PITCHING-PIECE, in staircasing an horizontal piece timber, having one of its ends wedged into the wall, at t top of a flight of steps, to support the upper ends of t rough-strings.

PIX, the casket in which the consecrated host was p served for the use of the sick. It was usually of me placed upon the altar under a canopy, but was sometimes ma in the form of a dove, and suspended over the altar.

PLACARD, the decoration of the door of an apartme which is sometimes a cornice supported by consoles.

PLACE-BRICKS, were originally kiln-burnt red bri of a full size, now entirely disused in the metropolis; bu lieu of them, the soft insufficiently burnt bricks from the side of the clamps are called, by way of distinction f stock or hard-burnt bricks, *place-bricks*. These are of a red colour, and will easily break or crush to pieces. The particular manner in which place-bricks were formerly made, was by dipping the mould in water before the clay was put in; which made the outer surfaces, when burnt, very coarse and hard. *See* Brick.

PLAFOND, or Platfond, (French) the ceiling of a room, whether it be flat or arched; lined with laths and plaster, and sometimes also enriched with paintings, &c. *See* Ceiling.

Plafond is also more particularly used for the bottom of the projecture of the larmier of the cornice; called also *the soffit.*

PLAIN ANGLE, an angle contained under two lines, or surfaces, so called in contradistinction to a *solid angle.*

Plain Figure, that of which the surface is a plane, bounded by one or more lines.

Plain Tiles, or Plane Tiles, such as are intended to have their surfaces planes.

Plain Triangle, a triangle included under three right lines, or surfaces; in opposition to a *spherical*, and a *mixed triangle.*

Plain Trigonometry, the doctrine of plain triangles, their measures, proportions, &c.

PLAN, (French) a representation of something drawn on a plane. Such are maps, charts, and inchnographies.

Plan, in architecture, is particularly used for a draught of a building; such as it appears, or is intended to appear, on the ground; showing the extent, division, and distribution of its area into apartments, rooms, passages, &c.

To render plans intelligible, it is usual to distinguish the massives with a black wash. The projectures on the ground are drawn in full lines, and those supposed over them, in dotted lines. The augmentations, or alterations, to be made are distinguished by a colour different from what is already built; and the tints of each plan are made lighter as the stories are raised. In large buildings, it is usual to have three several plans for the first three stories.

The plan is the first device, or sketch, the architect makes; it is also called the *ground plot*, *platform*, and *ichnography*, of the building.

Plan, *Geometrical*, that in which the solid and vacant parts are represented in their natural proportion.

Plan, *Perspective*, one that is conducted and exhibited by degradations, or diminutions, according to the rules of perspective.

Plan, *Raised*, that where the elevation, or upright, is shown, upon the geometrical plan, so as to hide the distribution. *See* Elevation.

Plan of a Bastion, in the military art, the same with the *face of the bastion.*

Plan, in ship-building, the section of a ship, as designed upon paper, previously to the actual building, of which three are the chief, viz., the plan of elevation or sheer-plan; the horizontal or half-breadth-plan; the plan of projection or body-plan; these three compose the *sheer-draught.* But it must be observed, that the extreme length, breadth, and height must be determined; by which the three plans aforesaid may be delineated. These may be called *the outlines*, and the several parts contained within them may be delineated so as to answer the intended purpose; and likewise have a distinct view of the whole design, so that any inconveniencies attending such a disposition may be easily remedied, and the true dimensions of every particular may then be had upon the draught. The delineating of a ship upon a plan is called *drawing*, and the representation is called *draught.*

PLANCERE, the soffit of the corona of a cornice.

PLANE, (from the Latin, *planus*,) a tool used by artificers who work in wood, to produce straight, flat, and even surfaces upon that material.

