiological doses of vitamin K are administered, especially when the individual's vitamin E status is marginal. Trauber[167] estimates that 90% of the population does not even meet the recommended daily intake (RDI) of 15 IU/day. High doses of either vitamin E or vitamin K can activate the xenobiotic pathways (via the PXR nuclear receptor) twofold to tenfold. Fig. 126.6 shows the interaction between vitamins A, E, and K in activating the PXR nuclear receptor. Landes et al. comment on this phenomenon as follows: "the organism handles such supranutritive dosages of vitamins like potential harmful xenobiotics."[168] One should keep in mind that the PXR-activated metabolic pathways are also involved in the clearance of many pharmaceutical drugs.

Because vitamin K seems to play an important role in reducing cardiovascular calcification, the interference by excess vitamin E (of various forms) on vitamin K metabolism may be one of the reasons why a few meta-analytic studies have found increased risk of cardiovascular events in populations that supplemented with alpha-tocopherol in excess of 400 IU. The effects of excess vitamin E may be most relevant when vitamin K status is marginal, which is very common. To put things in evolutionary perspective, an analysis by Cordain of the nutritional content of a typical Paleolithic diet found that the average intake of alpha-tocopherol was around 19 IU for a 2200-Kcal diet.[78] However, the average total content of the other forms of vitamin E in that diet (such as beta-, gamma-, or delta-tocopherol) has not been estimated, but it is known that they have many metabolic roles that are distinct from those of alpha-tocopherol. At an intake of alpha-tocopherol above 100 IU, certain metabolic pathways may be pushed beyond the range of "normal physiology."

Interactions With Pharmaceutical Drugs

Anticoagulants Based on Vitamin K Antagonism

Anticoagulants, such as warfarin or coumarin, interfere with vitamin K activation and recycling. Specifically, they inhibit the enzymes epoxide reductase and quinone reductase. It has been estimated that the body reuses the same vitamin K molecule in the range of 100 times before it metabolizes it for excretion through bile or urine. When an anticoagulant is present, vitamin K recycling is greatly reduced. Anticoagulants also interfere with vitamin K activity in extrahepatic tissues, and studies have shown them to increase the risk of osteoporosis and fracture and to delay fracture healing; they may also contribute to arterial or heart valve calcification and hypertension.[169,170] If the total amount of vitamin K from food and supplements is increased by 100 mcg/day, it will most likely require an adjustment in anticoagulant dose. Consequently, vitamin K intake from food and supplements must be closely monitored with this therapy. See the previous discussion about the potential benefits of supplementing with a small dose of vitamin K_2 along with the anticoagulant therapy.

Anticoagulants With Mechanisms of Action Independent of Vitamin K Metabolism

Vitamin K does not interfere with the action of blood thinners such as heparin, antiplatelet agents (clopidrogel, abciximab, tirofiban, and eptifibatide), direct thrombin inhibitors (hirudin, argatroban), or thrombolytic agents (clot-dissolving proteolytic enzymes).[171]

Aspirin and Salycilates Interfere Slightly With Vitamin K Metabolism

Aspirin (acetylsalicylic acid) and salicylates exert most of their blood-thinning effect by reducing platelet aggregation via the inhibition of COX enzymes and potentially other mechanisms. In addition, these compounds have a mild anticoagulant action by inhibiting vitamin K recycling (similar to that of warfarin but a lot milder).[172] Aspirin has been shown to increase bone loss and impair fracture healing, and although the mechanisms have not been elucidated, this could certainly be caused in part by its mild anti–vitamin K effect.

Antibiotics Interfere With Vitamin K Metabolism

Antibiotics may increase the need for vitamin K supplementation because (1) they may kill gut bacteria that normally produce vitamin K_2 in the intestinal tract, (2) they may interfere with vitamin K activation and recycling (similar but milder than anticoagulants like warfarin), and (3) they may inhibit the activation of various proteins (carboxylation) by vitamin K.[173] Examples include broad-spectrum cephalosporins such as cefamandol, moxalactam, and cefoperazone.

Anticonvulsant Drugs

Anticonvulsant drugs induce vitamin K deficiency. Supplementation of rats on phenytoin with very high doses of K_2 (MK-4) (30 mg/kg body weight) prevented BMD reduction.[174]

Butylated Hydroxytoluene Interferes With Vitamin K Metabolism

Butylated hydroxytoluene (BHT), a preservative still used in some packaged foods and topical creams, inhibits vitamin K epoxide

reductase by as much as 20%, which is similar to warfarin's mechanism of action. This may be relevant to the metabolism of vitamin K in the skin when BHT is applied topically, and could, for example, increase the risk of calcification of the elastin fibers, thus decreasing skin elasticity.

VITAMIN K STATUS BIOMARKERS

A big portion of the ingested vitamin K_1 is metabolized and excreted (through bile and urine) within 12 to 24 hours. However as average intake of vitamin K_1 increases, so does fasting plasma level of K_1.[81,82,129] Plasma vitamin K_1 may be useful in monitoring patients on anticoagulants in conjunction with the typical coagulation-related tests such as the international normalized ratio (INR) and prothrombin time.

A complete assessment of vitamin K status should reflect the degree of vitamin K sufficiency for all physiological functions in the body that require vitamin K_1 and/or K_2 for their optimal activity. Unfortunately, such a complete assessment is not available at this time, partly because there are so many VKDs in the body that are carboxylated by vitamin K, and researchers predict that new ones may still be uncovered in future research. Also, many of vitamin K's functions and physiological effects are unrelated to its carboxylation effect.

Unlike other fat-soluble vitamins, vitamins K_1 and K_2 have not been found to be stored in excess anywhere in the body. Even after long-term dosing, such as a few years, supplementation with supraphysiological doses of vitamin K_1 or K_2 (10 or 45 mg, respectively), apparently no toxic storage levels or effects have been observed. Every molecule of vitamin K is reused multiple times through a recycling mechanism before it is excreted, and perhaps that is why there is no need to store large amounts of it in the tissues.

Prolonged intake of a significant dose of vitamin K has been shown to have a cumulative effect in improving functional markers of vitamin K status. For example, it has been shown to cause a progressive increase over many months of the percentage of carboxylated osteocalcin (Oc) and increased levels of total Oc (the sum of carboxylated plus uncarboxylated Oc).

Currently Available Tests for Vitamin K Status

Vitamin K deficiency results in the appearance of undercarboxylated VKDs (ucVKDs) in the plasma and various tissues and organs throughout the body. It is also conceivable, although not yet completely demonstrated, that if the vitamin K intake reaches a high enough level, all VKDs in the body would be close to 100% carboxylated; consequently, all levels of ucVKDs would be close to zero.

Typical biochemical markers of vitamin K status used in studies are plasma levels of ucVKDs or their normalized values. However, one should keep in mind that plasma levels of any one type of ucVKD or carboxylated VKD (cVKD) do not always correlate with their total amounts found throughout the body.

The following vitamin K status tests have been used in studies: plasma undercarboxylated prothrombin (PIVKA II, which stands for proteins induced by vitamin K absence or vitamin K antagonism by anticoagulant drugs), plasma or urine ucOc, and plasma undercarboxylated matrix GLA protein (dp-ucMGP). Of all the tests mentioned, PIVKA II is available from many commercial laboratories in the United States; plasma levels of ucOc are available from only one specialty laboratory in the United States (Genova Diagnostics) and dp-ucMGP is available from Immunodiagnostics Systems Ltd. in the United Kingdom.

It is important to note that as vitamin K_1 and/or K_2 intake increases, clotting-related VKDs (such as prothrombin synthesized in the liver) are carboxylated with higher priority than the extrahepatic VKDs (such as Oc and MGP). This is an example of the "triage theory" presented by McCann and Ames in their review.[30] There they present evidence for the concept that evolutionary pressure may have led to prioritizing nutrient allocation in the order of importance for the "survival of the species." In this case, clotting is obviously more important for survival than bone or arterial health, so the carboxylation of the clotting-related proteins is prioritized.

For example, one study has shown that for patients on a small dose (1 mg) of warfarin, PIVKA II started decreasing when vitamin K_1 intake was around 100 mcg, whereas ucOc plasma levels did not start decreasing until vitamin K_1 intake reached around 300 mcg/day.[147]

Consequently, PIVKA II may decrease significantly and approach zero for vitamin K_1 intakes in the lower range of the average intakes, whereas ucOc levels may not approach zero until vitamin K intake is much higher. One landmark study showed that the percentages of ucOc levels may approach zero when intakes of vitamin K_1 are in the range of 1000 to 2000 mcg.[79] No studies have found an equivalent amount of vitamin K_2 that can achieve the same decrease in percentage of ucOc, which corresponds to an almost complete carboxylation of Oc. Suggestions for possible biomarkers of vitamin K status:

1. PIVKA II is the inactive form of prothrombin, and it is a sensitive marker of vitamin K_1 status at very low intakes (for example, in the vicinity of 100 mcg of vitamin K_1/day).

It is not clear how PIVKA II levels are affected by vitamin K_2 (in various forms) compared with vitamin K_1. One study showed that the INR was lowered similarly by a lower amount of vitamin K_2 (MK-7) compared with vitamin K_1.[175] Consequently, patients taking supplements and foods containing various forms of vitamin K (such as vitamin K_1, MK-4, MK-7) should be very closely monitored for changes in INR.

1. Plasma ucOc level is a test currently available only from one commercial laboratory in the United States specializing in nutrition status-related tests (Metametrix). Some studies have also measured the normalized value of ucOc relative to total osteocalcin (called %ucOc = ucOc/total Oc, or the ratio OCR = ucOc/iOc, iOc with meaning "intact or carboxylated osteocalcin").

The plasma levels of ucOc and its normalized ratios, %ucOc and OCR, have good sensitivity for a wide range of vitamin K_1 and/or K_2 intakes. The upper threshold of sensitivity seems to be achieved for a vitamin K_1 intake in the range of 1000 to 2000 mcg. However, ucOc measurements may not be adequately sensitive for patients on anticoagulant therapy or with very low vitamin K intakes (which represents an alarming 60%–70% of the population).

The measurement of both PIVKA II and ucOc may give a good approximation of vitamin K status with good sensitivity over a wide range of vitamin K intakes even though they reflect only a few facets of the vitamin K status.

It should be noted that even if a patient has a considerably high intake of vitamin K_1 (around 1000–2000 mcg/day) and a corresponding low ucOc level, this does not rule out a deficiency of vitamin K_2 if one were to consider vitamin K_2 a conditionally essential nutrient. This is especially important for certain patients who are older and have genetic polymorphisms or certain severe conditions such as advanced osteoporosis and/or arterial calcification, cancer, multiple sclerosis, or rheumatoid arthritis.

Oc has an established role in bone metabolism and studies have revealed significant direct correlations between ucOc or %ucOc and fracture risk and bone density.[176]

However, the ucOc marker may be useful for the management of diseases besides the ones related to bone because it conceivably correlates with the percentage of carboxylation of other extrahepatic VKDs in the body.

For example, one study found a positive correlation between plasma levels of %uOc and the risk of prostate cancer.[151]

It is important to note that average populations deemed "apparently healthy" were found to have an average of 15% to 50% ucOc. Specifically, one study found teenage girls to have an average %ucOc of 21.9%.[177] This is considered by many researchers a sign of subclinical vitamin K deficiency, which may have various detrimental consequences for bone development, cartilage, brain, and the nervous system, because vitamin K is so critically involved in the physiology of all these tissue and organs. This is just one example why the RDI for vitamin K is outdated.

1. ucMGP is currently assessed only in the United Kingdom but hopefully may be offered in the future by US commercial laboratories because it has good potential in evaluating and devising nutritional interventions for patients at risk of or with existing arterial calcification.

Plasma levels of ucMGP were found to directly correlate with arterial calcium buildup and calcium scores but only for patients with relatively low amounts of arterial calcium and in early stages of cardiovascular disease.[124] Thus the plasma level of ucMGP is thought to be a good indicator of current mild buildup of calcium in the arterial wall and/or of future risk of arterial calcification.

If this test becomes commercially available in the future, it may be helpful in guiding clinicians to devise the appropriate vitamin K intake for each patient so as to maximally reduce the risk of further cardiovascular calcification and possibly even reverse it.

Because the ucMGP measurement is not yet offered in the United States, the best available surrogate marker for it is plasma ucOc and its normalized ratio, which may also predict to a certain extent current or future risk of arterial calcification. However, it is also important to keep in mind that when the ucOc level is close to zero, it may not necessarily mean that the level of ucMGP in the body is also the lowest possible or that vitamin K intake has reached a level high enough to support complete carboxylation of all MGPs in the body and thus is providing significant protection from arterial calcification.

Some researchers point to the fact that osteocalcin contains three GLA residues, whereas MGP contains five; therefore they hypothesize that the carboxylation of MGP may require a higher vitamin K intake than that of Oc. This may be another example of the triage theory presented by McCann and Ames in their review, discussed previously.

In summary, until more vitamin K assessments are available, plasma ucOc is the best biomarker for guiding patients toward optimization of their vitamin K status with vitamin K_1 and/or K_2 from diet and supplements, although it is only a partial marker of vitamin K sufficiency in the body.

Warfarin causes, by design, an impairment in the carboxylation of various clotting proteins, but unfortunately it also affects all other extrahepatic VKDs. For example, one study found that a "minidose" of warfarin of 1 mg/day induced an increase in %ucOc from 8% to around 20%, and it will most likely increase ucMGP as well.[178]

By monitoring ucOc and ucMGP in addition to PIVKA II, along with standard clotting parameters (such as prothrombin time and INR) in these patients, it may be possible to find the appropriate dose of vitamin K_2 for each individual that may reduce to a certain extent the effects of warfarin on extrahepatic tissues. All this would be done while keeping the INR within the therapeutic range.

In interpreting tests that measure the levels of undercarboxylated VKDs, it is important to keep in mind that there are other factors, other than vitamin K, that may affect these results, as follows:

1. Deficiencies of vitamin B_6 and manganese, as well as low sex hormone status (estrogen or testosterone), may reduce the carboxylation rate of VKDs.[3]
2. Factors that can lower the production of osteocalcin or MGP include low vitamin D and K status (including treatment with warfarin), excess or deficiency of vitamin A, corticosteroid therapy, hypothyroid state (defined as suboptimal T3 levels), and possibly high endogenous production of cortisol.[179]
3. Total plasma levels of Oc may be elevated by vitamin D supplementation and in states of increased bone turnover (e.g., during adolescence, after injury, or after menopause).

Because so many factors can influence the levels of osteocalcin, some researchers believe that the normalized values of ucOc (OCR and %ucOc), rather than absolute values of ucOc, may be a better indicator of vitamin K status. However, this is still under debate, and researchers who favor the absolute levels of uOc argue that ucOc may be released more easily from the bone matrix into the blood compared with carboxylated Oc because carboxylation enhances its ability to bind calcium in the bone matrix. Thus the plasma ratios of these two biomarkers may not correlate with their tissue ratios.

1. MGP expression is decreased in hypothyroidism, which will also affect the body's ability to reduce arterial calcification.

Other factors that may increase the need for vitamin K intake and affect the interpretation of the ucVKDs tests include genetic polymorphisms, aging, fat maldigestion and/or malabsorption, pharmaceuticals (antibiotics, antiepileptic drugs, aspirin), or excess vitamin E.

One should keep in mind that oxidative stress may impair the tissues' ability to recycle vitamin K to reuse it for carboxylation multiple times. Thus the vitamin K status should be thought of based not only on vitamin K intake but also how well it increases tissues stores and on how many times each vitamin K molecule can be recycled.

It is also important to note that during active cancer development, various clotting factors may become upregulated, including thrombin.

DOSAGE

Current RDI Versus Expanded Criteria for Defining Optimal Vitamin K Intake

The adequate intake (AI) of vitamin K, specifically for the K_1 form, is 90 mcg for women and 120 mcg for men, or 1 mcg/kg per day.[180] For vitamin K, the AI criterion was initially adequate blood clotting, because that was the only vitamin K role recognized at the time. A new AI may have to be increased significantly to support the function of various tissues and organs affected by vitamin K status.

The average intake of vitamin K_1 in United States was found to be 70 mcg/day for the younger and 120 mcg/day for the older population. Whereas intakes of vitamin K in the United Kingdom are similar to those in the United States, in other European countries, such as Holland, average vitamin K_1 intakes are significantly higher, at 246 mcg.

Surveys have found severe population deficiencies of vitamin K_1, even relative to the current AI.[181] Sixty to seventy percent of the US population does not even meet the current AI (90–120 mcg) for vitamin K, which is already well below what may be necessary for optimal health. Some 5% to 15% of people have been found to have undetectable levels of plasma vitamin K_1.

The majority of vitamin K_1 consumed in the United States is derived from vegetable oils as opposed to vegetables. Owing to the high prevalence of hydrogenated and fried oils and storage in transparent bottles (which allows vitamin K to be destroyed), it is possible that the active amount of vitamin K_1 ingested may be even lower than previously estimated. This widespread deficiency of vitamin K_1 is not surprising, because consumption of vegetables is deficient in the American diet. The well-founded recommendation of consuming five to nine servings of fruits and vegetables per day could provide an amount of vitamin $K_{1\ close}$ to 1000 mcg/day.

Guidelines for Optimal Vitamin K_1 Intake: Preventative Versus Therapeutic Strategies

As discussed, vitamin K_1 has multiple extrahepatic functions. The only function studied with escalating doses of vitamin K_1 was osteocalcin carboxylation. From the results of that study, we can hypothesize that an intake of 1 to 2 mg of vitamin K_1 may be the best preventive dose for supporting bone health, because it supports a virtually complete carboxylation of Oc. However, based on the intake surveys discussed earlier, it is not realistic to assume that individuals would change their diet enough to achieve this level of intake, thus supplementation with 0.9 to 1.0 mg K_1 may be needed in a large proportion of the general population.

One study showed that 5 mg/day of vitamin K_1 may significantly reduce fracture risk and cancer incidence of all types, but it did not include comparison groups taking any other doses between 1 and 5 mg.[104] This dose may be safe to use because there is no UL established for K_1, but one has to keep in mind that this is a supraphysiological dose.

Based on the studies that investigated effects on CVD, vitamin K_1 doses of 0.5 mg or 1.0 mg would likely have a beneficial effect on reducing progression of arterial calcification of the medial layer. It is not clear whether increasing this dose or adding vitamin K_2 may have the potential to completely prevent it. More studies are needed to establish the optimal intake of vitamin K_1 that can minimize the levels of nonfunctional MGP (dp-ucMGP), because carboxylated MGP is a major player in reducing calcification of various cardiovascular tissues (arteries, veins, heart valves). In addition, the 1 mg dose was shown to completely prevent an increase in arterial stiffness caused by supplementation with vitamin D and calcium.

Another line of evidence for optimal vitamin K_1 intake comes from the evolutionary adaptation to its content in the Paleolithic diet. Studies have looked at many nutritional components of this type of diet and preliminary data suggest that Paleolithic humans were ingesting vitamin K_1 in the vicinity of 1.0 mg/day on average.[78] It is likely not a coincidence that the Paleolithic levels of vitamin K_1 intake overlap with the amount of vitamin K_1 needed to completely activate Oc.

It has been established that vitamin K_1 needs to convert to K_2 (MK-4) to reduce arterial calcification. Aging, genetic polymorphisms, various metabolic factors, and treatment with statins (possibly also with bisphosphonates) may reduce K_1 to K_2 (MK-4) conversion, thus the need to consider additional supplementation with K_2 (MK-4).

Guidelines for Optimal Vitamin K_2 Intake: Preventive Versus Therapeutic Strategies

Currently there is no AI set for vitamin K_2, even though blood clotting needs may be satisfied by vitamin K_2 (MK-4) or other long-chain menaquinones at physiologically equivalent doses. However, it is not clear whether any form of vitamin K_2 can satisfy all the extrahepatic functions provided by K_1, simply because not all have been elucidated yet. Vitamin K_2 does not convert to K_1 and many tissues seem to prefer K_1, because they store much higher levels of K_1 compared with those of K_2 (MK-4).

Thus vitamin K_2 may not be used as a substitute for vitamin K_1 needs but may be added to it, based on average evolutionary intake, for basic health support or for therapeutic purposes. The commercially available forms of K_2 are K_2 (MK-4), K_2 (MK-7), or a blend of K_2 (MK-6, MK-7, MK-9).

Evolutionary Intake of Vitamin K_2

The human need for preformed vitamin K_2 may be grounded in an evolutionary perspective of the Paleolithic diet. Its vitamin K_2 content has not been estimated yet, but it was very likely higher than in modern times for several reasons: (a) The modern human's gut flora may be often impaired owing to therapeutic antibiotic use or antibiotics ingested within animal foods and dairy. (2) The gastrointestinal tract of the Paleolithic human was most likely populated with a larger variety of bacteria producing a fair amount of long-chain vitamin K_2 (MK-n)s. (3) Vitamin K_1 intake was higher and a substrate for intestinal bacteria to produce abundant quantities of K_2 (MK-n). (4) Fiber was also more abundant, which is critical in supporting gastrointestinal bacteria.

The only significant dietary sources of long-chain MK-ns for modern humans are cheeses and sauerkraut (in Europe and the United States) or fermented vegetables (kimchi) or soy fermented foods (such as natto, mostly in Asia). The modern content of K_2 (MK-4) in meats may be low because animals are fed mostly corn and not grass. It is unlikely that Paleolithic humans were ingesting any purposely fermented foods, but they may have eaten partially "spoiled" (thus naturally fermented) foods. Dairy foods were probably not often consumed, and neither were grains, legumes, or soy foods.[78]

Average modern intakes of vitamin K_2 (a mix of menaquinoes of various lengths) have been evaluated by a few epidemiological studies in European populations at 29.1 mcg. On the other hand, K_2 (MK-7) has been consumed traditionally in Japan (by approximately 42% of the population) at average levels of 58 mcg/day, with the upper range up to 165 mcg/day. This level of K_2 (MK-7) is typically derived from consuming an average of 400 mcg per serving of natto (one to three times per week).

As discussed earlier, the correlations found between intake of vitamin K (as K_2 and/or K_1) and CVD mortality, overall mortality, or fracture risk are conflicting, with some studies pointing to vitamin K_1 and others to vitamin K_2 to be the form that has more potential to be protective and therapeutic. However, the range of intakes of vitamin K reported by these studies are much lower than intakes able to support complete carboxylation of Oc or lower dp-ucMGP to a large degree. In conclusion, it is not possible to make a recommendation for the amounts and forms of vitamin K_2 that may provide basic health benefits when added to an optimal intake of 1 mg of K_1.

Therapeutic Dosage of Vitamin K_2

Vitamin K_2 may be conditionally essential for certain organs and certain individuals who have difficulty converting vitamin K_1 to vitamin K_2 because of age-related changes, those who need intensive intervention for certain disease states, or have genetic polymorphisms.

If the supplementation goal is to try to compensate for the poor vitamin K_1 to vitamin K_2 (MK-4) conversion, then a dose around 1 mg/day of vitamin K_2 (MK-4) may be appropriate, knowing that 90% of 1 mg vitamin K_1 may convert to vitamin K_2 (MK-4) by the time it is stored inside various tissues.

If the supplementation goal is a major therapeutic intervention for osteopenia, osteoporosis, osteoarthritis, arterial calcification, a high dose may be used, such as 45 mg/day, the same as in the drug form Glakay. This was prescribed in Japan for more than 20 years and was proven effective especially for bone and cardiovascular health. The 45 mg of vitamin K_2 (MK-4) should be administered in 15 mg doses, three times daily for optimal utilization.

Therapeutic doses of vitamin K_2 (MK-7) have not been proven more effective than those with vitamin K_1 or vitamin K_2 (MK-4).

SAFETY

No upper level of toxicity (UL) has been established for vitamin K_1, even though it belongs to the family of fat-soluble vitamins, which all have a UL because of their typical tendency to be stored and accumulated in various organs. This may be because vitamin K_1 is rapidly metabolized out of the plasma and the majority is excreted via bile and urine (50% and 20%, respectively) within a day, with complete excretion of the rest in about 3 days. No evidence has been found so far of toxic accumulation anywhere in the body. A level of 1 mg vitamin K_1 per day may be considered intrinsically safe because it could be normally derived from diets high in leafy greens, seeds, oils, and some organ meats.

Will such very high intakes increase clotting excessively? Some studies suggest that once the liver clotting factors are maximized (by complete carboxylation), no amount of excess vitamin K_1 or K_2 can increase clotting performance any further.[182]

Whenever supplementation with vitamin K is initiated, most people will experience an increase in clotting factors because a large proportion (60%–70%) of the population has a vitamin K intake below the optimal clotting requirement. However, vitamin K also supports the activation of anticlotting proteins that keep overall clotting tendencies in an optimal range (proteins C, Z, S). One study looked at the effects of supplementing postmenopausal women with 45 mg of vitamin K_2 (MK-4) and found that although clotting markers increased, the anticlotting activity increased as well; thus the clotting balance was maintained.[90]

Numerous 2- to 3-year studies have employed doses of 45 mg and even 90 mg of vitamin K_2 (MK-4) for various interventions and none have reported clotting or thrombotic abnormalities.

Regarding vitamin K_1, there are only a few short-term studies that supplemented with vitamin K_1 doses from 500 mcg up to 10 mg, and they have not reported clotting or thrombogenic abnormalities.

The Japanese studies that used 45 to 90 mg of vitamin K_2 (MK-4) have not noted any side effects, which were closely monitored as a result of the drug status of this formulation.

SUMMARY

The current paradigm shift in vitamin K knowledge is very similar to that of vitamin D, for which there is also a big discrepancy between the fast-accumulating new research and the outdated AI and UL or therapeutic guidelines.

Many researchers who performed recent reviews of vitamin K_1 and K_2 call for establishing a higher AI and for more research to be done to further clarify vitamin K physiology and provide more evidence for clinical applications. However, there is no consensus on what the new AI for vitamin K should be and on what doses of vitamin K_1 and/or K_2 may be used effectively and safely for therapeutic purposes.

It certainly makes sense to recommend acquiring as much vitamin K as possible from one's diet in a balance of all forms: K_1, K_2 (MK-4), and some long-chain K_2 (MK-n) from fermented foods. Another aspect to address is the health of the intestinal tract, to allow adequate amounts of K_2 (MK-n) to be derived from intestinal bacterial production. In that respect, avoidance of unnecessary antibiotic treatments and favoring grass-fed animal products would be helpful.

Vitamin K may be supplemented for two major purposes:

1. For complementing the patient's dietary deficiencies and correcting any physiological deficiencies of vitamin K_1, K_2 (MK-4), and various long-chain menaquinones. In most cases, it makes sense to supplement with 1 mg vitamin K_1 as a foundation, and add small amounts of a variety of menaquinones.
2. For therapeutic purposes, the best evidence is available for 1 and 5 mg vitamin K_1 and 45 mg MK-4 (as discussed in the osteoporosis and CVD sections). In this application the patient must be closely monitored for potential side effects and dose adjustments.

Another important aspect to consider is the dose distribution of vitamin K intake throughout the day. For example, a once-a-day high dose of vitamin K_1 or K_2 may not be metabolized properly and may be more likely to have unwanted side effects. One has to keep in mind that for vitamin K_1 supplementation to realize some of its physiological roles in extrahepatic tissues, it may have to be cleaved to form vitamin K_3 by the intestinal cells or convert peripherally to vitamin K_2 in various tissues and organs.

Dietary fat stimulates biliary and pancreatic secretions, so it would be best to incorporate a reasonable amount of fat (for example, 30 g) with the meal ingested at the same time as a vitamin K supplement.

In natural foods, vitamin K_1 is bound in the thykaloid membranes of chloroplasts, whereas mechanical processing, such as blending, juicing, or cooking may further enhance vitamin K_1 bioavailability from food.

The bottom line is that vitamin K_1 or K_2 requirements may vary between individuals based on their particular genetics, health status, dietary habits, and health goals.

Ideally (only theoretical at this time), vitamin K status should be at the level that supports optimal activity for all vitamin K-related functions. Therapeutic supplementation with supraphysiological doses of vitamin K has great potential for the reversal of severe diseases through complex effects. Patients should be monitored for various side effects and interactions with other pharmaceutical drugs, such as statins and bisphosphonates, and through specific vitamin K status tests and other tests relevant to vitamin K action pathways, as discussed previously in the "Status Biomarkers and Commercially Available Assessments" Section.

Vitamin Toxicities and Therapeutic Monitoring

Tennille Marx, ND, CFS, and *Joseph E. Pizzorno*, ND*

OUTLINE

INTRODUCTION

Vitamin deficiencies are a much greater problem worldwide than vitamin toxicities. However, when nutrients are being used at high doses for pharmacological effects, physicians must be vigilant in identifying any possible toxicity or adverse effects. In general, vitamin therapy is virtually nontoxic and careful monitoring of the patient can further reduce the small risk of developing any toxicity. Physicians should also be aware of toxicity resulting from self-administered vitamins. At each patient visit, it is important for physicians to inquire and record/update the use of any self-administered vitamins. Specific forms of each vitamin should also be noted, as new innovations have led to preparations that can increase the bioavailability of certain vitamins. For example, micellar applications can enhance the water-solubility of fat-soluble vitamins. The primary signs and symptoms of vitamin toxicity are listed in Tables 127.1 and 127.2, which are complemented by a more detailed discussion of toxicity and guidelines for monitoring select vitamins.

LIPID-SOLUBLE VITAMIN TOXICITY

Vitamin A

Clinical and subclinical toxicities have been associated with excessive intakes of preformed vitamin A. Many cases of hypervitaminosis A involve ingestion of a large quantity at one time by young children who, along with the elderly, are more susceptible to toxicity.[1,2] Acute toxicity is thought to occur when, within a short period of time, adults ingest more than 100 times the recommended daily allowance (RDA) and children ingest more than 20 times the RDA. However, in addition to acute toxicity, chronic intakes of high-dose vitamin A have also been associated with harm.[3]

Adverse reactions to acute toxicity in children can occur with intakes as low as 1500 international units per kilogram daily (IU/kg/day),[4] and they are usually transient. Symptoms of acute hypervitaminosis A in children given 100,000 to 300,000 IU include diarrhea, headache (possibly resulting from elevated intracranial pressure), nausea, vomiting, occasional dizziness, and fever as well as a transient bulging of the fontanelle in infants. In adults, symptoms of toxicity may also include blurred vision and lack of muscular coordination.[5] Chronic vitamin A excesses can precipitate alopecia, arthralgias, anemia, erythema, skin peeling, cheilitis, thickened epithelium, hypertriglyceridemia, hypercholesterolemia and fatty liver as well as heart, kidney, and testicular defects. Other, less commonly reported symptoms include dysphagia caused by vertebral hyperostosis, intrahepatic cholestasis, hepatotoxicity, pseudotumor cerebri syndrome, and renal dysfunction.[6–8] Interestingly, in a small number of case reports of dysphagia, none of the patients reported vitamin A supplementation despite high serum retinol levels, suggesting an impairment of vitamin A metabolism rather than excessive intake.[9] Usually, most of the untoward effects of excess vitamin A intake are resolved with cessation of its use.

Teratogenicity is the most severe and worrisome adverse effect of vitamin A. Fetal effects can include craniofacial, cardiac, thymic, and central nervous system abnormalities.[7] According to one large observational study published in the *New England Journal of Medicine,* women consuming greater than 10,000 IU of vitamin A during pregnancy (specifically during the first 7 weeks after conception) had a 1 in 57 risk for having a child born with a birth defect.[10] Therefore, supplementation above the RDA is not warranted in pregnant or potentially pregnant women. However, vitamin A levels during pregnancy must be carefully assessed because both deficiency and excess can bring about undesirable results. Also to be considered is that this research is in the context of very common vitamin D deficiency. Theoretical considerations suggest that, except at very high dosages, this teratogenicity may be more a result of an imbalance between vitamins A and D.

Another well-recognized result of chronic excessive vitamin A intake is an adverse effect on bone, including bone spurs, calcinosis, and bone resorption resulting in hypercalcemia.[7] Several prospective studies have also indicated that excessive vitamin A can have a lasting detrimental effect on bone by reducing bone mineral density (BMD) and increasing risk of fracture.[11,12] However, the data are mixed and may be confounded by other variables, including vitamins D and K_2 status. After over a decade of research, the association between vitamin A and risk of fracture is still controversial.

TABLE 127.1 Toxic Dosages and Side Effects of Lipid-Soluble Vitamins

Vitamin	Toxic Dosage	Toxic Signs and Symptoms
Carotenoids	Long-term: none	No apparent toxicity, even at large doses (250 mg/day); synthetic form poses a risk for heavy smokers or asbestos-exposed persons not taking other antioxidants
Vitamin A	Short-term	
	Infants: 75,000–300,000 IU	Anorexia, bulging fontanelle, hyperirritability, vomiting
	Adults: 2–5 million IU	Headache, drowsiness, nausea, vomiting.
	Long-term	
	Infants: 18,000–60,000/day	Premature epiphyseal bone closing, long bone growth retardation
	Adults: 100,000 IU/day	Anorexia, headache, blurred vision, loss of hair, bleeding lips, cracking and peeling skin, muscular stiffness and pain, severe hepatic damage and enlargement, anemia, teratogenesis (craniofacial, cardiac, thymic and central nervous system (CNS) abnormalities)
Vitamin D	Short-term: 1000–3000 IU/kg	Anorexia, nausea, vomiting, diarrhea, headache, polyuria, polydipsia
	Long-term: >40,000 IU/day	Hypercalcemia (unlikely)
Vitamin E	Long-term: >800 IU/day	Severe weakness, fatigue, exacerbation of hypertension, potentiation of anticoagulants. α-tocopherol used alone may increase disease risk
Vitamin K	Long-term: none	Phylloquinone (K_1), unlike menadione (K_3), is not associated with side effects when given orally. Caution is in order with anticoagulant medications

TABLE 127.2 Toxic Dosages and Side Effects of Water-Soluble Vitamins

Vitamin	Toxic Dosage	Toxic Signs and Symptoms
Ascorbic acid	Short-term: usually >10 g	Nausea, diarrhea, flatulence
	Long-term: >3 g/day	Increased urinary oxalate and uric acid levels in rare cases, impaired carotene utilization, chelation and resultant loss of minerals
Biotin	Long-term: >10 mg/day	No reported side effects from oral administration at therapeutic doses
Folic acid	Long-term: 15 mg/day	Abdominal distention, anorexia, nausea, sleep disturbances. May pose increased cancer risk (see text)
Niacin	Short-term: >100 mg	Transient flushing, headache, cramps, nausea, vomiting
	Long-term: 3–7 g/day	Anorexia, abnormal glucose tolerance, increased plasma uric acid levels, gastric ulceration, liver enzyme elevations. In severe cases, elevation of serum bilirubin and ammonia and prolonged prothrombin time
Niacinamide	Long-term: >2000 mg/day	Same as for niacin
Pantothenic acid	Long-term	Occasional diarrhea
Pyridoxine	Short-term	No acute effects have been noted at therapeutic dose
	Long-term: 300 mg/day	Sensory and motor neuropathies
Riboflavin	Long-term	No toxic effects have been noted
Thiamine	Long-term	No toxic effects noted for humans after oral administration
Vitamin B_{12}	Long-term	No side effects from oral administration have been reported

One 9.5-year prospective cohort study involving almost 35,000 postmenopausal women with hip and other fractures found little evidence of an increased risk of fracture with higher intakes of vitamin A or retinol. There was also no evidence of a dose-response relationship in hip fracture risk with increasing amounts of vitamin A or retinol from supplements. Furthermore, the results showed no association between vitamin A ingestion from food and supplements or food only and the risk of fractures of any kind.[13] Similar results were seen in a 2013 intervention study, where no association was found between long-term high retinol intake (25,000 IU retinyl palmitate/day) and risk for any fracture.[14] In another large observational study that included more than 75,000 participants from the Women's Health Initiative, retinol and vitamin A intake were not significantly associated with either hip or total fracture incidence among postmenopausal women. However, women in the highest quintile of retinol and vitamin A intake who also had a low intake of vitamin D did have a modestly (15%–20%) increased total fracture risk.[15] A smaller study that enrolled Spanish postmenopausal women did find an independent risk for osteoporosis among those with the highest vitamin A intake, but this risk was magnified when combined with low vitamin D levels.[16] More recently, an analysis of data from 6481 subjects from the Korea National Health and Nutrition Examination survey revealed that total hip and femoral BMD were positively correlated with dietary vitamin A intake in subjects with serum 25-OH vitamin D levels >75 nmol/L.[17] However, in men with serum 25-OH vitamin D levels <50 nmol/L, both top and bottom tertiles of vitamin A intake were associated with lower BMD. A similar U-shaped relationship between blood retinol levels and hip fractures was noted in 2014 and 2017 meta-analyses, in which both low and high levels of vitamin A had a negative effect on bone.[18,19] The interaction between high vitamin A and low vitamin D levels appears biologically plausible, as vitamin A may antagonize some of vitamin D's actions, including calcium absorption.[20] This may be relevant not only to bone health but possibly to susceptibility to respiratory infection as well.[21]

Interestingly, a 2015 Dutch prospective study in elderly men and women (the Rotterdam study) indicated that dietary vitamin A intake was associated with a higher BMD and lower fracture risk and vitamin D intake or status did not appear to modify these effects.[22] However, the favorable association between vitamin A and BMD disappeared after adjustment for body mass index (BMI). Additionally, when stratified for BMI categories, the positive association between vitamin A intake and fracture risk was only present in overweight subjects and not normal weight subjects.

A 2007 review of the bone effects of vitamin A concluded that the poor sensitivity of laboratory markers and assessment of dietary intake may contribute to the conflicting findings; it suggested that future studies incorporate superior analytic techniques, specifically stable-isotope-dilution methodology.[23] Although serum retinol is often employed to screen for vitamin A toxicity, it is thought to have poor sensitivity because it is subject to homeostatic control over a wide range of intakes as well as hepatic concentrations, and thus does not necessarily represent liver stores.[24] Additionally, many clinical factors interfere with its accuracy. One alternative is the measurement of fasting retinyl ester concentrations. When more than 5% to 10% of circulating vitamin A is in the form of retinyl esters, it may indicate either hepatic storage capacity or the capacity of the retinol-binding protein has been exceeded. Unfortunately, elevated retinyl esters do not necessarily indicate impaired liver function and are not sensitive to subclinical toxicity.[22,25] Although expensive and not widely available, stable isotope dilution techniques appear to correlate well with values determined by liver biopsy and may emerge as the best marker of total vitamin A stores in both deficiency and toxicity. Indeed, variations of this method may be used to determine the intake needed to maintain target body storage levels. In animal models they have shown 100% sensitivity for the diagnosis of hypervitaminosis A.[26,27] Although the deuterated retinol dilution method has been validated in both children and adults to give a quantitative estimate of internal stores, it needs further verification among diverse populations and greater accessibility.[28]

When large doses of vitamin A are being given, careful monitoring is necessary. Rather than sudden ingestion of large doses, a gradual stepwise increase in dosage is indicated, with an evaluation of symptoms made before the dosage is increased. Usually, the first symptom of hypervitaminosis to be recognized is frontal headache. If signs or symptoms appear, supplementation should be discontinued until they disappear. Levels of liver enzymes should be determined periodically to check for hepatic damage. Typically, levels of aspartate transaminase are the first to be affected.[1,2,29,30] Patients whose liver function is compromised by viral hepatitis, protein-energy malnutrition, cirrhosis, or hemodialysis seem to be the most vulnerable to vitamin A toxicity and to require close monitoring.[4]

Finally, as a result of the conflicting results in studies on vitamin A and bone health, anyone consuming large doses of vitamin A longterm should ensure adequate vitamins D and K_2 levels and be monitored for any bone density changes.

Carotenoids

Carotenoids appear to be without toxic effects at the therapeutic doses customarily used. The only effect of large dosages is an apparently benign yellowing of the skin. While carotenoid toxicity is limited, there is concern that some individuals have difficulty converting carotenoids to vitamin A and may be more prone to vitamin A deficiency.[31–33]

Several large, widely publicized therapeutic trials with synthetic beta-carotene have found that it appears to raise the risk of lung cancer in heavy smokers. It may also pose an increased risk for gastric cancer, particularly among smokers and those exposed to asbestos.[34] However, several factors complicate the interpretation of these results. The significance of these trials is fully discussed in Chapter 57.

Vitamin D

Significant advances have been made in understanding the role and importance of vitamin D in human health. The recent implications of vitamin D deficiency in a number of chronic diseases has led to an eightyfold increase in physician requests for serum vitamin D concentration measurements between the years 2000 and 2010.[35] Deficiency is now known to be widespread, with suboptimal levels much more prevalent than toxicity. The use of 25-OH vitamin D is widely accepted as a reliable biomarker, with most indicators suggesting that a level of 75 to 110 nmol/L (or 30–44 ng/mL) is sufficient, although some studies indicate that even higher levels may be optimal.[36,37] Unfortunately, the majority of US adolescents and adults do not sustain vitamin D levels within this range. A 2009 study indicated that only 23% of the population had serum 25-OH vitamin D levels higher than 75 nmol/L.[38] Therefore the evaluation of vitamin D levels should be part of a normal annual preventative checkup. Those in northern latitudes with less sun exposure, as well as the elderly whom have a lower the capacity for vitamin D production, warrant special attention.

The upper limits of 25-OH vitamin D are not clearly established, although levels less than 250 nmol/L are considered safe.[39] Therapeutic strategies should target 25-OH vitamin D levels rather than a specific supplemental dose, as the effect of supplementation on serum levels varies considerably between individuals. Doses between 2000 IU and 4000 IU will bring the majority of individuals within the range of 75 to 110 nmol/L and are without adverse effects.[35,40,41] Nevertheless, some will require higher dosing, and this is also a consideration for individuals with less functional vitamin D receptor polymorphisms. The Endocrine Society, as well as others, suggest levels up to and including 10,000 IU vitamin D (a dose equivalent to full-body sunlight exposure) will maximize physiological benefits and are safe.[42–44]

According to researchers, there are three major hypotheses for vitamin D toxicity: (1) raised plasma 1,25-OH vitamin D concentrations lead to increased intracellular 1,25-OH vitamin D concentrations (not a popular hypothesis as a result of levels of 1,25(OH)D being normal or only marginally elevated in vitamin D toxicity); (2) vitamin D intake raises plasma 25-OH vitamin D levels to concentrations that exceed DBP binding capacity, and "free" 25-OH vitamin D has direct effects on gene expression once it enters target cells; (3) vitamin D intake raises the concentrations of many vitamin D metabolites and these concentrations exceed the DBP binding capacity and release free 1,25-OH vitamin D, which enters target cells.[45,46]

Vitamin D intoxication manifests primarily as hypercalcemia and hypercalciuria as a result of vitamin D's ability to increase calcium absorption in the gastrointestinal tract. Symptoms can include gastrointestinal (nausea, vomiting, constipation), neurological (confusion, lethargy, fatigue), musculoskeletal (muscle weakness and bone pain), cardiovascular (cardiac arrhythmias), and nephrotic (polyuria, polydipsia, and renal calculi) effects. In extreme cases, renal failure can occur.[47] Testing for vitamin D toxicity should include 25-OH vitamin D levels as well as serum calcium levels. It has also been suggested that hypercalciuria may be a more sensitive indicator of vitamin D toxicity than hypercalcemia.[42] A recent randomized, double-blind clinical trial indicated that hypercalciuria and hypercalcemia "episodes" occurred more frequently when participants were consuming 10,000 to 12,000 IU/day of vitamin D_3 compared with 600 to 800 IU/day when coadministered with 2000 mg of calcium. However, these incidences were not associated with kidney stone formation or other adverse effects.[48]

As a result of its wide therapeutic index, vitamin D intoxication is rare and is usually caused by manufacturing errors or incorrect/inappropriate administration.[49,50] In a review of case reports of vitamin D

toxicity spanning over 8 decades, only 13 laboratory-confirmed reports of vitamin D toxicity were found.[46] Of these 13 case studies, doses resulting in toxicity in children under the age of 5 were between 20,000 to 800,000 IU/day. Doses resulting in toxicity in adults ranged from 50,000 to 2,604,000 IU/day. The most common symptoms of toxicity were loss of appetite, vomiting, diarrhea, and altered sensorium. In these cases, serum 25-OH vitamin D concentrations were greater than 150 ng/mL and total calcium levels ranged from 11.1 to 23.08 mg/dL. Another report on data from calls to US poison centers confirmed that serious medical outcomes from vitamin D ingestion were rare (0.02%) and the most common clinical effects were gastrointestinal and mild neurological effects. They did note, however, that there was a 1600% increase in reported exposures in 2005 to 2011 compared with 2000 to 2005.[49]

Doses as high as 40,000 IU per day have not been associated with toxicity.[36] However, very high single doses (500,000 IU in a single annual dose) have been associated with an increased risk for fracture and falls in a temporal pattern, with the highest risk in the period after administration.[51] A 2018 study investigating the effect of monthly doses of 100,000 IU of vitamin D_3 over 3 to 4 years on cardiovascular disease, respiratory infections, and fall and fractures did not find any increased incidences of adverse effects with vitamin D supplementation compared with placebo.[52] However, there was a tendency to report more dizziness in the vitamin D group. Thus lower doses given more frequently (i.e., more physiologically) are preferred. Despite ongoing controversy, vitamin D_3 appears to be more potent and to produce greater storage than D_2.[53]

Oftentimes vitamin D hypersensitivity is mistaken for vitamin D toxicity. For example, granulomatous diseases, such as sarcoidosis, warrant special concern because these individuals are more susceptible to hypercalcemia. Although many have low levels of 25-OH vitamin D (which appears to increase the risk for sarcoidosis), they also have elevated levels of 1,25 dihydroxyvitamin D and thus require careful management.[54]Apparently there is overconversion of 25-OH vitamin D_3 to 1,25(OH)2-vitamin D_3 by macrophages in granulomatous disease.[55] Primary hyperparathyroidism is another example. In this case production of 1,25-OH vitamin D is upregulated by the high parathyroid hormone concentrations.[43] Patients with *Mycobacterium* infections and those treated with thiazide diuretics should also be closely monitored if supplementing with vitamin D because of the potential of these populations being vitamin D sensitive.[42]

Vitamin E

Although for many years observational studies found vitamin E supplementation to be safe, several controlled trials have been published suggesting harm with supplementation. For example, in a large meta-analysis of randomized placebo-controlled trials in which participants were given between 50 and 800 IU natural or synthetic vitamin E per day, supplementation was found to reduce the risk of ischemic stroke by 10% but to increase the risk of hemorrhagic stroke by 22%.[56] Similarly, a meta-analysis published in the *Annals of Internal Medicine* found that supplementation with more than 400 IU vitamin E increased all-cause mortality.[57] A 2012 Cochrane review also concluded that vitamin E seemed to increase all-cause mortality[58]; however, this analysis has been criticized by others for excluding hundreds of studies that had zero mortality.[59] In addition, most vitamin E research is performed with synthetic vitamin E, which is a DL racemic mixture and/or only alpha-tocopherol.

Although the use of synthetic versus natural vitamin E may explain some of the increase in adverse effects, the natural but incomplete form of vitamin E (d-alpha tocopherol) used in many clinical trials is not without risk. For example, supplementation with natural vitamin E at 400 IU per day was associated with an increased risk of heart failure among patients with diabetes or vascular disease.[60] The vitamin E family includes eight isomers. As discussed next, high dosages of a single isomer competes with the absorption of the others.