Almost all trades which fabricate articles of wood, employ planes at times; but as joiners make a greater use of these tools than any others, they are usually considered as joiners' and carpenters' tools. Planes have been of late years used by some artists to produce flat surfaces in metals. A plane operates to cut off a thin chip, or shaving, from the wood on which it is applied, by the sharp edge of a steel cutter, or broad chisel, called, very improperly, the *plane iron:* this is fixed in a hole made through a wooden block, called the *plane stock*, and the edge of the iron projects in a very small degree through the lower side of the stock, called the *face of the plane;* the surface of which face is made a perfectly true plane.

The iron is fixed in an inclined position in the hole through the stock, by means of a *wedge* driven in before it, to jamb it fast in the hole, which being wider than the thickness of the iron, leaves an aperture before the iron, called the *mouth* of the plane; this is very narrow where it opens in the lower side, or face, but grows wider as it rises up through the stock: the wedge is also cut forked, to allow more room for the shavings which the plane-iron cuts, to pass up before it through the mouth. When a plane of this kind is applied with its face upon the surface of a piece of wood, and pressed down upon it whilst it is moved forwards, the edge of the iron penetrates the wood to the depth which it projects through the face, and removes a shaving of that thickness, the whole breadth of the edge of the iron; the shaving turning up before the iron, passing through the mouth, and escaping. The inclination of the iron makes it cut easily; and if the iron is *set fine*, that is, if the edge projects but very little beyond the face, it will remove very thin shavings, and produce a flat and smooth surface: on the other hand, if it is *set rank*, that is, with a considerable projection, it will cut away very fast, producing a flat, though rough, surface, and quickly reducing the wood to its intended thickness: if the wood has an irregular surface, it soon reduces it to a plane, because the face, being flat, will not suffer the edge of the iron to descend into the hollow places, but removes all the eminences it passes over till they are reduced to one level.

This is a general description of several kinds of planes, which are all known by different names, from their various dimensions and purposes.

Joiners use the *jack plane*, the *long plane*, *trying plane*, *shooting plane*, or *jointer*, and the *smoothing plane;* all which they denominate *bench planes*, because the wood they are used upon is generally laid on the work-bench. They have also the *straight block*, for straightening short edges; *rebating planes*, for forming rebates; others for the same use, are called the *moving fillister*, *sash fillister*, and *side-rebating plane.* The *plough* is a narrow plane, provided with an apparatus to guide it, in moving straight forward, to plow a groove or trench at any required distance from the edge of a board, or other piece of wood, and to any depth or width. The *dado grooving plane* is also for forming grooves.

There are several other tools, which, having an iron fitted into a stock, are called *planes*, because they cut in the same manner, though, in strictness, they are not planes, for they do not make plane surfaces; these are *moulding planes*, with faces and cutting edges curved, to produce all the varieties of ornamental mouldings, and which are known by the names of *snipe's-bills*, *side snipe's-bills*, *beads*, *hollows*, *and rounds*, *ovolos*, and *ogees.* The varieties and different sizes of these form a vast number, with which every complete joiner is furnished. It is impossible to describe the terms applied to these tools without figures, as they are arbitrary, though generally known among workmen. The faces of all these planes are straight in the direction of their length, but a section across the face is the impression or reverse of the moulding they are intended to make, and the edge of the iron is curved to correspond with this curve when in its place, though in reality it is a very different figure, because it is inclined to the face of the plane at an angle of about forty-five degrees. Another distinction between these and the bench planes is that their mouths do not open so as to discharge the shaving through the stock at the top thereof, but the wedge completely fills the hole, and the shaving passes out sideways through a hole for that purpose: in some, these apertures are on the right, and in others on the left side; in the first case, the shaving is said, by the workmen, to be thrown on the bench, that is, upon the right side of the plane; but when the orifice of discharge is on the left, and consequently the shaven thrown upon the left, then the plane is said to throw the shaving off the bench. The *compass plane* is used by coach-makers, cabinet-makers, &c.; it is made with a convex face, formed to an arc of a circle in the direction of its length, and it therefore forms the concave surface of a cylinder. The *fork-staff plane* is straight in the direction of its length, but its face is made concave in its breadth, to the arc of a small cylinder; the edge of the iron is of course curved in the same manner, and it planes cylindrical surfaces. Coopers also employ long and heavy planes to form the edges of the staves of barrels, these are mounted in an inclined position on legs like a stool, with their faces upwards, and the stave is drawn backwards and forwards upon them.

Planes are so necessary for all kinds of work, that any who intend to work in wood, should understand the structure, and the manner of using them. The *jack plane* is used for taking off the rough and prominent parts from the surface of the wood, and reducing it nearly to the intended thickness, in coarse shavings, or slices. The stock of this plane is about seventeen inches in length, three inches high, and three and a half inches broad; all the sides are straight, and at right angles to each other: the mouth is cut through the solid of the stock to receive the iron, and hold it at such an elevation, as to make an angle of forty-five degrees with the face of the plane; the iron is a thin metal plate, one side consisting of iron, the other of steel; the lower end of the iron is ground to an acute angle off the iron side, forming a sloping part called *the basil of the iron*, so as to bring the steel side to a sharp edge: the wedge which fixes the iron in its place is let into two grooves of the same form, on the sides of the opening or mouth: two sides of the wedge are parallel, and it is forked, or cut away in the middle, leaving the sides like two prongs, to fill the lower part of these grooves; this allows the shaving to pass up, without obstruction, before the wedge: for the mouth or opening through the stock must be uninterrupted from the face to the top, and must be no wider on the face of the plane, than is sufficient for the thickest shaving to pass with ease; and as the shaving is discharged at the upper side of the plane, the opening through it must expand or increase from the face to the top, so as to prevent the shavings from sticking therein. A handle, called the *tote*, is fixed to the upper side of the stock, immediately behind the iron; it is formed to the shape of the hand, and the direction of the motion, so as to produce the most power in pushing the plane forward.

A workman in using the jack-plane, lays the piece of wood on the bench parallel to its sides, with the farther end lodged against the bench-hook; then laying the fore part of the plane upon the hind end of the wood, with the right hand he takes the handle, and pressing with his left upon the fore-end, thrusts the plane forward in the direction of the fibre of the wood and length of the plane, until he has extended the stroke the whole length of his arm, the shaving being discharged at the orifice; he then draws back the plane, and repeats the operation in the next adjacent rough part, proceeding in this manner until he has removed the rough parts throughout the whole breadth. He then steps forward the distance of the length he has planed, and operates upon another length in the same manner, proceeding this way by steps until the whole length is gone over and rough-planed. To do this is very easy; but a workman will not make good progress, nor do clean work, unless he has first adjusted his tool properly for the work. The methods for doing this are nearly the same for all planes. The first care is to obtain a sharp cutting-edge to the iron; if it requires grinding on the grindstone, the carpenter places his two thumbs under the iron, and the fingers of both hands above, laying the basil side to the grindstone, and holding it to the angle he intends it shall make with the steel side of it, keeping it steady while the stone revolves; and pressing the iron to the stone with his fingers; in order to prevent the stone from wearing the edge of the iron into irregularities, he moves it alternately from edge to edge of the stone, with so much pressure on the different parts, as will reduce it to the required bevel, and make the edge straight.