An explanation that appears more plausible is that despite the physiological benefits of alpha-tocopherol, high-dose supplementation depletes other forms of naturally occurring vitamin E, such as beta- or gamma-tocopherol, or tocotrienols, which have greater physiological significance. For example, in an observational study of elderly patients, higher plasma levels of beta-tocopherol were associated with a reduced risk of developing Alzheimer disease, whereas other forms of vitamin E were only marginally significant.[61] The use of both gamma- and alpha-tocopherol in patients with the metabolic syndrome was shown to be superior to either used alone. Moreover, in vitro and in vivo evidence indicates that alpha-tocopherol not only failed to demonstrate anticancer properties but also blocked the anticancer effects of gamma-tocopherol.[62,63] Gamma-tocopherol is actually more prevalent than the alpha form in the US diet as well as in many plant seeds, although the vast majority of trials and available products use alpha-tocopherol.[64] Tocotrienols have been shown to have superior antioxidant capabilities than alpha-tocopherol.[65,66] Thus it may not be "vitamin E" that has the harmful effects mentioned previously, but rather the isolated use of alpha-tocopherol. As such, researchers have called for manuscripts to be titled with the specific form of the vitamin rather than the umbrella term "vitamin E."[67] Additional factors are likely to have an influence as well, such as age and vitamin C intake.[68] Genetics are also likely to play a role, as diabetic patients with the haptoglobin 2-2 genotype are more likely to receive benefit from supplementation.[69]

Unfortunately, most laboratory evaluations of vitamin E's toxicity are based on alpha-tocopherol plasma or serum levels and thus may not be helpful in determining toxicity. The tolerable upper intake level (UL) established by the Institute of Medicine for vitamin E, which refers to all stereoisomers, is based on the potential risk of bleeding. However, it has been suggested that vitamin E only affects coagulation if vitamin K deficiency is also present.[70,71] Conflicting evidence and a lack of long-term studies adequately analyzing vitamin E's toxicity leaves much to be known about vitamin E and its true safety profile.

Vitamin K

Synthetic water-soluble vitamin K_3, menadione, is thought to interfere with the antioxidant glutathione, resulting in oxidative damage to cell membranes.[72] Large doses of menadione administered to infants may cause liver damage and destruction of red blood cells resulting in hemolytic anemia, hyperbilirubinemia, hepatomegaly, and possibly death. Adults with glucose-6-phosphate dehydrogenase deficiency may show hemolytic reactions.[73] This form vitamin K is no longer used in the United States due to these toxic effects.

The natural vitamin K_1 (phylloquinone) and the menaquinones (MK-4, MK-7) do not appear to cause toxicity when given orally unless huge doses (e.g., 200 mg) are given.[74] In fact, no tolerable upper intake level for vitamin K has been established as a result of the lack of adverse effect data. Dr. Bruce Ames, professor of biochemistry and molecular biology, has provided compelling evidence for the triage theory; that given a suboptimal intake, vitamin K is shunted to basic functions necessary for survival at the expense of less essential functions, which are likely to be associated with aging and chronic disease. Given that many individuals have suboptimal vitamin K intake, supplementation with menaquinones has the potential to reduce the incidence of chronic disease.[75]

All forms of vitamin K can interfere with some anticoagulant medications, such as warfarin (Coumadin), and should be used with

caution. Given that the menaquinones may have greater potency than vitamin K_1, an upper limit of 50 mcg/day (MK-7) has been proposed for those patients on anticoagulant therapy.[76] However, the longer half-life of MK-7 (compared with other forms of vitamin K) may help maintain a more stable international normalized ratio while also protecting these patients from the arterial calcification and osteoporosis for which they are at increased risk.[77]

Water-Soluble Vitamin Toxicity

Ascorbic Acid (Vitamin C)

Vitamin C has been reported to have perhaps the lowest toxicity of all vitamins. Linus Pauling and colleagues began using vitamin C in therapeutic doses—10 g/day intravenously (IV) and orally—in the 1970s and 1980s for cancer patients without toxic effects. Almost a half a decade later, IV vitamin C has been used in Phase I and Phase I/II trials and is widely used in integrative settings both alone and in combination with chemotherapy. A 2014 review of IV vitamin therapy studies that utilized 1 g to more than 200 g ascorbic acid per infusion 2 to 3 times per week confirmed vitamin C's modest, but inconsistent, therapeutic benefit in cancer patients as well as its excellent safety profile.[78] Although one study found IV vitamin C associated with a small increase in urinary oxalate excretion, no related adverse events were noted. The most common adverse events reported were nausea, headache, diarrhea, and flushing. There were a few cases of hypernatremia and hypokalemia and one incident of kidney stone in a patient with a previous history of kidney stones. In a similar 2018 review of 9328 patients using IV vitamin C therapy, the adverse event rate was only 1% and included mild events such as nausea, dizziness, dry mouth, perspiration, and weakness.[79]

Diarrhea, intestinal distention, and gas are the most common complaints when vitamin C is consumed orally at higher dosages. These effects are rare at doses of 2 g/day or less. It has been shown that high doses of vitamin C can:

- Increase the urinary excretion of calcium, iron, and manganese
- Increase the absorption of iron
- Raise urinary oxalate or uric acid levels, but only in a small subgroup of the population (This may vary with the form of vitamin C, as ester-C has been shown to reduce oxalate levels in a crossover study.[80])
- Alter many routine laboratory parameters (e.g., serum vitamin B_{12}, aminotransferases, bilirubin, glucose, stool occult blood)

Clinicians must take these effects into consideration when supplementing with megadoses of vitamin C. Also, the ability of oral vitamin C to increase plasma levels is limited, with IV administration of vitamin C having been shown to raise levels seventyfold higher.[81] Even at the high plasma levels documented with IV therapy, toxicity does not appear to be a significant concern.

One concern with high dosages of vitamin C often cited in the medical literature is the development of calcium oxalate kidney stones. As mentioned previously, various forms of ascorbic acid may negate this effect, as demonstrated with ester-C versus ascorbic acid. Additionally, in vitro oxidation of ascorbic acid to oxalic acid during storage or analysis is thought to be a common confounder in these studies. Nonetheless, 500 mg/day may be a reasonable limit for those prone to stone formation.[82] With regard to IV administration of vitamin C, less than 0.5% of a 100-g dose was converted to oxalic acid in individuals with normal renal function, much less than might be expected from such a large dose.[83]

A second, more theoretical concern about vitamin C relates to its excess use in progressive inflammatory diseases such as rheumatoid arthritis and Crohn's disease. It is theorized that available surplus vitamin C may interact with metal ions, eliciting a prooxidant consequence.[84] Alternatively, more recent data suggest that vitamin C may chelate metal ions, actually reducing their ability to generate reactive oxygen species, and animal models suggest that megadosing may reduce inflammation.[85,86] Although no clinical information is available to clarify this concern, it may be prudent to consider limiting the megadosing of vitamin C in patients with unresponsive or worsening chronic inflammatory conditions and to be cautious about giving large doses of vitamin C to patients with known conditions of iron or copper excess. This may also be relevant to the dietary intake of iron. For example, high dietary heme intake among women taking more than 500 mg vitamin C per day was found to increase the risk of lung cancer, whereas high zinc intake reduced the risk.[87]

There have been reports that abrupt cessation of high-dose vitamin C intake leads to rebound scurvy, which has also been reported to occur after birth in the babies of pregnant women who have been taking high doses. However, other studies do not support the existence of rebound scurvy under these conditions. Although some experts question the existence of rebound scurvy, it is better to err on the side of caution. At this time a safe recommendation to pregnant women would be a daily dosage of 500 mg vitamin C.

Folic Acid (Vitamin B_9)

Although generally considered safe, caution should be exercised in supplementing with folic acid in the presence of a vitamin B_{12} deficiency. Although folic acid will correct a macrocytosis, it will not correct the underlying neurological degeneration caused by vitamin B_{12} deficiency. Additionally, high folic acid levels appear to accentuate the toxicity of low vitamin B_{12}.[88,89]

High-dose folic acid (15 mg/day) has been used without adverse effects in several studies. For example, when given as 5-methyltetrahydrofolate to postmenopausal women, it significantly reduced their blood pressure and homocysteine levels and improved their insulin sensitivity.[90] Folic acid given at 5 mg/day with vitamins B_{12} and B_6 was found to reduce subclinical atherosclerosis among individuals with a fasting homocysteine level greater than 9.0 μmol/L when given over 3 years. This was a randomized placebo-controlled trial with more than 500 participants, and no difference in adverse effects between groups was cited.[91] A meta-analysis also found that folic acid supplementation reduced the risk of stroke in primary prevention, especially when continued for a longer period of time.[92]

A very important placebo-controlled randomized trial, published in 2008, found that folic acid given at 5 mg/day over 3 years reduced the recurrence of colorectal adenomas; the recurrence rate in the placebo group was twice as high as in the folic acid group. Additionally, none of the patients who received folic acid were found to have histologically aggressive adenomas or carcinoma at their final endoscopy.[93] This study is particularly relevant because concerns have been raised that both low and high folate levels may increase the risk of cancer.[94,95] For example, in two previous trials, folic acid given at 1 mg/day was associated with more advanced colorectal lesions as well as an increased risk of prostate cancer.[96,97] It is possible that the high folic acid content of fortified foods can be a confounding variable when a low dose of 1 mg/day is used. Additionally, there is most likely a difference between synthetic folic acid and the more natural reduced and methylated forms, primarily 5-methyl tetrahydrofolate.

In 2015 the US National Toxicology Program (NTP) partnered with the NIH Office of Dietary Supplements and convened an expert panel to evaluate the current state of science surrounding the safe use of folic acid at levels above the RDA. They prioritized four general health categories that had areas of uncertainty when considering the safe use of folic acid: cancer, cognition in conjunction with vitamin B_{12} deficiency, hypersensitivity-related outcomes, and thyroid and

diabetes-related disorders. The panel did not identify conclusive evidence of adverse effects of folic acid; however, they did conclude that more research could be done on all of the topics. With respect to folic acid and cancer, the expert panel indicated there was a "consistent enough suggestion in human studies of an adverse effect on cancer growth from supplemental folic acid to justify further research."[98]

Until a more definitive conclusion exists on folic acid supplementation and the risk of cancer, it seems prudent to limit folic acid supplementation to the RDA unless the benefits outweigh the risks. It is important to point out that folate from food is not a concern.

Finally, a serum folate level greater than 45.3 nmol/L is often used to define elevated levels, but it is arbitrarily chosen because of technical difficulties in analysis rather than a functional toxicity.[99]

Niacin (Vitamin B_3)

The acute side effects of niacin (nicotinic acid) are well known. The most common and bothersome is the skin flushing that typically occurs 20 to 30 minutes after the niacin is taken. A gradual increase in daily dose and/or administration of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) 30 minutes to 1 hour before taking niacin can help reduce the flushing effect of niacin.[100,101] Long-term consequences of niacin therapy include gastric irritation, nausea, jaundice, and liver damage. Other rare complications include cardiovascular (palpitations, tachycardia) and ocular (blurred vision, cystoid macular edema) effects.[100]

In an attempt to combat the acute reaction of skin flushing, several manufacturers began marketing "sustained-release," "timed-release," and "slow-release" niacin products. These formulations allow the niacin to be absorbed gradually, thereby reducing the flushing reaction. However, although these forms of niacin reduce skin flushing, they have actually proved to be more toxic to the liver, particularly the slow-release products. One study strongly recommended that the use of slow-release niacin be restricted because of the high percentage (78%) of patient withdrawals from the study because of side effects; 52% of the patients taking the sustained-release niacin had liver damage compared with none of the patients taking immediate-release niacin.[102] "Extended-release (ER)" niacin (Niaspan) appears to have similar toxicity as immediate-release niacin, with a 2008 review documenting that significant increases in liver enzymes with either extended- or immediate-release niacin are rare and that elevations leading to severe hepatotoxicity occur rarely, if at all.[103] A 2014 review of the safety profile of Niaspan in the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) trial indicated that there were no significant differences in number of serious adverse events between the extended-release niacin and placebo and the rate of serious hemorrhagic events were low.[104]

Niacin has also been shown to cause a 4% to 5% increase in fasting glucose and a 20% to 28% reduction in insulin sensitivity. For this reason it should be used with caution in diabetic patients and those at risk for diabetes. However, its cardiovascular benefit often significantly outweighs the risk, even in these patients. In a 2010 meta-analysis published in *Atherosclerosis,* nicotinic acid given alone or in combination was associated with a reduction in the risk of coronary events and stroke (approximately by 75%) as well as positive effects on the evolution of atherosclerosis when used at 1 to 3 g/day. The authors of this analysis also point out that it reduces low-density-lipoprotein cholesterol to a similar degree as statin medications, and is the only effective therapy for reducing lipoprotein (a).[105] When extended-release niacin was given to diabetic patients at 1000 to 1500 mg/day, it was associated with only a 0.3% increase in hemoglobin A_{1c} compared with placebo, with a dose-dependent improvement in levels of triglycerides and high-density-lipoprotein cholesterol. However, increases in diabetes medications may have prevented a larger increase in hemoglobin A_{1c}.[106] Given that improving high-density-lipoprotein cholesterol is a primary goal in diabetes, the use of nicotinic acid is often indicated for these patients.[107]

Side effects can occur with any form of niacin, including niacinamide. Although niacinamide does not cause the acute flushing of the skin, it can also cause liver damage and has not demonstrated the same benefit to lipid profiles as nicotinamide. Inositol hexaniacinate is an alternative form of niacin that may have very few side effects, but large, well-designed studies to document its benefit are lacking.[108]

Regardless of the form of niacin being used, periodic checking (at least every 3 months) of liver function is indicated when high-dose (i.e., 2–6 g/day) niacin, inositol hexaniacinate, or niacinamide therapy is being used. Niacin should be used with caution in patients with preexisting liver disease or elevation in liver enzyme values, gout, or peptic ulcers. Physicians should also be aware of the promotion and use of niacin as an agent to influence urine drug screens. Several case reports have been published on severe niacin toxicity caused by large doses being consumed for this purpose.[109,110]

Pyridoxine (Vitamin B_6)

Vitamin B_6 is one of the few water-soluble vitamins that is associated with toxicity when taken in large doses or in moderate dosages for long periods, and it is known to cause a transient sensory neuropathy. Large doses of vitamin B_6 are currently being used for a wide variety of conditions.

Doses greater than 1000 mg/day can produce symptoms of nerve toxicity (tingling sensations in the feet, loss of muscle coordination, and degeneration of nerve tissue) in some individuals, with ataxia being the clinical hallmark of vitamin B_6 hypervitaminosis.[111] Long-term intake of dosages greater than 500 mg/day can be toxic if taken daily for several months.[112] There are also a few rare reports of toxicity occurring at chronic long-term dosages as low as 150 mg/day.[113–115] One animal study reports the increased possibility of nerve toxicity in individuals with renal failure who have uremia, owing to decreased pyridoxine excretion, which induces an increase in susceptibility to pyridoxine-induced neuropathy.[116] Because patients with renal failure are commonly given long-term pyridoxine therapy, caution is advised, and it is prudent to look for neuropathic signs in pyridoxine-supplemented uremic patients with renal failure. Although rare, it has also been reported that pyridoxal-5-phosphate (PLP) therapy can exacerbate blood clotting disorders, such as hemophilia, so it is important that a clinician be prudent in using vitamin B_6 therapy in those patients.[117]

Toxicity is thought to occur when supplemental pyridoxine overwhelms the liver's ability to add a phosphate group to produce the active form of vitamin B_6 (PLP). As a result, it is speculated that pyridoxine is either toxic to the nerve cells or that it actually acts as an antimetabolite by binding to PLP receptors, thereby creating a relative deficiency of vitamin B_6. A 2017 in vitro study seemed to confirm both of these hypotheses, demonstrating that pyridoxine significantly increased neuronal cell death whereas other B vitamers did not.[118] When PLP was added to neuronal cells before the addition of pyridoxine, it was able to prevent pyridoxine-induced cell death. Further, it was demonstrated that pyridoxine was able to competitively inhibit PLP-dependent enzymes tyrosine decarboxylase and alanine aminotransferase. Some controversy exists suggesting that vitamin B_6 analog contaminants produced during synthesis may be the actual culprits.

Doses of pyridoxine should therefore be limited to 50 mg. If more than 50 mg is desired, then the doses should be spread throughout the day or the active form (PLP) could be used.

TABLE 127.3 Laboratory Tests for Vitamin Toxicity

Vitamin	Laboratory Measurement
Vitamin A	AST, serum retinol, serum free retinyl esters, stable isotope dilution (preferred)
Vitamin D	Serum calcium, 25(OH) vitamin D
Niacin	AST, ALT
Vitamin C	Urinary oxalate and uric acid

ALT, Alanine transaminase; *AST*, aspartate aminotransferase.

Vitamin B_{12} (Cobalamins)

Vitamin B_{12}, a generic term for a group of cobalt-containing corrinoids, has no appreciable toxicity. Vitamin B_{12} has a long history of safe, long-term use even at high therapeutic doses (1000 mcg/day for years; 100,000 mcg one time dose).[119] In a 1986 study in dialysis patients who could not excrete vitamin B_{12} normally, IV doses of 2.5 mg resulted in a fourfold elevation of plasma vitamin B_{12}. These levels were not associated with any toxic effects.[120] Rare allergic/immune reactions have been reported with IV administrations.[121]

LABORATORY TESTS FOR VITAMIN TOXICITY

Only a limited number of routine laboratory tests are available for detecting vitamin toxicity. These are presented in Table 127.3.

Vitex agnus castus (Chaste Tree)

Michael T. Murray, ND

OUTLINE

Vitex agnus castus (family: Verbenaceae)
Common name: chaste tree

GENERAL DESCRIPTION

Vitex agnus castus, also known as chaste tree, is a shrub with finger-shaped leaves and slender violet flowers. It grows in creek beds and on riverbanks in valleys and lower foothills in the Mediterranean and Central Asia (Fig. 128.1 A–B). The plant blooms in high summer and, after pollination, develops dark-brown to black fruit the size of peppercorns. The fruit possesses a pepper-like aroma and flavor. The ripe, dried fruit of *V. agnus castus* is the part of the plant used in medicinal preparations today.[1]

CHEMICAL COMPOSITION

The fruit of *Vitex* contains essential oils, iridoid glycosides, and flavonoids.[2] The essential oils include limonene, 1,8-cineole, and sabinene.[3] The primary flavonoids are castican, orientin, and isovitexin. The two isolated iridoid glycosides are agnuside and aucubin (Figs. 128.2 and 128.3).[4] Agnuside serves as a reference material for quality control in the manufacture of *Vitex* extracts, although the flavonoid casticin appears to be the most active component.

HISTORY AND FOLK USE

The genus name *Vitex* is derived from the word *vitilium,* which means "plaiting." The flexible but tough and hard branches were used to construct fences. Plinius, in the first century AD, made the earliest reference to the plant as *Vitex.* The species name *agnus castus* originates from the Latin *castitas* ("chastity") and the equating of the Greek *agnos* with the Latin *agnus* ("lamb").

The English name for *V. agnus castus,* "chaste tree," is derived from the belief that the plant would suppress libido in women who took it. In Greek cities, festivals in the honor of Demeter included a vow of chastity by the local women. The Roman Catholic Church in Europe developed a variation on this theme by placing the blossoms of the plant in the clothing of novice monks to supposedly suppress libido. Interestingly, another common name for *V. agnus castus,* "monk's pepper," derived from the fact that monks in southern Europe commonly used the fruit as a spice in their cooking.

PHARMACOLOGY

Vitex acts on the hypothalamic-pituitary axis. One observed effect is that it increases the production of luteinizing hormone (LH) (Fig. 128.4), resulting in a corpus luteum–like hormonal effect that shifts the estrogen/progesterone ratio in favor of progesterone.[5] The ability of *Vitex* to increase or modulate the body's progesterone levels is therefore an indirect effect and not a direct hormonal action.[6]

Vitex also modulates the secretion of prolactin from the pituitary gland. In studies with rats, it was shown to inhibit prolactin release by the pituitary gland, particularly in conditions of stress. The mechanism of action appears to involve the ability of *Vitex* to directly bind dopamine receptors and subsequently inhibit prolactin release in the pituitary.[7,8] The flavonoid casticin appears to be responsible for this antihyperprolactinemia effect.[9] *Vitex* also possesses significant antioxidant effects.[10,11]

CLINICAL APPLICATIONS

The causes of menstrual disorders are multifaceted and can vary greatly in their manifestations. Frequently, therapeutic interventions must be used on a trial-and-error basis over a number of menstrual cycles to determine their efficacy. Nutritional interventions like vitamin B_6, magnesium, and vitamin E, as well as evening primrose oil for cyclic mastalgia, have all shown greater efficacy when used over several months. This characteristic reflects the gradual balancing effect that many of these interventions have on the female hormonal system. *Vitex* certainly fits this mold.

The majority of earlier clinical studies completed with *Vitex* were uncontrolled studies with large populations of female patients in European gynecology practices. *Vitex,* which has a Commission E Monograph in Germany, is commonly used in these practices as an initial intervention in a number of menstrual disorders, as follows:

- Anovulatory cycles

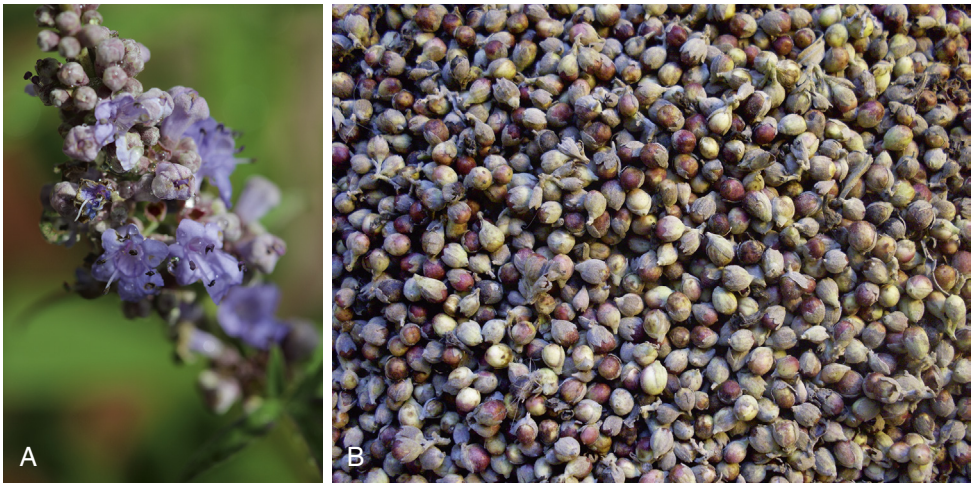

Fig. 128.1 (A) *Vitex agnus castus* flower. (B) *Vitex agnus castus* fruit.

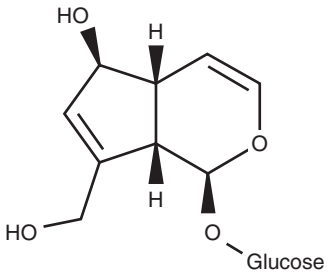

Fig. 128.2 Aucubin.

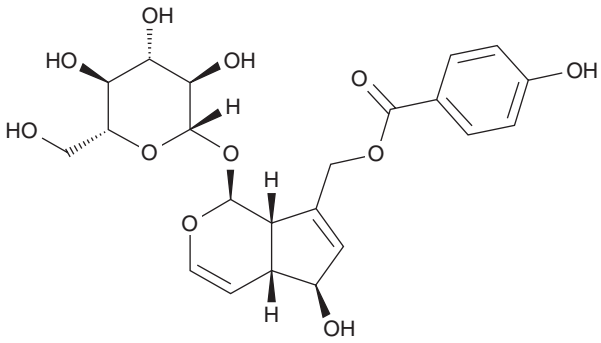

Fig. 128.3 Agnuside.

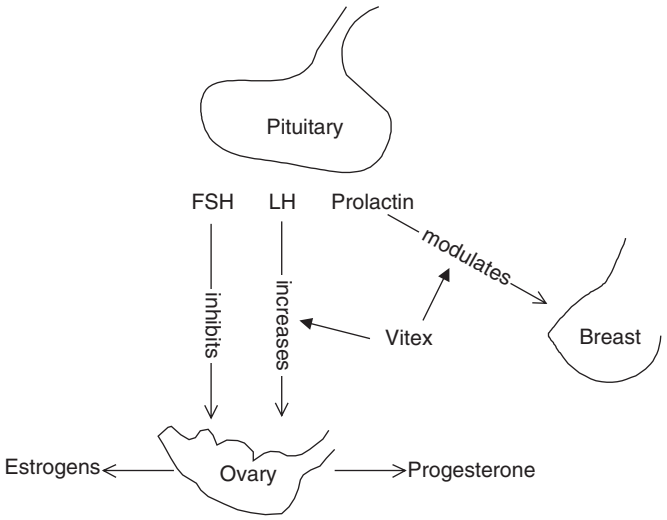

Fig. 128.4 Effect of *Vitex* on pituitary hormone secretion.

- Hypermenorrhea
- Hyperprolactinemia
- Infertility
- Mastalgia
- Polymenorrhea
- Premenstrual syndrome
- Secondary amenorrhea

Many of these conditions have been linked to corpus luteum insufficiency.

Corpus Luteum Insufficiency

Corpus luteum insufficiency (also referred to as luteal phase defect) is a manifestation of suboptimal ovarian function. In laboratory terms, corpus luteum insufficiency is usually defined as an abnormally low progesterone level 3 weeks after the onset of menstruation (serum progesterone below 10–12 ng/mL). This state is normal during puberty and at menopause; however, it is usually considered abnormal in women between the ages of 20 and 40 years.[12]

Corpus luteum insufficiency points to abnormal formation of ovarian follicles, an abnormality that may be so pronounced that no secondary or tertiary follicles are produced, with a resulting lack of ovulation (anovulation). Corpus luteum insufficiency also leads to a relative deficiency of progesterone. Insufficient levels of progesterone may also result in the formation of ovarian cysts.

Corpus luteum insufficiency may give rise to a myriad of menstrual abnormalities. Table 128.1 lists the most common clinical conditions in 1592 women diagnosed with corpus luteum insufficiency. Foremost are hypermenorrhea (heavy periods), polymenorrhea (abnormally frequent periods), and persistent anovulatory bleeding. Secondary amenorrhea (lack of a period) may sometimes be observed in women with corpus luteum insufficiency.

Disturbances of other hormones may also be associated with corpus luteum insufficiency. One study found hyperprolactinemia in 70% of cases.[13] Also noted is an exaggerated response to the thyroid-releasing hormone test, which is associated with manifest or latent hypothyroidism.

Premenstrual Syndrome and Cyclic Mastalgia

Premenstrual syndrome (PMS) is one of the most common complaints found in gynecology practices. Table 128.2 lists the different subgroups of PMS and the symptoms associated with them. Nearly 20 double-blind, placebo-controlled studies have been conducted with *Vitex* extract in PMS. A meta-analysis of the top eight studies in terms of quality concluded that *Vitex* extract is a safe and effective treatment

TABLE 128.1 The Most Common Clinical Conditions in 1592 Women Diagnosed With Corpus Luteum Insufficiency

Diagnosis	No. of Patients	Percentage of Total (%)
Hypermenorrhea	418	26.3
Polymenorrhea	369	23.2
Persistent anovulatory bleeding	216	13.6
Secondary amenorrhea	202	12.7
Dysmenorrhea	186	11.7
Anovulatory cycles	175	11.0
Involuntary sterility	145	9.1
Oligomenorrhea	69	4.3
Menorrhagia/metrorrhagia	66	4.1
Irregular menstrual cycles	32	2.0
Primary amenorrhea	1	0.1

TABLE 128.2 Subgroups of Premenstrual Syndrome (PMS)

Subgroup	Symptoms	Prevalence (%)
PSM-S	Anxiety Nervous tension	75–80
PMS-H	Irritability Fluid retention Weight gain Swollen extremities Abdominal bloating Breast tenderness	60–70
PMS-C	Increased appetite Craving for sweets Headache Fatigue Fainting spells	35–40
PSM-D	Depression Insomnia Forgetfulness	30–35

for PMS and premenstrual dysphoric disorder (PMDD). Three different preparations of *Vitex* extract were tested, and there was significant variability in the measurement of treatment outcomes between the studies. Nevertheless, all eight studies were positive for *Vitex* extract in the treatment of PMS or PMDD and *Vitex* extract was well tolerated.

In a double-blind study, 170 women (mean age, 36 years) with a diagnosis of PMS were randomly assigned to receive either 20 mg of a *Vitex* extract (dried ethanolic extract [6–12:1]) or placebo once a day for three menstrual cycles. Twenty-three women were taking oral contraceptives (11 in the *Vitex* group and 12 in the placebo group) during the study period. At the end of the treatment period, women taking the *Vitex* extract had a significantly greater reduction in overall PMS symptom score than those taking placebo ($P < 0.001$). Five of the six self-assessment items indicated a significantly greater reduction for the *Vitex* group with the exception of the item listed "others and bloating," which was measured as unaffected by treatment with *Vitex*. The Clinical Global Impressions (physician's assessment) also showed a significantly greater reduction in PMS symptoms in the *Vitex* group than in the placebo group ($P < 0.001$). The overall response rate was 52% for the *Vitex* group compared with 24% for the placebo group.[15]

TABLE 128.3 Efficacy of *Vitex*

Outcome	Percentage of Patients
Patient's Assessment	
Improved	57
Relieved	33
No change	4
No data	5
Physician's Assessment	
Very good/good	71
Satisfactory	21
Unsatisfactory	4
No data	3

One study compared the efficacy of *Vitex* (3.5–4.2 mg/day of dried fruit extract) with vitamin B_6 (200 mg/day) in 175 women with premenstrual tension syndrome.[16] Although both agents were effective (the symptom scale decreased from 15.2 to 5.1 in the *Vitex* group and from 11.9 to 5.1 in the vitamin B_6 group), 24.5% of subjects reported excellent results for *Vitex*, compared with only 12.1% for B_6. However, more than twice as many women (12) reported side effects from *Vitex* than from vitamin B_6 (5).

Two double-blind placebo-controlled studies have been conducted in Chinese women. In one double trial in 67 women, *Vitex* reduced the premenstrual syndrome diary (PMSD) sum score from 29.38 at baseline to 4.28 at the third cycle in the treatment group.[17] In the other double-blind study comprising 208 women in the *Vitex* group, the mean total PMSD score decreased from 29.23 at baseline to 6.41 at termination (third cycle) for the treatment group and from 28.14 at baseline to 12.64 at termination (third cycle) for the placebo group.[18] A placebo effect near 50% was found in both studies.

Other studies with *Vitex* for PMS have been uncontrolled or clinical monitoring trials. A monitoring survey of gynecology practices in Germany examined the effect of *Vitex* on 1542 women with a diagnosis of PMS.[19] The patients' mean age was 34.7 years, with a range of 13 to 62 years. Additional diagnoses noted in these patients included corpus luteum insufficiency ($n = 1016$) and uterine fibroids ($n = 170$). Patients were instructed to take 40 drops per day of a *Vitex* liquid extract. The average duration of treatment was 166 days. The efficacy of treatment was assessed by both patients and their physicians. These assessments are listed in Table 128.3.

In more than 90% of the patients, symptoms were completely relieved, with a report of side effects in only 2% (listed in Table 128.3). Only 17 of the 1542 women studied had to stop treatment because of side effects. Improvement in symptoms began after an average treatment duration of 25.3 days. After completion of the monitoring period, 562 patients continued taking *Vitex*. Similar results have been reported in three uncontrolled studies.[20–23]

Vitex has been shown to reduce cyclic breast pain (mastalgia) in many of the PMS studies. In a detailed review of data from randomized and nonrandomized studies regarding the efficacy and safety of *Vitex*, the authors concluded that *Vitex* can be considered a safe and effective agent in the treatment of mastalgia.[24] In one double-blind study of 97 patients suffering from cyclic mastalgia, the intensity of mastalgia, as measured by visual analog score, in patients treated with a liquid product combining *Vitex* with several homeopathic ingredients

significantly decreased after one or two treatment cycles and remained reduced after the third cycle.[25] Not only the intensity but also the duration of pain improved on *Vitex* treatment. In the *Vitex* group, after two cycles 50% of patients did not have severe pain at all during menstrual cycle. Clinicians should expect it to take three or four cycles for *Vitex* to work for mastalgia as well.

Hyperprolactinemia

As mentioned previously, *Vitex* has shown a modulating effect on prolactin and is regarded as a useful agent for the treatment of hyperprolactinemia.[26] A double-blind, placebo-controlled study examined the effect of *Vitex* on 52 women with luteal phase defects caused by latent hyperprolactinemia. The daily dose of the *Vitex* extract was 20 mg and the study lasted for 3 months. Hormonal analysis was performed at days 5 through 8 and day 20 of the menstrual cycle before and after 3 months of therapy. After 3 months of therapy, 37 cases were available for analysis (20 placebo and 17 *Vitex*). Prolactin release was significantly reduced in the *Vitex* group. Both shortened luteal phases and deficits in progesterone production were normalized. No side effects were noted, and two women in the *Vitex* group became pregnant.[27]

Infertility and Secondary Amenorrhea

Twenty patients with secondary amenorrhea were enrolled in a 6-month study using *Vitex* liquid extract at 40 drops daily. Laboratory monitoring of progesterone, follicle-stimulating hormone (FSH), and LH values as well as Papanicolaou smears were performed before the study and at 3 and 6 months. At the end of the study, data were available in 15 patients. The onset of menstrual cycles was observed with *Vitex* treatment in 10 of the 15 patients. The hormone values showed increased values for progesterone and LH, but FSH values either did not change or dropped slightly.[28]

A nonblinded uncontrolled trial studied the effect of *Vitex* on corpus luteum function in 48 infertile women between 23 and 39 years of age. The inclusion criteria were normal prolactin levels (<20 ng/mL), normal results in the prolactin and thyroid-stimulating hormone tests, and an abnormally low serum progesterone levels (<12.0 ng/mL on the 20th day of the cycle). Treatment consisted of *Vitex* liquid extract 40 drops daily without any other medication for 3 months. Forty-five women completed the trial (3 were excluded because of concurrent hormone use). The outcome of therapy was assessed through evaluation for normalization of the midluteal progesterone level and correction (lengthening) of any preexisting shortening of the phases of the cycle. Treatment was deemed successful in 39 of the 45 patients. Seven women became pregnant, serum progesterone was restored to normal (>12 ng/mL) in 25 patients, and there was a trend toward normalization of progesterone levels in 7 patients.[29]

A double-blind, placebo-controlled study involving 89 women with infertility, luteal phase defect, or secondary amenorrhea looked at the effect off a liquid *Vitex* extract (32.4 mg) with homeopathic ingredients on progesterone, LH, and prolactin levels and conception rates over a 3-month span. Of the 66 women evaluated at the end of the study, 31 had normal hormone values. More importantly, 15 women (7 with amenorrhea, 4 with infertility, and 7 with luteal phase defect) conceived during the study.[30]

DOSAGE

The recommended daily dose of *Vitex* is a dried or liquid extract delivering the equivalent of 30 to 40 mg of the dried fruit a day.[31] *Vitex* is typically taken once in the morning before breakfast; it should be taken for at least three menstrual cycles to evaluate efficacy.

TABLE 128.4 Side Effects from *Vitex* in 1542 Women

Side Effect	No. of Patients Reporting
No information	7
Nausea	5
Gastric complaints	3
Acne	3
Changes in menstrual rhythm	2
Diarrhea	2
Erythema	2
Allergy	1
Weight gain	1
Giddiness	1
Heartburn	1
Hypermenorrhea	1
Pruritus	1
Alopecia	1
Cardiac palpitations	1

TOXICOLOGY

Human and animal studies have determined *Vitex* to be safe for most women of childbearing age. *Vitex* is not recommended for use during pregnancy,[32] and its use during lactation is being questioned owing to its possible dopaminergic actions, which might lead to a suppression of lactation. The safety of *Vitex* in children has also not been determined.

Data from clinical trials, postmarketing surveillance studies, surveys, spontaneous reporting schemes, manufacturers, and herbalist organizations indicate that the adverse events after *Vitex* treatment are mild and reversible.[33,34] The most frequent adverse events are nausea, headache, gastrointestinal disturbances, menstrual disorders, acne, pruritus, and erythematous rash. Side effects noted in one large population study are listed in Table 128.4.

DRUG INTERACTIONS

Because of theoretical interactions, some authorities suggest that *Vitex* be avoided by women taking oral contraceptives or on hormone therapy.[35] However, two clinical studies have found no adverse interactions in women taking oral contraceptives concomitantly with *Vitex*.[15,23] The potential dopaminergic action of *Vitex* also suggests that it should not be used concomitantly with dopamine antagonist drugs, such as haloperidol and metoclopramide.

Water: The Most Basic Nutrient and Therapeutic Agent

Joseph Katzinger, ND, and *Herb Joiner-Bey*, ND*

OUTLINE

Pure water has been undervalued as a therapeutic tool because of a number of false assumptions and beliefs, according to Dr. Fereydoon Batmanghelidj. Conceptual fallacies in regard to the body's need for and use of water are as follows:

- Dry mouth is the only sign of water need.
- Water is merely a passive solvent with no chemical properties of its own.
- The human body can never become depleted of water because water is free and readily available.
- The water needs of the body can easily be met by any commercially prepared fluids.[1]

WATER AND THE HUMAN BODY

Water is the predominant compound in the human body. At birth, a baby's body is 78% water by weight. The average young adult is 70% water, and although the body's water content declines with age, water content remains at no less than 50% even in the geriatric individual. During youth, most cells with the exception of adipose cells are 90% water. In adulthood, two thirds of body water resides within cells; the remainder resides in the extracellular spaces.[2] Even bone tissue is 22% water.

Water has numerous roles to play in human physiology[3]:

- Building material. Water molecules facilitate the folding of amino acid chains assembled on the basis of DNA genetic sequences and reinforce the structural integrity of proteins. Water molecules fill every space not occupied by other molecules in every nook and cranny of every cell.
- Solvent. The ionic nature of water molecules makes water an excellent solvent of ionic compounds: salts, glucose, amino acids, etc.[4] The tendency of water molecules to surround ions and molecules of solutes allows chemical agents to move freely to wherever they are needed.
- Reaction medium and reactant. The biochemical reactions that sustain life occur within the medium of water. Yet water is not just the medium in the background; it is also an active participant—a reactant in the hydrolysis of macromolecules such as proteins, carbohydrates, and fats. Water is also a by-product of the metabolism of food energy molecules that contain hydrogen: carbohydrates, proteins, and fats.
- Carrier for nutrients and waste products. Water is the transport medium that moves nutrients into cells and waste products out of cells and then out of the body. Water is also the most basic constituent of blood, indispensable to the function of the cardiovascular, respiratory, urinary, and nervous systems.[5]
- Thermoregulation. The electromagnetic bonds among water molecules give water a great capacity to absorb heat, hold heat, and resist temperature changes. This property allows water to support homeostasis by helping maintain body temperature. In addition, the evaporation of water from the skin as perspiration releases heat sufficiently to maintain body temperature even when the surrounding atmospheric temperature is higher than body temperature.

*Previous edition contributor

- Lubricant. Water combines with molecules, forming viscous substances that lubricate and protect tissue functions. Examples include the mucus of the respiratory and gastrointestinal mucous membranes, synovial fluid in joints, saliva, tears, etc.
- Shock absorber. Within the cell, water takes the structural configuration of a gel that maintains cellular shape and form. This property cushions tissues against the shock of movement and mild trauma. Water molecules have an affinity for the electronegative molecules of connective tissue matrix (e.g., chondroitin, keratin, etc.), including the nucleus pulposus of the vertebral discs. It is the water molecules surrounding the compounds of the connective tissue matrix that provide the cushioning effect.

Causes of Dehydration

The most common are:
- Vomiting
- Diarrhea
- Blood loss
- Malnutrition
- Failure to replenish liquids lost from sweating and urination
- Among older adults in which dehydration is much more common, lower muscle mass, reduced kidney function, physical and cognitive disabilities, blunted thirst, and polypharmacy may all contribute.[6]
- Other causes include diabetic ketoacidosis, diabetes insipidus, burns, medications, and many others.

THIRST: THE SENSE THAT CANNOT BE TRUSTED?

The osmoreceptors in the forebrain are sensitive to only certain solutes in the blood (e.g., sodium) but insensitive to others (e.g., urea).[7] Thus the osmoreceptors are not accurate gauges of all blood solute concentrations but directly detect changes to the osmolality of the blood. We now know that these changes are detected by two small structures in the forebrain, outside of the blood–brain barrier, known as the subfornical organ (SFO) and organum vasculosum of the lamina terminalis. The precise mechanism remains unknown but has been speculated to be mediated via stretch-sensitive ion channels embedded in the plasma membranes of specialized neurons in these locations.[8]

Originally thought to be a limiting factor for optimal hydration, the sense of thirst in the mouth (dryness) is quickly and easily satiated by small amounts of water, stimulating the moisture receptors within the mucous membranes of the mouth, throat, and upper gastrointestinal tract. Now it is understood that thirst is simply not quenched by the same process that initiated it. "Instead, the brain terminates thirst by using sensory cues from the oropharynx to track ongoing water consumption and then estimate how this water intake will alter fluid balance in the future, after the water has been absorbed."[8] Thus thirst is quenched in anticipation of water absorption, likely as a preventative factor for overconsuming water and creating dangerous imbalances.

Signs and Symptoms of Dehydration

Clinical dehydration is a serious medical condition that must be treated immediately. Here are the indications to look for, though unfortunately most are low reliability indicators, especially in an older population[9]:
- Fatigue and weakness
- Headache
- Rough, dry skin or tenting of the skin
- Dry mucous membranes in the nose, mouth, or throat
- Nosebleeds (especially in dry interior air during winter)
- Dark, concentrated, strong-smelling urine produced in small quantities
- Irritability, irrational behavior (altered mental status)
- Constipation
- Nausea
- Intestinal cramps
- Weak, irregular pulse
- Low blood pressure
- Shallow, rapid breathing
- Increased capillary refill time
- Increased blood urea nitrogen, hematocrit, or serum sodium

Sources of Water for the Body

Human beings derive their water intake from these basic sources:
- Beverages (70%–80%)
- Foods with high water content (20%–30%)
- Liberation of water molecules during oxidative metabolism of food sources[10]

Water Losses From the Body

Water exits the body via several portals:
- Skin—insensible perspiration (450 mL daily in temperate climates). Of course, elevations in body temperature can lead to massive increases in water losses in the form of sweat.
- Kidneys—1 to 2 L of urine daily. Water loss via urine increases during hyperglycemia (diabetes mellitus) as well as in disorders involving antidiuretic hormone (vasopressin).
- Respiratory mucous membranes—breath (250–350 mL daily). Additional water loss occurs during respiratory infections, which trigger increased discharge of mucous secretions.
- Digestive system, including feces (200 mL daily). Dramatic water losses arise from disorders whose symptoms include vomiting and/or diarrhea.

Perspiration is hypotonic; that is, it has lower electrolyte content than plasma or extracellular fluid. This phenomenon means that sweating leads to more water loss than electrolyte loss. As the electrolyte concentration in the extracellular fluid rises, it draws water out of cells (intracellular fluid), leading to cellular dehydration. This state of hypertonic dehydration demands replenishment with hypotonic beverages, such as pure water. Water need supersedes salt need during endurance exercise.[11]

Factors That Influence Water Need

Water intake requirements vary according to individual needs and circumstances. Some of the factors that affect water need are:
- Physical activity/exercise
- Metabolism
- Diet
- Ambient atmospheric temperature
- Humidity
- Health status

Ideal Water Intake

In units of liters per day, the water intake levels recommended by the US Food and Nutrition Board, based on age and gender, are as follows[12]:
- Infants, 0.7 to 0.8 L
- Children
  - 1 to 3 years, 1.3 L
  - 4 to 8 years, 1.7 L
- Males
  - 9 to 13 years, 2.4 L

  - 14 to 18 years, 3.3 L
  - 19+ years, 3.7 L
- Females
  - 9 to 13 years, 2.1 L
  - 14 to 18 years, 2.3 L
  - 19+ years, 2.7 L
  - During pregnancy, 3.0 L
  - During lactation, 3.8 L

Hydration for Athletes and Laborers

The National Athletic Trainers' Association has published guidelines for athletic hydration. Here are some highlights of their recommendations that apply equally to "weekend warriors" and those involved in heavy physical labor[13]:

- Establish hydration protocols, accommodating sweat rate, rest breaks, fluid access, environmental factors, acclimatization state, exercise duration and intensity, and personal preferences.
- Make fluid-replacement beverages easily accessible in individual containers to permit easier monitoring of fluid intake.
- Ensure that athletic activity begins in a well-hydrated state. Preexercise hydration entails consuming 500 to 600 mL (17–20 fl oz) of water 2 to 3 hours before exercise and 200 to 300 mL (7–10 fl oz) of water 10 to 20 minutes before exercise.
- Replace fluids sufficiently to meet sweat and urine losses and maintain hydration by preventing at less than 2% body weight reduction. This need requires 200 to 300 mL (7–10 fl oz) every 10 to 20 minutes.
- Hydrate postexercise to correct any fluid loss, ideally within 2 hours after exercise. When rehydration must be rapid, compensate for urine losses during rehydration by drinking 25% to 50% more than sweat losses to assure optimal rehydration 4 to 6 hours after exercise.
- Be alert for signs and symptoms of dehydration—thirst, irritability, general discomfort, followed by headache, weakness, dizziness, cramps, chills, vomiting, nausea, head or neck heat sensations, and decreased performance.

In 2017 this position statement was updated, with a number of changes that recognize the danger of both hypohydration as well as hyperhydration, and that encourage all athletes to develop individualized plans to accommodate unique differences in "sweat rate, environment, acclimatization state, body size, exercise duration, exercise intensity, and individual fluid preferences and tolerance."[14]

PURE WATER VERSUS OTHER BEVERAGES

By definition, *osmosis* is the diffusion of water molecules from a place of relatively high concentration across a semipermeable membrane to a place of relatively low concentration. The amount of pressure that must be applied against this osmotic movement of water is called *osmotic pressure*. It is a measure of how vigorously water is attempting to cross the membrane. The differences in water concentration across membranes define the "water concentration gradient" across that membrane. Thus the osmotic pressure is proportional to the concentration gradient. The higher the water concentration on one side of the membrane relative to the other side, the higher the osmotic pressure and the greater the vigor of movement of water molecules across the membrane. Any solutes dissolved in water outside the membrane decrease the water concentration gradient across the membrane and the vigor of water movement. If the concentration of solutes in the water outside the cell is less than the concentration of solutes within the cell, the concentration of water molecules will be greater outside the cell than within it. Therefore water molecules will move by osmosis down their concentration gradient from the exterior to the interior and the cell will be hydrated.[15]

Conversely, if the concentration of solutes is higher in the exterior than the interior, water molecules are in higher concentration within the cell. Therefore water molecules will move down their concentration gradient from the interior to the exterior; thus the cell becomes dehydrated.

Obviously, the beverage that has the least amount of solutes and therefore the highest osmotic drive to hydrate the body down to the cellular level is pure water. If anything is dissolved in water (coffee, tea, sugar, flavorings, colors, protein, etc.), osmosis is reduced. Body and cell hydration are therefore inhibited by the consumption of beverages containing solutes. Thus the basic principles of physiology indicate that pure water is the beverage of choice for optimal hydration of the body.[16] Exceptions to this may be made for athletes participating in events lasting longer than 1 hour (e.g., marathon runners) or those with high sodium sweat concentrations (>60 mEq/L), which may benefit from replacement sodium only, not beyond the amount lost.[17]

WATER TEMPERATURE

According to the principles of traditional Chinese medicine, the consumption of cold food and drink is a bane of optimal health and wellness among Western people. The interior temperature of the body is higher than oral, axillary, or rectal temperature. For example, the interior temperature of the stomach is about 102°F and that of the heart is approximately 106°F. These warm temperatures are appropriate for the optimal physiological functions and biochemical processes that sustain life. The ingestion of large amounts of cold food and beverages tends to inhibit these processes. Interestingly, cool water inhibits subfornical organ thirst neurons more effectively than warm, possibly because of a learned association between cooling of the oropharynx and water consumption.

For this reason, it is prudent to ensure that water consumed is at room temperature or warmer.

SPECIAL NEEDS

Particular care must be taken to adequately hydrate people who, because of special circumstances, may need an even greater intake of water than recommended earlier. These persons include the following:

- Infants fed high-protein formulas (with caution not to overhydrate infants)
- Persons eating high-protein diets
- Patients suffering from disorders whose symptoms include fever, vomiting, diarrhea, respiratory discharges, and other types of water loss
- Patients taking diuretics
- People living in environments with high atmospheric temperatures

PHYSIOLOGY OF WATER METABOLISM

Oxygen Transport

In the alveoli and in tissue capillaries and connective tissue, water is the medium in which gas exchange occurs. Without the ready solubility of oxygen and carbon dioxide in water, gas exchange in living systems would not be possible. Oxygen diffuses from atmospheric air into the water of alveolar tissues and plasma before it associates with hemoglobin in red blood cells. After being carried to peripheral tissue capillaries, oxygen dissociates from hemoglobin into the water of plasma and connective tissue. Water carries oxygen into the cell through membrane aquaporins.[18,19]

Role of Water in Protein Structure and Function

The function of a protein is determined by its form—its three-dimensional shape. The unique sequence of amino acids, coded by DNA, determines the shape or form of a protein. That sequence is determined by the sequence of the coding genes on chromosomal DNA that initiate the synthesis of that protein.[20]

Water molecules provide the environment that not only allows proteins to function but also supports their endeavors in unrecognized ways. To fulfill their respective missions, the amino acid strands of proteins must bend, twist, and contort their primary linear structure into secondary, tertiary, and quaternary forms. The hydrophobic and hydrophilic interactions between water and amino acid strands drive the conformational changes needed for proteins to realize their ultimate functional shapes. The final shape of a protein is determined by the manner in which water and amino acid strands are bonded to each other. As a lubricating agent, water facilitates the breaking and reestablishing of hydrogen bonds and other links between the various parts of protein. Once the appropriate bonding is in place, water molecules are critical to the continued integrity and stability of protein structure.[21] It can therefore be suggested that the DNA genetic code is arranged in a fashion that specifically anticipates the conformational interaction of water molecules required to finish protein-generating tasks.[22,23]

Cell Hydration and Cell Behavior

Because of the lack of routine techniques for measuring cell hydration and volume in patients, naturopaths and conventional practitioners alike often fail to consider cell hydration state during clinical assessment. This is an unfortunate oversight because of the effect of cell hydration state on the behavior of cells.

There is evidence that cell hydration state is an important determinant of protein and RNA turnover—anabolism and catabolism. It appears that hormones and amino acids modify protein turnover, partly by altering the cell hydration state, which alters cell volume. Changes in cell volume can serve as signals mediating hormone and amino acid effects, which control protein turnover. Increases in cell volume (swelling) inhibit protein catabolism and RNA degradation while stimulating the synthesis of protein, DNA, and RNA. Loss of cell volume (shrinkage) has the opposite effect on RNA, DNA, and protein. Consequently, cell swelling stimulates anabolic proliferative metabolism, whereas cell shrinkage has a catabolic and antiproliferative influence.[24,25]

In view of the protein catabolism that arises in disease states, researchers have proposed that cell shrinkage or loss of cellular volume caused by a loss of intracellular water volume, as is often seen in skeletal muscle and liver tissue, may be a common endpoint triggering protein catabolism in a variety of disease states.

CLINICAL APPLICATIONS

Hydration and the Elderly

Dehydration is one of the most common causes of hospitalization among persons over the age of 65. It has been estimated that one half of those admitted for clinical dehydration die within a year of admission.

There are many factors leading to clinical and subclinical dehydration among seniors:

- Lower body water percentage
- Lack of awareness of hydration needs
- Lack of mental clarity and attentiveness to personal needs
- Illnesses that accelerate water loss by inducing vomiting, fever, and/or diarrhea
- Decline of thirst sensation with age
- Higher likelihood of multiple medication usage, including diuretics, which increase fluid loss, and or sedating medications, which reduce the desire for fluid intake[26]

Gradual total body dehydration is a hallmark of the aging process, and occurs in 20% to 30% of older adults.[27] In addition, the preponderance of body water shifts gradually with age from cell interiors to the exterior connective tissue, and a decline in fat-free mass and muscle reduce the fluid reserve from these tissues. Kidney function also declines, limiting the ability to concentrate urine and retain fluid. Even death itself is frequently linked to dehydration. Long-term chronic disease eventually wears the body down to the point where patients can no longer ingest water and food, ultimately succumbing to dehydration.

To make matters worse, our sense of thirst declines with age, though the reaction to thirst does not. Researchers have concluded that after water deprivation, "there is a deficit in thirst and water intake in healthy elderly men, compared with younger men." This is true despite the fact that the antidiuretic hormone response is maintained.[28]

Chronic "subclinical" dehydration (or "hypohydration") contributes to the aging process. In its struggle for survival, the body shifts precious resources away from processes that increase longevity toward those needed for short-term survival.

Winter Hydration

The human body loses water in many ways during winter. Some are obvious; others are not:

- Exercising in cold weather mutes the experience of sweating in many people, deceiving them into thinking that their bodies are not losing much water.
- Cold air cannot hold as much moisture as warm air. Therefore winter air is drier than summer air. The drier air draws more water from the lungs as we breathe, so we exhale more moisture during winter months.
- Interior environments are usually very dry in the winter because of the use of dehumidifying heating methods. The decreased interior humidity increases water loss from the lungs and skin.
- When the body gets chilled, blood is shifted away from the periphery toward the interior organs to preserve vital heat. The shunting of blood to the interior increases renal arterial flow, glomerular filtration rate, and urine output. This effect is called cold diuresis.
- Cold weather increases body metabolism and the associated water needs required to maintain healthy body temperature.
- Respiratory illnesses of winter cause the body to generate large amounts of mucus to dispose of pathogens. The water in these discharges must be replaced.
- Intestinal influenza, with diarrhea and vomiting, requires additional water and perhaps electrolyte replacement.

Dehydration and Jet Lag

The cabin atmospheric pressure of modern passenger jets is equivalent to that found on land at an elevation of 8000 ft above sea level. Although the relative humidity of the Sahara Desert is typically 20% to 25%, the humidity of jet cabin air can be as dry as 1% to 10%. For these reasons, dehydration is a major factor in the experience of jet lag. People should keep thoroughly hydrated with pure water and avoid the other beverages offered by flight attendants. It is prudent to drink at least 8 ounces of pure water per hour.

Effect of Hydration State on Blood Flow

Whole-blood viscosity has been identified as an independent risk factor for atherosclerosis and cardiovascular events. The most dangerous time of day for heart attack is the last period of sleep and the first few hours in the morning after awakening. A number of factors may play

a role in this trend; hydration state may be one of them. Overnight fasting from fluid intake increases blood viscosity and adversely affects blood flow (rheology) to major organs. Consumption of 200 mL of water under these circumstances helps normalize blood flow to major organs.[29]

Cognitive-Motor Function and Hydration State

In young adults, neither cognitive-motor function nor neurophysiological function differs between people under water deprivation and controls. On the other hand, subjective ratings of mental performance during water deprivation point to increased fatigue as well as impaired alertness and the concentration needed to complete tasks. Healthy people tend to employ compensating mechanisms for increased fatigue and reduced alertness. Test of reaction time reveal significant gender differences in the response to dehydration. Water deprivation induces a prolonged reaction time in women but a shortened one in men.[30]

Multiple-Organ-System Effects of Chronic Subclinical Dehydration

The insidious effects of chronic hypohydration are wide ranging and staggering. Consider the following effects:

- Disintegration of cellular structure
- Impaired flow of nutrients into the cell as a result of compromised membrane protein channels and insufficient carrier solvent (water)
- Local tissue resistance to endocrine hormones caused by faulty integrity and responsiveness of membrane receptors
- Chronic fatigue resulting from lack of enzyme-catalyzed energy production[31]
- Free radical damage to cell structures, including DNA, as a result of reduced enzymatic free radical scavenging
- Inadequate repair of nuclear DNA damage resulting from faulty enzyme repair activity
- Reduced production of key bioactive compounds, such as hormones, digestive enzymes, neurotransmitters, etc.
- Accumulation of toxins within cells
- Increased synthesis of histamine within the central nervous system[32]
- Chronically elevated levels of antidiuretic hormone (vasopressin)
- Chronically elevated levels of cortisol, with adverse effects on bone integrity, muscle mass, connective tissue, blood pressure, and immunity[2]
- Development of chronic kidney disease, exacerbated by increased vasopressin release, cortical aldose reductase activation (which leads to uric acid production and oxidative stress), and hyperuricemia[33]

Subclinical Dehydration (Hypohydration): The Missing Diagnosis

Water cures nothing except dehydration. However, once dehydration has been corrected at the cellular level, healing is possible. This is because hypohydration at the cellular level is a major contributing factor to many ailments. Based on years of research with inmates of an Iranian prison, Dr. Fereydoon Batmanghelidj has proposed a new paradigm of disease and healing. It states that the suffering associated with many disorders is triggered or worsened by dehydration.

The reason for this effect is that, under the stress of dehydration, the body takes desperate measures to conserve water. Part of this effort involves the synthesis and release of histamine. It appears that histamine release activates other systems designed to save body water. Antidiuretic hormone decreases water loss in urine. Histamine and kinin compounds influence the escape of water from capillaries into connective tissue. Decreasing blood water content decreases blood volume and increases plasma sodium concentration, activating the renin-angiotensin system and vasopressin to elevate blood pressure.[4,5,34]

A key concept of Dr. Batmanghelidj's new paradigm is based on his years of clinical observation and practice with only the simplest crude healing tools at his disposal. He writes, "Chronic cellular dehydration painfully and prematurely kills. Its initial outward manifestations have until now been labeled as diseases of unknown origin."

Recurrent noninfectious conditions associated with pain and discomfort in various parts of the body, which cannot be explained by other identifiable causes, can be interpreted as expressions of water deficits at the sites of the tissue manifesting symptoms.[4,35]

COMMON CONDITIONS IMPROVED BY WATER

On the basis of empirical experience, the scope of application of water as a therapeutic tool is immense. The only caveat is that kidney filtration must be intact and healthy to allow the excretion of water and accompanying toxins. Additionally, given the vast number of pollutants found in most water sources, an effort to provide pure water must be made.[36,37] The following is a list of disorders in which water therapy is indicated:

- Coronary heart disease
- Peptic ulcers
- Arthritis
- Hypertension
- Low back pain
- Intermittent claudication
- Fibromyalgia
- Migraine headache
- Hangover headache
- Constipation
- Colitis
- Obesity
- Edema of unknown origin
- Chronic fatigue syndrome

A few of these are considered in more detail later.

Coronary Heart Disease and Fatal Myocardial Infarction

It has been known for some time that high blood and plasma viscosity, high hematocrit, and high blood concentrations of fibrinogen are correlated with coronary heart disease and atherosclerosis. Remarkably, even high "normal" levels of these parameters are considered independent risk factors.[21,31,34,35,38–43] These factors have also been linked to intermittent claudication.[41] High hematocrit has been associated with tachycardia, the magnitude of heart tissue damage from myocardial infarction, reduced oxygen transport, and reduced blood supply to heart tissue.

Based on this evidence, researchers at the Heart Institute of Loma Linda University analyzed lifestyle data to determine what influence the consumption of pure water and other beverages would have on the risk of fatal heart attack.

Compared with those who drank two or fewer glasses of pure water daily, men who drank five or more had only 46% of the risk of having a fatal heart attack and women had only 59% of the risk. Even more remarkable, compared with those who drank two or fewer glasses of fluids other than pure water (e.g., tea, soft drink, juice, etc.), women who drank five or more had 147% greater risk and men had 46% greater risk. Moreover, these relative risk relationships held regardless of adjustments for any other factors. In essence, the consumption of pure water decreases the risk of fatal heart attack; consumption of other beverages increases the risk.[32]

According to the researchers, failing to drink enough water can be as harmful to heart health as smoking. Just by increasing pure water intake, one can reduce the risk of death from heart attack by one half. This amount of benefit is greater than that gained by ceasing smoking, reducing cholesterol, exercising, or maintaining ideal body weight. Thus increasing one's intake of pure water could be the cheapest and simplest imaginable method of reducing fatal heart attack risk.

Peptic Ulcers and Dyspepsia

These conditions were the first that brought hidden, subclinical dehydration to the attention of Dr. Batmanghelidj in the Iranian prison. Thousands of cases successfully treated with water therapy lend credence to this modality. Chronic inflammation of the stomach and duodenum, with heartburn and acid reflux, are prime indications for water intervention. The concept here is not farfetched when the function of the intestinal organs is understood. The gastrointestinal mucous membranes must produce sufficient mucus to protect themselves from damage from digestive acid and enzymes. All of these secretions are water-based. Hypohydration inhibits both digestion and membrane protection. In addition, water deficits reduce the volume of bicarbonate-containing fluids released from the pancreas. This deficit results in a failure to properly neutralize stomach acid, leading to duodenal ulcers.[44]

Asthma and Allergies

Histamine is a prime mediator of allergy and asthma. It is generated in the central nervous system when the body is dehydrated. It is also released by mast cells located on the mucous membranes of the respiratory and gastrointestinal tracts. Histamine works with the immune system, facilitating the movement of white blood cells to sites of microbial invasion.

Of particular note is the new scientific light being shed on exercise-induced asthma. Studies indicate that dehydration during exercise can increase the intensity of asthma symptoms in persons subject to asthmatic attacks. Dehydration can increase spasms of the bronchial smooth muscle because of overly dry airway membranes. Dehydration of mucous membranes occurs before the asthmatic athlete even begins training. Dehydrated asthmatics begin exercise with reduced hydration capacity; therefore a pathological respiratory state occurs more rapidly. Researchers have concluded that, "Exercise induced asthma is an exaggerated airway response to airway dehydration." Airway narrowing from exercise in elite athletes and otherwise healthy subjects is now considered a physiological response to pathological changes in airway cells resulting from "dehydration injury."[45] These changes also occur in healthy subjects exercising intensely for long periods and breathing cold air, dry air, or both.[46]

To minimize the risk of asthmatic attacks during exercise, it is imperative for the athlete to be in a state of optimal hydration before training begins and for good hydration status to be maintained throughout the exercise and during recovery. Pure water can be a very dear friend to an asthmatic.

Migraine Headache

As with allergies and asthma, histamine is believed to be a contributing factor in migraine headache. (See Chapter 198, Migraine, for more complete discussion.) Hypohydration induces the central nervous system to increase its synthesis of histamine. Thus optimal hydration should minimize histamine synthesis as well as associated migraine headache. Additionally, hydration status may also affect other variables known to trigger migraines. For example, changes in physical exercise and weather may be related to water loss, and a drop in osmolality during the luteal phase of the menstrual cycle may have an effect.[47] Anecdotal clinical evidence is mounting in support of pure water as a helpful adjunct to other natural approaches.

Weight Loss

A higher water intake has been associated with more significant weight and body fat loss over time, independently of other variables.[48] Additionally, in a randomized controlled trial, water preloading before a meal was also associated with additional weight loss.[49] This is likely mediated via a reduced energy intake with the subsequent meal.[50]

Zingiber officinale (Ginger)

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

Zingiber officinale (family: *Zingiberaceae*)
Common name: ginger

GENERAL DESCRIPTION

Ginger is an erect perennial herb with thick tuberous rhizomes (underground stems) from which the aerial stem grows to a height of 2 to 4 ft. Grasslike alternate leaves 6 to 12 in. long and 0.75 in. wide shoot off from the aerial stem. Wild ginger produces a beautiful flower, but cultivated ginger rarely flowers.

Although ginger is native to southern Asia, it is now extensively cultivated throughout the tropics (e.g., India, China, Jamaica, Haiti, and Nigeria). Jamaica is the major producer, with exports to all parts of the world amounting to more than 2 million pounds annually.

The knotted and branched rhizome, commonly called the root, is the portion of ginger used for culinary and medicinal purposes (Fig. 130.1A and B). Extracts and the oleoresin are produced from dried unpeeled ginger because peeled ginger loses much of its essential oil content.[1,2] Ginger oil is produced from the fresh ginger via steam distillation.

CHEMICAL COMPOSITION

The following compounds have been isolated from ginger[1,2]:

- Starch (up to 50%)
- Protein (about 9%)
- Lipids (6%–8%) composed of triglycerides, phosphatidic acid, lecithins, and free fatty acids
- A protease (2%)
- Volatile oils (1%–3%), the principal components of which are sesquiterpenes (bisabolene, zingiberene, and zingiberol) and various "pungent" principles, aromatic ketones, known collectively as gingerols vitamins (especially niacin and vitamin A)
- Resins

The pungent principles are thought to be the most pharmacologically active components of ginger. Gingerol and its derivatives can be found in concentrations as high as 33% in ginger oleoresin (Fig. 130.2). The fresh oleoresin will have a higher percentage of the more pungent gingerol because gingerol can be dehydrated during storage to form shogaol or have its fatty-acid moiety cleaved to form zingerone (Figs. 130.3 and 130.4). The oleoresin is made by extracting the oily and resinous materials with the aid of a solvent (alcohol, hexane, or acetone). Pharmacokinetic studies in humans show that the major pungent principles are absorbed after oral dosing and can be detected as glucuronide and sulfate conjugates in the blood.[3]

HISTORY AND FOLK USE

Ginger has been used for thousands of years in China for medicinal purposes. Chinese records dating from the 4th century BC indicate that it was used to treat the following conditions[1]:

- Stomachache
- Diarrhea
- Nausea
- Cholera
- Hemorrhage
- Rheumatism
- Toothache

It was used by eclectic physicians in the United States in the late 1800s as a carminative, diaphoretic, appetite stimulant, and local counterirritant.[4]

Ginger is widely used as a spice, especially in Asian and Indian cuisine. It is also used in many baked goods, beverages (ginger ale), candy, liqueurs, and cosmetic products (perfumes, soaps, creams, etc.).

PHARMACOLOGY

Ginger possesses numerous pharmacological properties; the following are the most relevant:

- Antioxidant effects
- Inhibition of prostaglandin, thromboxane, and leukotriene synthesis
- Inhibition of platelet aggregation
- Cholesterol-lowering actions
- Choleretic effects
- Cardiotonic effects
- Gastrointestinal actions
- Thermogenic properties
- Antibiotic activities

Antioxidant Effects

Ginger has shown antioxidant effects in experimental studies.[5] In a study in rats, ginger significantly lowered lipid peroxidation by maintaining the activities of the antioxidant enzymes superoxide dismutase, catalase, and glutathione peroxidase. The blood glutathione content was significantly increased in ginger-fed rats. To achieve a similar effect with vitamin C, the dosage required was 100 mg/kg body weight.[6]

Ginger's strong antioxidant properties have led to its being investigated for preventing the development of rancidity in meat products.[7] Ginger has been shown to prolong the shelf life of fresh, frozen, and precooked pork patties. Because the use of many synthetic antioxidants is prohibited by law, ginger may one day be used commercially to extend the shelf lives of meats and other foods.

Effects on Prostaglandin and Leukotriene Metabolism

Numerous constituents in ginger have been shown to be potent inhibitors of prostaglandin and leukotriene synthesis through blocking of the cyclooxygenase (COX) enzymes.[8–13] The most potent components appear to be the pungent principles, although the aqueous extract has also demonstrated inhibition. Inhibition of prostaglandin and leukotriene formation could explain some of ginger's historical use as an anti-inflammatory agent. However, ginger and its extracts also have strong antioxidant activities, and fresh ginger contains a protease with action that may be similar to that of other plant proteases (e.g., bromelain, ficin, papain) on inflammation.[1] Repeated ginger administration to mice augmented corticosteroid secretion, indicating that chronic ingestion may produce an anti-inflammatory effect via this mechanism as well.[14]

Effects on Platelets and Fibrinolysis

Ginger, like garlic and onions, is an inhibitor of platelet aggregation.[11] However, ginger's effects may be far more powerful. In a comparison, an aqueous extract of ginger was shown to exert greater inhibitory effects on platelet aggregation than aqueous garlic and onion extracts.[15] Ginger was shown to produce a greater inhibition of thromboxane formation and proaggregatory prostaglandins. Ginger, but not onion or garlic, also significantly reduced platelet lipid peroxide formation. In another model, gingerol compounds and their derivatives were more potent antiplatelet agents than aspirin.[11]

The superiority of ginger over onions was also demonstrated in a controlled study.[16] Female volunteers given either 70 g raw onion or 5 g raw ginger demonstrated that ginger has a pronounced effect in lowering platelet thromboxane production, whereas onion actually produced a mild elevation (pooled results).

In addition to acting on platelets, ginger promotes fibrinolysis. In one study, administration of 50 g of fat to 30 healthy adult volunteers decreased fibrinolytic activity from a mean of 64.20 to 52.10 U.[17] Supplementation of 5 g of ginger powder with the fatty meal not only prevented the drop in fibrinolytic activity but actually increased the activity significantly.

Cholesterol-Lowering and Hepatic Effects

Ginger has been shown to significantly reduce serum and hepatic cholesterol levels in cholesterol-fed rats by impairing cholesterol absorption as well as stimulating cholesterol-7-alpha-hydroxylase, the rate-limiting enzyme of bile acid synthesis.[18–20] In addition, ginger has been shown to increase bile secretion.[21] Therefore ginger works to lower cholesterol by promoting excretion and impairing absorption.

Cardiotonic and Hypotensive Properties

Gingerol has shown potent cardiotonic activity (positive inotropic and chronotropic effects) on isolated guinea pig left atria.[22,23] These effects are a result of the acceleration of calcium uptake by the sarcoplasmic reticulum. Gingerol was the first substance shown to produce these effects.

Individuals with heart problems or high blood pressure may benefit more from using fresh ginger rather than a dried preparation. This recommendation is based not only on the fact that gingerol is the more potent cardiotonic but also because animal studies demonstrate that shogaol has a blood pressure–elevating effect.[24] Gingerol is found predominantly in fresh ginger, whereas shogaol is rarely found in dried ginger.

Analgesic Effects

Ginger has demonstrated analgesic effects in experimental studies in animals.[25] This effect is thought to be a result of inhibition by shogaol of the release of substance P, much like that by capsaicin, the pungent principle of red pepper *(Capsicum frutescens)*.

Gastrointestinal Smooth Muscle Effects

Another aspect of ginger is its ability to simultaneously improve gastric motility and exert antispasmodic effects. This action is consistent with its use as a gastrointestinal tonic. A lipophilic ginger extract was shown in one study to enhance gastric motility, as evidenced by increased intestinal transport of a charcoal meal fed to rats,[26] and various fat-soluble components of ginger, such as galanolactone, demonstrated antagonism of serotonin receptor sites.[27] This latter mechanism may be responsible for ginger's antispasmodic effects on visceral and vascular smooth muscle.

In a human study, 1000 mg of dried ginger did not affect lower esophageal sphincter (LES) pressure at rest or esophageal contractile amplitude and duration when swallowing but caused more relaxation of the LES (after 90, 150, and 180 minutes, when swallowing) and decreased the esophageal contraction velocity, which may produce the expulsion of gastric gas or have an antiflatulent effect.[28] Ginger has also been shown to inhibit serotonin-induced diarrhea and exert antiemetic effects in experimental models.[29,30]

Via inhibition of prostaglandin production, ginger also prevents the slow-wave dysrhythmias produced by acute gastrointestinal hyperglycemia.[31]

Ginger accelerates gastric emptying and stimulates antral contractions in healthy volunteers.[32] Oral ginger extract was also shown to improve gastroduodenal motility in the fasting state and after a standard test meal in healthy human volunteers.[33]

Antiulcer Effects

Ginger has demonstrated significant antiulcer effects in a variety of animal models.[34–36] Ginger prevents ulcer formation from ethanol, indomethacin, aspirin, and other common ulcerogenic compounds. The pungent principles appear to be responsible for this effect. In one study, roasted ginger inhibited ulcer formation in three gastric ulcer models, but dry ginger had no such effect.[37]

A methanol extract of the dried powdered ginger rhizome, fractions of the extract, and the isolated constituents gingerol and shogaol were tested against 19 strains of *Helicobacter pylori*—a bacterium associated with peptic ulcers and gastric cancer. The methanol extract of ginger rhizome inhibited the growth of all 19 strains in vitro, with a minimum inhibitory concentration range of 6.25 to 50 mg/mL. One fraction of the crude extract, containing the gingerols, was active and inhibited the growth of all strains with a minimum inhibitory concentration range of 0.78 to 12.5 μg/mL.[38]

Thermogenic Properties

Ginger is noted for its ability to subjectively warm the body and has historically been used as a diaphoretic. In animal studies, ginger has been shown to help maintain body temperature and to inhibit serotonin-induced hypothermia.[29,39]

Crude extracts and the pungent components of ginger have been shown to increase oxygen consumption, perfusion pressure, and lactate production in the perfused rat hind limb.[40] These effects signify increased thermogenesis. Gingerol is the most potent thermogenic component of ginger. A human study demonstrated that consuming a ginger sauce (containing unspecified amounts of ginger principles) with a meal had no significant effect on metabolic rate.[41] However, there were two problems with this study: (1) the concentration of gingerol in the preparation used was probably low or zero, and (2) the effective concentration range of gingerol for its thermogenic effects is quite narrow.

Given ginger's historical use as a "warming" substance, these scientific investigations appear to support its use as a diaphoretic and thermogenic aid, although confirmation in humans is still lacking.

Antibiotic Activity

Ginger, shogaol, and zingerone have been shown to be strongly inhibitory against *Salmonella typhi, Vibrio cholerae,* and *Trichophyton violaceum,* whereas aqueous extracts at 2.5%, 5%, and 25% concentrations have been shown to be effective against *Trichomonas vaginalis.*[42] Ginger and its pungent principles were also demonstrated to possess significant antifungal activity against pathogenic yeast.[43]

Anticancer Effects

Ginger extracts and some pungent constituents present in ginger have exhibited antitumor activity in experimental models of carcinogenesis.[44] In 2018 a comprehensive review examined the literature pertaining to the use of ginger extract and [6]-gingerol against tumorigenic and oxidative and inflammatory processes associated with cancer, along with the underlying mechanisms of action involved in signaling pathways.[45] Data collected from in vitro or in vivo experiments and clinical studies indicate that ginger extract and [6]-gingerol exert their action through important mediators and pathways of cell signaling, including Bax/Bcl2, p38/MAPK, Nrf2, p65/nuclear factor (NF)-κB, tumor necrosis factor-α (TNF)-α, ERK ½, SAPK/JNK, ROS/NF-κB/COX-2,

caspase-3 and caspase-9, and p53. This suggests that ginger derivatives (extract or isolated compounds) exhibit relevant antiproliferative, antitumor, invasive, and anti-inflammatory activities.

Effects on Insulin and Blood Glucose

Patients with type 2 diabetes mellitus (T2DM) or metabolic syndrome (MetS) share common characteristics of raised blood sugar, decreased insulin sensitivity, obesity, dyslipidemia, and hypertension, which often appear simultaneously rather than alone. Ginger has been documented to ameliorate hyperlipidemia, hyperglycemia, oxidative stress, and inflammation and may therefore be a promising therapy for T2DM and MetS mediated by transcription factors, such as peroxisome proliferator-activated receptors, adenosine monophosphate-activated protein kinase, and NF-κB.[46] Additional proposed mechanisms of ginger include the inhibition of hepatic phosphorylase preventing glycogenolysis in hepatic cells, inhibition of hepatic glucose-6-phosphatase activity, and increasing glucose transporter type 4 (GLUT-4) to promote glucose uptake in adipocytes and skeletal muscle cells.

A thorough review and meta-analysis of randomized controlled trials revealed that ginger significantly reduces fasting blood glucose and HbA_{1c}, significantly improves fasting insulin and Homeostatic Model Assessment of Insulin Resistance (HOMA-IR), and ameliorates most of the MetS risk factors.[47] As an example, one randomized, double-blind, placebo-controlled trial of 88 patients with T2DM investigated the effect of ginger supplementation on insulin resistance and glycemic indices.[48] The cohort was randomly assigned to ginger or placebo groups. The ginger group consumed three 1-g capsules containing ginger powder daily, whereas the placebo group received capsules of the same color and number but containing cellulose microcrystalline. After 8 weeks, fasting blood sugar mean showed a decrease of 10.5% in the ginger group, whereas the mean had an increase of 21% in the placebo group. Variations in HbA_{1c} mean correlated with that of fasting blood sugar. A statistical difference was also found before and after the intervention in the median of fasting insulin level, insulin sensitivity, and HOMA-IR.

Two additional randomized, double-blind, placebo-controlled trials evaluated the effects of ginger on glycemic indices in patients with T2DM. The first study involved 64 patients with T2DM randomly assigned to either ginger (2 g/day) or placebo (2 g/day) groups.[49] After 2 months of intervention, ginger supplementation significantly lowered the levels of insulin, low-density lipoprotein (LDL) cholesterol, triglycerides, and the HOMA-IR. However, no significant changes were observed in fasting blood glucose, total cholesterol, high-density lipoprotein (HDL), and HbA_{1c}. In the second study, 20- to 60-year-old patients with T2DM who did not receive insulin were given 3 g of powdered ginger (intervention group) or 3 g of lactose (placebo group) daily for 3 months.[50] In addition to glycemic indices, the researchers also examined the effects of ginger on total antioxidant capacity (TAC), malondialdehyde (MDA), C-reactive protein (CRP), and serum paraoxonase (PON-1). At the end of the study, compared with placebo, the intervention (ginger) group had statistically significant reductions in serum glucose, HbA_{1c} percentage, insulin, insulin resistance, high-sensitive CRP, and MDA as well as statistically increased TAC and PON-1 activity. Although promising, further high-quality studies with larger sample sizes and longer duration of treatment are needed to examine these findings and evaluate discrepancies.

CLINICAL APPLICATIONS

Ginger is widely used as a condiment for its unique flavors, but from the previously described pharmacology, it obviously has important medicinal effects as well. In general, like many other culinary herbs and spices, such as garlic and onions, ginger provides many health-promoting effects. Specifically, ginger provides benefit to many body systems, including the digestive, hepatobiliary, and cardiovascular systems.

Historically, the majority of complaints for which ginger was used concerned the gastrointestinal system. A clue to ginger's efficacy in alleviating gastrointestinal distress is offered in several double-blind studies on motion sickness, hyperemesis gravidum, and postoperative nausea and vomiting. Human studies have also shown a positive effect in arthritis and migraine headaches.

Motion Sickness

Ginger was first shown to be effective in treating motion sickness by Mowrey and Clayson in 1982.[51] In their study, ginger (940 mg) was shown to be far superior to dimenhydrinate (Dramamine) 100 mg in relieving symptoms of nausea and vomiting. Since this initial study, several better-designed follow-up studies have evaluated the effectiveness of ginger as a motion sickness medication.

The appearance of motion sickness trials using ginger prompted an interest in ginger by the National Aeronautics and Space Administration, which subsequently funded a study at Louisiana State University. This study compared ginger, both fresh and dried powdered, with scopolamine by measuring the number of head movements experimental subjects could make in a rotating chair until they reached an end point defined as motion sickness short of vomiting. Ginger was not shown to produce any protection against motion sickness in this model or in two additional protocols (vestibular stimulation only and combined vestibular-visual stimulation).[52] However, in a double-blind trial, perhaps a more "real-life" test, ginger (1 g) given to naval cadets unaccustomed to sailing in heavy seas was shown to reduce the tendency toward vomiting and cold sweating in comparison with a placebo.[53]

Mowrey and Clayson[51] proposed that the anti–motion sickness effects of ginger were due to local gastrointestinal tract effects rather than to central nervous system effects. Although ginger's mechanism of action in alleviating gastrointestinal distress has yet to be fully elucidated, there is evidence to support this hypothesis. Ginger has been shown to partially inhibit the excessive gastric motility characteristic of motion sickness.[52] To further support a gastric versus a central nervous system mechanism of action, one study clearly demonstrated that neither the vestibular system nor the oculomotor system, both of which are critical in the occurrence of motion sickness, was influenced by ginger (1 g).[54] However, in a double-blind, crossover, placebo-controlled study, ginger (1 g) was shown to significantly reduce induced vertigo but not nystagmus.[55]

It has been hypothesized by others that ginger ameliorates the nausea associated with motion sickness by preventing the development of gastric dysrhythmias and the elevation of plasma vasopressin. To test this hypothesis, 13 volunteers with a history of motion sickness underwent circular vection, during which nausea (scored 0–3, i.e., none to severe), electrogastrographic recordings, and plasma vasopressin levels were assessed with or without ginger pretreatment in a crossover, double-blind, randomized, placebo-controlled study.[56] Circular vection induced a maximal nausea score of 2.5 and increased tachygastric activity and plasma vasopressin. Pretreatment with ginger (1000 and 2000 mg) effectively reduced nausea, tachygastric activity, and vasopressin release induced by circular vection.

The overall effectiveness of ginger in motion sickness has yet to be definitively determined. Issues that the studies have raised include the variability in the quality of commercial ginger preparations and the time required for ginger to produce its effects. Commercial preparations vary widely in chemical composition and often contain adulterants, and in the ginger study conducted at sea, ginger reduced

symptoms of cold sweating and vomiting only at the end of 4 hours. In other words, it appears that ginger may prove to be more effective when well-defined preparations are given at least 4 hours before motion is experienced.

Nausea and Vomiting

The mechanisms of action underlying ginger's efficiency in reducing nausea and vomiting have been investigated, and dual antiemetic actions have been highlighted: (1) gingerols and shogaols act as antagonists of cholinergic M3 and serotonin 5-HT3 receptors of the central nervous system; and (2) ginger's constituents improve the gastric tonus, motility, and emptying due to peripheral anticholinergic and antiserotonergic actions.[57] Ginger's antiemetic action has been studied in hyperemesis gravidum, the most severe form of pregnancy-related nausea and vomiting. This condition usually requires hospitalization. In a double-blind, randomized, crossover trial, ginger root powder at a dose of 250 mg four times a day brought about a significant reduction in both the severity of the nausea and the number of attacks of vomiting in 19 of 27 patients in the early stages of pregnancy (<20 weeks).[58]

Another natural approach to nausea and vomiting of pregnancy is vitamin B_6. In one double-blind study, 138 women were given either 500 mg of ginger or 10 mg of vitamin B_6 three times daily for 3 days.[59] Subjects graded the severity of their nausea using visual analog scales before treatment and recorded the number of vomiting episodes in the previous 24 hours and again during 3 consecutive days of treatment. The ginger and vitamin B_6 significantly reduced the nausea scores from 5 to 3.6 and 5.3 to 3.3, respectively, and the number of vomiting episodes from 1.9 to 1.2 and 1.7 to 1.2, respectively. There was no significant difference between ginger and vitamin B_6 for the treatment of nausea and vomiting during pregnancy. However, in another study, ginger was shown to be more effective.[60] In that study, 70 women were randomized to receive either ginger 1 g/day or vitamin B_6 40 mg/day for 4 days. Subjects graded the severity of their nausea using a visual analog scale and recorded the number of vomiting episodes in the 24 hours before treatment and during 4 consecutive days while taking treatment. Compared with baseline, the decrease in scores of posttherapy nausea in the ginger group was significantly greater than that for the vitamin B_6 group. In the ginger group, 29 of 35 women reported an improvement in nausea symptoms compared with 23 of 34 women in the vitamin B_6 group. These results indicate that ginger is more effective than vitamin B_6 for relieving the severity of nausea and is equally effective for decreasing the number of vomiting episodes in early pregnancy.

In a placebo-controlled study, 70 women with nausea and vomiting of pregnancy were randomly assigned to receive either oral ginger 1 g/day or an identical placebo for 4 days.[61] Subjects graded the severity of their nausea using visual analog scales and recorded the number of vomiting episodes in the 24 hours before treatment and again during 4 consecutive days during treatment. At a follow-up visit 7 days later, the number of vomiting episodes had decreased significantly in the ginger group; 28 of 32 in the ginger group had an improvement in nausea symptoms, compared with 10 of 35 in the placebo group.

In a double-blind study comparing ginger with dimenhydrinate, 170 pregnant women with the symptoms of nausea and vomiting in pregnancy were randomly allocated to take one capsule of ginger twice daily (one capsule contained 0.5 g of ginger powder), whereas the patients in group B received an identical capsule of 50 mg dimenhydrinate twice daily.[62] The results showed that ginger is as effective as dimenhydrinate in the treatment of nausea and vomiting during pregnancy and has fewer side effects. Specifically, there was a statistically significant difference in the side effect of drowsiness after treatment in diphenhydramine group compared with the ginger group (78% vs. 6%, respectively).

These clinical results and those reported by others,[63–67] along with the safety and the relatively small dose of ginger required and the problems (e.g., teratogenicity) with antiemetic drugs in pregnancy, support the use of ginger for nausea and vomiting in pregnancy. This recommendation is becoming a well-accepted prescription even in orthodox obstetrical practices.

Ginger appears to be very safe for use during pregnancy. A systematic review evaluating the efficacy and safety of ginger for nausea and vomiting of pregnancy did not identify any major toxicities from in vivo studies, and after observations of clinical studies, the use of ginger showed a significant decrease in nausea and vomiting and no risk for the mother or her future baby.[68]

The antiemetic action of ginger has also been observed in women who had undergone major gynecological surgery. In four double-blind studies, 1000 to 1500 mg of dried powdered ginger root per day was shown to significantly reduce the incidence of nausea compared with placebo in a manner similar to the drug metoclopramide.[69–72]

Ginger also has shown good results in alleviating chemotherapy-induced nausea and vomiting. In one study, 60 chemotherapy cycles of cisplatin/doxorubicin in patients with bone sarcoma were randomized to ginger root powder capsules or placebo capsules as an additional antiemetic to ondansetron and dexamethasone in a double-blind design.[73] Acute moderate to severe nausea was observed in 28 of 30 (93.3%) cycles in the control group compared with 15 of 27 (55.6%) cycles in the ginger group. In a study in women receiving cisplatin for gynecological cancers, the addition of ginger to a standard antiemetic regimen had no advantage in reducing nausea or vomiting in the acute phase of cisplatin-induced emesis.[74] However, after the initial 24 hours after cisplatin, ginger was shown to be equal to metoclopramide. In still another study, ginger provided no additional benefit in reducing the prevalence or severity of acute or delayed chemotherapy-induced nausea and vomiting when given with 5-HT3 receptor antagonists and/or aprepitant (Emend).[75]

Inflammatory Conditions

Ginger's ability to inhibit the formation of inflammatory prostaglandins, thromboxanes, and leukotrienes and its strong antioxidant activities and protease component suggest a possible benefit in inflammatory conditions. To test this hypothesis, a preliminary clinical study was conducted in seven patients with rheumatoid arthritis, in whom conventional drugs had provided only temporary or partial relief.[76] One patient took 50 g/day of lightly cooked ginger, and the other six took either 5 g of fresh or 0.1 to 1 g of powdered ginger daily. All patients reported substantial improvement, including relief of pain, greater joint mobility, and decreased swelling and morning stiffness.

In the follow-up to this study, 28 patients with rheumatoid arthritis, 18 with osteoarthritis, and 10 with muscular discomfort who had been taking powdered ginger for periods ranging from 3 months to 2.5 years were evaluated. On the basis of their clinical observations, Srivastava and Mustafa[77] reported that 75% of the patients with arthritis and 100% of the patients with muscular discomfort experienced relief in pain or swelling. The recommended dosage was 500 to 1000 mg/day, but many patients took three to four times this amount. Patients taking the higher dosages also reported quicker and better relief.

Three double-blind studies with standardized and highly concentrated extracts of ginger provide additional support for the usefulness of ginger in osteoarthritis, although in one study ginger was effective only after 3 months of use.[78–80] In the largest of the three studies, 261 patients with osteoarthritis of the knee were given either ginger extract or placebo twice daily, with acetaminophen allowed as rescue medication.[79] The primary efficacy variable was the proportion of responders experiencing a reduction in "knee pain on standing," with the use of an intent-to-treat

analysis. The percentage of responders experiencing a reduction in knee pain on standing was superior in the ginger extract group to that in the control group (63% vs. 50%). Analysis of the secondary efficacy variables revealed a consistently greater response in the ginger extract group compared with the control group in the following mean values: reduction in knee pain on standing (24.5 vs. 16.4 mm), reduction in knee pain after walking 50 ft (15.1 vs. 8.7 mm), and reduction in the Western Ontario and McMaster Universities' Osteoarthritis Composite Index (12.9 vs. 9 mm). Change in global status and reduction in intake of rescue medication were also numerically greater in the ginger extract group.

The effect of ginger on proinflammatory cytokines in patients with osteoarthritis was examined in a randomized, double-blind, placebo-controlled, 3-month clinical trial.[81] 120 participants were assigned to one of two groups: the ginger group (500 mg ginger powder) or the placebo group (500 mg starch). Although proinflammatory cytokine levels did not differ by group at baseline, at the end of the trial, serum levels of tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) decreased in the ginger group relative to placebo.

One evaluation looking at ginger's ability to reduce muscle pain consisted of two identical double-blind, placebo-controlled randomized studies with participants consuming either 2 g of raw (study 1) or heated (study 2) ginger or placebo for 11 consecutive days.[82] Participants performed 18 eccentric actions of the elbow flexors to induce pain and inflammation. Pain intensity, perceived effort, plasma prostaglandin E(2), arm volume, range of motion, and isometric strength were assessed before and for 3 days after exercise. Raw and heat-treated ginger resulted in similar pain reductions 24 hours after eccentric exercise compared with placebo (25% and 23% reduction, respectively). In another study, a single 2-g dose of ginger did not attenuate eccentric exercise-induced muscle pain, inflammation, or dysfunction 45 minutes after ingestion, indicating that ginger's effects are likely more cumulative in reducing the day-to-day progression of muscle pain.[83]

It has also been reported that ginger is beneficial in migraine headache.[84] A double-blind, placebo-controlled, randomized clinical trial evaluated the potential of ginger to improve acute migraine as an add-on strategy to standard treatment.[85] Sixty participants were randomized into two groups in which they received 400 mg of ginger extract (5% active ingredient) or placebo (cellulose), in addition to an intravenous drug (100 mg of ketoprofen) to treat the migraine attack. Patients treated with ginger showed a significantly better clinical response after 1 hour, 1.5 hours, and 2 hours. Furthermore, ginger treatment promoted a reduction in pain and improvement in functional status at all times assessed. Given ginger's effects on platelets, eicosanoids, and serotonin inhibition, this recommendation makes sense.

DOSAGE

Many questions remain concerning the best form of ginger and the proper dosage. Most research studies have used 1 g of dried powdered ginger root. Practically speaking, this is a small dose. For example, ginger is commonly consumed in India at a daily dose of 8 to 10 g. Furthermore, although most studies have used powdered ginger root, fresh (or possibly freeze-dried) ginger root or extracts (concentrated for gingerol) at an equivalent dosage may yield even better results because they may deliver higher levels of gingerol as well as the active protease.

In the treatment of nausea and vomiting due to motion sickness or pregnancy or after surgery, a dosage of 1 to 2 g of dried powdered ginger may be effective. This would be equivalent to approximately 10 g or 1/3 oz of fresh ginger root, roughly a ¼-in. slice. For inflammatory conditions like rheumatoid arthritis, the dosage should be double this amount.

For ginger extracts standardized to contain 20% gingerol and shogaol, an equivalent dosage in treating motion sickness or nausea and vomiting would be 100 to 200 mg. For other applications, the dosage is 100 to 200 mg three times daily.

TOXICOLOGY

Ginger does not appear to produce any toxicity problems when used at normal dosages. Although ginger extracts and several components in ginger have been shown to possess potent mutagenic activity, ginger also contains several equally potent antimutagenic substances.[86,87] The significance of this mutagenicity (the study was conducted in *Escherichia coli* and did not use the Ames test) has not been entirely determined, but the long history of ginger's use and the lack of carcinogenic or toxic effect in animals suggest that toxicity is not a problem.

In acute toxicity tests in mice, ginger extract administered as a lavage was tolerated up to 2.5 g/kg with no mortality or side effects during a 7-day trial period.[88] Increasing the dosage to 3 to 3.5 g/kg resulted in a 10% to 30% mortality rate. In comparison, 0.6 g/kg of aspirin produced mortality in 25%, stomach ulcers in 40%, and hypothermia in 60% of subjects.

Some individuals consuming high doses—more than the equivalent of 6 g of dried powdered ginger—alone on an empty stomach may experience some gastrointestinal discomfort. Administration of 6 g of dried powdered ginger has been shown to increase the exfoliation of gastric surface epithelial cells in human subjects.[89] This effect may cause some gastric distress and ultimately could lead to ulcer formation. Therefore it is recommended that dosages consumed on an empty stomach be less than 6 g.

DRUG INTERACTIONS

Ginger may potentiate antiplatelet therapy.[90] However, ginger administration had no such effect in 12 healthy male subjects who received coumadin alone or with ginger. No changes in platelet aggregation, the international normalized ratio of prothrombin time, warfarin enantiomer protein binding, warfarin enantiomer concentrations in plasma, or S-7-hydroxywarfarin concentration in urine were seen.[91]

SECTION 5

Syndromes and Special Topics[1]

Careful study of the various diseases to which humans are heir indicates that a limited number of underlying problems either cause or significantly contribute to most diseases. The reductionist philosophy underlying most of conventional medical research and practice results in more accurate diagnosis and more specific therapies for a given disease but makes recognition of broad patterns of disease causation progressively more difficult.

We believe the reader will find the syndromes discussed in this section interesting, relevant, and a compelling inducement for the development of a more holistic approach to patients. Old-fashioned ideas such as "bowel toxemia" and "liver toxicity" not only are intuitively reasonable but now have solid scientific evidence to support their validity. As one reads the chapters in this section, a compelling concept of medicine emerges:

Poor diet + unhealthy lifestyle + toxin exposure
↓
Nutritional deficiencies + toxicity
↓
(In the context of genetic susceptibility)
Metabolic dysfunction + subacute disease
↓
Clinically recognizable diseases that are apparently unrelated to the underlying causes

[1] Users of a previous edition of the TBNM will notice that this section moved from IV to V. This was done to improve the flow of the sections and to more logically combine Sections V and VI into the second volume.