The basil being brought to a proper angle, and the edge to a regular and slight curvature, the roughness occasioned by the gritty particles of the stone is taken away by rubbing its edge on a smooth flat stone, or turkey-stone, sprinkled with olive-oil on its surface. As the basil is generally ground, to give a more acute angle than the edge of the iron would stand, for the quicker dispatch of wetting it, the face of the iron is inclined nearer to the perpendicular, while it is rubbed backwards and forwards with the same inclinatio[n] throughout. Every time the iron becomes dull or blunt by use, the sharpening is produced by grinding on the rubber stone, or flat grindstone, or on a turkey-stone; but, in repeating this, after the edge gets thick, it requires so much tim[e] to bring it up to an edge, that recourse must be had to th[e] grindstone. The iron being thus sharpened, must be fixed i[n] the plane by its wedge: the projection of the cutting-edg[e] must be just so much beyond the face of the plane, as tha[t] the workman may be able to work it freely in the act o[f] planing, and must be regulated by the stuff to be wrough[t] whether it be hard or soft, cross-grained or curling; so tha[t] a man may be able to perform the most work, or reduce th[e] substance most in a given time. If the stuff is good an[d] clean-grained, it is evident that a considerable projection ma[y] be allowed, as a thicker shaving may be taken. The extrem[e] ends of the edge of the iron must never enter the wood, a[s] this not only retards the progress of working, but chokes an[d] prevents the regular discharge of the shavings at the orifi[ce] of the plane. The projection of the cutting-edge is calle[d] *iron*, and the plane is said to have more or less iron, as th[e] projection is greater or less; when there is too much iro[n] the workman knocks with a hammer on the fore end of th[e] top of the stock, and the blows will loosen the wedge, an[d] raise the iron in a certain degree, after which the head of th[e] wedge must be knocked down to fix it again. When the wor[k]man has occasion to take out the iron to sharpen it, he strik[es] the fore end of the top of the stock smartly with the hamm[er] which loosens both the wedge and the iron.

All the other bench-planes are adjusted in the same mann[er] and indeed do not differ, except in dimensions, as we sh[all] explain, from the jack-plane. Of late years a great impro[ve]ment has been introduced in the irons of planes, to ca them to cut smooth; these are called *double-ironed;* they were at first only used in the finest shooting planes, but the advantages have been found so great, particularly in planing bad wood, that they have become general for all sorts of planes. The double iron consists of a second iron, with a reversed basil, screwed against the front side of the iron, so that its edge lies against the iron at a very small distance from, and parallel to, the cutting-edge; and applying closely to the steel side of the iron; it forms an inclined plane, which turns the shaving over immediately after it is separated or cut by the edge, and thus it prevents the iron from splitting the shaving deeper down than it will afterwards cut, and therefore leaving a rough or torn surface. This second iron is called *the cover of the iron;* and the basil of its edge, instead of being ground flat, as that of the iron, is rounding; the screw, which binds the cover upon the iron, passes through a slit in the cover, and thus admits of its edge being adjusted at any required distance from the cutting-edges of the iron, and this distance depends altogether on the nature of the wood the plane is to be worked upon. If the stuff is clean-grained, the edge of the cover may be set at a considerable distance, because the difficulty of pushing the plane forwards becomes greater, as the edge of the cover is nearer the edge of the iron, and the contrary when more remote: this is occasioned by the edge of the cover turning the shaving over, immediately upon its being cut up. The *trying-plane* is usually twenty-two inches long, three inches and three-quarters broad on the face, and three inches and one-eighth in height; it does not differ from the jack-plane, except in having a double handle, adapted for greater force; in use, it succeeds the operation of the jack-plane, to straighten the wood, and remove the ridges left by the former; it is set with less iron, and cuts a finer shaving: the mouth is also much narrower. When it is used upon a long piece of work, the workman takes every shaving the whole length, by stepping forwards, instead of stopping at arm's length, as with the jack-plane. The shaving of this plane, though finer, is so much broader than that of the jack, that it requires as much force to push it forwards.

The *long plane* is set very fine, for finishing work which is to be very straight; it is twenty-six inches long, three and a half broad, and three inches and one-eighth in height.

The *shooting plane*, or *jointer*, is the longest, and most correct plane used; it is employed after all the others, chiefly in shooting the straight-edges of boards which are to be jointed together; it is generally made two feet and a half long, three inches and three quarters broad, and three and a half high; it is used like the others, but with great care to move it steadily from one end of the work to the other, without pressing it down, as that might spring the plane, or the work, and cause the iron to cut when the work was something hollow, whereas the object is to make a perfectly straight edge. The face of this plane must be kept quite true, and therefore it is a great object to make it of a fine piece of clean-grained, hard beech, well seasoned, that it may not warp, or vary, by the weather.