131

Lifestyle Factors in Cancer

Lise Alschuler, ND

OUTLINE

INTRODUCTION

The mainstays of conventional cancer treatment—namely, surgery, chemotherapy, and radiation therapy—although preserving and prolonging the lives of many, present toleration challenges and often lack the desired effectiveness. An integrative naturopathic approach offers an adjunctive strategy that can improve both the toleration and efficacy of conventional cancer treatment. Fundamental to the naturopathic approach are diet, exercise, and stress management. Diet can be used to improve tolerance to radiation and chemotherapy, and specific dietary nutrients offer synergistic antineoplastic actions. Exercise is perhaps one of the most effective strategies to improve both tolerance and outcome. Finally, the effect of stress on prognosis is proving to be significant, pointing to the important role of stress management during any form of cancer treatment.

NUTRITION

Diet

There are several data points demonstrating a protective role of diet in cancer prevention and cancer control. Further, diet has considerable potential to optimize tolerance to conventional cancer therapies. Notably, there is evidence to suggest that patients who undergo conventional treatments without receiving nutritional support have higher complication rates.[1] Diet can be used to support optimal weight, specifically to prevent weight loss during treatment, to support bowel regularity, and to reduce localized areas of inflammation and pain (e.g., headaches, arthralgia, and mucositis).[2] Although the full arsenal of dietary interventions is beyond the scope of this chapter, several dietary approaches will be highlighted.

DIETARY PATTERNS

There are several dietary patterns and specific nutrients associated with improved survival in cancer treatment. However, when one looks across at the body of data as a whole, it is evident that the common denominator is a plant-based diet. Fruit, vegetables, and certain components of plant foods, such as fiber and polyphenols, have a large body of data supporting a protective effect against cancer.[3] Adherence to a Mediterranean diet (a diet high in plant foods, as well as olive oil, fish, and moderate wine) was found to be associated with a reduced risk of cancer incidence in the Greek EPIC trial, which comprised 25,623 participants. Adherence to the diet was assessed using a 10-point scale, and every 2-point increase in the score corresponded to a 12% reduction in cancer incidence (adjusted hazard ratio [HR], 0.88 [95% confidence interval (CI) 0.80, 0.95]).[4] The effect of this general dietary pattern of a plant-based diet has also been studied in specific populations of cancer patients.

In women diagnosed with breast cancer and treated with chemotherapy, self-report of hot flashes (HFs) after treatment for early-stage breast cancer has been associated with an approximately 25% to 30% decreased risk for additional breast cancer events, independent of the subsequent type of antiestrogen therapy. The HFs are due, in part, to lowered levels of circulating estrogen. With this in mind, the protective effect of a whole-foods, vegetable-rich diet might be especially relevant to women without HFs—essentially women with potentially higher circulating estradiol levels and worse prognosis.[5] Specifically, changes in dietary patterns to either decrease energy from fat or to increase fiber intake can alter the enterohepatic recirculation of estrogens, leading to lower circulating estrogen concentrations. A low-fat/high-fiber diet can be expected to reduce serum estradiol by an average of 7.5%,[6] an effect of particular importance to women diagnosed with estrogen receptor–positive (ER+) breast cancer. Although this effect is modest, if it persists over years, this would have biological significance. A secondary analysis of the Women's Healthy Eating and Living (WHEL) Randomized Trial[7] was conducted to determine whether HF-negative women gained specific benefit from the study diet, which consisted of the following: 5 vegetable servings plus 16 oz of vegetable juice, 3 fruit servings, 30 g of fiber, and limited energy intake from fat of 15% to 20% of total caloric intake.[8] Among women who reported no HFs (therefore presumably with higher estradiol levels and at greater risk) at baseline, there was a 31% lower recurrence rate in the group of women following these dietary recommendations than in the HF-negative women in the comparison group (no dietary intervention) over 7.3 years of follow-up. Among HF-negative postmenopausal women, the intervention effect was more significant, with a 47% reduction in risk compared with HF- women assigned to the comparison group.

The beneficial effect of fiber specifically has been noted in other trials. For instance, women diagnosed with breast cancer who, within 12

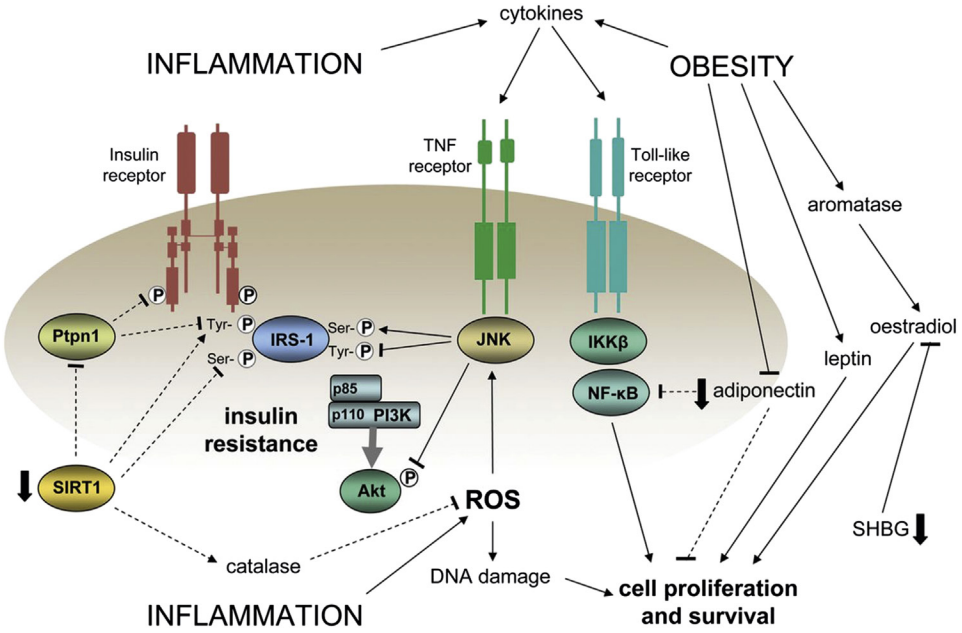

Fig. 131.1 Coincident promotion of insulin resistance and cell proliferation and survival in inflammation.[28] Activated cells of the immune system release cytokines and ROS, which induce insulin resistance via JNK and cell proliferation and survival via NF-κB. Positive influences are shown by lines ending in arrows and inhibitory influences by lines ending in bars. (Source: Godsland Ian F. Insulin resistance and hyperinsulinemia in the development and progression of cancer. *Clinical Science.* 118(5):315–332.)

months of their diagnosis, consume significant fiber (average consumption of 15.5 g/day of insoluble dietary fiber) experience a 49% reduction in the likelihood of having elevated C-reactive protein (CRP) concentrations (odds ratio [OR], 0.51; 95% CI, 0.27, 0.95) compared with those who consumed an average of 5.4 g/day ($P = 0.053$). This suggests an anti-inflammatory effect of fiber consumption, which in turn improves treatment toleration and is associated with improved survival.[9]

A dietary pattern characterized by a significant reduction in the consumption of saturated fat, increased consumption of vegetable proteins, and reductions in animal proteins and dairy products has been shown to significantly increase the doubling time of prostate-specific antigen (PSA) in men with prostate cancer.[10] The slowed PSA doubling time reflects decreased prostate cancer progression.

Colon cancer development and progression are also influenced by diet. Frequent consumption of red meat, refined carbohydrates, dairy, and eggs is associated with an increased risk for the development of colorectal cancer compared with infrequent consumption.[11] There is also a significant inverse relationship between total fiber intake and the risk of colorectal cancer (OR 0.57, 95% CI 0.47–0.68). Vegetable fiber appears to be more protective than either fruit or grain fiber.[12] In patients with diagnosed colon cancer, a dietary pattern that emphasizes plant foods and minimizes animal sources of protein would be expected to exert a beneficial effect on the colon, perhaps influencing progression risk.

Obesity

It is now estimated that 2.4% to 3.9% of cancer deaths can be attributed to obesity.[13] In an analysis of 70 clinical trials comprising 80,000 patients with early-stage breast cancer, the relative risk of dying from breast cancer was increased by 34% in obese (body mass index [BMI] > 30) premenopausal women (younger than age 55 y) with ER+ tumors.[14] In other words, the absolute 10-year breast cancer mortality for premenopausal women with ER+ disease was 21.5% for obese women compared with 16.6% for nonobese women. Postmenopausal obese women with ER+ disease had a 6% increased risk of dying from breast cancer. There was no association between obesity and breast cancer death in women with estrogen receptor–negative (ER–) tumors. Genetic analysis of pretreatment tumor biopsies has identified 121 genes with statistically significant changes in expression between obese and nonobese women.[15] In addition, obesity is characterized by hyperinsulinemia, estrogen signaling, and inflammation—all of which play important roles in obesity-accelerated breast cancer aggressiveness.

Obesity is also associated with unfavorable outcomes for patients with prostate cancer. A higher BMI (consistent with being overweight and obese) is predictive of a greater likelihood of rising PSA after surgery, indicating prostate cancer recurrence.[16] Furthermore, overweight and obese men experience shorter times to biochemical recurrence after surgery than normal-weight men.

Obesity is a known risk factor for the development of colorectal cancer, as well as its progression. Obesity-related dyslipidemias, increased adipokines, and elevated insulin and insulin-like growth factor-1 (IGF-1) are collectively associated with both increased colorectal cancer incidence and increased mortality in both men and women (see Fig. 131.1).[17] Obesity also negatively affects the effectiveness of conventional treatment with a mainstay of colorectal cancer treatment, bevacizumab. Bevacizumab is the main targeted therapy for inhibiting tumor angiogenesis by blocking the vascular endothelial growth factor (VEGF)/VEGF-receptor pathway. Obesity is associated with increased levels of VEGF, which could lead to resistance to anti-VEGF bevacizumab therapy. In fact, a prospective clinical trial demonstrated that in patients with metastatic colorectal cancer who were treated with bevacizumab, those who were overweight (BMI > 25 kg/m^2) experienced a significantly shorter time to progression ($p = 0.01$; HR: 4.37).[18]

Insulin Resistance

An important driver of malignant behavior in many cancer cell types is the significant expression of insulin and IGF-1 receptors.[19] As noted previously, insulin and IGF-1 are direct growth factors in these cancer cells.[20] Insulin and IGF-1 stimulate cellular proliferation in malignant cells via the constitutively "turned on" insulin receptor (IR) and IGF-1 receptors

(IGF-1R), culminating in mTOR activation. Activated mTOR drives proliferation, alters mitochondrial metabolism toward anabolism (aerobic glycolysis), and decreases apoptosis.[21] Interestingly, some cancers rely exclusively on insulin and IGF-1 for their growth, including an estimated 27% of breast cancers. Approximately 8% of these cases have upregulation of the PIK3/Akt pathway.[22] Additionally, IGF-IR is autophosphorylated in breast cancer cells with a predilection for metastasis to the brain. In vivo models demonstrate that experimental deactivation of IGF-IR attenuates the invasive and metastatic potential of these breast cancer cells, thereby delaying the development of brain metastases and prolonging survival. These preclinical findings are corroborated by the fact that 25% to 40% of patients with Her2+ and those with triple-negative breast cancer have a significantly increased risk of brain metastasis. This clinical finding correlates with increased IGF-IR signaling in these breast cancer subtypes.[23]

This concept has clinical application in the dietary advice given to patients. A trial followed 87 women with metastatic breast cancer receiving first-line liposomal doxorubicin and cyclophosphamide chemotherapy for a median of 15 months.[24] Of the subjects, 87% had hormone receptor–positive disease, and 48% were insulin resistant, with insulin resistance defined as a Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) score of greater than 2.5. (Of note, the HOMA-IR score can be calculated as serum glucose [mg/dL] × plasma insulin [uU/mL]/405, with a value greater than 2.5 indicative of insulin resistance.) Even after adjusting for other prognostic factors, such as patient age, the endocrine status of the tumor, visceral disease, and BMI, patients with advanced breast cancer and insulin resistance had a statistically significant higher risk of disease progression ($P = .035$). The median progression-free survival was 8 months in women with insulin resistance, compared with 14 months for those who did not have insulin resistance ($P = .04$).

A prospective, observational study of 1011 patients with stage III colon cancer reported their dietary intake during and for 6 months after conventional treatment.[25] The median follow-up from the time of completion of adjuvant therapy was 7.3 years. A higher dietary glycemic load was associated with statistically significant worse disease-free, recurrence-free, and overall survival. Specifically, patients with stage III colon cancer who were in the highest quintile of dietary glycemic load experienced an adjusted HR for disease recurrence of 1.79 (95% CI = 1.29–2.48) compared with those in the lowest quintile (HR = 1) (P trend across quintiles < .001). Increased glycemic load was associated with decreased overall survival (P trend across quintiles < .001). These associations were strongest for overweight patients (BMI > 25; HR 2.26). These data points support the use of a low-glycemic, nutrient-dense diet in people diagnosed with cancer.

Anti-Inflammatory Nutrients

Plant foods and spices concentrate polyphenols, which possess uniquely potent anti-inflammatory effects. The anti-inflammatory effects of polyphenols are illustrated, for instance, in a parallel-designed, placebo-controlled clinical trial of 120 men and women aged 40 to 74 years that compared the effect of 300 mg of an anthocyanin-rich drink isolated from bilberries and black currants to placebo over a 3-week period.[26] Consumption of the proanthocyanin-containing beverage was found to decrease nuclear factor kappa B (NF-κB)–controlled proinflammatory chemokines and interferon (IFN)-alpha (an inducer of NF-κB activation) by 45% and 40%, respectively, versus 20% and 15% in the placebo group ($P < 0.050$). Another trial assessed the effect of 30 grams of freeze-dried vegetable soup added to the daily diet of five patients with stage I non–small-cell lung cancer (NSCLC) in a toxicity study group and 6 patients with stage III and IV NSCLC in a treatment group for up to 24 months.[27] These patients were matched to 13 patients with stage III and IV NSCLC in the control group. The vegetable soup was a freeze-dried medicinal vegetable soup that included soybean, shiitake mushroom, mung bean, red date, scallion, garlic, lentil bean, leek, hawthorn fruit, onion, ginseng, angelica root, licorice, dandelion root, senegal root, ginger, olive, sesame seed, and parsley. All patients were treated with conventional therapies, including radiation, surgery, and/or chemotherapy. Those patients eating the vegetable soup had a median survival time of 15.5 months compared with a median survival time of 4.5 months in the control group ($P < 0.01$). There was no adverse toxicity in the vegetable group.[28]

In a controlled trial, 87 patients, 36 with resected colon cancer and 51 patients after polypectomy, were divided into two groups.[29] One group of 31 patients was treated daily with a flavonoid mixture of 20 mg apigenin and 20 mg epigallocatechin-gallate and compared with a matched control group of 56 patients. Both groups were observed for 3 to 4 years by surveillance colonoscopy and by questionnaire. Among the 14 patients with resected colon cancer and treated with the flavonoid mixture, there was no cancer recurrence, and only one adenoma developed. The cancer recurrence rate of the 15 matched untreated controls was 20% (3 of 15), and adenomas evolved in 4 of those patients (27%). The combined recurrence rate for neoplasia was 7% (1 of 14) in the treated patients and 47% (7 of 15) in the controls ($P = 0.027$).

In a trial of 26 men with newly diagnosed localized prostate cancer, the subjects were randomized to either 30 mg lycopene or no supplement before radical prostatectomy.[30] In the lycopene group, at surgery, 84% had tumors less than 4 mL, versus 45% in the control group. Additionally, 73% of the lycopene group and only 18% of the control group had clean margins. Prostate intraepithelial neoplasia was present in 67% of the lycopene group compared with 100% of the control group. Finally, PSA decreased by 18% in the lycopene group versus an increase of 14% in the control group.

A pooled analysis of three large prospective trials—the Shanghai Breast Cancer Survival Study (SBCSS), the Life After Cancer Epidemiology (LACE) Study, and the Women's Healthy Eating & Living (WHEL) Study—collectively representing 9514 breast cancer survivors with a mean follow-up of 7.4 years, assessed the effect of soy isoflavone.[31] Consumption of more than 10 mg isoflavones per day was associated with a 25% reduced risk of recurrence. This inverse association was seen in tamoxifen users, ER– women, and ER+ women.

The polyphenols found in plant foods both down-regulate inflammatory NF-κB and upregulate the transcription factor Nrf2. Nrf2 is normally sequestered in the cytoplasm as an inactive complex with its cytosolic repressor Keap-1. Phytochemicals, specifically polyphenolic flavonoids, activate diverse upstream kinases, which in turn stimulate dissociation of Nrf2 from Keap-1. Once released from Keap-1 repression, Nrf2 translocates to the nucleus, forms a heterodimer with small Maf protein, and binds to ARE/EpRE sequences located in the promoter region of genes encoding antioxidant and detoxifying enzymes.[32] This effect is synergistic with chemotherapy insofar as intracellular antioxidants are required to preserve the apoptotic (cell death) cascade initiated by chemotherapy. Additionally, polyphenols directly upregulate apoptosis, the ultimate step in removing aberrant cells. There are many examples of these proapoptotic polyphenols, such as transresveratrol[33] from grapes, peanuts, berries, and red wine. Genistein[34] from soy and curcumin[35] from turmeric activate apoptosis.

Fasting

A promising approach to improve patient tolerance of chemotherapy is concurrent fasting during chemotherapy. This approach has gained significant momentum from the research of Valter Longo, PhD. The premise of short-term starvation (STS) in an oncology context is twofold. First, when energy is scarce, cells will use energy preferentially for maintenance functions at the price of growth. Furthermore, IGF-1 levels decrease dramatically in response to short-term (36–120 hours)

of starvation. Cells throughout the body use IGF-1 to signal their growth. Thus fasting results in growth arrest of normal cells. However, most tumor cells have mutations in pTEN, p53, and the PI3K/Akt/mTOR pathway, leading to constitutive upregulation of insulin and the IGF-1–initiated proliferation pathway.[36] Thus, in malignant cells, STS and the resultant decrease in IGF-1 do not downregulate the PI3K/Akt/mTOR pathway and therefore do not arrest growth in cancer cells. This differential effect can be used concurrently with chemotherapy to preferentially protect healthy cells that will be in a dormant, maintenance, and nonproliferative state. This state renders these cells somewhat immune to the effects of chemotherapy. At the same time, the malignant cells retain their proliferation during STS and so remain susceptible to chemotherapy.

The effects of STS were demonstrated in a case-series report of 10 patients (7 females and 3 males) with cancer (4 with stage IIA breast cancer, 2 with prostate cancer [stage II and stage IV], 1 with stage IA ovarian cancer, 1 with stage IV endometrial cancer, 1 with stage IV NSCLC, and 1 with stage IVB esophageal cancer). [37] All patients received chemotherapy and underwent a water-only fast for 48 to 140 hours pre-chemotherapy and continued for 5 to 56 hours post-chemotherapy. Patients served as their own controls, and during fasted cycles, they experienced less toxicity even after nonfasted accumulation of toxicity. Patients received an average of our cycles of various chemotherapy drugs, including docetaxel/cyclophosphamide, docetaxel/carboplatin/±5-FU, carboplatin/paclitaxel, gemcitabine/docetaxel, docetaxel, and doxorubicin/cyclophosphamide. Specifically, the chemotherapy received during the water fast resulted in less fatigue, weakness, and gastrointestinal side effects.

Although the benefit and safety of this approach, specifically the effect of fasting on treatment response and survival, are still under clinical investigation, it could be considered empirically in patients who experience significant chemotherapy-induced toxicity to a level that is threatening their ability to complete treatment. Of note, preclinical research has indicated that fasting may reduce multidrug resistance in malignant cells[38]; however, this needs to be confirmed in human clinical trials. The exact protocol to optimize fasting regimens is under investigation. One fasting protocol being studied includes 24-, 36-, or 48-hour fasts before chemotherapy.[39] Another active clinical trial of women with gynecological cancers is studying the effect of modified fasting with daily caloric intake of < 400 kcal by juices starting 36 to 48 hours before beginning chemotherapy and lasting to 24 hours after ending each chemotherapy.[40]

Although not clinically evaluated, a variation of STS can also be considered between chemotherapy treatments and as a follow-up to conventional treatment. In the absence of active treatment, diet can be used to influence the same constitutively overactive IGF-1 and insulin-stimulated PI3K/Akt/mTOR pathway in malignant cells. This proliferation pathway's activity is enhanced in the presence of IGF-1 and insulin, both of which are reduced during caloric and carbohydrate restriction. Furthermore, dietary caloric restriction stimulates AMPk, which directly blocks mTOR activation (Fig. 131.2). The result of downregulating mTOR is reduced proliferation. Despite the promising theoretical basis for this approach, the clinical data on the effect of caloric and carbohydrate restriction on overall survival and recurrence risk in humans is yet to be determined.

Cachexia

Of note, this approach should not be considered for any patient at risk for cachexia, a condition of significant weakness and wasting caused by inflammatory cytokines released by malignant tissue. Certain cancers, such as lung cancer, pancreatic cancer, and many

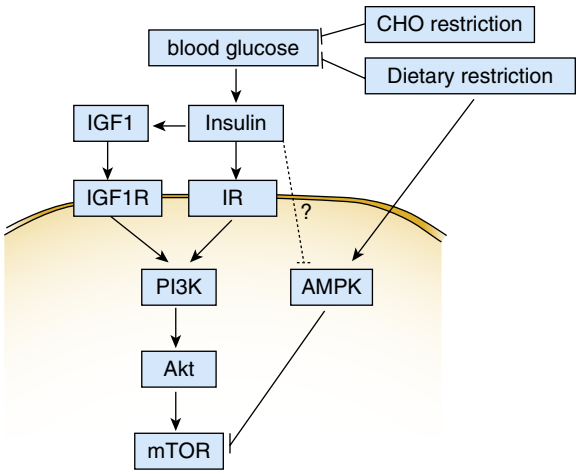

Fig. 131.2 Dietary Restriction and mTOR.

advanced cancers, carry a high risk of cachexia. The consumption of protein and essential fatty acids is a clinically validated way to both prevent and delay cachexia.[41] Protein requirements may exceed 80 gm/day in people at risk for cachexia. Typically, at least 0.45 to 0. 9g protein/2 kg body weight is needed to prevent and manage cachexia. Omega-3 fatty acids, especially eicosapentaenoic acid (EPA) at 2 to 3 g daily, is associated with weight gain and improved quality of life. Feeding (increased caloric intake) has not proven to control cachexia.

EXERCISE

Exercise is a critical component of a lifestyle-based support program during cancer treatment. Data collected over a median of 23 months postdiagnosis (interquartile range 18–32 months) were pooled in the After Breast Cancer Pooling Project (n = 13,302).[42] The study found that 2.5 h (10 metabolic-equivalent tasks [MET]-hours/week) of moderate-intensity physical activity per week was associated with a 27% reduction in all-cause mortality and a 25% reduction in breast cancer mortality compared with women who did not meet the physical activity guidelines (<10 MET-hours/week). In another study, women who engaged in the equivalent of at least 2 to 3 hours of brisk walking each week in the year before they were diagnosed with breast cancer were 31% less likely to die of the disease than women who were sedentary before their diagnosis (HR = 0.69 [95% CI, 0.45–1.06; P = .045]).[43] Women who increased physical activity after diagnosis had a 45% lower risk of death (HR = 0.55; 95% CI, 0.22–1.38) compared with women who were inactive both before and after diagnosis. Conversely, women who decreased physical activity after diagnosis had a fourfold greater risk of death (HR = 3.95; 95% CI, 1.45–10.50).

From a cohort of 184,194 adults without colorectal cancer at baseline in 1992 to 1993, 2293 participants were diagnosed with invasive, nonmetastatic colorectal cancer up to mid-2007.[44] The mean follow-up time from diagnosis to death or the end of the study was 6.8 years. Participants completed detailed questionnaires that included information concerning recreational physical activity and leisure time spent sitting at baseline, before their cancer diagnosis, and again after their cancer diagnosis. The highest prediagnosis recreational physical activity category (8.75 or more MET-hours per week, which is the equivalent of greater than 150 minutes/week) compared with the lowest category (3.5 MET-hours per week) was associated with a 28% lower risk of all-cause mortality. The same comparison for postdiagnosis recreational physical activity resulted in a 42% reduced risk of

mortality. Additionally, leisure time spent sitting 6 or more hours per day on the prediagnosis survey was associated with a statistically significant 36% higher risk of all-cause mortality. Postdiagnosis sitting time was associated with a statistically significant 62% higher risk of colorectal cancer–specific mortality. These studies support recommendations for recreational physical activity and the avoidance of sedentary time among people diagnosed with cancer—throughout the continuum of care.

STRESS MANAGEMENT

A third foundational component of lifestyle-based support of people undergoing cancer treatment is stress management. Elevated and prolonged stress hormones, namely cortisol, epinephrine, and norepinephrine, are associated with the carcinogenic process and shortened survival. The effects of stress on survival was elegantly demonstrated in a prospective trial of 217 participants with newly diagnosed metastatic renal cell cancer, all with a life expectancy of greater than 4 months, with good performance status and no major concurrent diseases.[45] All participants completed depression questionnaires, had salivary cortisol levels assessed, and provided blood samples for genomic analysis at baseline and at 4 months. The following factors were associated with decreased survival time: depression, poor quality of life, and flattened diurnal cortisol slope (with elevation of average cortisol). Genomic analyses identified upregulation of genes involved in inflammation and immune response and downregulation of genes that activate programmed cell death (all $p < .0001$) as well as genes involved in cell trafficking, adhesion, oxygen transport, and hemostasis (all $p < .05$).

Based on rodent models of triple-negative breast cancer, social isolation causes a heightened stress response that, in turn, increases expression of genes in adipocytes that increase glucose metabolism, lipid synthesis, and leptin secretion. These metabolic changes increase the conversion of mammary carcinoma in situ to invasive carcinoma. Mammary fat, in particular, has heightened sensitivity to stress hormones over visceral fat, making breast tissue especially vulnerable to stress.[46] Although the clinical evidence for the negative effects of stress is still developing, early evidence indicates the benefit of stress management on prognosis in people being treated for cancer. Furthermore, a more robust body of data demonstrates the improvement in quality of life that people diagnosed with cancer experience after active stress management.[47–49]

Mindfulness-based stress reduction (MBSR) is a particularly well-researched stress management behavior. A meta-analysis of 10 studies showed a significant improvement in psychological and physical quality of life with the practice of MBSR.[50] MBSR has been shown to reduce depression and fear of recurrence in women diagnosed with breast cancer.[51] MBSR lowers cortisol, reduces interleukin-6 (IL-6), lowers systolic blood pressure, and improves natural killer (NK) cell activity—each of which is correlated with a higher quality of life and a better prognosis.[52]

CONCLUSION

There is ample evidence to support the inclusion of a lifestyle-based approach in people diagnosed with cancer. A plant-based, Mediterranean-style diet is the foundation of such an approach. Intermittent or continuous caloric restriction may have unique benefits to the improved toleration of treatment and overall survival. Exercise remains a potent strategy to increase overall and cancer-specific survival. Finally, stress management has a direct effect on reducing the risk of recurrence and in optimizing the quality of daily living.

Dietary Fiber

John Nowicki, ND

OUTLINE

INTRODUCTION

Anthropology

Early humans obtained fiber principally in the form of soluble fiber from fruits, vegetables, and root vegetables. With the advent of grain cultivation, the human diet shifted more toward insoluble fiber, which has less beneficial metabolic effects, particularly in the context of a higher carbohydrate intake. Although the original Inuit diet of the far north was, calorically speaking, very high in animal fat and, to a lesser extent, animal protein, they supplemented their diet extensively with seasonal berries, roots, various plants, and seaweeds; thus they consumed relatively large amounts of fiber. Further south, aboriginal peoples made extensive use of numerous plant foods that contributed to a large intake of dietary fiber.[1] Around the world, there are few examples of indigenous peoples whose traditional diet did not provide very high quantities of fiber. Only with the advent of commercial food processing and refining has the human diet been so characteristically meager in dietary fiber.

History

Although there is a contemporary revival in medical interest surrounding fiber, references to dietary fiber have long existed in the medical literature in the writings of such historical figures as Hippocrates, the 9th-century Persian physician Hakim, and the Kellogg brothers of the United States.[2] However, the contemporary interest in fiber among physicians, as well as the widespread understanding of fiber's importance among the general public, began with a zealous campaign instituted by the missionary surgeon Denis Burkitt (also the discoverer of Burkitt's lymphoma), beginning in the early 1970s. Over his 20-year career in Africa, Dr. Burkitt observed a dramatic difference in the incidence of many diseases, such as coronary heart disease, diabetes, diverticulosis, and gallstones, among the local tribesmen. He noted that the largely agrarian Africans consumed very large amounts of dietary fiber, often more than 100 g/day. He determined that as a result of this diet, their stool transit time was far more rapid than that of Westerners, and their stools were more frequent and bulky. On the basis of his research, he launched a worldwide campaign to raise awareness of the importance of dietary fiber among medical professionals and the general public. Without a doubt, Dr. Burkitt's zeal was an important factor that catalyzed a veritable revolution in research surrounding dietary fiber.[3] During Burkitt's campaign, contemporaries published the first studies on fiber-related concepts, such as the glycemic index.[4] The complex mechanisms by which fiber exerts its many health effects are now recognized beyond just its effect on laxation.

FIBER

Classification

In the simplest definition, dietary fiber is a nonstarch polysaccharide in (mostly) plant food that is poorly digested by humans. Based on a government consensus report, fiber can exist as dietary fiber (naturally occurring in food) or functional fiber (added during the processing or preparation of food).[5] Fiber can be either insoluble or soluble in water. Insoluble fibers include cellulose, hemicellulose, and lignins, whereas soluble fibers include various gums, pectins, β-glucans, oligosaccharides, resistant dextrans, and resistant starches. Chitin and chitosan are indigestible amino-polysaccharides that are found in or are derived from the exoskeletons of arthropods, such as crabs and lobster, as well as the cell walls of most fungi. Although they could functionally be regarded as fiber, most regulatory authorities do not recognize them as fiber. The distinction between soluble and insoluble fibers is due to the chemical properties of the fiber, resulting in its tendency to absorb water. Various physicochemical properties of fiber (viscosity, water-holding capacity, cation-exchange capacity, adsorption of organic materials, and fermentability) are thought to be fundamental to its beneficial physiological effects. The Institute of Medicine has proposed a new definition of dietary fiber that encompasses both its physical characteristics and its physiological effects in humans.[6] Viscosity, water-holding capacity, and fermentability are the chief determinates of fiber's physiological effects.

The regulatory classification of fiber varies considerably in different countries. In the United States, dietary fiber is defined based on analytic methods rather than its physical or physiological characteristics.

Sources

The typical Western diet is largely devoid of dietary fiber, being composed principally of refined grains and other highly digestible sources of starch, sugar, various fats, and animal products. Children, in particular, are commonly fiber deficient, with daily intakes often under 5 g and with nearly no soluble fiber. Likewise, many adults in Western society consume 5 to 10 g of fiber daily as opposed to the 35 to 50 g that is considered desirable or at least minimal for optimal health. Moreover, because most fiber in the Western diet is derived from cereal grains, the intake of viscous soluble fiber is typically highly inadequate.

A whole-foods-based diet focusing on a large intake of vegetables and fruits as well as unrefined whole grains and legumes should be the foundation of a healthy lifestyle. With a whole-foods-based diet, it is certain that dietary fiber intake will substantially increase.[7] Efforts continue to fortify the Western diet with dietary fiber through the use of various fibers as food additives or ingredients as well as the use of readily accepted fiber supplements.

Health Effects

There are compelling epidemiological and experimental data associating numerous disorders, at least in part, with a lack of dietary fiber. Ischemic heart disease, stroke, atherosclerosis, type 2 diabetes, overweight and obesity, insulin resistance, hypertension, and dyslipidemia, as well as gastrointestinal disorders such as diverticulosis, irritable bowel disease, colon cancer, and cholelithiasis are just a few of the many conditions that seem to be influenced by the adequacy of dietary fiber intake.[8]

Numerous studies have demonstrated that certain fibers decrease the glycemic response to food, promote satiety, lower serum cholesterol, promote bowel regularity, positively influence colonic microflora, provide nutritional substrates for colonic mucosal cells, improve mucosal barrier function, and sequester and eliminate toxic and carcinogenic dietary and environmental compounds.

Viscous dietary fibers are clearly correlated with moderation in blood glucose and cholesterol concentrations, prolonged gastric emptying, and slower transit time through the small intestine.[9] Among viscous fibers, fermentability is mostly associated with large bowel function. Rapidly fermented fiber sources provide substrates for short-chain fatty acid (SCFA) production by microflora in the large bowel, whereas slowly or incompletely fermented fiber sources improve bowel health by promoting laxation, reducing colonic transit time, and increasing stool weight.[10]

MECHANISMS OF ACTION OF DIETARY FIBER

Dietary fiber exerts its effects through an interaction between the physical properties it imparts to food and a complex array of microbiological, biochemical, and neurohormonal influences. Dietary fiber has a strong influence on the palatability of food, thus influencing ingestive behavior. In the stomach, fiber affects the volume and viscosity of food, which has a significant effect on satiety. This "volumetric" effect on food promotes a sense of fullness and a delay in gastric emptying, which tends to naturally result in a decrease in caloric intake. Various fibers differ dramatically in their ability to impart volume and viscosity to foods. Becoming familiar with the use of highly viscous soluble fibers enables healthcare providers to teach patients to choose an eating strategy that promotes and maintains satiety while consuming a diet that is lower in caloric density.

Viscosity of Fiber

Viscosity as related to dietary fiber refers to the ability of some polysaccharides to thicken or form gels when mixed with fluids, resulting from physical entanglements and hydrophilic interactions among the polysaccharide constituents within the fluid or solution.[11] Gums, pectins, and β-glucans make up the majority of viscous dietary fibers. The viscosity that a fiber imparts to the gastric and small intestinal contents is directly correlated with the ability of the fiber to reduce postprandial glycemic response, promote satiety, decrease serum cholesterol, and decrease serum uric acid.[12] The viscosity of fiber is also thought to play an important role in the augmentation of gut mucosal protection through the stimulation of enteral mucus production and goblet-cell hypertrophy and replication.[13] Additionally, those viscous fibers that are largely fermented by colonic microflora exert a wide array of physiological effects through the production of SCFAs (the principle energy substrates of colonocytes), the promotion of beneficial colonic microbial populations, and the augmentation of important gut-derived peptide hormones.

The viscosity of fiber is best measured by methods that quantify a hydrated fiber's internal friction and its ability to resist flow. Viscosity is usually expressed in units of millipascal seconds or centipoise.[14] Other factors, such as shear stress (e.g., mastication, peristalsis), acid pH, dilution, and chemical components of food, determine the real viscosity that a fiber will impart to food rather than just its in vitro viscosity.

The concept of the glycemic index came about through the work of Jenkins et al. as they examined the effect of viscous fiber ingestion on glucose tolerance.[15] The glycemic index of a carbohydrate-containing food is directly correlated to the viscosity of that food after ingestion.

One research group was involved in several studies looking at the effects of adding a novel, highly viscous functional fiber (Polyglycoplex [PGX]) to various foods on the glycemic index, serum cholesterol, hunger, and satiety in healthy humans. The novelty of this fiber relates to its viscosity, which is higher than that of most other forms studied. Unlike some viscous fibers, such as psyllium, which are not fermented, PGX is highly fermentable and prebiotic.[16] PGX, made from glucomannan, sodium alginate, and xanthan gum, is taken through several steps of processing, and the resultant modified fiber is approximately three times the viscosity of glucomannan, a naturally occurring fiber from the Konjac root that may possess the highest viscosity of any naturally occurring fiber. In addition, it was demonstrated that PGX is a novel and stable molecular entity with viscosity that is severalfold higher than its constituent ingredients, through a wide range of pH and shear-stress conditions, and when added to a variety of foods and beverages.[17,18] In addition, this fiber is tasteless and disperses readily when added to food or mixed with beverages. Its viscosity evolves several minutes after initial hydration, making it very easy to consume the small amounts needed to create a highly viscous gastric milieu, leading to its resultant physiological effects.

Substantial reductions in postprandial glycemia along with reduced hunger and increased satiety can be achieved with a very modest quantity of this highly viscous fiber. These findings support the contention that the viscosity that a fiber imparts to the gastric contents is more important than simply the grams of the fiber consumed.[19–23] In a study of Zucker Diabetic Fatty (ZDF) rats, the effects of diets supplemented with nonviscous, insoluble fiber (cellulose); nonviscous, prebiotic fiber (inulin, oligofructose); or a highly viscous, prebiotic fiber (PGX) were compared. Results showed that only the diet supplemented with highly viscous fiber substantially decreased postprandial blood glucose and insulin secretion, decreased hepatic fatty infiltration, and preserved pancreatic β-cell mass. These effects were accompanied by an increase in the production of the important glucoregulatory incretin hormone glucagon-like peptide-1 (GLP-1) and, in a human clinical trial, the appetite-reducing hormone peptide YY (PYY).[24] The substantial glycemic-index–modifying effects have been well confirmed in human studies.[18–20]

Water-Holding Capacity

The ability of a fiber to absorb and hold on to water as it transits the gut is another factor that contributes to its functional effects. Soluble fibers have the capacity to create a stable gel that results in stomach volume being occupied and a sense of satiety being created without the addition of significant calories. The "volumetric" properties of a food consist of a food's volume and viscosity per net quantity of calories. Those who work in the field of obesity management believe that teaching patients strategies that promote a high consumption of low-calorie-density, highly volumetric foods is a mainstay in the dietary management of overweight and obesity.[25–27]

Laxation

The most common clinical application of fiber is in the maintenance of bowel regularity. Insoluble fiber, perhaps in combination with soluble fiber, is most effective in increasing stool bulk, reducing gut transit time, and increasing the frequency of defecation.[28] The health-promoting effects of insoluble fiber from the bran of grains is well documented and certainly extends past its laxative effects.[29] However, the benefits of reduced stool transit time and increased fecal frequency may have more profound long-term benefits beyond the comfort that accompanies bowel regularity.[30–32]

Prebiotics

It is recognized that certain forms of fiber are fermentable, providing an important substrate in the metabolism of gut flora. By definition, humans lack the enzymes specific to digest fiber. In the case of insoluble fiber, most gut microbes cannot use it as an energy source, and so it is typically excreted without any molecular alteration other than by forming a surface for the adsorption of organic matter and cations. Soluble fibers vary in their fermentability and in the specific microbes that can use them as substrates. The term "prebiotic" was coined by Gibson and Roberfroid in 1995 and was defined as an indigestible carbohydrate that is fermentable in the lower gastrointestinal tract that selectively promotes the growth of desirable (prebiotic) microflora and is associated with a positive health outcome.[33,34] Although there may be exceptions, prebiotics tend to reduce populations of potentially pathogenic flora while promoting desirable commensals such as *Bifidobacteria*.

Evidence suggests that this effect might play an important role in both the reduction in adiposity and in a reduction in the contribution of adipocytes to inflammation. It was demonstrated that prebiotic supplementation might reduce the development of large adipocytes (those that predominate in the visceral compartment), which are highly involved in the overactivation of a wide variety of inflammatory processes that may contribute to overeating, obesity, diabetes, cardiovascular disease, and pain.[35,36]

Pathways of inflammation associated with atopic disease are also intimately associated with gut flora. Both prebiotics and probiotics are believed to hold significant promise in the prevention and treatment of allergies and atopic disorders, such as eczema.[37–40]

The lack of sufficient intake of prebiotics early in life has lasting ill-effects on gluco-regulation, which may result in a substantial predilection toward obesity, diabetes, and cardiovascular disease later in life.[41] Decreased intake of fermentable soluble fiber may have serious consequences and may be one of the reasons for the obesity epidemic. The food industry has responded to this with the introduction of prebiotic-fortified infant formulas. Because breast milk contains significant quantities of prebiotic oligosaccharides, adding analogous agents to infant formulas would help make these more closely mimic the natural diet. This strategy results in a gut flora predominated by *Bifidobacteria* rather than potential pathogens such as *Clostridia* and *Enterobacter* that tend to predominate in formula-fed infants.[42]

Prebiotics, namely lactulose, have been used for many years in the management of hepatic encephalopathy.[43] It has long been a marvel for modifying the colonic flora, and giving lactulose can restore sanity to a delirious patient with liver failure. It is recognized that the prebiotic effects of this treatment result in a reduction in neurotoxic bacterial metabolites that can normally be eliminated by the healthy liver. Similarly, prebiotics have found their place in the treatment of patients with HIV[44] and in allergy prevention and treatment.[45]

Prebiotics may play an important role in the modification of carcinogens and in the promotion of substances that reduce cancer risk, at least in the gastrointestinal tract.[46] Dietary fiber has the capacity to sequester and increase the elimination of a wide range of organic molecules as well as metal ions. This effect, along with the resultant decrease in colonic transit time, results in reduced colonocyte exposure to potentially harmful xenobiotics and endogenously produced, but potentially harmful, compounds. Fermentable soluble fiber is metabolized anaerobically into SCFAs such as butyrate, acetate, and propionate. These simple molecules are the principal energy substrates of colonocytes, and an adequate and ongoing supply of these may reduce the risk of cancer, metabolic disorders, and other gastrointestinal disorders, such as diverticulosis and inflammatory bowel disease.[47,48]

Neuroendocrine Effects of Fiber

Perhaps the most intriguing discovery is related to the role played by dietary fiber in the modulation of important neuroendocrine physiology, which may be fundamentally related to the etiology of several serious disorders. Of particular interest is the effect of fiber on the density and activity of a specialized enteroendocrine cell known as the L-cell.[49] The L-cell is located throughout the terminal ileum and colon, and it is responsible for the secretion of the peptide hormones GLP-1, PYY, and oxyntomodulin.[50] After a meal, oxyntomodulin and PYY are released synchronously; both act as potent anorexigens. The rapid rise of circulating hormone levels signals a change in energy status to the brain and also acts locally to enhance digestive processes. GLP-1 is an incretin hormone that is also secreted by the L-cell and, as well as being an anorexigen, it plays a pivotal role in glucoregulation through the stimulation of accurately timed insulin secretion and suppression of glucagon secretion from the pancreas. It has been established that diminished GLP-1 production plays a central role in the etiology of diabetes, a discovery that has led to the development of the most important class of diabetes drugs (the incretin analogs) since the discovery of insulin. A randomized clinical study demonstrated that select SCFA-producing gut bacteria were promoted by dietary fibers, improving hemoglobin A1c and alleviating type 2 diabetes, partly via increased GLP-1 production.[51] Studies demonstrate that (bariatric) gastric bypass surgery results in rapid amelioration of diabetes that is out of proportion with and precedes significant weight loss.[52] Evidence points to a rapid and sustained increase in circulating GLP-1 and PYY after this procedure, which has profound effects on appetite and glucoregulation. It is thought that the malabsorption of carbohydrates and rapid gastrointestinal transit after gastric bypass results in increased delivery of carbohydrate fermentation products (SCFAs) and bile acids, both of which activate L-cells via free fatty acid (FFA) receptors and bile acid receptors.[53–57]

It is most interesting that fermentable soluble fiber has the potential to generate a significant supply of SCFAs that might mimic, on a lesser scale, the mechanism of gastric bypass surgery through the stimulation of FFA receptors, with a resultant increase in GLP-1 and PYY.[58] Because viscous soluble fiber also effectively sequesters bile acids, reducing their usual absorption through the jejunum and delivering them to the same L-cells, viscous soluble fiber that is also fermentable

may exert an appetite-reducing and glucoregulating effect through L-cell activation via both FFA receptors and bile acid receptors as well as by suppression of the orexigenic (appetite stimulating) hormone ghrelin.[59,60]

Sequestration of bile acids by viscous soluble fiber is also known to be a principal mechanism by which viscous fiber lowers serum cholesterol because sequestration of bile acids decreases the enterohepatic recycling of bile acids, a major cholesterol reservoir for the human.[61]

CLINICAL APPLICATIONS

With the abundant and ever-growing evidence that has elevated the role of fiber well beyond its place in the promotion of bowel regularity, dietary fiber should be respected by healthcare providers as an important prophylactic and therapeutic agent. The importance of viscous, fermentable soluble fiber in the prevention and management of obesity and diabetes is of particular importance to clinicians who are on the front lines facing the obesity epidemic.

It is clear that fiber, especially viscous and (prebiotic) fermentable soluble fiber, plays a key role in the risk of obesity, diabetes, cardiovascular disease, cancers, atopic illness, and a wide range of gastrointestinal disorders. It is also clear that the lack of adequate dietary fiber, particularly prebiotic and viscous fibers in childhood and infancy, may set the stage for a higher risk of the same array of disorders, and that some of that increased risk may linger for the remainder of life. Clinicians must develop effective strategies to educate their patients and assist them in the incorporation of much higher levels of fiber in their daily diet. Because the greatest benefits from fiber are derived from highly viscous, prebiotic fibers, clinicians should become especially knowledgeable in the effective use of these agents, particularly when treating patients who are obese or exhibit dysglycemia.

In 1968, polychlorinated biphenyl (PCB)–contaminated rice-bran cooking oil poisoned a great number of Japanese individuals in what came to be called "Yusho disease" (oil poisoning). Rice-bran fiber (RBF) has demonstrated the ability to bind PCBs and other toxicants, including the combustion by-product benzo(a)pyrene. When measured against other fibers, RBF dramatically reduced the reabsorption of PCBs from the intestines in animals, and in PCB-exposed animals, RBF increased fecal PCB excretion by 6.6 times and spinach fiber by 4.1 times.[62] Yusho patients who consumed 7 to 10 g of fermented RBF three times daily (after each meal) for a year enjoyed 81% greater elimination of furans and 74% greater elimination of dioxins compared with those not consuming the fiber.[63]

DOSAGE AND ADMINISTRATION

The dietary fiber intake for typical Americans is usually less than desirable, with typical intakes averaging only 14 to 15 g/day and children consuming less than 5 g/day.[64] The American Dietetic Association currently recommends that healthy adults should consume 20 to 35 g of fiber per day, and children should consume at least 5 g/day plus 1 g for every year of their age.[65] The American Dietetic Association points out that insoluble, nonfermentable, and low-viscosity fiber is principally consumed to promote laxation and other aspects of colon health, whereas viscous soluble fibers are necessary to reduce serum cholesterol, blunt postprandial glycemic response, and promote satiety. A fiber-rich meal, particularly a meal high in viscous, soluble fiber, is processed more slowly, promoting earlier satiety, and is frequently less calorically dense and lower in fat and added sugars. All of these characteristics are typical of a dietary profile optimized to treat and prevent obesity. Unfortunately, viscous soluble fiber is not easily incorporated into the regular diet, but fiber supplements may provide a practical means to ensure that most meals contain optimal quantities of viscous fiber. Pal et al.[66] at Curtin University in Australia demonstrated the utility of high-dose psyllium given as a premeal supplement as an adjunct to a calorie-reduced weight loss program. However, the dosage of psyllium used in this application was very large (12 g with each meal) and might pose a compliance problem for many subjects. Using very high-viscosity fiber (such as PGX) may overcome this limitation because the dosages required to achieve a reduction in postprandial glycemia and an increase in satiety may be much less than those of fibers with lesser viscosity.[19,67]

DRUG INTERACTIONS

Clinicians prescribing higher doses of supplementary fibers should be aware of the potential drug–food interactions in those patients requiring pharmaceuticals. Most fiber, especially viscous fibers, has the potential to modify the rate or total absorption of various drugs.[68] In most cases, taking medications 1 hour before or 2 hours after consumption of the supplementary fiber will reduce the effect of this phenomenon.

Digestive Support

Michael T. Murray, ND

OUTLINE

INTRODUCTION

Proper digestion, absorption, and elimination are necessary to gain the nutritional benefits from foods. Any disruption of these processes causes substantial, and usually progressive, health problems throughout the body. This chapter provides some overview of digestive dysfunction and ways to improve digestion. For specific digestive tract disorders (e.g., irritable bowel syndrome, peptic ulcers, inflammatory bowel disease, celiac disease, gastroesophageal reflux disease [GERD]), see Section 6. For information on the various laboratory procedures for evaluation of digestive function (e.g., comprehensive digestive stool analysis, intestinal permeability assessment, small intestinal bacterial overgrowth breath test), see Section 2.

The recommendations in this chapter are designed to support digestive function in those patients with *true* functional gastrointestinal disorders (FGIDs). The emphasis on *true* FGID is to signify that with detailed clinical evaluation, the cause of the patient's gastrointestinal (GI) symptoms can often be identified. Small intestinal bacterial overgrowth (SIBO), dysbiosis, and intestinal barrier dysfunction likely account for the underlying cause in most of these patients.[1] Also of importance are hypochlorhydria and pancreatic enzyme deficiency. The latter is common in type 1 diabetes and, to a lesser extent, type 2 diabetes.

Classically defined, FGIDs are common disorders that are characterized by persistent and recurring GI symptoms due to abnormal functioning of the GI tract. More than 20 functional GI disorders have been identified, with irritable bowel syndrome (IBS) being the most common. Approximately 25 million Americans have functional GI disorders, and 50% to 80% of people with FGID symptoms do not consult a physician.

Conventional medicine focuses on three primary features of FGIDs: motility, sensation, and brain–gut dysfunction. More recent studies have also shown that psychological distress may alter the systemic and gut immunity, which is increasingly recognized as a pathophysiological feature of FGID (Fig. 133.1). The reason is likely the focus on a pharmacological approach in dealing with these three areas.

This chapter, instead, focuses on some considerations in aiding general digestion when no underlying disturbance can be found. This is becoming an infrequent occurrence due to the diagnostic tools physicians have access to as well as to the various effective dietary and natural approaches that appear to improve digestive function.

THERAPEUTIC CONSIDERATIONS

In a survey of more than 20,000 adults in the United States, the overall prevalence of at least one upper GI symptom was reported in 45% of those surveyed (based on the preceding 3-month period); symptoms included heartburn, early satiety, loss of appetite, and postprandial fullness (i.e., bloating).[2] These symptoms of indigestion can be attributed to several causes.

Patients use common terms to describe their digestive issues, such as *indigestion, gas,* and *bloating.* So, it is important to help them define the nature and timing of their symptoms because they can provide valuable clues. It is also important to address some of the basics of digestion with patients. For example, proper digestion requires the body to be in a parasympathetic-dominant state. Unfortunately, many patients with digestive issues eat on the run or in a state of stress, and they often also fail to chew their food thoroughly. Teaching mindfulness and diaphragmatic breathing has been shown to help with common FGIDs like IBS and GERD. There are good reasons for this response. The diaphragm muscle is closely linked to the vagus nerve, which is a mixed nerve consisting of 20% efferent cholinergic descendent fibers and 80% afferent ascending fibers. In patients affected by IBS, GERD, and other GI disorders, the diaphragmatic muscles and corresponding activation of the vagus nerve and other accommodation mechanisms do not function properly. Patients often experience a paradoxical effect consisting of a contraction of the diaphragm muscle and a relaxation of the upper portion of the abdominal wall, whereas in healthy subjects, concomitant relaxation of the diaphragm muscle and activation of the rectus abdominis (the upper part) and external oblique usually happen. This phenomenon can lead to dyspepsia and feelings of bloatedness. The technical name for this occurrence is "abdomino-phrenic dyssynergia." The solution is teaching mindfulness and diaphragmatic breathing to patients. This intervention is efficacious in relieving the symptoms of IBS and GERD.[3,4]

Many patients with minor digestive disorders treat themselves with over-the-counter medications and dietary supplements such as antacids, acid-blocking drugs, or probiotics. Sometimes this results in effective relief of symptoms. However, the use of antacids and acid-blocking drugs can lead to deterioration of digestive functions.

Antacids and acid-blocking drugs typically raise the gastric pH above 3.5, effectively inhibiting the action of pepsin, the enzyme involved in protein digestion that can be irritating to the stomach. Although raising the pH can reduce symptoms, it also substantially

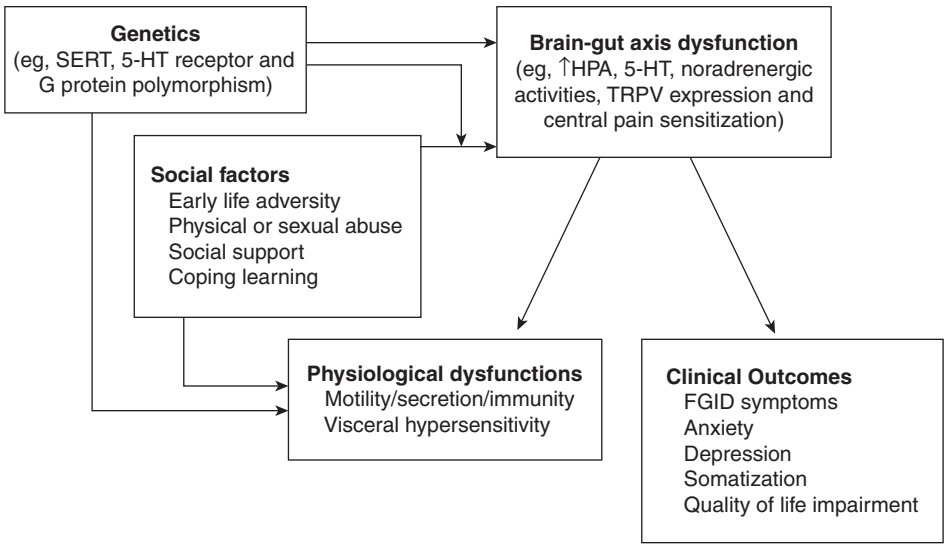

Fig. 133.1 Schematic diagram illustrating the pathophysiological links between functional gastrointestinal disorder and psychiatric disorders. *SERT,* serotonin reuptake transporter; *5-HT,* serotonin; *HPA,* hypothalamic-pituitary-adrenal; *TRPV,* transient receptor potential vanilloid; *FGID,* functional gastrointestinal disorder. (From Wu JC. Psychological co-morbidity in functional gastrointestinal disorders: epidemiology, mechanisms and management. *J Neurogastroent. Motil.* 2012;18[1]:13–18. PubMed PMID: 22323984.)

impairs protein digestion and mineral disassociation. In addition, the change in pH can adversely affect gut microbial flora, including the promotion of an overgrowth of *Helicobacter pylori.* Finally, most nutrition-oriented physicians believe that lack of acid, not excess, is the true culprit in most patients with indigestion.

Most people use these drugs because they self-diagnose hyperacidity. However, in most cases, the symptoms of reflux esophagitis are most often caused by overeating or eating foods that promote gastric reflux, not excessive acid production. See the chapter on GERD for a more complete discussion. Other common causes of heartburn or indigestion are as follows:

- Obesity
- Cigarette smoking
- Chocolate
- Fried foods
- Carbonated beverages
- Alcohol
- Coffee

These factors most often either increase intraabdominal pressure or decrease the tone of the esophageal sphincter.

Another important dietary consideration is the glycemic load of a meal. In the Study on the Epidemiology of Psychological, Alimentary Health and Nutrition (SEPAHAN), a high-glycemic-load meal or habitual diet was significantly associated with heartburn/dyspepsia, especially in men.[5]

Complaints of indigestion and heartburn may also be a sign of a hiatal hernia. Although 50% of people older than 50 years have hiatal hernias, only 5% of patients with hiatal hernias experience reflux esophagitis and/or symptoms of GERD. Perhaps the most effective treatment of chronic reflux esophagitis and symptomatic hiatal hernias is to use gravity. The standard recommendation is to place 4-inch blocks under the bedposts at the head of the patient's bed. This elevation of the head is very effective in many cases. Another recommendation is for the patient to drink a glass of alkaline water (pH > 8.8) or lemon water after a meal. This practice was compared with proton pump inhibitors in patients with laryngopharyngeal reflux and was found to produce better results based on changes in Reflux Symptom Index (RSI).[6]

BOX 133.1 Common Signs and Symptoms of Low Gastric Acidity

Bloating, belching, burning, and flatulence immediately after meals
A sense of "fullness" after eating
Indigestion, diarrhea, or constipation
Multiple food allergies
Nausea after taking supplements
Itching around the rectum
Weak, peeling, and cracked fingernails
Dilated blood vessels in the cheeks and nose
Acne
Iron deficiency
Chronic intestinal parasites or abnormal flora
Undigested food in stool
Chronic *Candida* infections
Upper digestive tract gassiness

Hypochlorhydria

In the patient with chronic indigestion, rather than focusing on blocking the digestive process with antacids, the natural approach focuses on aiding digestion. Although much is said about hyperacidity conditions, a more common cause of indigestion is a lack of gastric acid secretion. Many symptoms and signs suggest impaired gastric acid secretion, and several specific diseases have been associated with insufficient gastric acid output.[7–17] They are listed in Boxes 133.1 and 133.2.

Several studies have shown that the ability to secrete gastric acid decreases with age.[18–20] Some studies found low stomach acidity in more than half of the subjects older than 60 years. The best method of diagnosing a lack of gastric acid is the Heidelberg gastric analysis (see Chapter 17).[21] Wright[22] suggested that the response to a bicarbonate challenge during Heidelberg gastric analysis, not simply resting pH, was the true test of the functional ability of the stomach to secrete acid.

Because the Heidelberg gastric acid analysis is not widely available, a clinical trial of hydrochloric acid (HCl) supplements can be used, as described in Appendix 8.

BOX 133.2 Diseases Associated With Low Gastric Acidity

- Addison's disease
- Asthma
- Celiac disease
- Dermatitis herpetiformis
- Diabetes mellitus
- Eczema
- Gallbladder disease
- Graves' disease
- Chronic autoimmune disorders
- Hepatitis
- Hyperthyroidism/hypothyroidism
- Hives (chronic)
- Myasthenia gravis
- Osteoporosis
- Pernicious anemia
- Psoriasis
- Rheumatoid arthritis
- Rosacea
- Sjögren's syndrome

Etiology of Hypochlorhydria

Like peptic ulcer disease, achlorhydria and hypochlorhydria have been linked to the overgrowth of the bacteria *H. pylori.* Approximately 90% to 100% of patients with duodenal ulcers, 70% of patients with gastric ulcers, and about 50% of people older than 50 years test positive for *H. pylori.* The presence of *H. pylori* is determined by measuring the level of antibodies to *H. pylori* in the blood or saliva or by culturing material collected during an endoscopy as well as measuring the breath for urea. A breath test is also available for assessment of current *H. pylori* activity.

Low gastric output is thought to predispose to *H. pylori* colonization, and *H. pylori* colonization increases gastric pH, thereby setting up a positive-feedback scenario and increasing the likelihood of colonization of the stomach and duodenum by other organisms. Not surprisingly, HCl antisecretory drugs (H_2 receptor antagonists and proton pump inhibitors) may promote *H. pylori* overgrowth. Patients with *H. pylori* experience an exaggerated response in elevations of pH with antisecretory therapy. Eradication of *H. pylori* is associated with a return to normal gastric acidity and pepsinogen ratio.[23]

Although the typical conventional medicine approach is to focus only on the infective agent, the usual host defense factors are equally important. Unfortunately, research has focused on eradicating the organism, and there is little information on protective factors against infection. Proposed protective factors against *H. pylori*–induced intestinal damage include maintaining a low pH and ensuring adequate antioxidant defense mechanisms. Low levels of vitamin C and vitamin E and other antioxidant factors in the gastric juice appear to not only lead to the progression of *H. pylori* colonization but also to contribute to ulcer formation because the mechanism by which *H. pylori* damages the stomach and intestinal mucosa is oxidative.[24] Furthermore, antioxidant status and gastric acid output appear to explain the observation that most people infected with *H. pylori* do not experience peptic ulcer disease or gastric cancer. For more information on natural approaches for eradicating *H. pylori,* see Chapter 207.

One natural medicine that may be useful against *H. pylori* is bovine lactoferrin. Lactoferrin exerts broad-spectrum antimicrobial action because it has been shown to be effective in inhibiting the growth of disease-causing protozoa, yeast, bacteria, and viruses. More important than its ability to kill organisms is the discovery that lactoferrin prevents the attachment of disease-causing organisms to cells that line the mouth and entire gastrointestinal tract. At the same time, lactoferrin is a powerful booster of health-promoting bacteria like *Bifidobacteria* and *Lactobacillus* species. By preventing the growth of harmful bacteria while promoting the growth of beneficial *Bifidobacteria,* lactoferrin assists in the development of proper intestinal flora.

The standard medical treatment of *H. pylori* infection is a 1- or 2-week course of triple-drug therapy. It involves taking two antibiotics to kill the bacteria and an acid-suppressor drug. Based on the results of clinical trials, lactoferrin alone or in combination with triple therapy may be an excellent treatment option. In one study, 151 patients testing positive for *H. pylori* with indigestion symptoms were given either triple therapy alone or with lactoferrin. *H. pylori* status assessed 8 weeks after the end of the treatment indicated a 95.9% eradication rate for the group receiving the lactoferrin; the other group had only a 72.5% eradication rate.[25] The effective dose of lactoferrin in this application is 300 mg/day.

Pancreatic Insufficiency

The most severe level of exocrine pancreatic insufficiency (EPI) is seen in cystic fibrosis. Next in severity is the EPI associated with the late stages of pancreatitis. These more severe causes of EPI are most often easily recognized, but causes of mild EPI are more insidious and difficult to diagnose. Patients with type 1 diabetes not only have damaged beta cells, but the enzyme-producing alpha cells are damaged as well.

Both physical symptoms and laboratory tests can be used to assess pancreatic function in patients in whom mild EPI is suspected. Common symptoms of EPI are abdominal bloating and discomfort, gas, indigestion, and the passing of undigested food in the stool. For laboratory diagnosis, a comprehensive stool and digestive analysis (discussed in Chapter 28) is quite useful. In addition, the measurement of fecal elastase 1 concentrations using an enzyme-linked immunosorbent assay is an accepted indirect test of the exocrine pancreatic function. It shows higher sensitivity and specificity for EPI than does fecal chymotrypsin determination and is comparable to oral pancreatic function tests, such as the pancreolauryl test.[26] However, the test may not show levels of active secreted enzymes. Each pancreatic enzyme has a very narrow range of pH activity as well as being inhibited by several foods, microbial compounds, persistent organic pollutants, heavy metals, and many other factors. Even so, the measurement of fecal elastase has shown that pancreatic insufficiency is associated with normal aging in healthy populations, especially after age 70 years.[27] Patients may have few symptoms associated with EPI, for example, steatorrhea, diarrhea, abdominal pain, and weight loss, but they may experience gas, bloating, and indigestion.

Digestive Enzyme Supplements

Pancreatic enzyme products are an effective treatment for EPI and are widely used. Most commercial preparations are prepared from fresh hog pancreas (i.e., pancreatin) (see Chapter 100 for a full discussion). Enzyme products are often enteric coated, primarily to protect the more fragile porcine lipase. However, some studies have shown that non–enteric-coated enzyme preparations outperform enteric-coated products if they are given before a meal (for digestive purposes) or on an empty stomach (for anti-inflammatory effects). In general, there is no significant difference in clinical response to various delivery forms of pancreatin.[28]

Alternatives to porcine pancreatin include plants (e.g., bromelain, papain, etc.) and enzymes extracted from various microbes or

yeast (e.g., *Aspergillus oryzae*). These enzymes are more resistant to digestive secretions and have a broader range of activity, including pH range (see Chapter 59, Bromelain, and Chapter 95, Microbial Enzyme Therapy). One double-blind crossover trial in 17 patients with severe EPI and steatorrhea compared the effects of a non–enteric-coated pancreatic enzyme preparation (360,000 lipase U/day), an enteric-coated pancreatic enzyme preparation (100,000 lipase U/day), and a fungal enzyme preparation (75,000 lipase U/ day).[25] All three treatment preparations in both groups yielded a significant reduction in total daily stool weight and total daily fecal fat excretion compared with controls. It is interesting to point out, however, that the fungal enzyme preparation produced similar benefit at three-fourths the dose of the enteric-coated pancreatic enzyme and one-fifth the dose of the non–enteric-coated pancreatic enzyme preparation.

PROBIOTIC SUPPLEMENTS

Probiotic supplementation may be useful in improving digestion. However, it is important to point out that although probiotics may play a role in general digestive health, immune function, and other aspects of the microbiome, probiotics do not directly aid digestion in terms of breaking down food into smaller units.

Homocysteine Metabolism: Nutritional Modulation and Effect on Health and Disease

Jessica Tran, ND, MBA, Gregory S. Kelly, ND,* and *Alan L. Miller*, ND*

OUTLINE

INTRODUCTION

Homocysteine is an intermediate in the conversion of the amino acid methionine to cysteine. Elevated homocysteine levels are an independent risk factor for coronary heart disease, stroke, and other vascular conditions. Homocysteine and its relationship to cardiovascular disease emerged in the late 1960s, when Kilmer McCully, MD, encountered two children with homocystinuria (a rare autosomal-recessive condition) who had advanced atherosclerosis, although the coronary plaques contained no lipids. Increased homocysteine levels have been implicated in several other clinical conditions, including neural tube defects, spontaneous abortion, placental abruption, renal failure, non–insulin-dependent diabetes and complications of diabetes, rheumatoid arthritis, alcoholism, osteoporosis, and neuropsychiatric disorders.

HOMOCYSTEINE METABOLISM

Homocysteine is metabolized along two pathways: remethylation to methionine (which requires methionine synthase along with vitamin B_{12} and folate or betaine) or transsulfuration to cysteine (which requires vitamin B_6). A defect in either of these pathways leads to the accumulation of homocysteine. Insufficient dietary intake of vitamin B_6, vitamin B_{12}, and folate can lead to increased homocysteine levels.

Gender and Genetics

Studies of healthy men and women indicate that certain acquired and genetic determinants may affect total plasma homocysteine. Women tend to have lower basal levels than men,[1] and neither contraceptives nor hormone replacement therapy seem to alter their levels significantly.[2] However, in postmenopausal women, hormone replacement therapy might slightly decrease elevated homocysteine concentrations. No significant lowering effect was observed in women with low homocysteine levels.[3] Generally, homocysteine concentrations are significantly higher in postmenopausal women than in premenopausal women; however, the previously mentioned sex differences in homocysteine concentrations persist even in elderly populations.[4–6] The antiestrogen drug tamoxifen, used in the long-term treatment of breast cancer patients, was reported to decrease homocysteine levels in postmenopausal women with breast cancer.[7]

A number of reports also demonstrated that elevated plasma total homocysteine in children was correlated with either cardiovascular disease or death in their parents or close relatives. This relationship

*Previous edition contributor

was observed in both white and black children and in white children with hypercholesterolemia. In the latter study group, the 5,10-methylenetetrahydrofolate reductase (MTHFR) *TT* genotype tended to be most frequent in children with a parental history of cardiac disease.[8] Epidemiological evidence showed homocysteine levels to be more than 45% lower in Westernized adult black Africans than in age-matched white adults, revealing racial genetic differences in homocysteine metabolism.[9]

The *MTHFR* gene has two different alleles, where the "T" allele is associated with decreased enzyme activity, hyperhomocysteinemia, and increased risk for thromboembolism in coronary heart disease. The presence of the "C" allele is correlated to lower homocysteine levels and, not surprisingly, may even provide protection against occlusion of coronary arteries. One Hungarian study concluded that the carriers of the T allele with coronary heart disease died earlier due to myocardial infarction.[10]

Lifestyle

An association between coffee and black tea consumption and the concentration of total homocysteine in plasma has been reported.[11] A marked positive dose–response relation between coffee consumption and plasma homocysteine levels was observed. The relationship was most marked in males and females consuming more than eight cups of coffee per day. The combination of cigarette smoking and high coffee intake was associated with particularly high homocysteine concentrations.[12] Long-term ingestion of alcohol has also been associated with increased homocysteine levels.[13,14] Plasma total homocysteine is inversely related to exercise.[15]

Nutritional Relationships

Nutrition affects homocysteine concentrations in both men and women. For example, individuals in the lowest quartiles for serum folate and vitamin B_{12} have significantly higher concentrations of homocysteine, and men in the lowest quartile of serum pyridoxal 5′-phosphate (P^5P; the bioactive form of vitamin B_6) also have increased homocysteine concentrations.[2]

Methionine

Metabolism of the amino acid methionine, a limiting amino acid in the synthesis of many proteins, affects several biochemical pathways involving the production of nutrients that are essential to the optimal functioning of the cardiovascular, skeletal, and nervous systems.

Homocysteine is an intermediate product of methionine metabolism and is metabolized by two pathways: the remethylation pathway, which regenerates methionine; and the transsulfuration pathway, which degrades homocysteine into cysteine and then taurine. In essence, the intermediate metabolite homocysteine is located at a metabolic crossroads, so it directly and indirectly affects all methyl and sulfur group metabolism occurring in the body. Experiments demonstrated that high levels of L-homocysteine and adenosine in the cell inhibit all methylation reactions.[16]

The remethylation pathway (Fig. 134.1) comprises two intersecting biochemical pathways and results in the transfer of a methyl group (CH_3) to homocysteine by either methylcobalamin or betaine (trimethylglycine). Methylcobalamin originally receives its methyl group from S-adenosylmethionine (SAMe) or 5-methyltetrahydrofolate (5-methylTHF). After remethylation, methionine can be reused

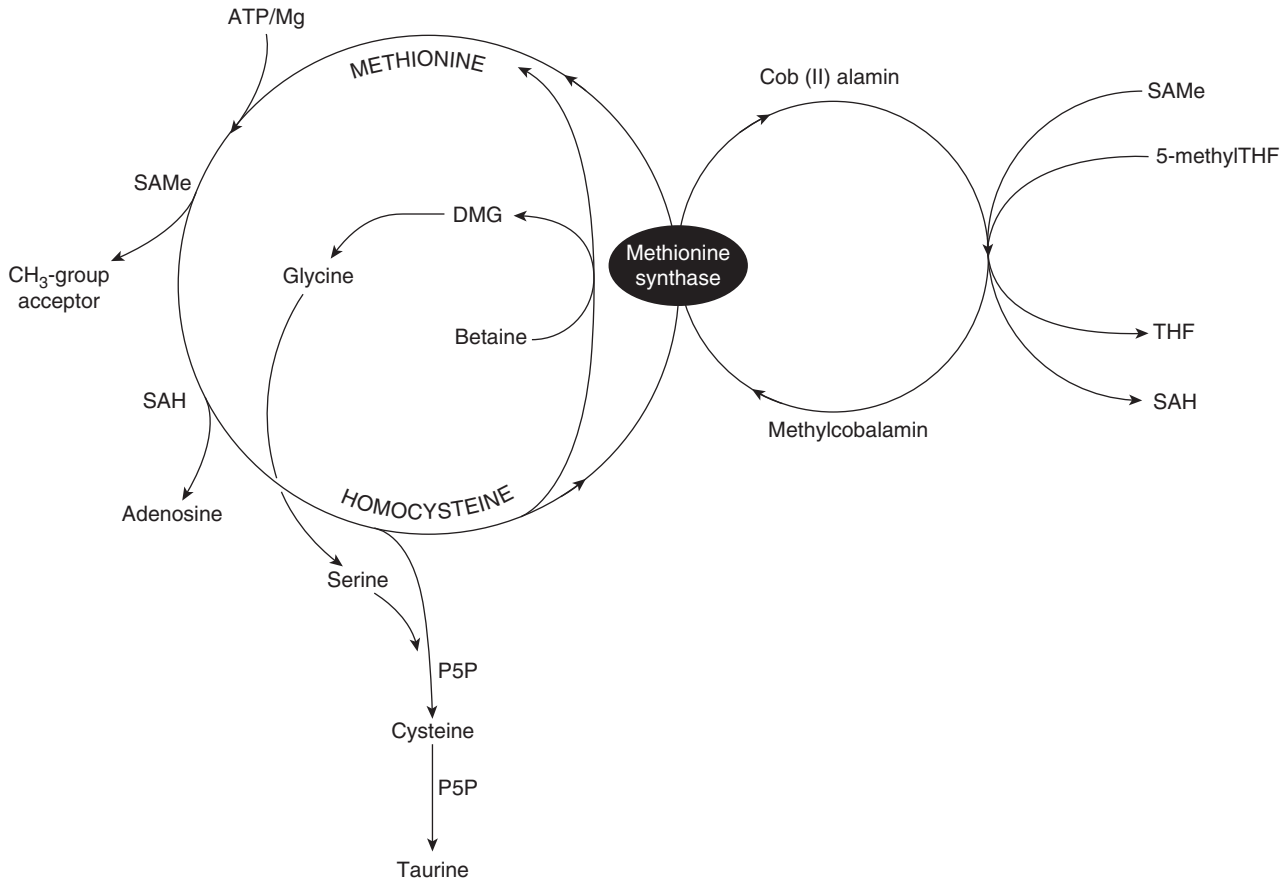

Fig. 134.1 Homocysteine metabolism. *DMG,* dimethylglycine; *5-methylTHF,* 5-methyltetrahydrofolate; *P5P,* pyridoxal 5′-phosphate (vitamin B_6); *SAH,* S-adenosylhomocysteine; *SAMe,* S-adenosylmethionine; *THF,* tetrahydrofolate.

to produce SAMe, the body's "universal methyl donor," which participates in several key metabolic pathways, including methylation of DNA and myelin, synthesis of carnitine, coenzyme Q_{10} (CoQ_{10}), creatine, epinephrine, melatonin, methylcobalamin, and phosphatidylcholine (PC), as well as Phase II methylation detoxification reactions.

The transsulfuration pathway of methionine/homocysteine degradation (see Fig. 134.1) produces the amino acids cysteine and taurine, which are important nutrients for cardiac health, hepatic detoxification, cholesterol excretion, bile salts formation, and glutathione (GSH) production. This pathway depends on adequate dietary intake and hepatic conversion of vitamin B_6 into its active form, P^5P. The amino acid serine, a down-line metabolite generated from betaine via the homocysteine remethylation pathway, is also necessary.

In addition to 5-methylTHF, methylcobalamin, betaine, and P^5P, *N*-acetylcysteine (NAC) has been reported to significantly lower homocysteine levels.[17]

S-Adenosylhomocysteine

The metabolic precursor of homocysteine in all tissues is S-adenosylhomocysteine, which is more difficult to measure than homocysteine but has recently been indicated as a more sensitive marker for cardiovascular disease and Alzheimer's disease. S-adenosylhomocysteine is formed by the demethylation of SAMe (Fig. 134.2). S-adenosylhomocysteine hydrolase catalyzes the hydrolysis of S-adenosylhomocysteine to adenosine and homocysteine. S-adenosylhomocysteine hydrolase deficiency is a genetic disorder of methionine metabolism that results in slow psychomotor development.

Increased levels of S-adenosylhomocysteine may occur when the intracellular concentration of homocysteine increases.[18–20]

Methyltetrahydrofolate

Folates function as carbon donors in the synthesis of serine from glycine, directly in the synthesis of purines and pyrimidine bases, and indirectly in the synthesis of transfer RNA. Folates also function as methyl donors to create methylcobalamin, which is used for remethylation of homocysteine to methionine.

Folic acid is the synthetic form of folate and requires several metabolic steps within the cell to be converted into the metabolically active tetrahydrofolate. It is an oxidized synthetic water-soluble member of the vitamin-B complex family and is found in fortified foods, supplements, and pharmaceuticals. L-5-methyl-tetrahydrofolate (L-5-methyl-THF) is the predominant form of dietary folate that is transported into peripheral tissues to be used for cellular metabolism.

Synthesis of the active forms of folate is a complex process requiring several enzymes, as well as adequate supplies of niacin, P^5P, and serine as cofactors (Fig. 134.3). In plants, folate is formed from a hetero-bicyclic pteridine ring, para-aminobenzoic acid, and glutamic acid. Folate is initially deconjugated in the cells of the intestinal wall to the monoglutamate form. This is then reduced to dihydrofolate and then to tetrahydrofolate (THF) via folate and dihydrofolate reductase. Both enzymes require reduced nicotinamide adenine dinucleotide phosphate (niacin dependent) as a cofactor. Serine combines with P^5P to transfer a hydroxymethyl group to THF. This results in the formation of 5,10-methylenetetrahydrofolate (5,10-methyleneTHF) and glycine. This molecule is of central importance, being the precursor of the metabolically active 5-methylTHF, which is involved in homocysteine metabolism, and 10-formyltetrahydrofolate (involved in purine synthesis), as well as functioning on its own in the generation of thymine side chains for incorporation into DNA.

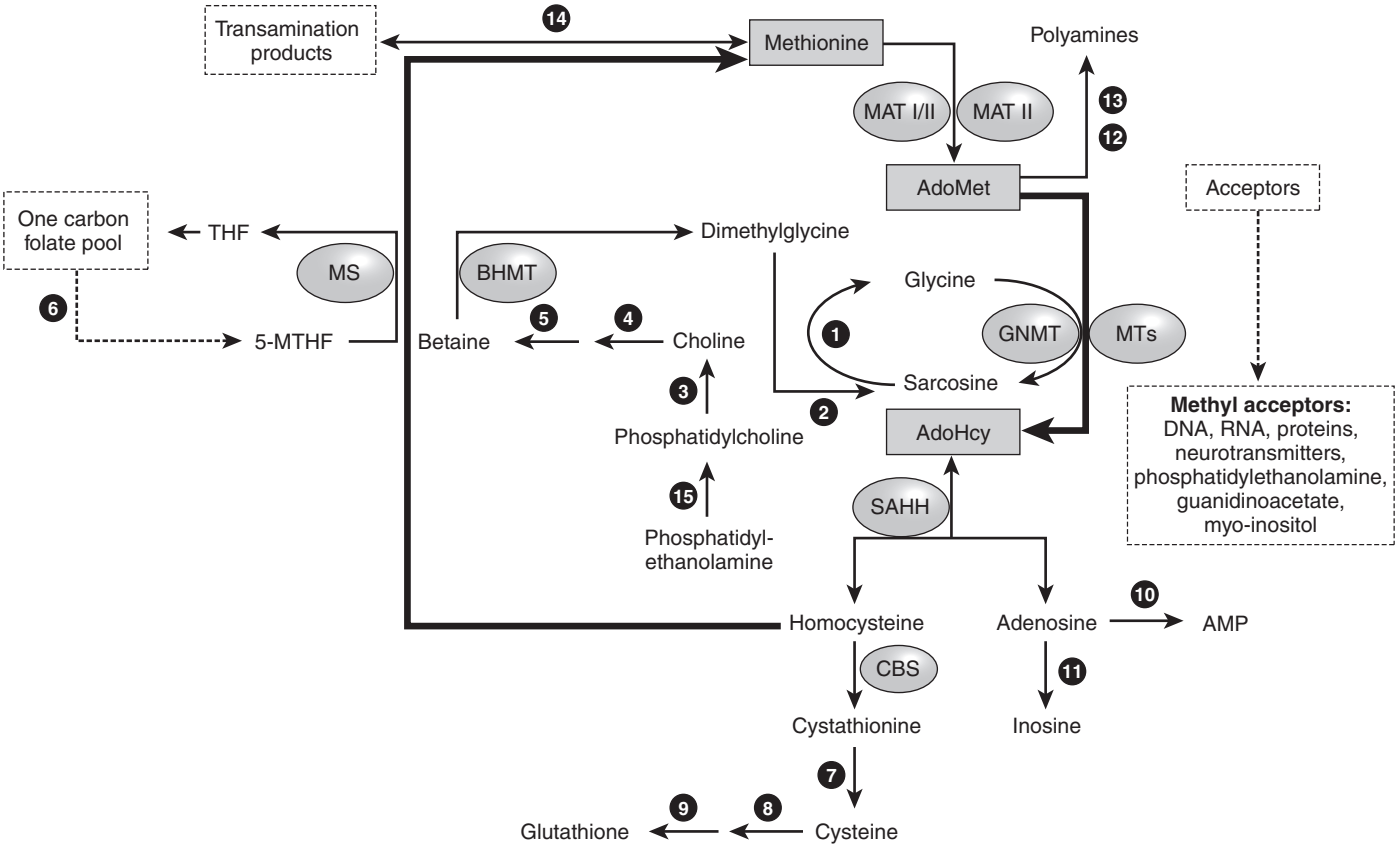

Fig. 134.2 Methionine, AdoMet (S-adenosylmethionine), and AdoHcy metabolism. (From Baric I, Fumić K, Glenn B, et al. S-adenosylhomocysteine hydrolase deficiency in a human: a genetic disorder of methionine metabolism. *Proc Natl Acad Sci.* 2004;101:4234–4239.)

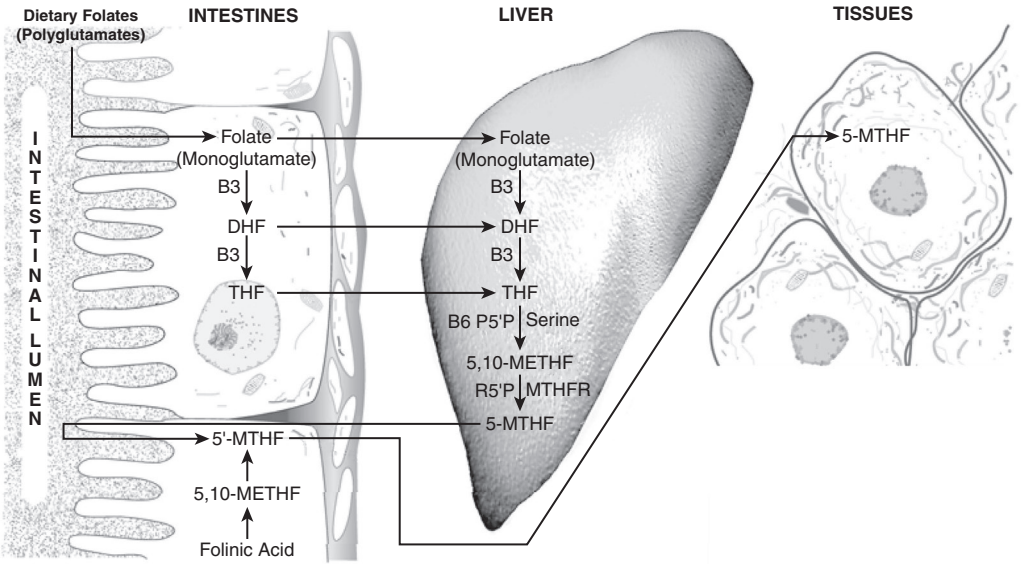

Fig. 134.3 Absorption and activation of folic acid. *DHF,* dihydrofolate; *5,10-METHF,* 5,10-methylenetetrahydrofolate; *5-MTHF,* 5-methyltetrahydrofolate; *MTHFR,* methylenetetrahydrofolate reductase; *P5′-P,* pyridoxal 5′-phosphate; *R5′-P,* riboflavin 5′-phosphate; *THF,* tetrahydrofolate.

The following may contribute to a deficiency of folate:

- A deficient food supply
- A defect in utilization, as in alcoholics
- Malabsorption
- Increased needs in pregnant women and cancer patients
- Metabolic interference by drugs
- Folate losses in hemodialysis
- Enzyme or cofactor deficiency necessary for the generation of folate

Individuals using supplements or consuming either breakfast cereals or green leafy vegetables have significantly greater plasma folate and lower homocysteine levels than those who do not.[1]

Folinic acid (5-formylTHF), available supplementally as calcium folinate (also known as leucovorin calcium), is an immediate precursor to 5,10-methyleneTHF and 5-methylTHF. Folinic acid can correct deficiencies of the active forms of folate, is more stable than folic acid, and has a longer half-life in the body. Folinic acid also readily crosses the blood–brain barrier and is slowly cleared, compared with folic acid, which is poorly transported into the brain and, once in the central nervous system (CNS), is rapidly cleared.[21]

Methylcobalamin

The coenzyme form of vitamin B_{12} is a complex molecule containing cobalt bound to five nitrogens and one carbon. The metal–carbon bond found on this coenzyme is the only known biological example of this type of linkage. The use of cobalt in the two biologically active forms of cobalamin, adenosylcobalamin and methylcobalamin, is the only known function of this metal in biological systems.

In humans, the cobalt in cobalamin exists in a univalent oxidation state, designated as cob(I)alamin. The compound commonly referred to as *vitamin B_{12}* has a cyanide molecule at the metal–carbon position, and the oxidation state of the cobalt is +3 instead of the biologically active +1. To be used in the body, the cyanide molecule must be removed. It is thought that the compound GSH may perform this function. Other available forms of vitamin B_{12} include hydroxocobalamin and the two active forms, adenosylcobalamin (cobamamide) and methylcobalamin.

The absorption of dietary cobalamin requires the formation of a complex between dietary vitamin B_{12} and R-proteins and the secretion, by the stomach mucosa, of intrinsic factor. The vitamin B_{12} complex is split by pancreatic proteases, and the released vitamin B_{12} attaches to intrinsic factor and is absorbed in the distal ileum. The amount of cobalamin required in the diet is low, and even people with pernicious anemia can generally absorb sufficient amounts if the coenzyme is supplemented at a high enough dosage.

Although the basic cobalamin molecule is only synthesized by microorganisms, all mammalian cells can convert this into the coenzymes adenosylcobalamin and methylcobalamin. Adenosylcobalamin is the major form in cellular tissues, where it is retained in the mitochondria. Methylcobalamin predominates in blood plasma and certain other body fluids and in cells found in the cytosol.

Adenosylcobalamin functions in reactions in which hydrogen groups and organic groups exchange places. In humans, adenosylcobalamin is required in only two reactions: the catabolic isomerization of methylmalonyl coenzyme A (CoA) to succinyl-CoA, and interconversion of α- and β-leucine. After its formation from methylmalonyl-CoA, succinyl-CoA is either involved in the synthesis of porphyrin molecules (along with glycine) or it transfers its CoA to form acetyl-CoA. The latter reaction is magnesium dependent, and the remaining succinate is fed into the citric acid cycle. Deficiencies in this coenzyme form of vitamin B_{12} result in increased amounts of methylmalonyl-CoA and generally an increase in glycine levels.

Methylcobalamin's only known biological function in humans is in the remethylation of homocysteine to methionine via the enzyme methionine synthase, also known as 5-methyltetrahydrofolate-homocysteine methyltransferase. To originally form methylcobalamin from cyanocobalamin or other Cob(III)alamin or Cob(II)alamin precursors, SAMe must be available to supply a methyl group. Once methylcobalamin is formed, it functions in the regeneration of methionine by transferring its methyl group to homocysteine. Methyl-cobalamin can then be regenerated by 5-methylTHF (Fig. 134.4). The cell's ability to methylate important compounds such as proteins, lipids, and myelin is compromised by a deficiency of either folate or vitamin B_{12}.[22] Shortages of folate, SAMe, or a dietary deficiency of cobalamin lead to a decrease in the generation of methylcobalamin and a subsequent impairment of homocysteine metabolism. Because lack of methylcobalamin leads to depressed DNA synthesis, rapidly dividing cells in the brain and elsewhere are affected.

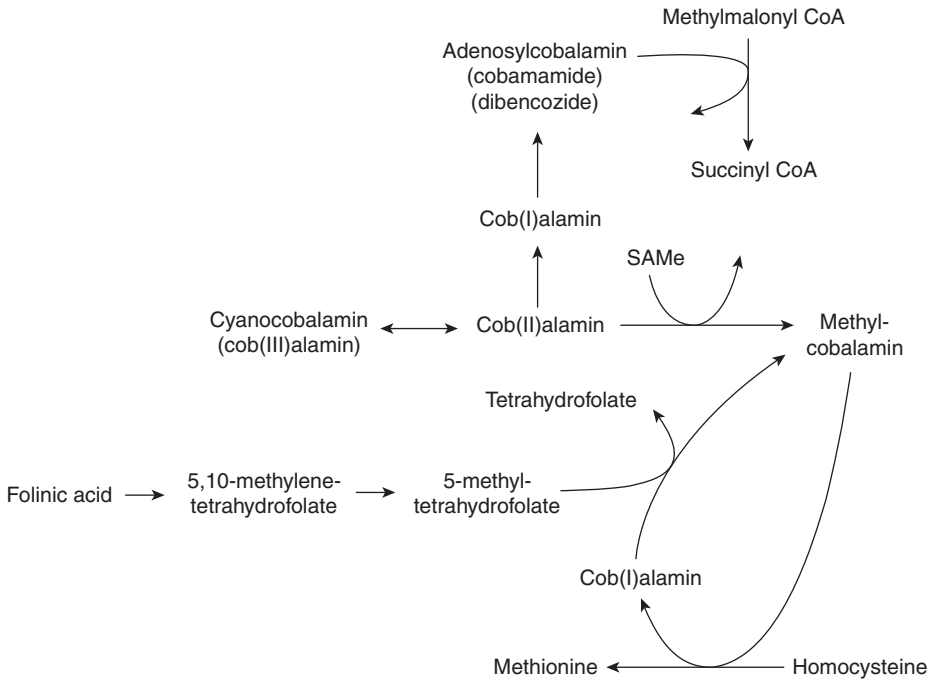

Fig. 134.4 Cobalamin metabolism.

At least 12 different inherited inborn errors of metabolism related to cobalamin are known. Abnormalities are detectable by urine and plasma assays of methylmalonic acid and homocysteine and by plasma and erythrocyte analysis of cobalamin coenzymes, which can reveal deficiencies of methylcobalamin or adenosylcobalamin.[23]

Betaine

The metabolic pathways of betaine, methionine, methylcobalamin, and methylTHF are interrelated, intersecting at the regeneration of methionine from homocysteine. This regeneration is accomplished in one of two ways. One involves the generation in the cytosol of 5-methylTHF from methylene THF and the transfer of its methyl group to regenerate methylcobalamin, which then acts as a coenzyme in the regeneration of methionine. Because THF and its derivatives can only cross the mitochondrial membrane slowly, inside, the mitochondria regeneration of methionine relies on recovery of a methyl group from betaine.

Betaine donates one of its three methyl groups via the enzyme betaine-homocysteine methyltransferase to homocysteine, resulting in the regeneration of methionine. After the donation of the methyl group, one molecule of dimethylglycine remains. This molecule is oxidized to glycine and to two molecules of formaldehyde by riboflavin-dependent enzymes. The formaldehyde can combine with THF within the mitochondria to generate methylenetetrahydrofolate, which can be converted to 5-methylTHF and subsequently used as a methyl donor (Fig. 134.5).

In animal studies, a disturbance in the metabolism of either of the two methyl-donor pathways, due to limited availability of either betaine or folates and vitamin B_{12}, affects levels of nutrients in the coexisting pathway, because more of a drain is placed on the other pathway as a source of methyl groups. Rats fed diets deficient in choline and methionine had hepatic folate concentrations half that of controls after 5 weeks.[24] During choline deficiency, hepatic SAMe concentrations were also shown to decrease by as much as 50%.[25] Similarly, THF deficiency resulted in decreased hepatic total choline levels.[26]

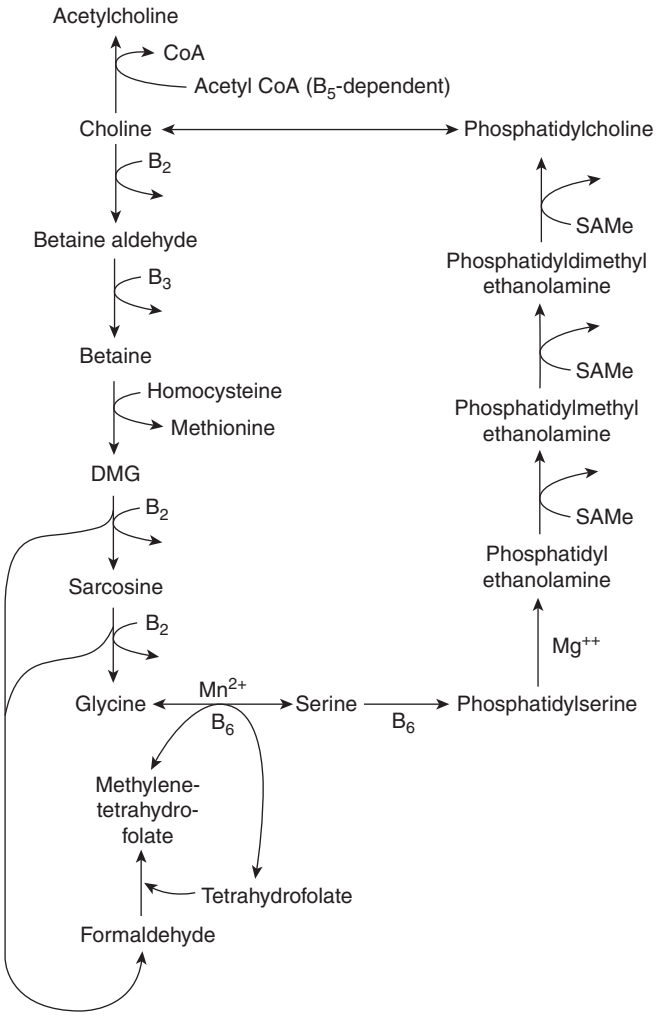

Fig. 134.5 Phosphatidylcholine metabolism.

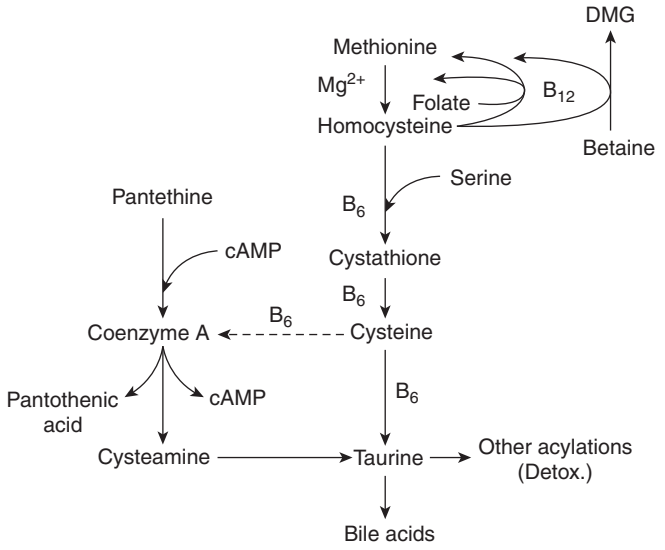

Fig. 134.6 Synthesis of taurine.