The *smoothing plane* is very short, without any handle, and its sides are curved, so that it very much resembles a coffin; it is seven inches and a half long, three broad at the mouth, and two inches and three quarters in height; it is used for finishing work when put together, and to give the greatest degree of smoothness to the wood, for which purpose it is set with as fine an edge as possible.

Rebating planes are used for cutting out rebates: these are a kind of semi-grooves upon the edge of a board, or other piece of wood, formed by cutting down or reducing a small part of the breadth of the board to half, more or less, of the general thickness: by this means, if a rebate be cut on the upper side of one board, and the lower side of another, the two may be made to overlap each other, without making them any thicker at the joint. Rebates are also used for ornamenting mouldings, and many other purposes in joiners' work. The planes for cutting them are of different kinds, some having the cutting-edge at the side of the iron and of the stock, others at the bottom edge of the iron and the face of the stock, and others cutting in both these directions; the former, being used to smooth the side of the rebate, are therefore called *side-rebating planes;* whilst the others are used for smoothing the bottom. There is also a third sort, called *fillisters*, used for sinking, or cutting away the edge of a piece of wood to form the rebate, leaving it for the others to smooth the surfaces when cut. The rebate planes are about nine inches and a half long, and of various widths upon the face, from half an inch to an inch and three quarters, in all cases they have the mouth and the edge of the iron coming out at one edge of the face, and the side of the iron also exposed at one of the upright sides of the stock, whether it is formed with a cutting-edge there or not; this exposed side is either on the right or left, and they are named accordingly. In all cases, they throw the shaving out on the side, instead of the top of the stock. The cutting-edges and mouths are generally situated obliquely across the face, instead of being at right angles to the length of the plane, as in others.

The *moving fillister* is a rebating plane, which has a ruler of wood, called the *fence*, fixed upon its face by screws, in the direction of its length, and exactly parallel to the edge of the face; it therefore covers part of the length of the cutting-edge, and can be fixed at any required distance from the edge, to leave more or less of the cutting-edge exposed, and this quantity will be the breadth of the rebate it will cut; because when it is used, the edge of the fence is applied against the edge of the piece to be rebated, and thus gauges the breadth its iron shall cut away. The cutting-edge of this plane is not situated at right angles to the length of the stock, but has an obliquity of about forty-five degrees, the exposed side of the iron being more forwards than the other. By this obliquity, when the plane is worked it has a tendency or drift to run farther into the breadth of the wood, but as the fence, silding against the edge, prevents this, the drift always keeps the fence in contact with the edge, without the attention of the workmen; it also causes the iron to cut the bottom of the rebate smoother, particularly in a transverse direction to the fibres, or where the stuff is cross-grained, than could otherwise be done, when the steel face of the iron is perpendicular to the vertical sides of the plane. The principal use is, however, to contribute with the form of the cavity to throw the shaving into a cylindrical form, and thereby make it issue from one side of the plane. The iron is what is called *shouldered*, that is, the lower part, or shoulder, where the edge is, has double the width of the upper part, which is received into the mortise, and jambed fast by the wedge. It is the edge of this wide part only which is exposed at the side of the stock. Besides this principal iron, there is another small iron, called the *tooth*, which precedes the other, to scratch or cut a deep crack at the width of the rebate, thus making the shavings, which the iron cuts up from the bottom, separate sideways from the rest of the wood. This tooth is inserted in a vertical mortise through the stock, between the fore end of the stock and the iron. The lower end of this little iron is ground with a basil on the inside, so as to bring the bottom of the narrow side of the iron to a very convex edge; it is fastened by a wedge passing down before it in the mortise in the stock. The use of this tooth is principally for cutting the wood transversely when wrought across the fibres, and, by this means, it not only cuts the vertical side of the rebate quite smooth, but prevents the iron from ragging or tearing the stuff. The iron between the fence and the edge of the face of the plane, must project the whole breadth of the uncovered part of the face, otherwise the wood of the plane will bear it up, and prevent the plane sinking as it cuts away the rebate, and the edge of the tooth, or little iron, should stand out a little farther on the side of the plane than the iron. The depth of the rebate, which this plane will cut, is regulated by a stop fixed on the outside of the plane, at the intended height, above the level of the face: then, when the plane has penetrated or sunk the intended depth of the rebate, the stop comes to bear upon the solid of the wood beyond the rebate, and bears it off from cutting any longer. The stop is a piece of brass, which moves in a vertical groove made in the side of the stock, between the iron and the fore end of the plane; in this it is moved up and down by a screw, which is inserted in a vertical perforation from the top of the plane to the groove, and passing through a part projecting from the stop into the groove: the upper part of the screw is formed to a thumb-nut, to turn it round by, and it is so confined by proper collars, that it can neither move up nor down; but being turned, the inclination of the threads will rise or fall according to the direction in which the thumb-screw is turned, and cause the stop to move up and down in the groove on the side of the plane, thus regulating it at pleasure to the depth to which the rebate is required to be sunk.