Patients with a congenital deficiency of the enzyme MTHFR, which is needed for the formation of 5-methylTHF, have reduced levels of both methionine and SAMe in the cerebrospinal fluid and show demyelination in the brain and degeneration of the spinal cord. Methionine is effective in the treatment of some of these patients; however, betaine was shown to restore cerebrospinal fluid SAMe levels to normal and to prevent the progression of neurological symptoms in all patients in whom it was tried.[27]

Betaine supplementation has been shown to reduce homocysteine levels[28] while resulting in modest increases of plasma serine and cysteine levels.[29] Stimulation of betaine-dependent homocysteine remethylation causes a commensurate decrease in plasma homocysteine that can be maintained as long as supplemental betaine is taken.[30]

Serine levels are depressed in some individuals with excess homocysteine who are treated with folic acid, cobalamin, and vitamin B_6.[31] Because serine is required (1) for the conversion of folic acid to its active form, (2) as a shuttle for methyl groups between the cytosol and the mitochondria, and (3) as a cofactor in the transsulfuration pathway of methionine/homocysteine metabolism, supplementation with betaine should be included with folic acid, cobalamin, and P^5P to optimize the interrelated pathways of homocysteine metabolism.

Pyridoxal 5´-Phosphate

P^5P is the active coenzyme form of vitamin B_6. This cofactor is involved in myriad biological processes, including the transsulfuration pathway of homocysteine. This degradation pathway involves a two-step process, resulting in the formation of cystathionine and its subsequent cleavage to cysteine. Cystathionine synthase and cystathionase require P^5P as a cofactor, and the committed first step in the degradation of homocysteine, cystathionine synthase, also requires serine, a downstream metabolite of betaine (Fig. 134.6). Some studies suggest that cystathionine could be a useful marker to assess the effect of vitamin B_6 and should be monitored with homocysteine to better elucidate clinical outcomes.[32]

Once cysteine is generated, it can be directed into several different pathways, including synthesis of GSH, acetyl-CoA, and taurine. Three pathways from cysteine to taurine are known; all require P^5P.

RENAL FUNCTION

Impaired kidney function appears to be a factor in raised homocysteine concentrations.[33] It has been shown that a decreased glomerular filtration rate may be a contributing factor, and some researchers suggest that hyperhomocysteinemia may actually reflect early nephrosclerosis,[8] although other studies demonstrate only a minor renal influence.[34] Fenofibrate treatment, known to increase homocysteine levels, is also known to promote elevations in serum creatinine (see "Pharmaceutic Drug Effects on Homocysteine").[35] Cystatin C, a creatinine-independent indicator of glomerular filtration rate, has also been shown to be well associated with homocysteine levels in kidney transplantation patients, as well as those with coronary disease.[35,36]

PHARMACEUTIC DRUG EFFECTS ON HOMOCYSTEINE

Fibrates such as gemfibrozil are a class of drugs used to lower triglycerides and raise high-density lipoprotein levels. In a paradoxical effect working against a safer cardiac risk profile, these drugs have been observed to raise homocysteine levels up to 40%.[35,37,38] The mechanism of this observation is unknown, although it seems that renal mechanisms may be involved (see "Renal Function").

Thiazides and angiotensin-converting enzyme inhibitors are often a first-line conventional treatment to lower elevated blood pressure. One preliminary, randomized, prospective treatment study investigated 40 patients with hypertension after treatment with hydrochlorothiazide or captopril. In this study, vitamins B_6, B_{12}, folic acid, creatinine, and cystatin C were used as parameters of renal function. For 31 and 29 days, respectively, 21 patients were prescribed hydrochlorothiazide, and 19 were prescribed captopril. It was found that hydrochlorothiazide, but not captopril, significantly raised homocysteine by 16%, as well as creatinine and cystatin C.[39]

EFFECT OF HOMOCYSTEINE ON KEY NUTRIENTS

Because of its central role in sulfur- and methyl-group metabolism, elevated levels of homocysteine would be expected to negatively affect the biosynthesis of all of the following: SAMe, carnitine, chondroitin sulfates, CoA, coenzyme Q10 (CoQ_{10}), creatine, cysteine, dimethylglycine, epinephrine, glucosamine sulfate, glutathione (GSH), glycine, melatonin, pantethine, phosphatidylcholine, phosphatidylserine, serine, and taurine.

S-Adenosylmethionine

SAMe is formed by the transfer of an adenosyl group from adenosine triphosphate to the sulfur atom of methionine. This reaction requires magnesium as a cofactor. When methyl groups are transferred from SAMe, S-adenosylhomocysteine is formed. This is then hydrolyzed to release the adenosine and results in the formation of homocysteine.

SAMe is known to be used in the synthesis of the following compounds: carnitine, CoQ_{10}, creatine, methylcobalamin from cob(III) alamin, 1-methylnicotinamide, *N*-methyltryptamine, PC, and polyamines. It is also used in methylation reactions as part of hepatic Phase II detoxification.

Carnitine

A trimethylated amino acid roughly similar in structure to choline, carnitine is a cofactor for the transformation of free long-chain fatty acids into acyl-carnitines and their transport into a mitochondrial matrix, where they undergo β-oxidation for cellular energy production. Synthesis of carnitine begins with the methylation of the amino acid L-lysine by SAMe. Methionine, magnesium, vitamin C, iron, P^5P, and niacin, along with the cofactors responsible for regenerating SAMe from homocysteine (5-methylTHF, methylcobalamin, and betaine), are required for optimal carnitine synthesis (Fig. 134.7).

A pivotal enzyme in carnitine synthesis, betaine aldehyde dehydrogenase, is the same enzyme responsible for the synthesis of betaine from choline. Studies suggest this enzyme has a preference for the choline–betaine conversion and that choline supplementation may decrease carnitine synthesis; therefore it may be of greater benefit to supplement with betaine rather than its precursor, choline.[40,41]

Chondroitin Sulfates, Glucosamine Sulfate, and Other Sulfated Proteoglycans

Proteoglycans are amino sugars found in all tissues, the highest being in cartilage, tendons, ligaments, synovial fluid, skin, fingers, toenails, heart valves, and the basement membrane of all blood vessels. Perhaps the most widely known of the amino sugars are the chondroitin sulfates and glucosamine sulfate (see Chapter 83 for further discussion).

Chondroitin sulfates are primarily composed of alternating residues of *N*-acetyl-D-galactosamine and D-glucuronate. Sulfate residues are present on C-4 of the galactosamine residues in one type of chondroitin and on C-6 in another. Glucosamine sulfate is a simple molecule composed of glucose, the amino acid glutamine, and a sulfate group. Other sulfated proteoglycans include dermatan sulfates, keratan sulfates, and heparan sulfates.

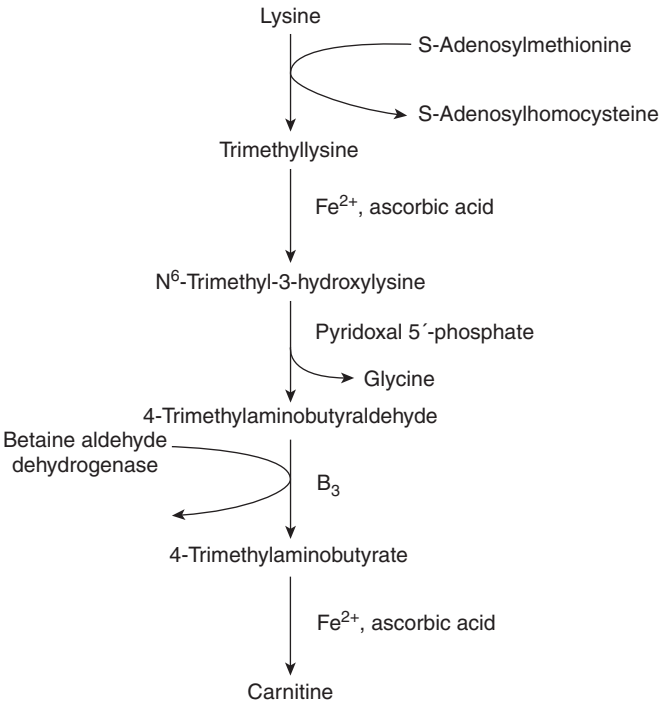

Fig. 134.7 Synthesis of carnitine.

High levels of homocysteine are likely to negatively affect the formation of the sulfated amino sugars because although some sulfates are present in the diet, the sulfoxidation of cysteine is an important source of sulfate molecules. The sulfoxidation pathway proceeds through the toxic intermediate sulfite and requires molybdenum as a cofactor.

Coenzyme A

CoA consists of an adenine nucleotide and phosphopantetheine. Contained within the structure of this coenzyme is pantothenic acid; however, the reactive component of the molecule is a sulfhydryl group that is not contained within the vitamin. To form the sulfhydryl-containing molecule (pantetheine), pantothenic acid must combine with cysteamine. Cysteamine is formed through conjugation and decarboxylation reactions of cysteine. The disulfate form of pantetheine, known as pantethine, as opposed to pantothenic acid, bypasses cysteine conjugation and decarboxylation. This might account for some of the clinical benefits seen with pantethine supplementation that have not been reproduced with the supplementation of pantothenic acid. See Fig. 134.8 A to D for the chemical structures of pantetheine, pantethine, pantothenic acid, and cysteamine.

Coenzyme Q_{10}

CoQ_{10} is a fat-soluble quinone occurring in the mitochondria of each cell (see Chapter 68 for a full discussion). The primary biochemical action of CoQ_{10} is as a cofactor in the electron transport chain, the biochemical pathway that generates adenosine triphosphate. Because most cellular functions depend on an adequate supply of adenosine triphosphate, CoQ_{10} is essential for the health of virtually all human tissues and organs. CoQ_{10} also functions as an antioxidant, assisting in the recycling of vitamin E.[42,43]

Biosynthesis of CoQ_{10} begins with the amino acid tyrosine. Pantothenic acid, P^5P, and vitamin C are all required for the initial steps in its synthesis. An isoprenyl side chain from farnesyl diphosphate, an intermediate in cholesterol synthesis between 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) and squalene, is then added. An inadequate supply of this intermediate, which can be caused by HMG-CoA reductase inhibitors (cholesterol-lowering drugs of the statin family), results in decreased levels of CoQ_{10}.[44]

In two of the final steps in the synthesis of CoQ_{10}, methyl groups are provided by SAMe (Fig. 134.9). Adequate dietary methionine and a sufficient supply of the nutrients required for the remethylation of homocysteine to methionine (5-methylTHF, methylcobalamin, and betaine) are required to generate sufficient SAMe. Suboptimal amounts of SAMe may negatively affect the body's ability to synthesize sufficient CoQ_{10}. This relationship between SAMe and CoQ_{10} has been suggested in various animal studies.[45,46]

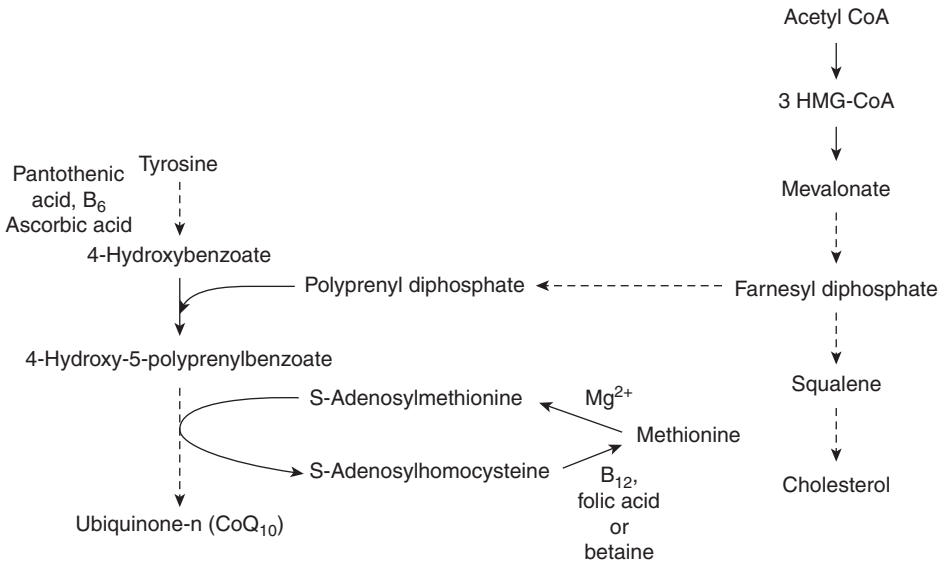

Fig. 134.9 Synthesis of coenzyme Q_{10}.

Creatine

In humans, more than 95% of the total creatine content is located in skeletal muscle, of which approximately one third is in its free form as creatine, also known as methyl-guanidinoacetic acid, whereas the remainder is present in a phosphorylated form as creatine phosphate (also called phosphocreatine). Creatine phosphate is used within skeletal muscle as a means of storing high-energy phosphate bonds.

Creatine is formed in the liver, kidney, and pancreas, beginning with the combination of arginine and glycine to produce guanidinoacetate. A methyl group from SAMe is then transferred, resulting in the formation of creatine. The by-product of this reaction, S-adenosylhomocysteine, is subsequently hydrolyzed into homocysteine and adenosine. To optimize the endogenous production of creatine, the amino acids arginine, glycine, and methionine must be available as substrates. Additionally, cofactors needed to optimize remethylation of homocysteine to form methionine are required to recycle the homocysteine to methionine for reuse as SAMe (Fig. 134.10). Serum creatine levels have been positively correlated with plasma homocysteine levels (i.e., as creatine levels rise, so do homocysteine levels).[47]

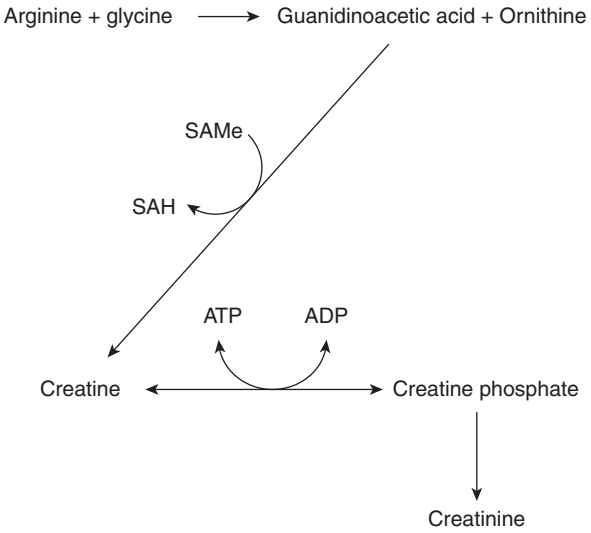

Fig. 134.10 Synthesis of creatine, creatine phosphate, and creatinine.

Epinephrine and Melatonin

Derivatives of the aromatic amino acids, L-tyrosine and L-tryptophan, require methylation for the biosynthesis of their down-line metabolites.

The biosynthesis of catecholamines begins with the amino acid L-tyrosine and proceeds through dopa and dopamine, resulting in the formation of norepinephrine, the neurotransmitter substance found in most sympathetic nerve terminals, as well as in some synapses of the CNS. In the chromaffin cells of the adrenal medulla, a methyl group is provided by SAMe, resulting in the formation of epinephrine from norepinephrine. A number of metabolites are formed from the degradation of both norepinephrine and epinephrine. Catecholamine degradation proceeds independently, and in conjunction with monoamine oxidase, by catechol-*O*-methyltransferase. This enzyme catalyzes the transfer of a methyl group donated by SAMe and, depending on the substrate, results in the formation of homovanillic acid, normetanephrine, and metanephrine.

The formation of melatonin from L-tryptophan proceeds through 5-hydroxytryptophan, serotonin, and *N*-acetylserotonin. Melatonin is then formed in the pineal gland by the donation of a methyl group. 5-Methoxytryptamine, an alternate metabolite of serotonin, also requires the addition of a methyl group.

Phosphatidylcholine

Phosphatidylcholine (PC) is a primary component of lecithin. It is the most frequently encountered phospholipid in animals and is structurally related to phosphatidylserine and phosphatidylethanolamine. PC consists of a glycerol backbone that is esterified with fatty acids on carbon atoms 1 and 2, with a phosphoric acid/choline complex in position 3. Although PC is usually referred to as if it were a single compound, it is actually a group of related compounds that vary depending on the fatty acid composition at positions C-1 and C-2.

Dietary choline is derived primarily from PC, which, after absorption by the intestinal mucosa, is metabolized to choline in the liver by the enzyme phospholipase D. Most choline is rephosphorylated to PC; however, a small amount is carried to the brain via the bloodstream, where it is converted to the neurotransmitter acetylcholine. If PC or choline is lacking in the diet, it can be synthesized from phosphatidylserine and phosphatidylethanolamine (see Fig. 134.5). Synthesis of PC depends on the availability of SAMe as a methyl donor because synthesis involves the transfer of methyl groups from three SAMe molecules to phosphatidylethanolamine to generate one molecule of PC.

The metabolic pathways of PC, methionine, methylcobalamin, and 5-methylTHF are interrelated, intersecting at the regeneration of methionine from homocysteine by betaine (see Fig. 134.1). The use of choline molecules as methyl donors in this process is probably the main factor that determines how rapidly a diet deficient in choline induces pathological changes.[25]

Taurine

Taurine is a unique amino acid because it carries a sulfonic acid group ($-SO_3H$) instead of a carboxyl group ($-CO_2H$). Taurine is biosynthesized from methionine or from cysteine via the transsulfuration pathway (see Fig. 134.6). Once cysteine is generated, it can be directed into several different pathways, including synthesis of GSH, acetyl CoA, 3′-phosphate 5′-phosphosulfate (PAPS), and taurine. The committed first step in the degradation of homocysteine requires cystathionine synthase, P^5P, and serine. P^5P is also required as a cofactor in the cleavage of cystathionine to cysteine. Homocystinuria, resulting from an absence of cystathionine synthase, can lead to mental retardation. Low levels of cystathionine synthase can also lead to abnormally high levels of homocysteine, especially when remethylation cofactors are also deficient.

CLINICAL APPLICATIONS

Phase II Detoxification

Because homocysteine is a critical intermediate in both methyl- and sulfur-group metabolism, elevated levels could indicate nutrient deficiencies that might compromise function in several of the hepatic Phase II detoxification reactions.

Amino acid conjugation reactions require either glycine, glutamine, or taurine. Glycine functions in the conjugation of aromatic acids (e.g., benzoic acid to hippuric acid). Elevated levels of homocysteine might indicate reduced nutritional levels of betaine and subsequently its down-line metabolite, glycine. Taurine functions in acylations (e.g., bile conjugation).

Sulfur conjugation requires NAC, GSH, PAPS, or methionine/cysteine. NAC is used for mercapturic acid synthesis and is involved in detoxification of a wide variety of compounds, including aromatic hydrocarbons, some phenols, halides, esters, epoxides, and caffeine. GSH is involved in dismutation reactions of organic nitrates (e.g., nitroglycerin). PAPS is used in sulfate ester synthesis, mostly with phenols, and some aliphatic alcohols (e.g., ethanol) and aromatic amines. Methionine and cysteine are used in cyanide-thiocyanate detoxification. A portion of the inorganic sulfur needed for the formation of all of these compounds passes through the homocysteine cycle.

Alkylation reactions require SAMe, methylcobalamin, or 5-methylTHF. These compounds provide methyl groups to detoxify compounds containing hydroxide, SH, or NH_2 groups. Examples of these reactions include norepinephrine to epinephrine, epinephrine to metanephrine, guanidoacetic acid to creatine, and *N*-acetylserotonin to melatonin.

Other Phase II detoxification reactions that might be affected by elevated homocysteine as a biological marker of reduced nutrient formation include acetylation by acetyl-CoA, which requires cysteine as a source of its cysteamine component, and the use of carnitine for the conversion of valproic acid to valpropylcarnitine.

Heart Disease

Increased blood levels of homocysteine are correlated with significantly increased risk of coronary artery disease (CAD),[48–54] myocardial infarction,[55,56] peripheral occlusive disease,[57–60] cerebral occlusive disease,[57,60] and retinal vascular occlusion (Box 134.1).[61]

BOX 134.1 What Homocysteine and Homocysteine Thiolactone Do to Arteries

- Generate superoxide and hydrogen peroxide, which have been linked to damage to arterial endothelium
- Change coagulation factor levels so as to encourage clot formation
- Prevent small arteries from dilating, so they are more vulnerable to obstruction
- Cause smooth muscle cells in the arterial wall to multiply
- Interact with low-density lipoproteins, causing them to precipitate and damage endothelial tissue
- Cause platelets to aggregate

Inborn errors of homocysteine metabolism result in high levels of homocysteine in the blood and severe atherosclerotic disease; even within the range considered normal (4–16 μmol/L), there is a graded increase in risk for CAD. In a study of 304 patients with CAD versus controls, the odds ratio for CAD increased as plasma homocysteine increased, even within the normal range. A 5 μmol/L increase in plasma homocysteine was correlated with an increase in the odds ratio of 2.4 ($P < 0.001$), with no "threshold effect."[51]

A review of numerous studies found that mild hyperhomocysteinemia after a methionine load test occurred in 21%, 24%, and 32% of patients with CAD, cerebrovascular disease, and peripheral vascular disease, respectively.[46] Another group of researchers found a 29.3% incidence of hyperhomocysteinemia (>14 μmol/L by their definition) in a group of 1160 elderly (ages 67–96 years) individuals in the Framingham Heart Study. The study also indicated that plasma homocysteine levels increased with age.[57]

A number of interrelated atherogenic mechanisms are thought to be involved with hyperhomocysteinemia. These include advanced thickening and smooth muscle cell proliferation of endothelial vessel wall intima, enhanced lipid deposition in the vessel wall, forced detachment of endothelial cells, activation of leukocytes and thrombocytes, increased low-density lipoprotein oxidation, initiation of platelet thromboxane synthesis, enhanced oxidative stress induced by peroxide formation during homocysteine oxidation, and prothrombotic coagulation interference.[62,63] One way homocysteine assists this process is by the generation of hydrogen peroxide.[64] By creating oxidative damage to low-density lipoprotein cholesterol and endothelial cell membranes, hydrogen peroxide can then catalyze injury to vascular endothelium.[64,65]

Nitric oxide and other oxides of nitrogen released by endothelial cells (also known as endothelium-derived relaxing factor) protect endothelial cells from damage by reacting with homocysteine, forming S-nitrosohomocysteine, which inhibits hydrogen peroxide formation. However, as homocysteine levels increase, this protective mechanism can become overloaded, allowing damage to endothelial cells to occur.[65–67] Because of the role of sulfate compounds in the formation of amino sugars needed to form the basement membrane of blood vessels, high levels of homocysteine are likely to contribute to the formation of blood vessels that are more susceptible to oxidative stress.[67] The end result of the combination of oxidative damage and endothelial collagen instability can be the formation of atherosclerotic plaques.

Decreased plasma folate levels are correlated with increased levels of homocysteine, as well as a subsequent increased incidence of CAD. In a 15-year Canadian study of CAD mortality in 5056 men and women ages 35 to 79 years, lower serum folate levels were correlated with a significantly increased risk of fatal CAD.[68] In a cohort from the Framingham Heart Study, concentrations of folate and P^5P were inversely correlated with homocysteine levels and the risk of

extracranial carotid artery stenosis.[57] Low P5P and low vitamin B_{12} have also been linked with hyperhomocysteinemia and a significantly increased risk of CAD.[51] Another study of 160 cardiac transplantation patients followed for an average of 28 days found that the high homocysteine levels seen in 99 of these patients surprisingly demonstrated no causal role in the atherothrombotic vascular complications of transplantation. Vitamin B_6 deficiency was seen in 21% of recipients with, and in 9% without, cardiovascular complications or death, or both. Compared with patients with normal B_6 levels, there was a 2.7-fold increase in untoward cardiac events for those patients with B_6 levels less than or equal to 20 nmol/L.[69]

Remethylation of homocysteine and the subsequent formation of SAMe are critical for biosynthesis of L-carnitine, CoQ_{10}, and creatine. Similarly, the transsulfuration pathway must be functioning properly for optimal biosynthesis of cysteine, GSH, pantethine, and taurine. All of these nutrients are used clinically to reduce oxidative stress, improve risk factor markers, or treat heart disease.

Plasma S-adenosylhomocysteine is a more sensitive indicator of cardiovascular disease than plasma homocysteine.[18]

Peripheral Vascular Disease

Elevated homocysteine levels have been established as an independent risk factor for intermittent claudication and deep vein thrombosis. Elevated homocysteine levels corresponded with an increased incidence of intermittent claudication and decreased serum folate levels in a study of 78 patients with intermittent claudication.[70] A fourfold increase in the risk of peripheral vascular disease was noted in individuals with hyperhomocysteinemia compared with those with normal homocysteine levels.[71] A group of researchers in the Netherlands found high homocysteine levels to be a significant risk factor for deep vein thrombosis, with a stronger relationship among women than men.[72]

An increased risk of peripheral vascular occlusion was noted in women taking oral contraceptives, which might be linked to the significantly increased homocysteine levels in women so affected. It is already known that oral contraceptives can cause declines or deficiencies in vitamins B_6, B_{12}, and folate, nutrients integral to the processing of homocysteine. Laboratory assessment of plasma homocysteine levels may be helpful to detect women who may be predisposed to peripheral vascular occlusion while on oral contraceptives.[73]

Stroke

Stroke patients have significantly elevated homocysteine levels compared with age-matched controls,[74] with a linear relationship between risk of stroke and homocysteine levels[75] and a significant decrease in blood folate concentrations in those with elevated homocysteine.[76] One investigation revealed that people with a dietary intake of at least 300 mcg/day of folic acid reduced their risk of stroke and heart disease by 20% and 13%, respectively, compared with those who consumed less than 136 mcg of folic acid per day.[77]

Pregnancy

Biochemical enzyme defects and nutritional deficiencies can contribute to neural tube defects (NTDs), as well as other negative pregnancy outcomes, including spontaneous abortion, placental abruption (infarct), preterm delivery, and low infant birth weight. Evidence has suggested that derangement of methionine-homocysteine metabolism could be the underlying mechanism of pathogenesis of NTDs and might be the mechanism of prevention observed with supplementation of folic acid.[78,79] It has been firmly established that a low dietary intake of folic acid increases the risk for delivery of a child with an NTD and that periconceptional folic acid supplementation reduces the occurrence of NTDs.[80–86] Research also indicates that supplemental folic acid intake results in increased infant birth weight and improved Apgar scores, along with a concomitant decreased incidence of fetal growth retardation and maternal infections.[87–90]A derangement in methionine-homocysteine metabolism has also been correlated with recurrent miscarriage and placental infarcts (abruption).[91]

The amino acid homocysteine, when elevated, might be a teratogenic agent contributing to congenital defects of the heart and neural tube. Evidence from experimental animals lends support to this belief. When avian embryos were fed homocysteine to raise serum homocysteine to over 150 nmol/mL, dysmorphogenesis of the heart and neural tube, as well as of the ventral wall, was observed.[92]

Because homocysteine metabolism, through the remethylation and transsulfuration pathways, affects several biochemical pathways involving the production of nutrients that are essential to the optimal functioning of the cardiovascular, skeletal, and nervous systems, it is not surprising that these other nutrients have been linked to complications of pregnancy in animal models and humans. Low plasma vitamin B_{12} levels have been shown to be an independent risk factor for NTD.[93,94] Methionine has been shown to reduce the incidence of NTD by 41% in an animal model when administered on days 8 and 9 of pregnancy.[95,96] This evidence indicates that a disturbance in the remethylation pathway with a subsequent decrease in SAMe may be a contributing factor to these complications of pregnancy.

PC, due to its role as a precursor to acetylcholine and choline, is acknowledged as a critical nutrient for brain and nerve development and function.[97–99] Because the metabolic pathways of choline (via betaine), methionine, methylcobalamin, and 5-methylTHF are interrelated, intersecting at the regeneration of methionine from homocysteine, a disturbance in the metabolism of either of these two methyl-donor pathways, due to limited availability of key nutrients or decreased enzyme activity, directly affects the body's ability to optimize levels of SAMe.

Evidence suggests that women with a history of NTD-affected pregnancies have altered folate metabolism.[100–103] Patients with a severe congenital deficiency of the enzyme MTHFR, which is needed for the formation of 5-methylTHF, have reduced levels of both methionine and adenosylmethionine in their cerebrospinal fluid and show demyelination in the brain and degeneration of the spinal cord.[2,104] Because of its direct effect on the activation of folic acid to its methyl derivative, a milder version of this enzyme defect is also strongly suspected to increase the incidence of NTDs.[105]

It is established that high vitamin A intake during the first 2 months of pregnancy is associated with a severalfold higher incidence of birth defects.[106,107] Although the mechanism of action remains to be elicited, in an animal model, the activity of hepatic MTHFR was suppressed with high vitamin A levels, suggesting that its teratogenic effect during early pregnancy might be associated with a subsequent derangement in the remethylation of homocysteine.[108]

Because a more significant correlation has been found between high homocysteine levels in women experiencing placental abruption, infarction, and spontaneous abortion than in control women, and homocysteine and CoQ_{10} synthesis depend on the methionine-SAMe-homocysteine pathway, it is possible that low CoQ_{10} and elevated homocysteine independently found in complicated pregnancy may also be found in related conditions.[109,110]

Nutritional intervention with the cofactors required for optimal metabolism of the methionine-homocysteine pathways offers a new integrated possibility for primary prevention of NTD and several other complications of pregnancy. Supplementation with betaine and the active forms of cobalamin and folic acid, such as methylcobalamin and folinic acid, along with riboflavin-5′-phosphate (because of its role as a cofactor for the MTHFR enzyme), may play a significant role in reducing or preventing these emotionally devastating outcomes.

There is an effect of thyroid hormone on folate and vitamin B_{12}-dependent biochemical processes during early growth and development. Higher thyroid function is associated with higher homocysteine concentration in pregnant women and in neonates.

Neurological and Mental Disorders

In addition to the known effect of homocysteine on the cardiovascular system and micronutrient biochemical pathways, numerous diseases of the nervous system are correlated with high homocysteine levels and alterations in vitamin B_{12}, folate, or vitamin B_6 metabolism, including depression, schizophrenia, multiple sclerosis, Parkinson's disease, Alzheimer's disease (AD), and cognitive decline in the elderly.

Methylation reactions via SAMe, including methylation of DNA and myelin, are vitally important in the CNS. The neurological complications of vitamin B_{12} deficiency are likely due to a reduction of activity of the vitamin B_{12}-dependent enzyme methionine synthase and the subsequent reduction of SAMe production. The CNS lacks the alternate betaine pathway of homocysteine remethylation; therefore if methionine synthase is inactivated, the CNS has a greatly reduced methylation capacity.[111] Other causes of reduced methionine synthase activity include folic acid deficiency and nitrous oxide anesthesia exposure.[112]

Homocysteine has also been found to be a neurotoxin, especially in conditions in which glycine levels are elevated, including head trauma, stroke, and vitamin B_{12} deficiency.[113] Homocysteine interacts with the *N*-methyl-D-aspartate receptor, causing excessive calcium influx and free radical production, resulting in neurotoxicity.[94] The neurotoxic effects of homocysteine or reduced methylation reactions, or both, in the CNS contribute to the mental symptomatology seen in vitamin B_{12} and folate deficiency. Increased homocysteine levels can also be seen in schizophrenics.[114]

Significant deficiencies in vitamin B_{12} and folate are common in the elderly population and can contribute to a decline in cognitive function.[115–117] An investigation of cognitive ability in older men (54–81 years old) found poorer spatial copying skills in those with higher homocysteine levels. Better memory performance was correlated with higher vitamin B_6 levels.[118]

Vitamin B_{12} deficiency and increasing severity of cognitive impairment have been seen in patients with AD compared with controls and patients with other dementias.[119] In a study of 52 AD patients, 50 hospitalized nondemented controls, and 49 elderly subjects living at home, patients with AD were found to have the highest homocysteine levels and the highest methylmalonic acid (an indicator of vitamin B_{12} deficiency) levels.[120]

In another Framingham study cohort with an average of 8 years' follow-up, dementia developed in 111 of 1092 nondementia subjects, including 83 who were diagnosed with AD. The adjusted relative risk of dementia was 1.4 for each increase of 1 standard deviation in the logarithmically adjusted homocysteine value. The relative risk of AD was 1.8 per increase of 1 standard deviation at baseline and 1.6 per increase of 1 standard deviation 8 years before baseline. Additionally, in those with a plasma homocysteine level that was greater than 14 μmol/L, the risk of AD nearly doubled.[121]

In a study of 741 psychogeriatric patients, high plasma homocysteine levels were found in demented and nondemented patients; however, only demented patients also had lower blood folate concentrations compared with controls. Patients with concomitant vascular disease had significantly higher plasma homocysteine than those without diagnosed vascular disease. Significantly higher homocysteine levels, compared with controls, have also been found in Parkinson's disease patients.[122]

Homocysteine's effects on neurotransmitter metabolism, along with its potential reduction of methylation reactions, could be a contributing factor to the etiology of depression. Folate and vitamin B_{12} deficiency can cause neuropsychiatric symptoms, including dementia and depression. SAMe is used therapeutically as an antidepressant in Europe and was the third-most-popular antidepressant treatment in Italy in 1995.[123,124] Long-term treatment of poststroke survivors with folic acid (2 mg), vitamin B_6 (25 mg), and vitamin B_{12} (0.5 mg) was associated with a reduction in major depression in a 563-patient, randomized, double-blind, placebo-controlled trial.[125]

Methylation of myelin basic protein is vital to the maintenance of the myelin sheath. The worst-case scenario of folate and vitamin B_{12} deficiency includes demyelination of the posterior and lateral columns of the spinal cord, a disease process called subacute combined degeneration of the spinal cord (SCD).[111] SCD can also be precipitated by nitrous oxide anesthesia, which causes an irreversible oxidation of the cobalt moiety of the vitamin B_{12} molecule and the subsequent inhibition of methionine synthase activity, a decrease in homocysteine remethylation, and decreased SAMe production.[112] This has been treated using supplemental methionine, which further supports the theory of a nitrous oxide–induced biochemical block at methionine synthase.[126] Particularly at risk for this condition are vitamin B_{12}-deficient individuals who visit their dentist and receive nitrous oxide.[112,127]

Abnormal methylcobalamin metabolism is one of the proposed mechanisms for the pathophysiology of the demyelinating disease multiple sclerosis (MS). Deficiency of vitamin B_{12} has been linked to some cases of MS, and it has been suggested that dietary deficiency, or more likely, a defect in R-protein–mediated absorption or methylation of vitamin B_{12}, might be a significant contributor to the pathogenesis of MS.[128]

Individuals with genetic variation in the 5,10-MTHFR gene are more susceptible to having a psychiatric disorder. The genetic variation MTHFR C677T was significantly associated with schizophrenia, bipolar disorder, and unipolar depressive disorder.[129]

Diabetes Mellitus

Homocysteine levels appear to be lower in individuals with type 1 diabetes mellitus. Forty-one subjects with type 1 diabetes (age 34.8 ± 12 years; duration of illness: 10.7 ± 11.1 years) were compared with 40 age-matched control subjects (age 34.2 ± 9.1 years). After an overnight fast, homocysteine was significantly lower ($P = 0.0001$) in the diabetic group (6.8 ± 2.2) than in the controls (9.5 ± 2.9). This difference was apparent in male and female subgroups.[130] However, increased levels of homocysteine have been reported in type 1 diabetics with proliferative retinopathy[131] and nephropathy.[131,132]

Evidence to date suggests that the metabolism of homocysteine is impaired in patients with non–insulin-dependent diabetes mellitus (NIDDM). After a methionine load, hyperhomocysteinemia occurred with significantly greater frequency in patients with NIDDM (39%) compared with age-matched controls (7%). The area under the curve over 24 hours, reflecting the total period of exposure to increased homocysteine, was also elevated with greater frequency in patients with NIDDM and macrovascular disease (33%) compared with controls (0%). The authors concluded that hyperhomocysteinemia was associated with macrovascular disease in a significant proportion of patients with NIDDM.[133] Other researchers reported a correlation between increased homocysteine levels and the occurrence of macroangiopathy in patients with NIDDM. Intramuscular injection of 1000 μg methylcobalamin daily for 3 weeks reduced the elevated plasma levels of homocysteine in these individuals.[134]

Elevated homocysteine levels appear to be a risk factor for diabetic retinopathy in individuals with NIDDM. This might be due to a point

mutation on the gene for the enzyme MTHFR.[135,136] A significantly higher percentage of diabetics with retinopathy exhibit this mutation.[137] Elevated homocysteine levels cause cell injury to the small vessels, which may contribute to the development of retinopathy, as well as macroangiopathy in the cardiovascular system.[135]

Rheumatoid Arthritis

Elevated total homocysteine levels have been reported in patients with rheumatoid arthritis (RA) and psoriasis. Twenty-eight patients with RA and 20 healthy age-matched control subjects were assessed for homocysteine levels while fasting and in response to a methionine challenge. Fasting levels were 33% higher in RA patients than in controls. Four hours after the methionine challenge, the increase in plasma homocysteine concentration was also higher in patients with RA.[137] Another study found statistically significant increases in homocysteine in RA patients ($P = 0.003$), with 20% of the patients having homocysteine levels above the reference range.[138] A mechanism for this increased homocysteine in RA patients has not been elucidated. Penicillamine, a common sulfhydryl-containing arthritis treatment, has been found to lower elevated homocysteine levels in vivo.[139]

Psoriasis

One study of 30 psoriasis patients and their matched controls were evaluated for blood concentrations of lipids, lipoproteins, acute-phase reactants, homocysteine, and atherothrombotic markers. This study observed that more than 50% of the patients with psoriasis had homocysteine levels that were higher than 15 mmol/L, whereas only 20% of the control individuals were above this cutoff point. It was concluded that the mean levels of serum homocysteine, fibrinogen, fibronectin, intercellular adhesion molecules, plasminogen activator inhibitor, and autoantibodies against oxidized low-density lipoprotein were increased in psoriatic patients, whereas tissue plasminogen factor, vitamin B_{12}, and folate levels were decreased significantly.[62]

Further investigation into both the prevalence of hyperhomocysteinemia and the mechanism of action affecting RA and psoriasis is necessary.

Kidney Failure

Because homocysteine is cleared by the kidneys, chronic renal failure, as well as absolute or relative deficiencies of 5-methylTHF, methylcobalamin, P^5P, or betaine, results in increased homocysteine levels. In 176 patients with end-stage renal disease on peritoneal or hemodialysis, homocysteine concentrations averaged 26.6 ± 1.5 μmol/L in patients with renal failure compared with 10.1 ± 1.7 μmol/L in normal subjects. Abnormal values exceeded the 95th percentile for normal controls in 149 of the patients with renal failure.[140] Data also indicated that plasma homocysteine values represented an independent risk factor for vascular events in patients on peritoneal and hemodialysis. Patients with a homocysteine concentration in the upper two quintiles (>27.8 μmol/L) had an independent odds ratio of 2.9 (confidence interval, 1.4–5.8; $P = 0.007$) of vascular complications. Vitamin B levels were also lower in patients with vascular complications than in those without such complications.[141]

Alcoholism and Ethanol Ingestion

Chronic alcoholism is known to interfere with one-carbon metabolism. Because of this, it is not surprising to find that mean serum homocysteine levels are two times higher in chronic alcoholics than in nondrinkers ($P < 0.001$). Beer consumers have lower concentrations of homocysteine compared with drinkers of wine or spirits ($P = 0.05$). In chronic alcoholics, serum P^5P and red blood cell folate concentrations have been shown to be significantly lower than in control subjects.[13] Plasma homocysteine was significantly higher, compared with controls, in 42 active alcoholics hospitalized for detoxification. In another group of 16 alcoholics who abstained from ethanol ingestion, plasma homocysteine did not deviate from that of controls.[14]

Feeding ethanol to rats produces prompt inhibition of methionine synthase, as well as a subsequent increase in activity of betaine homocysteine methyltransferase. Despite the inhibition of methionine synthase, the enhanced betaine homocysteine methyltransferase pathway uses hepatic betaine pools to maintain levels of SAMe.[142] Results indicate that ethanol feeding produces a significant loss in SAMe in the first week, with a return to normal SAMe levels in the second week. Betaine feeding enhances hepatic betaine pools in control animals, as well as ethanol-fed animals; attenuates the early loss of SAMe in ethanol-fed animals; produces an early increase in betaine homocysteine methyltransferase activity; and generates increased levels of SAMe in both control and ethanol-fed groups.[143] It has been shown that minimal supplemental dietary betaine at the 0.5% level increases SAMe twofold in control animals and fivefold in ethanol-fed rats. Concomitant with the betaine-generated SAMe, ethanol-induced hepatic fatty infiltration was ameliorated.[142] Betaine supplementation also reduces the accumulation of hepatic triglyceride produced after ethanol ingestion.[143]

Gout

Although homocysteine levels have been positively correlated with increased uric acid levels,[2,144,145] no studies have investigated homocysteine levels in gout patients. It is possible the increased uric acid levels in gout are due to decreased SAMe production because of the reduction in homocysteine recycling. The excess adenosine, which reacts with methionine to form SAMe, is degraded to form uric acid as its end product.

Niacin is contraindicated in gout because it competes with uric acid for excretion.[146] Animal studies have shown that increased levels of S-adenosylhomocysteine, and thus homocysteine, cause significant reductions in SAMe-dependent methylation reactions.[16] Therefore because degradation of the niacin-containing coenzyme nicotinamide adenine dinucleotide is dependent on methylation by SAMe, and SAMe activity is severely reduced in hyperhomocysteinemia, niacin levels might be higher in these people, resulting in less uric acid excretion, higher uric acid levels, and increased gout symptoms in susceptible individuals. This possibility and its mechanism need further investigation.

Osteoporosis

Osteoporosis is a common presenting symptom in children with homocystinuria due to cystathionine synthase deficiency, as a result of an autosomal-recessive error of sulfur amino metabolism.[147,148] Individuals with cystathionine synthase deficiency have decreased concentrations of cysteine and its disulfide form, cystine. Because of the role of sulfur compounds in the formation of sulfated amino sugars, disturbed cross-linking of collagen has been proposed as a possible mechanism of action. One group of researchers studying 10 patients with homocystinuria found normal synthesis of collagen but a significant reduction of cross-links.[149]

Because of the correlation between homocystinuria and osteoporosis in children with this amino acidopathy and the increase in homocysteine concentrations in postmenopausal women, several authors have implied that elevated homocysteine levels contribute to postmenopausal osteoporosis. The Framingham study of 825 men and 1174 women, ranging from 59 to 91 years old, affirmed this suspicion by evaluating plasma homocysteine levels and relative incident of hip fracture over a period of 16 to 19 years. The mean plasma total

homocysteine concentration was 13.4 ± 9.1 μmol/L with 41 hip fractures among men and 12.1 ± 5.3 μmol/L and 146 hip fractures among women. It was shown that both men and women in the highest quartile of plasma homocysteine had a greater risk of hip fracture than those in the lowest quartile, where the risk was almost 4 times as high for men and 1.9 times as high for women.[150] Because physical activity is well known to lower homocysteine, as well as prevent falls, it may therefore influence the association between homocysteine levels and the risk of fracture.[15] Therefore it seems prudent to prescribe exercise, as well as appropriate supplemental therapies, for women and men with high homocysteine and osteopenia/osteoporosis.

Autism

Children with autism have higher levels of urinary homocysteine than children without autism, which may reflect nutritional deficiencies of folic acid, vitamin B_6, and vitamin B_{12}.[151] The increase in homocysteine concentration is significantly and directly correlated with the severity of deficit in communication skills but is unrelated to a deficit in socialization or repetitive/restricted behavior.[152]

In addition, autistic children have elevated levels of S-adenosylhomocysteine (SAH) and adenosine, whereas levels of methionine, S-adenosylmethionine (SAM), and the SAM/SAH ratio are significantly decreased compared with age-matched controls.[153]

Nonalcoholic Fatty Liver Disease (NAFLD)

There are studies that have shown an association between increased homocysteine levels and NAFLD.[154–156] One study has determined increased homocysteine levels and increased prevalence of homozygote MTHFR 677C/T and MTHFR 1298A/C mutations in patients with NAFLD compared with healthy controls.[157] A meta-analysis has shown that the T/T genotype of MTHFR C677T polymorphism and C/C genotype of MTHFR A1298C are more likely to be associated with the susceptibility to NAFLD.[158] The increased homocysteine levels could possibly contribute to the development of NAFLD or be a result of impaired hepatic metabolism.[159,160]

Drug-Induced Hyperhomocysteinemia

Because fibrate drugs are known to increase homocysteine levels (see "Pharmaceutic Drug Effects on Homocysteine"), one randomized, double-blind crossover study investigated the effect of using fenofibrate adjunctively with 650 mcg of folic acid, 5 mg of vitamin B_6, and 50 mcg of vitamin B_{12} or just fenofibrate in men with hyperlipidemia. Subjects who received the fenofibrate plus placebo had an average increase in homocysteine concentration of 44%. Subsequent to the fenofibrate-plus-vitamin treatment, it was 13%. In this study, vitamins significantly prevented most of the homocysteine increase seen after fenofibrate plus placebo. The authors of this study suggested that routine use of these nutrients might be beneficial with this pharmaceutical therapy.[35]

DIAGNOSTIC CONSIDERATIONS

Many studies cited herein have used a reference range, with 12 to 16 μmol/L being the upper limit of normal for homocysteine. Researchers found a highly significant increase in relative risk of atherosclerotic cardiovascular disease and other disease processes as homocysteine levels increased, even within the "normal" range. Optimal levels of homocysteine and vitamin B_{12} are needed to maintain the methylation cycle, along with adequate levels of vitamin B_6 to convert to cysteine, which is a precursor to form GSH. A number of clinical laboratories currently perform plasma homocysteine determinations, by themselves or within a cardiovascular panel.

THERAPEUTIC CONSIDERATIONS

Although folic acid or folate supplementation (400 mcg/day) alone can reduce homocysteine levels in many subjects, given the importance of vitamins B_{12} and B_6 to proper homocysteine metabolism, all three should be used together. In one study, the prevalence of suboptimal levels of these nutrients in men with elevated homocysteine levels was 56.8%, 59.1%, and 25% for folic acid, vitamin B_{12}, and vitamin B_6, respectively, indicating that folic acid supplementation alone would not lower homocysteine levels in many cases.[161] In other words, folic acid supplementation will only lower homocysteine levels if there are adequate levels of vitamin B_{12} and B_6. This fact could reduce the effect of folic acid fortification of food. In 1998 the U.S. Food and Drug Administration mandated the fortification of food products with folic acid. Although homocysteine levels have decreased modestly after the fortification of food with folic acid, the effect on mortality has been minor at best.[22] This indicates the importance of more aggressive supplementary measures to reduce homocysteine-associated cardiovascular risk. In one study of 100 men with hyperhomocysteinemia, oral therapy with 650 mcg folic acid, 400 mcg vitamin B_{12}, 10 mg vitamin B_6, or a combination of the three nutrients was given daily for 6 weeks. Plasma homocysteine was reduced by 41.7% during folate therapy and 14.8% during vitamin B_{12} therapy, whereas 10 mg of vitamin B_6 did not reduce plasma homocysteine significantly. The combination worked synergistically to reduce homocysteine levels by 49.8%.[162]

Several studies using folic acid, vitamin B_6, vitamin B_{12}, and betaine, either alone or in combination, demonstrated the ability of these nutrients to normalize homocysteine levels.[29,32,58,60,163,179] Other studies confirmed that oral folate supplementation alone would almost always lower high homocysteine, whereas B_6 and B_{12} would lower homocysteine only in those with a genetic metabolic defect or dietary deficiency in those nutrients, or both.[163,164] Some studies used high-dosage oral folate therapy (2.5–5 mg) to effectively reduce hyperhomocysteinemia in patients with peripheral atherosclerotic vascular disease, 50% of whom had abnormally high fasting plasma homocysteine levels, whereas 100% had abnormal plasma homocysteine after a methionine load.

Despite the demonstrated efficacy of individual studies lowering homocysteine levels with folic acid and B vitamins, a meta-analysis of eight randomized trials of folic acid and vitamin B supplementation to lower homocysteine levels was found to have no significant effects within 5 years on cardiovascular events, cancer, or mortality.[165]

If a dietary deficiency or an increased demand resulting from genetic biochemical individuality exists for 5-methylTHF, methylcobalamin, P^5P, or betaine, treatment with these active forms of micronutrients should reduce homocysteine levels better than the nonactive forms (e.g., folic acid, cyanocobalamin, pyridoxine, betaine hydrochloride). In addition, betaine is important when there is a deficiency of the P^5P-dependent enzyme cystathionine synthase—the most common genetic abnormality affecting the transsulfuration pathway of homocysteine breakdown. Betaine supplementation in combination with vitamin B_6 corrects the hyperhomocysteinemia in these individuals.[28,163]

There is speculation that the fortification of foods and supplementation of folic acid, the synthetic form of folate, have contributed increased risk of carcinogenesis.[166] Although some studies have shown that moderate doses of folic acid reduce the risk of carcinogenesis, other studies suggest that larger doses or supplementation after a neoplastic lesion enhances the risk of carcinogenesis.[167–171] The genetic variants in folate metabolism may also be a factor in the risk of colorectal carcinoma and adenoma. The homozygous C677T variant of methylenetetrahydrofolate reductase (MTHFR) may modify the association of folate status with risk of colorectal carcinoma and adenoma.[172–174] Naturally occurring folates have a distinct metabolism that differs from folic acid.

Folic acid is inactive until it is metabolized into the natural reduced forms, including 5-methlytetrahydrofolate. There are studies that have demonstrated that the unmetabolized folic acid in the plasma reduces natural killer cell cytotoxicity in vitro.[175,176] Elevated levels of plasma methylated folates (the sum of 5-methyl-tetrahydrofolate and 4-alfa-hydroxy-5methyl-THF) are positively associated with increased risk of advanced or multiple colorectal adenomas. Therefore careful consideration should be given to the benefit and risk of folic acid and methylated folate supplementation.[177] There are advantages to using 5-methylTHF over folic acid, such as the potential negative effects of unmetabolized folic acid in the peripheral circulation. In addition, using 5-methylTHF instead of folic acid overcomes metabolic defects caused by methylenetetrahydrofolate reductase polymorphism, reduces interactions with drugs that inhibit dihydrofolate reductase, and reduces the potential for masking hematological symptoms of vitamin B_{12} deficiency.

Therapeutic Approach

Supplements

- Vitamin B_{12}: 800 to 5000 mcg/day
- Pyridoxine: 25 to 50 mg/day
- 5-MethylTHF: 400 to 1000 mcg/day

If unresponsive to the previous dosages, patients may take the following:

- Folinic acid: 800 mcg/day
- Methylcobalamin: 1000 to 5000 mcg/day
- P^5P: 20 mg/day
- Betaine (trimethylglycine): 1200 mg/day
- NAC: 500 to 1800 mg/day
- 5-MethylTHF: 1 to 15 mg/day

Injectable B_{12}

- Hydroxocobalamin: 1000 mcg weekly
- Methylcobalamin 25 mg/mL: 0.1 mL three times a week

For children with autism spectrum disorder (ASD) to improve behavioral symptoms and metabolic markers of abnormal redox and methylation metabolism[178]:

- 75 mcg/kg methylcobalamin subcutaneous injection in fatty tissue of the gluteal region every third day, plus oral supplementation with folinic acid (400 mcg twice daily) for 3 months

Hyperventilation Syndrome/ Breathing Pattern Disorders

Angela Sadlon, ND, and *Leon Chaitow*[*]*, ND, DO*

OUTLINE

INTRODUCTION

Hyperventilation Syndrome/Breathing Pattern Disorders Defined

Hyperventilation syndrome/breathing pattern disorders (HVS/BPDs) are described as follows:

- Hyperventilation is a pattern of overbreathing in which the depth and rate exceed the metabolic needs of the body at that time. This is usually seen at 30 breaths/min or more.
- Breathlessness usually occurs at rest or with only mild exercise.
- Physical, environmental, or psychological stimuli override the automatic activity of the respiratory centers, which are tuned to maintain arterial carbon dioxide ($Paco_2$) levels within a narrow range.
- Although at any given time the body's carbon dioxide (CO_2) production is set at a certain level, the exaggerated breathing depth and rate associated with HVS/BPDs eliminates CO_2 at a faster pace, resulting in arterial hypocapnia (low CO_2 in blood).
- The arterial hydrogen ion (pH) (acid/alkaline balance) rises into the alkaline region, thus inducing respiratory alkalosis.[1]

As a direct result of HVS/BPDs, many patients present with multiple symptoms, some of which mimic serious disease. However, blood tests, electrocardiograms (ECGs), and thorough physical examinations may reveal nothing out of the ordinary. Up to 10% of patients in general internal medicine practice reportedly experience HVS/BPDs as their primary diagnosis.[2] Many individuals with HVS/BPDs experience severe and genuinely distressing symptoms, and considerable medical expenses are incurred in excluding more serious pathology.

Gender

More females than males have HVS/BPDs, ranging from a ratio of 2:1 to 7:1. The peak age of incidence is 15 to 55 years, although other ages can be affected.[2] Women may be more at risk because of hormonal influences, because progesterone stimulates respiratory rate, and in the luteal (postovulation/premenstrual) phase, CO_2 levels drop 25% on average. Additional stress can then "increase ventilation at a time when CO_2 levels are already low."[3] A case report linked progesterone (medroxyprogesterone) therapy as a cause of hyperventilation in a 52-year-old menopausal woman.[4]

Normal Breathing Pattern

To recognize HVS/BPDs, one must be aware of the characteristics of a normal breathing pattern:

- The breathing rate should be 10 to 14 breaths/min, moving 3 to 5 L of air per minute through the airways of the chest.
- During the active inhalation phase, air flows in through the nose, where it is warmed, filtered, and humidified before being drawn into the lungs by the downward movement of the diaphragm and the outward movement of the abdominal wall and lower thoracic structures.

[*]Previous edition contributor

- The upper chest and accessory breathing muscles should remain relaxed.
- The expiratory phase is ideally effortless as the abdominal wall and lower intercostals relax downward and the diaphragm ascends back to its original domed position, aided by the elastic recoil of the lung.
- A relaxed pause at the end of exhalation releases the diaphragm briefly from the negative and positive pressures exerted across it during breathing.
- Under normal circumstances, individuals are quite unaware of their breathing.
- Breathing rates and volumes increase or fluctuate in response to physical or emotional demands, but in normal subjects, they return to relaxed, low-chest patterns after the stimuli cease.

Patients, especially those whose symptom presentation includes chronic fatigue or anxiety, or both, and who display or report a number of the following signs or symptoms, might be considered suitable candidates for respiratory treatment (see also "Diagnostic Considerations").

Benefits of Normal Respiratory Function

The exchange of gases involving the acquisition of oxygen (O_2) and elimination of CO_2 leads to enhanced cellular function and facilitates the following:

- Normal performance of the brain, organs, and tissues of the body
- Normal speech and human nonverbal expression (e.g., sighing)
- Fluid movement (lymph, blood)
- Spinal mobility through regular, mobilizing, thoracic cage movement
- Digestive function via rhythmic positive and negative pressure fluctuations, via normal diaphragmatic function

Any chronic alteration in breathing function automatically modifies these functions negatively.

The effect of habitual BPDs, such as hyperventilation, on an individual's physiology can be profound, potentially resulting in or exacerbating a wide range of health problems, sometimes severely, ranging from anxiety and panic attacks to fatigue and chronic pain.

The Carbon Dioxide–Oxygen Balancing Act

Chaitow et al.[5] addressed the misconception that oxygen is "good" and carbon dioxide is "bad" by stating:

> *Yet if one considers that life-giving oxygen can also be corrosive and toxic, and that a deficiency of the waste gas carbon dioxide (CO_2) can cause fainting, seizures, or death, then the "good/bad" distinction must be restated as "good within certain limits" and "bad within certain limits." Maintaining these two gases within those limits is a complex task for the body, even more so because the supply of each gas fluctuates with each breath.*

Respiratory Homeostasis

Jennett[6] described the delicate homeostatic balancing act in which pH and CO_2 are key features:

> *When there are not other overriding drives affecting breathing, the neural control system acts to maintain a constant arterial Pco_2. This must mean that the volume of CO_2 expired continually balances the volume produced by tissue metabolism. Measurements show that alveolar and arterial concentrations of CO_2 stay constant, which means that the volume of gas breathed out from the functional (alveolar) volume of the lungs must vary precisely with the rate of metabolic CO_2 production. In rest and activity, when the system is left to itself, it is so efficient that the matching occurs virtually breath-by-breath, even when metabolic activity is continually changing.*

Pathophysiology

Physiological and Pathophysiological Causes of Altered Patterns of Breathing

Hyperventilation can be an appropriate physiological response to the body's metabolic needs; for example, tachypnea (rapid breathing) or hyperpnea (increase in respiratory rate proportional to increase in metabolism) may result as the respiratory centers respond automatically and appropriately to rising CO_2 production due to exercise or organic disease that may be creating acidosis. It is therefore important to exclude organic causes that diminish PaO_2 or elevate $Paco_2$ levels.[7]

Organic causes of HVS/BPDs that should be excluded and/or identified before breathing rehabilitation is initiated include the following:

- Respiratory: asthma, chronic obstructive respiratory disease, pneumonia, pulmonary embolus, pneumothorax, and pleural effusion.
- A case of carbon monoxide poisoning presenting as HVS has been reported.[8]
- Cardiovascular: acute and chronic left heart failure, right heart failure, tachyarrhythmias
- Hematopoietic: anemia
- Renal: nephrotic syndrome, acute and chronic kidney failure
- Endocrine: diabetes with ketoacidosis, pregnancy
- Metabolic: liver failure
- Pharmaceutic: aspirin, caffeine, amphetamine, nicotine, progesterone therapy

BPDs may also emerge from a background of established pathology (e.g., asthma, cardiovascular disease, kidney failure, chronic pain). Even tumor infiltrates into brain respiratory centers and central chemoreceptors have caused hyperventilation.[9] Where this is the case, the aim of this chapter is not to explore these states because they are discussed elsewhere in this textbook.

Fluctuating blood glucose levels may trigger HVS/BPD symptoms in patients with high-carbohydrate diets, which produce rapid rises followed by sharp falls to fasting levels or below.[7,10]

Chaitow et al.[5] noted that the following factors could lead to altered breathing patterns through pH shifts:

- Ketoacidosis promotes deeper, faster breathing because the breathing centers respond to the higher CO_2 content.
- Diarrhea results in the loss of alkaline plasma bicarbonate ions, which if prolonged, leads to acidosis. This stimulates corrective overbreathing to remove CO_2 (as carbonic acid [H_2CO_3]) and normalizes the pH.
- Excessive vomiting causes loss of hydrochloric acid, shifting the body toward alkalosis, slowing breathing to allow CO_2 to build up and restore pH. Hypoventilation is the result.
- Use of steroids and diuretics can lead to alkalosis.

Categorization of Causes

It is possible to place the common etiological features of HVS/BPD into biomechanical, biochemical, psychological, environmental, pathological, and habitual categories.

The reasons for an individual breathing inappropriately can derive directly from structural, biomechanical causes, such as a restricted thoracic spine, rib immobility, or shortness of key primary and accessory respiratory muscles.

Causes of breathing dysfunction can also have a more biochemical etiology, possibly involving allergy or infection, which triggers narrowing of breathing passages and subsequent asthmatic-type responses. Acidosis, resulting from conditions such as kidney failure, also directly alters breathing function as the body attempts to reduce acid levels via elimination of CO_2 through hyperventilation.

The link between psychological distress and breathing makes this another primary cause of many manifestations of dysfunctional respiration. Examining a person with anxiety or depression without breathing dysfunction being noted is difficult to imagine.

Other catalysts that may affect breathing function include environmental factors (e.g., altitude, humidity).[11]

The etiology of HVS/BPD may involve combinations of the factors listed previously; however, in most instances, altered breathing patterns, whatever their origins, seem to be maintained by nothing more sinister than pure habit.[7,12]

The Hydrogen Ion Factor

Chaitow et al.[5] stated the following:

> *The story [of HVS/BPD] might best begin with pH, because this factor influences every organ of the body. The variable of relative acidity facilitates many metabolic exchanges and it must be kept in careful balance. Since pH describes proportion of hydrogen ions available for combination, and the pH is on a log scale, a small change in pH, such as 7.4 to 7.2, means roughly a doubling of the number of hydrogen ions present. The binding of hydrogen to negative sites helps to regulate enzymatic action, endocrine secretion, integrity of protein molecules, and cellular metabolism, including oxygen absorption and release. A pH of 7.2 would seriously compromise many physiologic functions. The physiologic normal pH in the arterial blood is around 7.4, with an acceptable range from 7.35 to 7.45. Outside these limits lie ill effects of many kinds. The body will sacrifice many other things in order to maintain proper pH.*

The Carbon Dioxide–Hydrogen Ion Connection

- The acidity of the blood is determined mainly by CO_2.
- CO_2 is the end-product of aerobic metabolism, deriving mainly from the mitochondria. CO_2 is odorless, heavier than air, and, if inhaled in its pure form, causes suffocation.
- CO_2 is present in the atmosphere at a concentration of around two-hundredths of 1% and is harmless to humans but adequate to sustain plant life.
- Transportation of CO_2 occurs from the tissues into the blood and then to the lungs for exhalation. The body converts CO_2 to H_2CO_3, of which there is a perpetual surplus.
- The lungs exhale around 12,000 mEq of H_2CO_3 per day, compared with less than 100 mEq of fixed acids excreted by the kidneys. The normal range of end-tidal CO_2 pressure is 35 to 45 mm Hg.[13]
- Any increase in bodily activity produces CO_2, acidifying the blood, unless more CO_2 is excreted and/or exhaled.
- It is therefore obvious that changes in breathing volume relative to CO_2 production regulate the moment-to-moment concentration of pH of the bloodstream (longer-term regulation of pH is shared with the kidneys).
- It is the concentration of CO_2 in the blood, not oxygen, that is the major regulator of breathing drive.
- Higher CO_2 levels immediately stimulate more breathing, apparently on the assumption that abundance of CO_2 means oxygen-poor air is being breathed, breathing has stopped, or something else is happening that is an antecedent to suffocation.

The Bicarbonate Buffer

Chaitow et al.[5] explained the following:

> *There exists a further balancing mechanism, the bicarbonate buffer. The bicarbonate ion (HCO_3–) is derived from CO_2 during its ride in the bloodstream; CO_2 dissociates into hydrogen ions (H+) and (HCO_3–). This bicarbonate reserve is adjustable as needed, up to a point, and constitutes a major alkaline buffer system which opposes rises in acidity. The kidneys regulate the regulators by adjusting the amount of bicarbonate returned to the bloodstream. If the kidneys detect excess acidity (a surplus of positively-charged hydrogen ions) they will try to retain more bicarbonate to balance the acid, but this is not a fast process; adjusting their filtration characteristics takes hours to days. In the short run, meanwhile, if bicarbonate buffering of excess acid is not sufficient, or if the bicarbonate is depleted, a faster back-up buffering system is available: hyperventilation. Excessive breathing exhales more CO_2 (acid), thereby bringing pH closer to normal.*

Oxygen Delivery and Smooth Muscle Constriction

The blood carries oxygen mainly in molecules of hemoglobin, which are contained in red blood cells. In an appropriate environment, hemoglobin combines readily with oxygen (to form oxyhemoglobin). This process varies according to local pH, as well as Po_2. This ability to combine is important for both absorbing oxygen through the alveoli and also for releasing oxygen through the capillary walls, where oxygen diffuses into the tissues.

These two properties are largely determined by local conditions, so when pH is low (i.e., the blood is more acidic), hemoglobin in that area is stimulated to release additional oxygen. This is true of metabolically active tissues in general but especially of muscles. An exercising muscle needs all the oxygen it can get, and this is assisted by its chemical nature, explained by West as follows:

> *An exercising muscle is acid, hypercarbic, and hot, and it benefits from increased unloading of oxygen from its capillaries.*[11]

The effect of pH on oxyhemoglobin dissociation is called the Bohr effect.

In the lungs, the need is to bind oxygen to hemoglobin, not release it. Not surprisingly, the lungs have a more alkaline environment.

The fact that a shift of the blood toward acidity promotes dissociation and release of oxygen from the hemoglobin is particularly important when considering hyperventilation because the resulting alkalinity causes the hemoglobin molecule to retain more oxygen than usual. With increased alkalinity encouraging smooth muscle contraction and therefore diminished diameter of blood vessels, as well as the reluctance of hemoglobin to release its oxygen, a relative oxygen deficit is likely in tissues and the brain, leading to symptoms such as fatigue, aching, cramping, and cognitive problems.

Psychology and Hyperventilation Syndrome/Breathing Pattern Disorders

On a psychological level, Bradley[14] described a "cascade of symptoms" (Fig. 135.1) in which an original cause (emotional or physical) leads to tension and anxiety that result in hyperventilation, possibly an acute hyperventilation attack, which (with repetition), over time, results in anticipation, anxiety, and avoidance behaviors or phobias, or both.

Chaitow et al. and others describe similar aspects of the influence of emotion on breathing[5,15–17]:

> *Increased variability from breath to breath is known to correlate with anxiety states. Low Pco_2 and increased frequency of sighing are typical of those with panic disorder even when not panicking. These generalizations miss individuals who do not have a chronic BPD, but who do experience disrupted breathing under particular conditions. These "conditions" can provoke either an amygdala "alarm" discharge or some specific, learned breathing response, as well as occasional panic.*

Conway et al.[18] used hypnosis to investigate the sources of hyperventilation episodes and found emotional events such as loss, separation, and impotent anger were common precipitating factors that

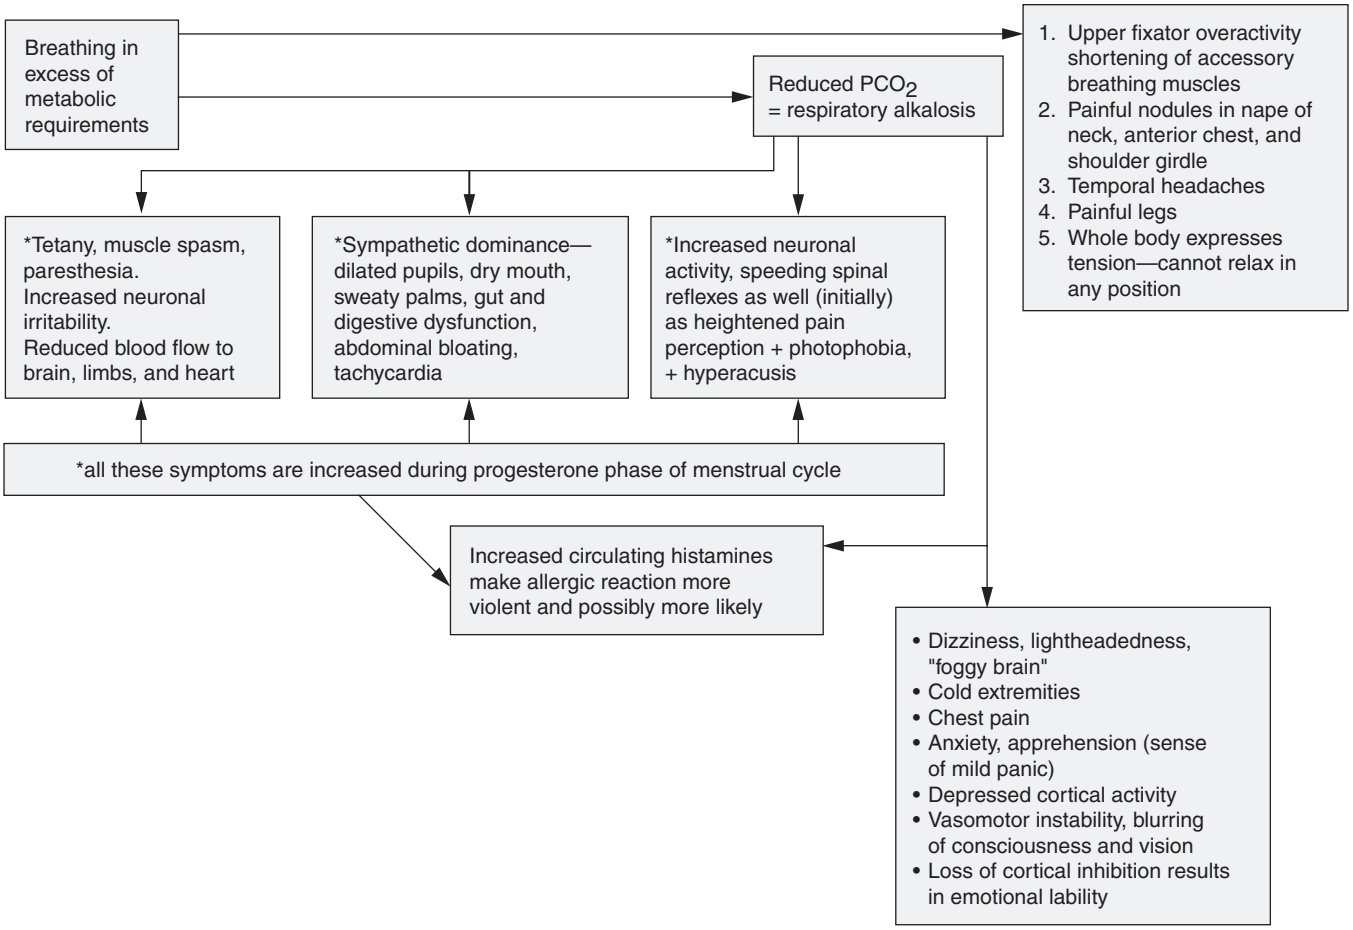

Fig. 135.1 Negative health influences of a dysfunctional breathing pattern such as hyperventilation. (From Chaitow L, Bradley D, Gilbert C. *Multidisciplinary Approaches to Breathing Pattern Disorders*. London: Churchill Livingstone; 2002: 90.)

began the hyperventilation trend. They concluded that hypnosis might be helpful in discovering the underlying cause of hyperventilation.

Freeman et al.[19] also showed that individuals who reported several symptoms indicating hyperventilation (including chest pain/palpitations and dizziness—not exclusively respiratory symptoms) displayed rather strong hyperventilation in response to recalling emotionally disturbing events, whereas the control subjects did not. Bereavement, loss of control, grief, and anger were common topics associated with the symptoms.

Chaitow et al.[5] concluded (Fig. 135.2):

> *Aside from medical problems, there are still many factors in the psychological and behavioral realms competing for control of breathing. Successful regulation must take all factors into account, with special consideration for priorities of survival. The human brain adds a layer of complication with its power to imagine, project, and recall, often stimulating breathing reflexes without apparent reason.*

DIAGNOSTIC CONSIDERATIONS

Symptoms

Acute hyperventilation represents approximately 1% of all cases of hyperventilation, which is well outnumbered by chronic hyperventilation.[20] The symptoms and signs of HVS are extremely variable, and none is absolutely diagnostic. The following symptoms are indications of possible breathing pattern dysfunction:

- A feeling of constriction in the chest
- Shortness of breath
- Accelerated or deepened breathing
- Inability to breathe deeply
- Feeling tense (the Nijmegen questionnaire avoids the use of the word *anxiety*)
- Tightness around the mouth
- Stiffness in the fingers or arms
- Cold hands or feet
- Tingling fingers
- Bloated abdominal sensation
- Dizzy spells
- Blurred vision
- Feeling of confusion or losing touch with environment

Table 135.1 is not fully comprehensive but presents the most common symptoms and signs of HVS/BPD. For greater depth, see Timmons and Ley,[7] Gardner,[21] Nixon,[22] and Chaitow et al.[5]

Metabolic Disturbances and Hyperventilation Syndrome

- Two tests of nerve hyperexcitability produced by hypocapnia-induced hypocalcemia are Trousseau's and Chvostek's signs.
- Chest pain associated with HVS/BPDs requires that heart disease is excluded as a diagnosis. Adrenaline-induced electrocardiographic changes can occur in hyperventilation, uncomplicated by coronary heart disease. One study suggested that up to 90% of noncardiac chest pain is thought to be induced by HVS/BPDs.[23]

In older patients, established coronary artery disease can be exacerbated by vasoconstriction arising from hypocapnia, which puts them at risk of coronary occlusion and myocardial damage.

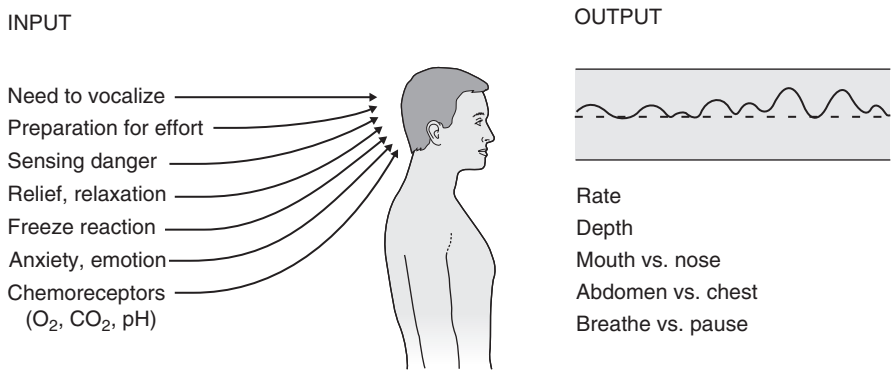

Fig. 135.2 Final modulation of the breathing act includes input from many possible sources: the need for vocalization (a cry for help, a shouted warning, perhaps a growl), preparation for exertion, the need to freeze and become less noticeable, the need to maximize sensory acuity by keeping the body still, and the need to either remain calm or return to a baseline state of calmness. These inputs often conflict with each other, but if there is a hint of a threat to survival, they seem to have priority over all other considerations. (From Chaitow L, Bradley D, Gilbert C. *Multidisciplinary Approaches to Breathing Pattern Disorders.* London: Churchill Livingstone; 2002: 122.)

TABLE 135.1 Most Common Symptoms and Signs of Hyperventilation Syndrome/Breathing Pattern Disorders

System	Symptoms	Suggested Causes
Cardiovascular	Chest pain and angina, palpitation and arrhythmias, tachycardia, lightheadedness and syncope, altered ECG features	Reduced coronary blood flow, altered excitability of SA and AV nodes of cardiac muscle, reduced cardiac output, peripheral vasodilatation
Gastrointestinal	Discomfort in lower chest and epigastric area, esophageal reflux and heartburn, bloating/distension, exacerbation of hiatal hernia symptoms, dry mouth, air swallowing and belching	Aerophagia, increased swallowing rate, mouth breathing
Neurological	Headache; numbness and tingling (mainly involving extremities and perioral); positive Trousseau's and Chvostek's signs; dizziness/giddiness; ataxia and tremor; blurred and tunnel vision; anxiety and panic; phobias; irritability; depersonalization; detachment from reality; impaired concentration, cognition, performance; easy fatigue; insomnia; hallucinations	Cerebrovascular constriction (see notes on smooth muscle contraction); vasoconstriction of vertebral or carotid arteries, or both; reduced oxygen delivery, neuronal excitability resulting from alkalosis; hypocalcemia
Respiratory	Breathlessness; restricted sensation around thorax; sighing/yawning; obvious use of upper chest, accessory breathing muscles (e.g., scalenes) on inhalation; chest tenderness	Overuse of accessory breathing muscles and fatigue of primary respiratory muscles
Muscular	Stiffness and aching, weakness in limbs, cramping, carpopedal spasm, tetany	Hyperexcitability of motor nerves, muscle fatigue, calcium/magnesium imbalance

AV, Atrioventricular; *ECG,* electrocardiogram; *SA,* sinoatrial.

Alternatively, hyperventilation can trigger spasms of normal-caliber coronary arteries.

- Rapid breathing or mouth breathing instigates aerophagia from air gulping, causing bloating, burping, and extreme epigastric discomfort. Irritable bowel syndrome is listed as a common symptom of chronic overbreathing. Fear and anxiety may induce abdominal cramps and diarrhea.[1] The median swallowing rate in healthy, nondyspeptic controls is three or four swallows per 15 minutes. In the absence of food, up to 5 mL of air accompanies saliva into the gastrointestinal tract with each swallow.[24]
- Hyperventilation leading to hypocapnia causes cerebral arterioles to constrict, increasing vascular resistance and reducing cerebral blood flow. This is a natural response to changes in CO_2 to regulate oxygen delivery to the brain.[25]

Acute Hyperventilation Progression

- The patient presenting with an acute hyperventilation episode appears distressed.
- The pattern of respiration is of deep, rapid breaths, using the accessory muscles visible in the neck and the upper chest.
- Wheezing may be heard as a result of bronchospasm triggered by hypocapnia.
- A stressful precipitating event is usually reported.
- Hypocapnia reduces blood flow to the brain (2% decrease in flow per 1 mm Hg reduction in arterial CO_2), causing frightening central nervous system symptoms. The reduced oxygenation of brain and tissues of the body results from the contraction of smooth muscle surrounding blood vessels and a reluctance of the hemoglobin carrier molecule to release oxygen in the increasingly alkaline environment caused by excessive loss of CO_2.
- Poor concentration and memory lapses may occur as a result, with tunnel vision and onset in those susceptible to migraine-type headaches or tinnitus.
- Sympathetic dominance brings on tremors, sweating, clammy hands, palpitations, and autonomic instability of blood vessels, causing labile blood pressures.[26]

- Bilateral perioral and upper extremity paresthesia and numbness may be reported. Unilateral tingling is most often confined to the left side.
- Dizziness, weakness, visual disturbances, tremor, and confusion—sometimes fainting or even seizures—are typical symptoms.
- Spinal reflexes become exaggerated through increased neuronal activity caused by loss of CO_2 ions from the neurons.
- Tetany and cramping may occur in severe bouts.[27]

Chronic Hyperventilation

The diagnosis of chronic and intermittent hyperventilation is more difficult than acute hyperventilation. A careful history and systemic inquiry, checking all other symptoms in the other body systems, usually highlights a suspicious pattern, particularly to the experienced clinician who can think beyond his or her own specialist area. Examination must exclude organic diseases of the brain and nervous system; the heart, particularly angina and heart failure; respiratory disease; and gastrointestinal conditions, especially if there are suspicious symptoms in these systems.

Careful inquiries as to the precipitating causes of attacks help with both the diagnosis and focusing on the choice of treatment. Nixon[22] suggested that there are often attacks where there is no preceding stressful event. For example, in chronic hyperventilators, the respiratory center may have been reset to tolerate a lower than normal partial pressure of $Paco_2$ levels in the blood. In such patients, a single sigh or one deep breath may reduce the $Paco_2$ enough to trigger symptoms.

Laboratory and Office Tests for Hyperventilation Syndrome/Breathing Pattern Disorders

Many possible tests for respiratory function exist. Some are difficult to perform (e.g., airway resistance), and some are invasive (e.g., blood gases).[14] A selection of tests is as follows:

- Preliminary tests should be conducted to exclude respiratory and cardiac disease, including peak expiratory flow rate, chest radiograph, ECG, and an exercise ECG if chest pain is present.
- Palpation and observation can demonstrate a paradoxical breathing pattern in which the abdomen retracts and the upper chest expands on inhalation (as opposed to normal abdominal protrusion and lower thorax expansion).
- The breath-holding time test does not require additional measurements or equipment. The time a hyperventilating patient can hold his or her breath is usually greatly reduced, often not beyond 10 to 12 seconds. Thirty seconds has been used as the approximate dividing line between hyperventilators and normals by some clinicians. It is worth noting that breathless patients without hyperventilation may have equal difficulty in breath holding.[21]
- A peak expiratory flow rate measurement, compared with age, sex, and height tables, provides a simply done, quick exclusion of significant respiratory restriction in the clinic room.
- If a hyperventilation provocation test (HVPT) is performed (during which the patient is asked to voluntarily overbreathe to bring on symptoms), ECG should be monitored (see "Caution" later).
- Elevated erythrocyte carbonic anhydrase (ECA) was recently (2009) suggested as a clinical marker for hyperventilation. The values of ECA were significantly elevated (~31 U/g hemoglobin) in patients who hyperventilated compared with controls (24.7 U/g hemoglobin). However, hyperventilation sensitivity and specificity were only 52.1% and 76.7%, respectively. There are other conditions that might elevate ECA, such as glucose-6-phosphate dehydrogenase deficiency and different anemias (aplastic, iron deficiency, autoimmune hemolytic, β-thalassemia).[28]
- Arterial blood gas determination is invasive and painful (arterial puncture) but appropriate in the emergency department, where the diagnosis of acute hyperventilation is required. For patients in whom chronic hyperventilation is suspected, the pressure of end-tidal carbon dioxide (PET CO_2) can be measured noninvasively from a continuous sampling through nasal prongs or cannula with the mouth occluded, or the tube can be sited in an oral airway for those with nasal obstruction to monitor CO_2 deficits. The PET CO_2 is the level of CO_2 released at the end of expiration.
- Capnography: PET CO_2 can be evaluated after a 4-minute quiet breathing rest period, followed by exercise and recovery, or a HVPT can be conducted in the recovery period. Most patients with chronic hyperventilation have a PET CO_2 at or below 30 mm Hg and a markedly delayed recovery from hypocapnia after overbreathing, sometimes lasting 30 minutes after testing.[29,30] By measuring PET CO_2 or transcutaneous CO_2 levels while a hyperventilation-provoking activity is performed, a potential link can be made between symptoms and CO_2 levels.[31]
- The think test[32] may be initiated 3 to 4 minutes into the recovery period. The patient is asked to recall a painful emotional experience during which symptoms developed. If the PET CO_2 drops 10 mm Hg, the test supports hyperventilation. Bradley[14] noted: "In some patients with hyperventilation the $Paco_2$ and the PET CO_2 may be in the normal range. In those who are asymptomatic at the time of testing, this finding could be accepted. However, a normal level while experiencing symptoms negates hypocapnia as the cause of symptoms. It prompts a search for an alternative explanation."
- Buteyko performed comparative studies with a simple breath-holding technique to test CO_2 levels and found that a simple technique of breath holding after expiration could predict the percent of alveolar CO_2 and therefore the degree of hyperventilation to a high degree of accuracy. According to his calculations, optimal levels of alveolar Pco_2 correlated with postexpiratory breath-holding time of 40 to 60 seconds. Many asthmatics and hyperventilators are found to be able to hold the breath out for less than 10 seconds.[33–35]

Caution

Bradley[14] cautioned the following:

> *The hyperventilation provocation test is best done before explanations of symptoms, to prevent suggestion and bias. Patients need to be warned only of a dry mouth. The patient is asked to concentrate on how they feel during the 1-2 minute period when they are over breathing at the rate of 30-40 per minute. The rate is set by the examiner's hand movements. The operator must stress the importance of the test and the need to continue for as long as they can. An arterial blood gas determination at the end of the test can be of use to establish the depth of hypocapnia. Some clinicians rely on as little as 12 deep breaths which the patient can recover from easily, and subjective symptoms produced are recorded. In both the breath holding and voluntary over-breathing tests, the skills of the clinician are important for maintaining the trust and co-operation of patients.*

The Nijmegen Questionnaire

Bradley[14] pointed out that no "gold standard" exists for chronic HVS, but the Nijmegen Questionnaire is noninvasive, with a high level of sensitivity (up to 91%)[36] and specificity (up to 95%).[37] It is also a way to monitor the progress of treatment by reevaluating symptoms. Bradley noted that the results of this simple test also helped indicate whether the initiating trigger causing the HVS/BPDs resolved, suggesting that the patient had to deal with only the "bad breathing" habit and musculoskeletal and motor pattern changes, or whether the initiating

	Never 0	Rare 1	Sometimes 2	Often 3	Very often 4

*Nijmegen. Patients mark with a tick how often they suffer from the symptoms listed. A score above 23/64 is diagnostic of hyperventilation syndrome.

Fig. 135.3 Nijmegen questionnaire. (From Chaitow L, Bradley D, Gilbert C. *Multidisciplinary Approaches to Breathing Pattern Disorders.* London: Churchill Livingstone; 2002: 176.)

triggers were ongoing or unresolved and might need further cognitive help (Fig. 135.3).

Warburton and Jack[30] stated that the Nijmegen Questionnaire was neither sensitive nor specific for chronic idiopathic hyperventilation without physiological testing, because many of the symptoms on the questionnaire are common to an organic respiratory disease.

BIOMECHANICAL (STRUCTURAL) CONSIDERATIONS

The Structure–Function Continuum

Nowhere in the body is the axiom of structure governing function more apparent than in its relation to respiration. Just as prolonged changes in patterns of use, such as an inappropriate (hyperventilation) breathing pattern, induce structural changes involving the muscles and joints (e.g., rib) of respiration, so do these changes ultimately prevent normal function.

Ultimately, the self-perpetuating cycle of functional change creating a structural modification, leading to reinforced functional tendencies, can become complete, from whichever direction dysfunction derives. Examples follow:

- Structural adaptations can prevent normal breathing function.
- Abnormal breathing function ensures continued structural adaptational stresses.[38]

The restoration of normal function demands the restoration of adequate structural mobility, whereas maintenance of restored biomechanical flexibility requires that function (how the individual breathes) should be normalized through reeducation and training.

Individually, neither approach is as useful as a combination of restoration of structural integrity, combined with functional improvement. It should be obvious that other underlying etiological features, whether these relate to psychosocial, biochemical, or biomechanical factors, should be addressed as far as possible as a prerequisite of rehabilitation.

The Muscles of Breathing

The muscles associated with breathing function can be grouped as either inspiratory or expiratory. They are either primary in that capacity or provide accessory support.

Because expiration is primarily an elastic response of the lungs, pleura, and "torsion rod" elements of the ribs, all muscles of expiration could be considered accessory muscles because they are recruited only during increased demand. They include internal intercostals, abdominal muscles, transverse thoracis, and subcostales. With increased demand, the iliocostalis lumborum, quadratus lumborum, serratus posterior inferior, and latissimus dorsi may support expiration, including during the high demands of speech, coughing, sneezing, singing, and other special functions associated with breathing.

Space does not permit in-depth discussion of the muscles of respiration, further details of which can be found in Chaitow et al.[5]

Neural Regulation of Breathing

Respiratory centers in the brainstem unconsciously influence and adjust alveolar ventilation to maintain arterial blood oxygen and CO_2 pressures at relatively constant levels to sustain life under varying conditions and requirements.[5]

The three main groups are as follows:

- The dorsal respiratory group, located in the distal portion of the medulla, receives input from peripheral chemoreceptors and other types of receptors via the vagus and glossopharyngeal nerves. These impulses generate inspiratory movements and are responsible for the basic rhythm of breathing.
- The pneumotaxic center in the superior part of the pons transmits inhibitory signals to the dorsal respiratory center, controlling the filling phase of breathing.

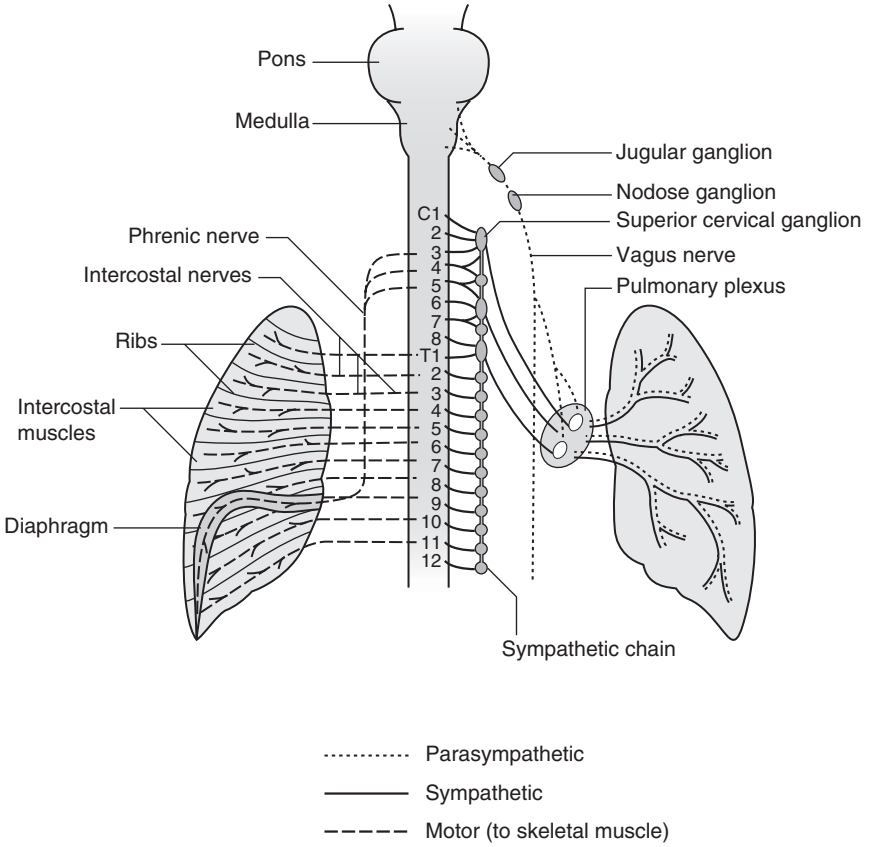

Fig. 135.4 Schema of the autonomic innervation (motor and sensory) of the lung and the somatic (motor) nerve supply to the intercostal muscles and diaphragm. (From Scanlan C, Wilkins R, Stoller J. *Egan's Fundamentals of Respiratory Care*. 7th ed. St. Louis: Mosby; 1999.)

- The ventral respiratory group, located in the medulla, causes either inspiration or expiration. It is inactive in quiet breathing but is important in stimulating abdominal expiratory muscles during levels of high respiratory demand.

The Hering–Breuer reflex prevents overinflation of the lungs and is initiated by nerve receptors in the walls of the bronchi and bronchioles, sending messages to the dorsal respiratory center, via the vagus nerve. The reflex "switches off" excessive inflation during inspiration, as well as excessive deflation during exhalation.

The autonomic nervous system enables the automatic, unconscious maintenance of the internal environment of the body in ideal efficiency and adjusts to the various demands of the external environment, be it sleep with repair and growth, quiet or extreme physical activity, or stress (Fig. 135.4).

A "third" nervous system regulating the airways has been recognized, called the nonadrenergic noncholinergic (NANC) system. Containing inhibitory and stimulatory fibers, nitric oxide has been identified as the NANC neurotransmitter.[39]

- NANC inhibitory nerves cause calcium ions to enter the neuron, mediating smooth muscle relaxation and bronchodilation.
- NANC stimulatory fibers—also called C-fibers—are found in the lung supporting tissue, airways, and pulmonary blood vessels, and appear to be involved in bronchoconstriction after exercise-induced asthma.[40]

Chemical Control of Breathing

The central role of respiration is to maintain balanced concentrations of oxygen and CO_2 in the tissues. Increased levels of CO_2 act on the central chemosensitive areas of the respiratory centers themselves, increasing inspiratory and expiratory signals to the respiratory muscles. In contrast, oxygen acts on peripheral chemoreceptors located in the carotid body (in the bifurcation of the common carotid arteries) via the glossopharyngeal nerves and the aortic body (on the aortic arch), which sends the appropriate messages via the vagus nerves to the dorsal respiratory center.

Voluntary Control of Breathing

Automatic breathing can be overridden by higher cortical conscious input (directly via the spinal neurons, which drive the respiratory muscles) in response to, for instance, fear or sudden surprise. Speaking requires voluntary control to interrupt the normal rhythmicity of breathing, as do singing and wind instrument playing. Evidence indicates that the cerebral cortex and thalamus also supply part of the drive for normal respiratory rhythm during wakefulness. (Cerebral influences on the medullary centers are withdrawn during sleep.) Habitual BPDs and HVS probably originate from some of these higher centers.[7]

THERAPEUTIC CONSIDERATIONS AND THERAPEUTIC APPROACH

Treatment and Rehabilitation of Hyperventilation Syndrome/Breathing Pattern Disorders

Different models of care in managing HVS/BPDs are available.

It is assumed that all organic causes of breathing pattern changes have been excluded and that coexisting problems such as asthma, chronic obstructive airway disease, chronic pain, and hormonal imbalances receive appropriate specialized attention. It is also assumed that manual therapy approaches would be incorporated as an essential element of rehabilitation.

Bradley's[14,41] physical therapy rehabilitation follows stages that are summarized in the acronym BETTER: breathing retraining, esteem/self-image, total body relaxation, talk/breath control, exercise prescription, rest/sleep.

Breathing retraining incorporates a number of elements:

- Awareness of faulty breathing patterns
- Relaxation of the upper chest, shoulders, and accessory muscles
- Abdominal/low-chest breathing pattern retraining
- Awareness of normal breathing rates and rhythms both at rest and during activity

The elements of the physical therapy protocol involving relaxation, exercise, talk/breath control, and sleep are all individualized and are not described here.

An Osteopathic/Naturopathic Protocol for Care of Hyperventilation Syndrome/Breathing Pattern Disorders

- Initial (and continual or periodic) assessment of breathing function based on functional evidence and palpation determines what needs to be done to improve breathing function.
- Education and information are vital for creating motivation and awareness as to why homework is essential in normalizing BPDs.
- The patient must understand clearly that the practitioner or therapist can do no more than create an environment, a possibility, for the restoration of more normal function, but the breathing work itself is up to the patient.
- Treatment of muscles and joints alone, no matter how appropriate, can never restore normal breathing patterns without cooperative effort.
- Conversely, breathing retraining without the freeing of restricted structures is far more difficult to achieve.
- Psychotherapy and counseling are also unlikely to be successful unless retraining is introduced and structural factors are dealt with.
- Manual attention to the upper fixators and/or accessory breathing muscles (upper trapezii, levator scapulae, scalenes, sternocleidomastoid, pectorals, and latissimus dorsi) is usually required.
- The diaphragm area also requires direct attention as a rule (lower anterior intercostals, sternum, costal margin, beneath costal margin, abdominal attachments, quadratus lumborum, and psoas).
- Active trigger points in these muscles may need deactivating manually or via acupuncture.
- Acupuncture being administered for 30 minutes, twice weekly, for 4 weeks showed a reduction in Nijmegen score from 31 to 24. The focus was on reducing anxiety, thereby reducing hyperventilation. The points used were colon 4, liver 3, and stomach 36 bilaterally.[42]
- The thoracic spine and ribs may require mobilization (osteopathic or chiropractic adjustments).
- Osteopathic lymphatic pump methods may be required if there is evidence of stasis.
- Retraining: various breathing exercises should be introduced, individualized to the specific needs of the patient, commonly on the basis of pursed-lip breathing and pranayama yoga methods (Box 135.1).[43–47]
- Relaxation methods, including autogenic training or progressive muscular relaxation, or both, might usefully be introduced. One small placebo-controlled trial showed improvement on anxiety and hyperventilation in HIV-infected patients after four Swedish massage sessions (once weekly for 30 minutes to the back).[48]
- Sleep pattern disturbances might require attention.
- Exercise of aerobic nature should be carefully introduced.
- Dietary advice and counseling should be introduced as appropriate.

BOX 135.1 Breathing Rehabilitation Exercises

1. Pursed lip breathing[44,45]: Pursed lip breathing, combined with diaphragmatic breathing, enhances pulmonary efficiency.
   - The patient is seated or supine with the dominant hand on the abdomen and the other hand on the chest.
   - The patient is asked to breathe in through the nose and out through the mouth, with pursed lips, ensuring diaphragmatic involvement by means of movement of the abdomen against the hand on inhalation.
   - Exhalation through the pursed lips is performed slowly and has been shown to relieve dyspnea, slow the respiratory rate, increase tidal volume, and help restore diaphragmatic function.

   Author's Note: Essentially, blowing firmly and slowly through a narrow aperture, such as pursed lips, effectively tones the diaphragm via eccentric isotonic activity.
2. Antiarousal breathing[43,46]: The patient is asked to sit or recline comfortably and exhale slowly and fully through pursed lips, and the following guidance is given:
   - Imagine a candle flame about 6 inches from your mouth, and blow a thin stream of air at it (pursed-lip breathing).
   - As you exhale, count silently to establish the length of the "out breath."
   - When you have exhaled fully, without strain, pause for a count of "1," then inhale through the nose.
   - Full exhalation creates a "coiled spring," making inhalation easier.
   - Count to yourself to establish how long your "in breath" lasts.
   - Without pausing to hold the breath, exhale slowly and fully, through pursed lips, blowing the air in a thin stream, and then pause for a count of 1.
   - Repeat the inhalation and exhalation for at least 30 cycles twice daily.
   - After some weeks of daily practice, you should achieve an inhalation phase that lasts 2 to 3 seconds and an exhalation phase of 6 to 7 seconds, without strain.
   - Exhalation should always be slow and continuous; there is little value in breathing the air out in 2 seconds and then simply waiting until the count reaches 8 before inhaling again!
   - Feelings of anxiety should reduce with this exercise.
   - Practice twice daily, and repeat the exercise for a few minutes (6 cycles takes about 1 minute) every hour if anxious or when stress increases.
   - Practice on waking, before bedtime, and if possible, before meals.
3. Recitation of mantra or prayer
   - The respiratory (and cardiovascular) effects of rosary prayer ("Ave Maria" in Latin) and recitation of a yoga mantra were assessed.[47]
   - Results were similar, showing a slowing of respiration to approximately 6 counts per minute and synchronization of all cardiovascular rhythms (Traube–Hering–Mayer oscillations), representing blood pressure, heart rate, cardiac contractility, pulmonary blood flow, cerebral blood flow, and movement of cerebrospinal fluid.
   - This influence on autonomic activity, represented by the Traube–Hering–Mayer oscillations, is clearly health enhancing because it slows the respiratory rate to the level considered optimal in breathing rehabilitation.[1,7,12]

Breathing Rehabilitation Exercises

Box 135.1 describes three breathing rehabilitation exercises.

Chronic HVS/BPDs are commonly successfully treated. However, a time frame of 12 to 26 weeks may be required, with active patient participation throughout to break well-established habits.

Lum[1] reported that more than 1000 anxious and phobic patients were treated using breathing retraining, physical therapy, and relaxation. The results indicated the following:

- Symptoms were usually abolished in 1 to 6 months, with some younger patients requiring only a few weeks.
- At 12 months, 75% were free of all symptoms, 20% had only mild symptoms, and about 1 in 20 patients had intractable symptoms.

Breathing rehabilitation therapy was evaluated in patients with HVS; the diagnosis was based on the presence of several stress-related complaints and reproduced by voluntary hyperventilation.[49] Patients with organic diseases were excluded, and most patients met the criteria for an anxiety disorder.

Therapy was conducted in the following sequence:

- Brief, voluntary hyperventilation to reproduce the reported complaints
- Reattribution of the cause of the symptoms to hyperventilation
- Explaining the rationale of therapy involving a reduction of hyperventilation by acquiring an abdominal breathing pattern, with slowing down of expiration
- Breathing retraining for 2 to 3 months working with a physiotherapist

After breathing therapy, the sum scores of the Nijmegen Questionnaire were markedly reduced. A canonical correlation analysis relating the changes of the various complaints to the modifications of breathing variables showed that the improvement of the complaints was correlated mainly with the slowing down of breathing frequency.

SUMMARY

HVS/BPDs are a common disorder affecting up to 10% of patients in a general internal medicine practice. However, it is rarely recognized or appropriately treated. Breathing retraining is effective clinically and economically, as long as enough patience is exercised to actively engage the patient in a program requiring weeks to months of behavioral change. Acupuncture was also shown to improve symptoms of HVS, especially with anxiety as the etiology.

Immune System Support

Michael T. Murray, ND, and *John Nowicki, ND*

OUTLINE

INTRODUCTION

The immune system is a complex integration of synergistic segments that are continuously barraged by stimuli from both internal and external sources. Immunology continues to be a rapidly developing field in which mechanisms are constantly being conceptualized and revised. For the physician interested in assessing and maintaining a patient's health, the development of a thorough understanding of the clinical aspects of the immune system and the many factors that enhance and/or inhibit normal function is essential. The immune system is truly "holistic," as evidenced by the close association of psychological, neurological, nutritional, environmental, and hormonal factors with immune function.

Supporting the immune system is critical to good health. Conversely, good health is critical to supporting the immune system. The best approach to supporting immune function is a comprehensive plan involving lifestyle, stress management, exercise, diet, nutritional supplementation, and the use of plant-based medicines.

IMMUNE SYSTEM OVERVIEW

The immune system has two fundamental and complementary components: the innate and adaptive immune systems, with the division largely defined by the speed and specificity of the response. The innate branch of the immune system is generally defined by a consistent response; however, when an antigen is encountered, the immune response includes phagocytic cells such as neutrophils, monocytes, and macrophages, as well as the various physical and chemical barriers to infection. The adaptive immune system, however, improves upon repeated exposure to a given infection because these cells develop a memory of past encounters. The adaptive immune system is composed of B (humoral) and T (cell-mediated) cells that work together to create antibodies specific to an invading organism.

Macrophages and dendritic cells, often referred to as antigen-presenting cells (APCs), are critical for the development of naïve T cells into either type 1 helper T (Th1) cells or type 2 helper (Th2) cells. After ingesting the pathogen, the macrophage will display the antigenic signature of the pathogen and send a chemical messenger, interleukin (IL)-1, to notify the T-helper cells (that have CD4 phenotype markings) of the pathogens' presence. From there, they will develop into Th1 and Th2 cells (based on the cytokine they produce). The cytokines produced by T-helper cells modulate other T-helper-type activities (Fig. 136.1). For example, Th1 produces interferon (IFN)-γ, tumor necrosis factor (TNF)-β, IL-2, IL-10, and lymphotoxin, which then stimulates the cell-mediated immune responses against viral and bacterial pathogens and tumor cells through activation of macrophages and cytotoxic T-cells. IFN-γ, among its other actions, activates macrophages and stimulates NK cell and lymphokine-activated killer activities. Th2 produces IL-4, IL-5, IL-10, IL-13, IL-21, and IL-31, which stimulate B cells to produce antibodies immunoglobulin (Ig)M, IgG1, IgA, and IgE. Type 3 helper T (Th3) cells help to maintain homeostasis between Th1 and Th2 cells, and type 17 helper T (Th17) cells appear to downregulate the production of both Th1 and Th2 cytokines.

PSYCHONEUROIMMUNOLOGY

Psychoneuroimmunology is the term used to describe the interactions between the emotional state, nervous system function, and the immune system.[1] Investigations into these interactions have documented that the mind and attitude play a significant role in the functioning of the immune system. However, a complete and detailed account of the many facets of psychoneuroimmunology, or behavioral immunology, is beyond the scope of this chapter. An overview of the role of attitude and emotions in immune function is discussed in Chapter 7, and the importance of stress management to a healthy immune system is discussed in Chapter 140.

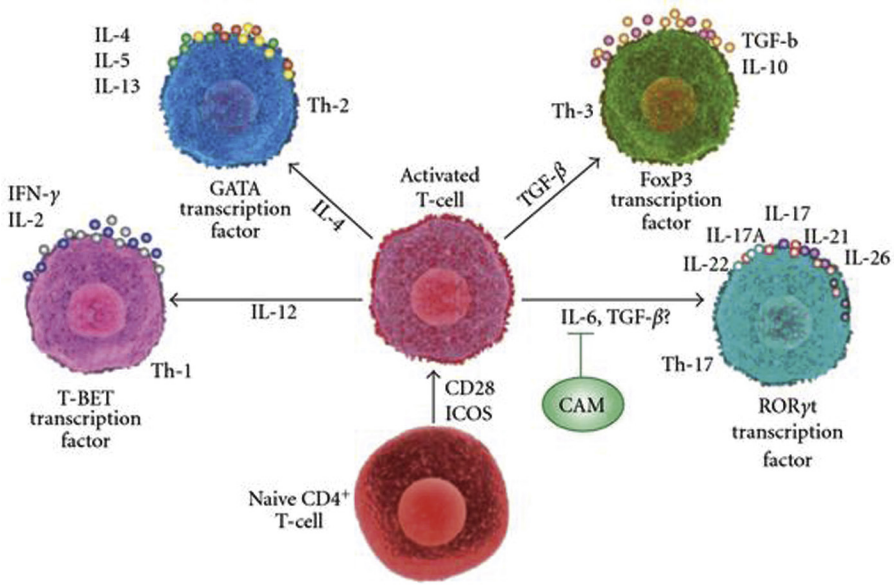

Fig. 136.1 General scheme of differentiation of T-helper cells. Naive CD4+ T cells, after activation by T-cell receptor and costimulatory molecules, such as CD28 and inducible T-cell costimulatory (ICOS), can differentiate into four effector T-helper cells: Th1, Th2, Th3, or Th17 cells. These cells produce different cytokines, which have specialized immunoregulatory functions. Interferon (IFN) produced by Th1 cells is important in the regulation of antigen presentation and cellular immunity. Interleukin (IL)-4, IL-5, and IL-13 produced by Th2 cells regulate B-cell responses, important mediators of allergic diseases. Transforming growth factor (TGF) and IL-10 are produced by Th3 cells to regulate Th1 and Th2 cells. Th17 cells regulate inflammatory responses by expressing IL-17, IL-21, IL-22, and IL-26. Complementary and alternative medicine (CAM) protocols can be implemented to reduce the level of proinflammatory cytokine IL-6, thereby inhibiting the conversion of activated T cells into pathogenic Th17 cells. (From Vojdani A, Lambert J. The role of Th17 in neuroimmune disorders: target for CAM therapy. Part I. *Evid.-Based Complem. Altern. Med.* 2011: 927294.)

Many clinical and experimental studies have clearly demonstrated that stress, personality, attitude, and emotion are etiological or contributory in suppressing the immune system as well as leading to the development of many diseases.[1] Reaction to stressful stimuli is entirely individual, reinforcing the fact that people differ significantly in their perceptions of and responses to various life events. The variations in response help account for the wide diversity of stress-induced illnesses. Stress-induced increases in corticosteroid and catecholamine levels lead to an immunosuppressed state, leaving the host susceptible to infectious and carcinogenic illnesses. This immunosuppression is proportional to the level of stress, and although the effects are numerous, they appear to involve a common mechanism: an increase in glucocorticoids, proinflammatory cytokines, and catecholamines resulting in significant alterations in hypothalamic–pituitary–adrenal (HPA) and the sympathetic-adrenal medullary axes, leukocyte function, thymic involution, and suppressed lymphopoiesis. More than 150 clinical studies have shown that stress can alter immune function and contribute to the development of significant disease and poor health.[1–3]

Lymphocytes, monocytes or macrophages, and granulocytes have receptor sites for the many regulating hormones and neurotransmitters of the HPA and sympathetic-adrenal medullary axes. Alterations in these compounds lead to disruption of cellular trafficking, proliferation, cytokine secretion, antibody production, and cytolytic activity. For example, glucocorticoids inhibit the production of IL-12, IFN-γ, IFN-α, and TNF-α by antigen-presenting cells and Th1 cells, but upregulate the production of IL-4, IL-10, and IL-13 by Th2 cells. This mechanism systemically causes a selective suppression of the Th1–cellular immunity axis and a shift toward Th2-mediated humoral immunity, rather than generalized immunosuppression. During an immune response and inflammation, the activation of the stress system, and thus increased levels of systemic glucocorticoids through induction of a Th2 shift, may protect the organism from systemic "overshooting" with Th1 proinflammatory cytokines and other products of activated macrophages with tissue-damaging potential. However, conditions associated with significant changes of glucocorticoids, such as acute or chronic stress or cessation of chronic stress, severe exercise, pregnancy, and the postpartum state, through modulation of the Th1–Th2 balance, may affect the susceptibility to or the course of infections as well as autoimmune and atopic and/or allergic diseases.[4,5] A study in medical students taking examinations found that psychological stress produced a shift in the cytokine balance toward a Th2 profile.[6] The data showed decreased synthesis of Th1 cytokines, including IFN-γ, and increased production of Th2 cytokines, including IL-10. Therefore a stress-induced decrease of Th1 cytokines results in dysregulation of cell-mediated immune responses.

To help demonstrate causal relations between psychosocial stressors and the development of infectious illness under well-controlled conditions, investigators inoculated subjects with several different types of vaccines to demonstrate clinically relevant alterations in the immunological response to challenge. The chronic stress associated with caring for a spouse with Alzheimer's disease or, for younger people, experiencing stressful life events was associated with a poorer antibody response to an influenza virus vaccine than in well-matched control subjects.[7,8] The premise was that the production of a delayed, weaker, and shorter-lived immune response to a vaccine would be analogous to impaired immune responses to other pathogens. Consistent with this concept, subjects who showed poorer responses to vaccines also experienced higher rates of clinical illness as well as longer-lasting infectious episodes. Healthy infants with a higher cortisol response to pain were shown to have differences in T-cell concentrations and a lower

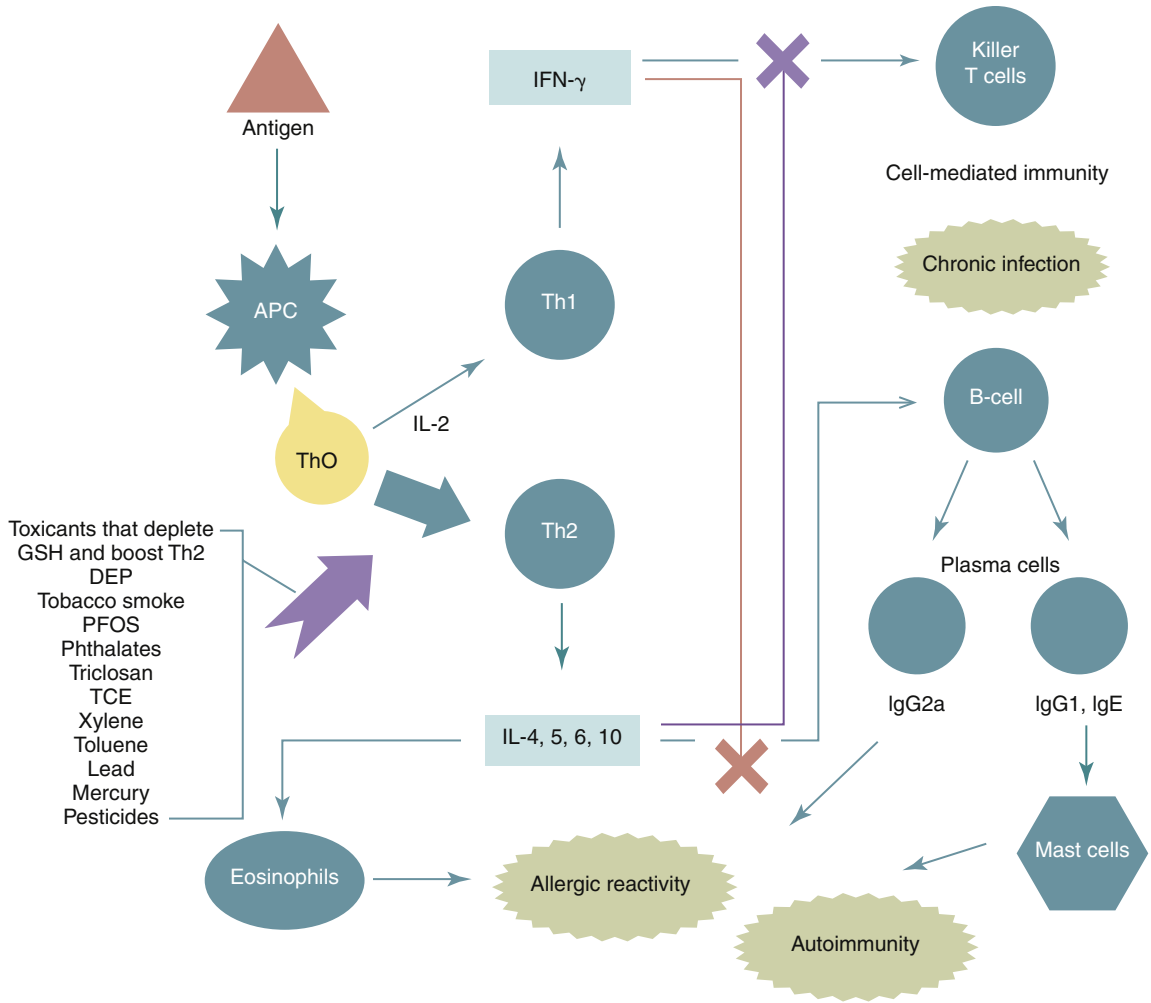

Fig. 136.2 Many immune-toxic pollutants reduce glutathione levels leading to immune system dysregulation increasing the risk for infections, allergies, autoimmunity, and cancer.

delayed-type hypersensitivity to vaccination, with sex differences in the immune system seen as early as 6 weeks of age.[9]

Fortunately, the effects of stress on the immune system can be attenuated or even overcome with positive mood, effective stress reduction techniques, humor, laughter, and guided imagery.[1,10]

ENVIRONMENTAL TOXINS AND IMMUNE FUNCTION

Toxic compounds exert several different effects, usually simultaneously, that cause complex dysfunction to the immune system. Toxins often deplete the glutathione (GSH) content in APCs, thereby affecting whether these cells will be Th1 or Th2 dominant.[11] Low GSH levels lead to an increase in Th2 dominance, whereas higher GSH levels promote Th1 immune response.[12] Many immune-toxic pollutants reduce glutathione levels, including mercury, lead, perfluorocarbons, phthalates, solvents, polychlorinated biphenyl (PCBs), chlorinated pesticides, organophosphate pesticides, particulate matter, tobacco smoke, and diesel exhaust particles (Fig. 136.2).[13] A diminished Th1 response will reduce the ability to respond to bacterial, viral, and fungal invasion, typically resulting in chronic infections.

In an animal model, the consumption of PCB containing fat resulted in diminished mitogen response, decreased phagocytosis, diminished numbers of CD8+ cells, and thymic atrophy.[14–16] Mobile home dwellers exposed to formaldehyde were found to have lower T and B cells and diminished mitogen response to phytohemagglutinin (PHA).[17] Mold exposure has also been shown to reduce mitogen responsiveness in humans.[18]

LIFESTYLE EFFECTS ON IMMUNE FUNCTION

A healthy lifestyle goes a long way in establishing a healthy immune system. This benefit is perhaps most obvious when one looks at the effects of lifestyle on natural killer cell activity.[19–21] Box 136.1 lists the lifestyle practices associated with higher natural killer cell activity. One lifestyle factor that is critical to healthy immune function is adequate sleep. In healthy humans, sleep deprivation has consistently been demonstrated to impair different parameters of immune function and mood. Interestingly, the deterioration of immune function precedes the plummeting of subjective well-being and psychosocial performance in sleep-deprived subjects.[22]

NUTRITIONAL FACTORS AFFECTING IMMUNE FUNCTION

The health of the immune system is greatly affected by a person's nutritional status. Dietary factors that depress immune function include nutrient deficiency, excess consumption of sugar, consumption of allergenic foods, and high cholesterol levels in the blood. Dietary factors that enhance immune function include all essential nutrients, antioxidants, carotenes, and flavonoids.

Consistent with good health, optimal immune function requires a healthy diet that has the following characteristics:

BOX 136.1 Lifestyle Practices Associated With Higher Natural Killer Cell Activity

- Not smoking
- Increased intake of green vegetables
- Regular meals
- Proper body weight
- More than 7 hours of sleep per night
- Regular exercise
- A vegetarian diet

- Is rich in whole, natural foods, such as fruits, vegetables, grains, beans, seeds, and nuts
- Is low in fats and refined sugars
- Contains adequate, but not excessive, amounts of protein

In addition, individuals are encouraged to drink five or six 8-ounce glasses of water (preferably pure) per day. These dietary recommendations, along with a positive mental attitude, a good high-potency multivitamin and mineral supplement, a regular exercise program, deep-breathing and relaxation exercises (meditation, prayer, etc.), and at least 7 hours of sleep daily, will go a long way in helping the immune system function at an optimum level.

Nutrient Deficiency

Nutrient deficiency is the most common cause of a depressed immune system. Although research relating nutritional status to immune function has historically concerned itself with severe malnutrition states (i.e., kwashiorkor and marasmus), attention is shifting toward marginal deficiencies of single or multiple nutrients and the effects of overnutrition. The plethora of clinical and experimental data has concluded that a single nutrient deficiency can profoundly impair the immune system.

Given the widespread problem of subclinical nutrient deficiency in Americans, it is likely that many have impaired immunity amenable to nutritional supplementation. This statement is particularly true in the elderly. Numerous studies have shown that most elderly Americans are deficient in at least one nutrient, and studies show that taking a multivitamin and mineral supplement enhances immune function in elderly subjects (whether they have an overt nutritional deficiency or not).[23–25] These findings have considerable fundamental, clinical, and public health significance.

Protein

The importance of adequate protein intake to proper immune function has been extensively studied.[10] Although all facets of immune function are ultimately affected, the most severe effects of protein–calorie malnutrition (PCM) are on cell-mediated immunity. PCM is associated with multiple nutrient deficiencies, and some immune dysfunctions attributed to PCM are likely the result of these deficits. Partial deficiencies of dietary vitamins produce a comparatively greater depression in the natural and inducible levels of cytotoxic activities than do partial protein deficiencies. Nonetheless, adequate protein is essential for optimal immune function.

Sugar

The oral administration of 100-g portions of carbohydrate as glucose, fructose, sucrose, honey, or orange juice significantly reduces neutrophil phagocytosis, but starch has no effect. As can be seen in Fig. 136.3, effects start within 30 minutes, last for more than 5 hours, and typically show a 50% reduction in phagocytic activity at the peak of inhibition (usually 2 hours after ingestion).[26,27] Because polymorphonuclear leukocytes (PMNs) constitute 60% to 70% of the total white blood cells (WBCs) and are a major portion of the defense mechanism, impairment of phagocytic activity leads to an immune-compromised state. Oral administration of increasing amounts of glucose progressively lowers neutrophil phagocytosis, with maximal inhibition corresponding to maximal blood glucose levels.

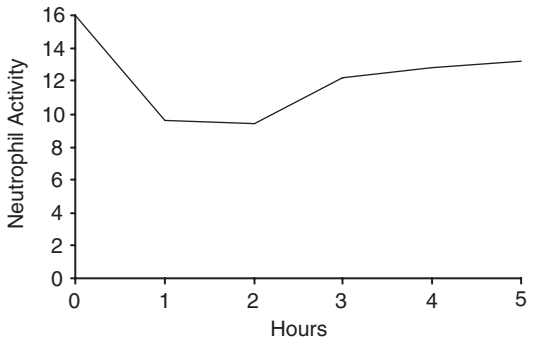

Fig. 136.3 The effects of sugar on white blood cell phagocytic activity.

In addition, oral ingestion of 75 g of glucose has been shown to depress lymphocyte response to mitogens, apparently through the elevation of insulin levels.[28] Other parameters of immune function are also undoubtedly affected by sugar consumption.

It has been hypothesized that the ill effects of high glucose levels result from the elevation of insulin values and competition with vitamin C for membrane transport sites.[29,30] This hypothesis is based on evidence that vitamin C and glucose appear to have opposite effects on immunological function and the fact that both substances require insulin for membrane transport into many tissues.

Considering that the average American consumes 125 g of sucrose, plus 50 g of other refined simple sugars each day, the conclusion that most Americans have chronically depressed immune systems is inescapable. It is clear, particularly during an infection, that the consumption of simple sugars, even in the form of fruit juice, is deleterious to the host's immune status.

Short-term fasting could be encouraged, particularly during the first 24 to 48 hours of an acute infectious illness, because it results in a significant (up to 50%) increase in phagocytic index.[26] The fast should not be continued for a long period; over time, the leukocytes' energy sources will become depleted.

Obesity

Obesity is associated with decreased immune status, as evidenced by reduced bactericidal activity of leukocytes, and higher morbidity and mortality from infections as well as from certain cancers in obese individuals.[31] Obesity also increases the risk of asthma, atopic, and autoimmune diseases by inducing decreased immunological tolerance as a consequence of immunological changes induced by adipokines (e.g., leptin and adiponectin) and cytokines (e.g., IL-6 and TNF-α) secreted by white adipose tissue.[32] In addition, cholesterol and lipid values are usually elevated in obese individuals, which contribute to impaired immune function.

Blood Lipids

Increased blood levels of cholesterol, free fatty acids, triglycerides, and bile acids inhibit various immune functions, including the following[33,34]:

- Lymphoproliferation
- Response to mitogens
- Antibody response
- PMN chemotaxis
- Phagocytosis

Therefore optimal immune function depends on control of these serum components. Interestingly, L-carnitine, even at minimal concentrations, has been shown to neutralize lipid-induced immunosuppression.[35] This effect is probably due to carnitine's role as a rate-limiting factor in the removal of fat emulsion from the blood.[36]

Alcohol

Alcohol increases the susceptibility to experimental infections in animals, and alcoholics are known to be more susceptible to infections, especially pneumonia. Studies of immune function in alcoholism showed a profound depression in most parameters of immunity.[37]

Vitamins

Vitamin A and Carotenes

Vitamin A plays an essential role in maintaining the integrity and secretions of the epithelial and mucosal surfaces. These systems constitute a primary nonspecific host defense mechanism. Vitamin A has been shown to stimulate and/or enhance numerous immune processes, including the following:

- Induction of cell-mediated cytotoxicity against tumors
- Natural killer cell activity
- Lymphocyte blastogenesis
- Mononuclear phagocytosis
- Antibody response

These effects are not simply the result of the reversal of vitamin A deficiency because many of them are further enhanced by the administration of (supposedly) excessive levels of vitamin A.[25,38] In addition, vitamin A prevents and reverses stress-induced thymic involution, and additional vitamin A can promote thymus growth.[39]

Carotenes have also demonstrated several immune-enhancing effects. In addition to being converted into vitamin A, carotenes function as antioxidants. Because the thymus gland is susceptible to damage by free radicals, β-carotene may be more advantageous in enhancing the immune system than retinol. For more information, see Chapter 125.

Vitamin C

Vitamin C (ascorbic acid) plays an important role in the natural approach to immune enhancement. Although vitamin C has been shown to be antiviral and antibacterial, its main effect is via improvement in host resistance. Many immunostimulatory effects have been demonstrated including enhancing lymphoproliferative response to mitogens and lymphotropic activity, as well as increasing INF levels, antibody responses, immunoglobulin levels, secretion of thymic hormones, and integrity of ground substance.[25,40] Vitamin C also has direct biochemical effects similar to those of INF.[41]

Numerous clinical studies support the use of vitamin C in the treatment of infectious conditions. In addition to its effects on the common cold, vitamin C has also been shown to be useful in other infectious conditions.[42] Vitamin C levels are quickly depleted during the stress of an infection as well as in chronic disease.[43]

It is useful to supplement vitamin C concurrently with flavonoids, which raise the concentration of vitamin C in some tissues and potentiate its effects as well as exert their own effects.[44]

Vitamin D

The importance of vitamin D on the regulation of cells of the immune system has gained increased appreciation with the discovery of the vitamin D receptor and key vitamin D metabolizing enzymes expressed by cells of the immune system. Effective in supporting both innate and adaptive immunity,[45–49] vitamin D has been shown to do the following:

- Upregulate antimicrobial peptides, namely cathelicidin, to enhance clearance of bacteria at various barrier sites and in immune cells
- Modulate the adaptive immune system by direct effects on T-cell activation and on the phenotype and function of APCs
- Protect against the development of autoimmune diseases (e.g., Crohn's disease, juvenile diabetes mellitus, multiple sclerosis, asthma, and rheumatoid arthritis)
- Reduce the frequency of viral upper respiratory infections

Vitamin D appears to be especially important in protection against viral or bacterial upper respiratory infection.[50] In Mongolian children with vitamin D deficiency who received milk fortified with 300 IU of vitamin D_3, supplementation significantly reduced the risk of acute respiratory infections in winter.[51] Additionally, 1200 IU/day of vitamin D_3 supplementation during the winter may reduce the incidence of influenza A and enhance innate immunity by upregulating antimicrobial peptides, especially in specific subgroups of schoolchildren.[52] In addition, weekly supplementation with 10,000 IU of vitamin D_3 is preventive for upper respiratory tract infections in young adults.[53] A meta-analysis that considered 25 eligible randomized controlled trials found that vitamin D supplementation is safe and protects against acute respiratory tract infection overall, and patients who are very deficient in vitamin D and those not receiving bolus doses experienced the most benefit.[54]

Vitamin E

Vitamin E enhances both humoral immunity and cell-mediated immunity. Deficiency in vitamin E results in lymphoid atrophy and decreases of lymphoproliferative response to mitogens, splenic plaque-forming colonies, antibody response, and monocyte function. Vitamin E supplementation (30–150 international units [IU]) has been shown to do the following[55]:

- Increase lymphoproliferative response to mitogens
- Prevent free-radical–induced thymus atrophy
- Enhance helper T-cell activity
- Increase splenic plaque-forming colonies, serum immunoglobulins, antibody response, PMN phagocytosis, and reticuloendothelial system activity

Elderly subjects may benefit from even higher dosages of vitamin E. One study sought to determine the effect of vitamin E supplementation at different dosages on immune function in 88 patients older than 65 years.[56] The researchers measured T-cell function by assessing delayed-type hypersensitivity skin response; antibody response to hepatitis B, tetanus, diphtheria, and pneumococcal vaccines; and autoantibodies to DNA and thyroglobulin to determine the effect of vitamin E on immune function. Vitamin E was given at 60, 200, or 800 IU for 235 days. Although the placebo group experienced an 8% increase in delayed-type hypersensitivity, the 60-IU group had a 20% increase, the 200-IU group had a 58% increase, and the 800-IU group had a 65% increase. Regarding antibody production, the best results were observed in the patients who received 200 IU daily. No effect on autoimmune antibodies was noticed. No adverse effects were observed at any of the three dosage schedules of vitamin E.

In another double-blind study of 451 elderly participants in a nursing home, vitamin E supplementation (200 IU/day) demonstrated a protective effect against upper respiratory tract infections, particularly the common cold.[57]

Pyridoxine

A pyridoxine deficiency results in depression of cellular and humoral immunity, lymphoid tissue atrophy, leukopenia, reduction in quantity and quality of antibody production, diminished lymphoproliferative response to mitogens, and decreased thymic hormone activity.[25]

Factors predisposing to deficiency are low dietary pyridoxine intake, excess protein intake, consumption of hydralazine (yellow) dyes, and use of alcohol and oral contraception.

Folic Acid and Vitamin B_{12}

The megaloblastic state induced by a deficiency of vitamin B_{12} and/or folate results in improper WBC production and abnormal lymphocyte responses. Folic acid deficiency (the most common vitamin deficiency in the United States) has been shown to result in lymphoid atrophy and decreased lymphoproliferative response to mitogens, splenic plaque-forming colonies, and antibody production. A B_{12} deficiency, besides producing a deficiency in folate conversion to its active tetrahydrofolate form, leads to impairment of PMN phagocytosis and bactericidal action.[25]

Other B Vitamins

Deficiencies of thiamin, riboflavin, and pantothenic acid lead to reduced antibody response, decreased splenic plaque-forming colonies, and lymphoid atrophy.

Minerals

Iron

Iron deficiency is a commonly encountered isolated nutritional deficiency causing immune dysfunction in large numbers of patients. Marginal iron deficiency, even at levels that do not lower hemoglobin values, can influence the immune system. Lymphoid tissue atrophy, decreased lymphoproliferative response to mitogens, defective macrophage and neutrophil function, and decreased T-cell/B-cell ratios are common experimental and clinical findings.[25]

Iron is an important nutrient for bacteria as well as for humans. During infection, one of the body's nonspecific defense mechanisms to limit bacterial growth is to reduce plasma iron, and in vitro studies have shown that the bacteriostatic effects and some of the bactericidal effects of serum are eliminated by the addition of iron to the serum.[58] As temperature rises, plasma iron levels drop, and when temperature is raised to fever levels, the growth of bacteria is inhibited, but not at high iron concentrations.

These observations suggest that iron supplementation may be contraindicated during acute infection, especially in patients with low transferrin levels. However, in patients with impaired immune function, chronic infections, and subnormal iron levels, adequate supplementation is essential.

Trace Minerals

Trace minerals function primarily as activators of enzyme–metal–substrate complexes in which they are loosely bound cofactors. The role of these elements in metalloenzymes is either structural, in which they influence the reactivity of the protein by stabilizing strained configurations of binding ligands about the metal atom, or catalytic, in which they act as centers of positive charge.

Zinc

Acrodermatitis enteropathica, a hereditary zinc-deficiency disease, offers an excellent model for understanding the role of zinc in immune function. In acrodermatitis enteropathica, the number of T cells is reduced, lymphoproliferative response to mitogens is diminished; thymic hormone levels are lower; delayed cutaneous hypersensitivity is decreased; and PMN phagocytosis, chemotaxis, and cytotoxic activities are impaired. All these effects are reversible upon adequate administration and absorption of zinc.[59]

Zinc serves a vital role in many immune system reactions, For example, it promotes the binding of complement (C1q) to immune complex, acts as a protectant against iron-catalyzed damage by free radicals, acts synergistically with vitamin A, is required for lymphocyte transformation, acts independently on lymphocytes as a mitogen, and is a necessary cofactor in activating serum thymic factor. In vitro, zinc inhibits the growth of several viruses, including rhinoviruses, picornaviruses, togaviruses, herpes simplex virus, and vaccinia virus.[60]

Adequate zinc nutrition is particularly important in the elderly, and zinc supplementation in elderly subjects results in increased numbers of T cells and enhanced cell-mediated immune responses.[60]

Throat lozenges containing zinc became popular in the treatment of the common cold because of a double-blind clinical trial in 1984 demonstrating that zinc-containing lozenges significantly reduced the average duration of common colds by 7 days.[61] The lozenges used in this study contained 23 mg of elemental zinc, which the patients were instructed to dissolve in their mouths every 2 waking hours after an initial double dose. After 7 days, 86% of the 37 zinc-treated subjects were symptom-free compared with 46% of the 28 placebo-treated subjects. Additional studies confirmed these results.[62] Meta-analyses demonstrated that zinc may shorten the duration of colds by approximately 33%, and patients with a common cold may be instructed to try zinc within 24 hours of the onset of symptoms.[63] Zinc gluconate lozenges were found to be as effective as zinc acetate lozenges. No evidence supports that zinc doses more than 100 mg/day might lead to greater efficacy in the treatment of the common cold. Because high doses of zinc can impair immune function, a daily intake higher than 150 mg for longer than 1 week cannot be recommended.

Selenium

Selenium plays a vital role in glutathione peroxidase and affects all components of the immune system, including the development and expression of all WBCs. Selenium deficiency results in depression of immune function, and selenium supplementation results in augmentation and/or restoration of immune functions. Selenium deficiency has been found to inhibit resistance to infection through impairment of WBC and thymus function, whereas selenium supplementation (100–200 mcg/day) has been shown to stimulate WBCs and thymus function.[64–67]

The ability of selenium supplementation to enhance immune function goes beyond simply restoring selenium levels. For example, in one study, selenium supplementation (200 mcg/day) to individuals with normal blood selenium concentrations resulted in a 118% improvement in the ability of lymphocytes to kill tumor cells and an 82.3% rise in the activity of natural killer cells.[65] These effects were related to the ability of selenium to enhance the expression of the immune-enhancing compound IL-2 and, consequently, the rate of WBC proliferation and differentiation into forms capable of killing tumor cells and microorganisms. The supplementation regimen did not produce significant changes in the blood selenium levels of the participants. The results indicated that the immune-enhancing effects of selenium in humans require supplementation above the normal dietary intake.

ENHANCING THYMUS FUNCTION

Perhaps the most effective method of reestablishing a healthy immune system is employing measures to improve thymus function. Promoting optimal thymus gland activity involves the following:

- Prevention of thymic involution or shrinkage by ensuring adequate dietary intake of antioxidant nutrients
- Use of nutrients that are required in the manufacture or action of thymic hormones

Antioxidants

The thymus gland shows maximum development immediately after birth. During the aging process, the thymus gland undergoes a process of shrinkage, or involution. Involution occurs because the thymus gland is extremely susceptible to free-radical and oxidative damage caused by stress, radiation, infection, and chronic illness.

Many patients with impaired immune function as well as conditions associated with impaired immunity (e.g., chronic fatigue syndrome, cancer, acquired immunodeficiency syndrome) experience a state of oxidative imbalance characterized by a greater number of prooxidants than antioxidants. This situation is quite detrimental to thymus function. One primary way that antioxidants affect the immune system, particularly cell-mediated immunity, may be by protecting the thymus gland from damage. The antioxidant nutrients most important for protecting the thymus include the carotenes, vitamin C, vitamin E, zinc, and selenium.

Nutrients

Many nutrients function as important cofactors in the manufacture, secretion, and function of thymic hormones. A deficiency in any one of these nutrients results in decreased thymic hormone action and impaired immune function. Zinc, vitamin B_6, and vitamin C are perhaps the most critical. Supplementation with these nutrients has been shown to improve thymic hormone function and cell-mediated immunity.

Zinc may be the critical mineral involved in thymus gland function and thymus hormone action. Zinc is involved in virtually every aspect of immunity. When zinc levels are low, the number of T cells is reduced, thymic hormone levels are lower, and many WBC functions critical to the immune response are severely lacking. All these effects are reversible with adequate administration and absorption of zinc.[68,69]

BOTANICALS

Many herbs have been shown to have antibacterial, antiviral, and immunostimulatory effects. A complete discussion is outside the scope of this chapter, but several immune-enhancing botanicals (e.g., *Echinacea, Hydrastis canadensis,* and *Panax ginseng*) are discussed in depth in Section 5.

Astragalus membranaceus is a traditional Chinese medicine used for viral infections. As with Echinacea, the polysaccharides contained in the root of *Astragalus membranaceus* contribute to the immune-enhancing effects. Clinical studies in China have shown it to be effective when used prophylactically against the common cold.[70] It has also been shown to reduce the duration and severity of symptoms in the acute treatment of the common cold as well as to raise WBC counts in persons with chronic leukopenia. Research in animals showed that *Astragalus* works by stimulating several factors of the immune system, including enhancing the phagocytic activity of monocytes and macrophages, increasing INF production and natural killer cell activity, improving T-cell activity, and potentiating other antiviral mechanisms.[70,71] *Astragalus* may be particularly useful in cases in which the immune system has been damaged by chemicals or radiation. In immuno-depressed mice, *Astragalus* was found to reverse the T-cell abnormalities caused by cyclophosphamide, radiation, and aging.[72]

Yeast Beta-Glucans and Medicinal Mushrooms

Extracts and preparations of Baker's yeast and medicinal mushrooms like maitake (*Grifola frondosa*), shiitake (*Lentinus edodes*), reishi (*Ganoderma lucidum*), and *Cordyceps sinensis* possess significant immune-enhancing effects. Much of the immune-enhancing activity is due to the presence of β-glucans. Numerous in vitro, in vivo, and clinical studies showed that yeast and fungal β-glucans activate WBCs by binding to receptors like dectin-1 on the outer membranes of neutrophils, macrophages, natural killer cells, and cytotoxic T cells.[73,74] Similar to a key in a lock, the binding of β-glucan to cellular receptors flips WBCs on and triggers a chain reaction leading to increased immune activity. In addition to increasing the ability of neutrophils and macrophages to engulf and destroy microbes, cancer cells, and other foreign cells, the binding stimulates the production of important signaling proteins such as IL-1, IL-2, and lymphokines. These immune activators ramp up defenses by activating immune cells.

One of the best-researched β-glucan sources is Wellmune WGP, a whole glucan particle composed of 1,3-1,6-β-glucan derived from the cell walls of a highly purified, proprietary baker's yeast *(Saccharomyces cerevisiae).* Once absorbed, Wellmune is taken up by macrophages, digested into smaller fragments, and slowly released over several days. The fragments bind to neutrophils, via complement receptor 3, and enhance their activity. Double-blind clinical studies have been conducted with Wellmune WGP, demonstrating positive results in reducing the signs, symptoms, frequency, and duration of upper respiratory infections. In a study involving marathon runners, Wellmune WGP significantly reduced symptoms of upper respiratory tract infection (e.g., sore throat, stuffy nose) in test subjects.[75] Furthermore, the Wellmune group reported 22% higher scores in vigor, a 48% reduction in fatigue, a 38% reduction in tension, and a 38% reduction in confusion over the control groups.

In a double-blind study during the cold and flu season, compared with the placebo group, the Wellmune WGP group reported (1) no incidence of fever compared with 3.5 incidences over a 90-day period; (2) no need to take a "sick day" from work or school, compared with 1.38 days of work/school missed for the placebo group; and (3) an increase in general health, including physical energy and emotional well-being.[76]

In a study of 122 healthy volunteers, participants taking 250 mg of Wellmune WGP daily for 12 weeks reported a 58% reduction in upper respiratory tract infection symptoms compared with individuals taking a placebo.[77] These subjects also experienced improvement in energy levels compared with the placebo group.

Microbiota

Bacterial colonization of the intestine is critical for the normal function of the human immune system. The specific molecules produced by commensal bacteria that contribute to the modulation of the host immune system are largely uncharacterized. However, polysaccharide A (PSA), produced by the human commensal *Bacteroides fragilis,* is a model symbiosis factor. PSA is capable of activating T-cell–dependent immune responses that can affect the development and homeostasis of the host immune system and also has a critical influence on the stimulation of IL-10–producing CD4+ T cells.[78] Consequently, PSA confers benefit to the host with regard to autoimmune, inflammatory, and infectious diseases. The effect of the microbiota composition on systemic immune-mediated diseases is just beginning to be appreciated. However, there is strong evidence for a functional link between the composition of the intestinal microbiota and susceptibility to several systemic immune disorders, such as type 1 diabetes, rheumatoid arthritis, and allergic diseases (Fig. 136.4).[79]

THERAPEUTIC APPROACH

A major challenge to the discerning clinician is determining which of the preceding factors is key to reactivating or supporting a patient's immune system. The regimen presented here is meant as a general approach and must be tailored to the patient's specific needs to maximize the desired effects and limit unnecessary treatment.

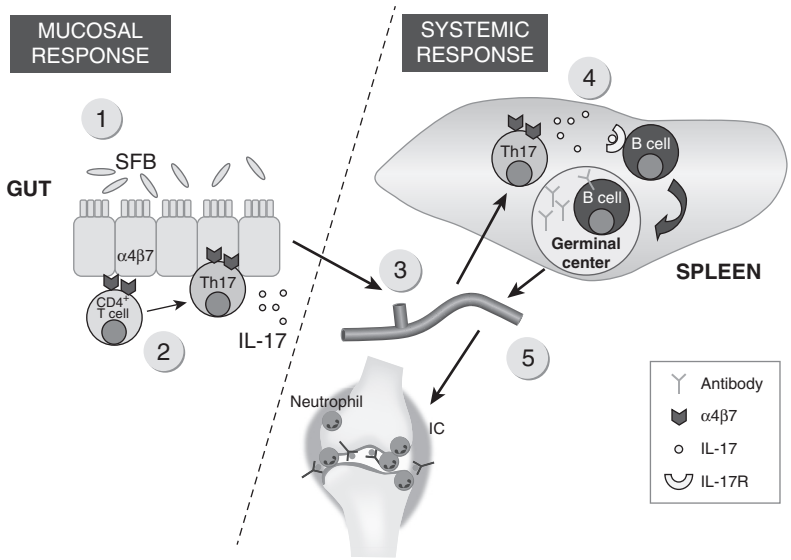

Fig. 136.4 An autoimmune arthritis model that demonstrates the link between gut microbiota and extraintestinal disease. *SFB,* Segmented filamentous bacteria The K/BxN arthritis model was used to demonstrate how the gut microbiota can influence a non–gut-associated disease. K/BxN mice express a transgene-encoded T-cell receptor that reacts to a self-peptide. Colonization of SFB in the gut induces the differentiation of Th17 cells (step 1 and 2), which subsequently exit the gut and migrate into the peripheral lymphoid tissue. The gut origin of Th17 cells can be identified by their expression of the α4β7 receptor, imprinted on these T cells by intestinal-mucosa-associated DCs (step 3). Interleukin (IL)-17, in turn, acts directly on B cells to provide help in the differentiation of germinal center B cells and the production of autoantibody in the spleen (step 4). The autoantibody then circulates into its target organ joints, which ultimately leads to the development of disease. (From Wu HJ, Wu E. The role of gut microbiota in immune homeostasis and autoimmunity. *Gut Microbes.* 2012;3[1]:4–14. PubMed PMID: 22356853.)

General Measures

- Get sufficient rest (bed rest is better).
- Drink a large amount of fluids (preferably diluted vegetable juices, soups, and herb teas).
- Limit simple sugar consumption (including fruit sugars) to less than 50 g/day.

Supplements

- High-potency multivitamin and mineral formula:
  - Vitamin C, 500 to 1000 mg every 2 hours
  - Bioflavonoids, 1000 mg/day
  - Vitamin A, 2500 IU/day (if patient has genetics to convert to vitamin A: β-carotene 25,000 IU/day can be used as an alternative)
  - Vitamin D_3, 2000 IU/day
  - Zinc, 30 mg/day

Botanicals

All doses of botanicals should be given three times per day.

Echinacea spp

- Dried root (or as tea), 0.5 to 1 g
  - Freeze-dried plant, 325 to 650 mg
  - Juice of aerial portion of *Echinacea purpurea* stabilized in 22% ethanol, 2 to 3 mL
  - Tincture (1:5), 2 to 4 mL
  - Fluid extract (1:1), 2 to 4 mL
  - Solid (dry powdered) extract (6.5:1 or 3.5% echinacoside), 150 to 300 mg

Astragalus membranaceus

- Dried root (or as decoction), 1 to 2 g
  - Tincture (1:5), 2 to 4 mL
  - Fluid extract (1:1), 2 to 4 mL
  - Solid (dry powdered) extract (0.5% 4-hydroxy-3-methoxy isoflavone), 100 to 150 mg

Yeast and Medicinal Mushrooms

The dosage for Wellmune WGP used in clinical trials was 250 mg of 1,3-1,6-β-glucan daily. For maitake, the dosage is based on body weight and β-glucan content, stated as MD- or D-fraction (typically 0.5–1.0 mg for every kilogram of body weight per day). The dosage for shiitake and reishi is based on historical dosage levels of the dried mushrooms of 6 to 9 g/day.