In grinding and fixing the iron of this plane, it is necessary that the cutting-edge of the iron should stand equally prominent in all parts out of the face, otherwise the plane cannot make shavings of an equal thickness; and, consequently, instead of keeping the vertical position, will, as it proceeds, become deeper on the side on which the shavings are thickest, and then the part cut away will not be regular, for the bottom of the rebate will not be parallel to the upper surface of the wood, and the side which ought to have been vertical, will be a kind of a ragged curved surface, formed by as many gradations or steps in the depth, as the number of shavings.

The *sash fillister* differs, in several particulars, from the moving fillister: the breadth of the iron is something more than the whole breadth of the sole, so that the extremities of the cutting-edge are, in a small degree, without the vertical sides of the stock: the fence is adapted to be moved to a considerable distance, not being fixed as in the moving fillister, by screws upon the face, but sustained by two bars fixed fast to it, which pass through the two vertical sides of the stock, at right-angles to the sides, fitting tight in the two holes through which they pass: these bars are made rounding upon the upper side, and flat on the lower side: at the point, where they are united to the fence, they have thicker parts, or shoulders, projecting downwards, because it is necessary to have the fence fixed on a lower level than the face of the plane; the ends of the bars are ferruled, to prevent their splitting when the ends are struck with the mallet, in order to move them in the holes through the stock, and this brings the fence either nearer, or more remote from the stock, as may be wanted; and to fix it fast, when so adjusted, two small tapering pieces of wood, called *keys*, are inserted into two small wedge-like mortises, cut at the sides of the mortises, in which the bars pass through the stem; these wedges being drawn in, they will stick fast, and press against the bars, keeping them fast at all points, and thereby regulate the distance of the fence from the vertical side of the stock. This plane is generally employed to rebate narrow pieces of wood, such as sash frames; and the fence is applied against the opposite edge of the wood to that on which the rebate is to be formed.

The *plough* is a plane with a very narrow face, made of iron, fixed beneath a wooden stock, and projecting down from the wood of the stock, the edge of the iron being the full width, or rather more, than the face; it is guided by a fence with bars, like the fillister above described, to make, or plough out a groove of the width of the iron, and at any required distance from the edge of the wood; it has also a similar stop to regulate the depth it cuts to. Joiners, cabinet-makers, &c., in plaining thin, or valuable woods for veneering, &c., sometimes use fluted irons, having teeth in their edge; and a plane, thus mounted, is called a *toothing plane;* these irons apply to the stocks of different planes. *See* Tools.

Plane, in geometry, a surface which will everywhere coincide with a straight line.

Wolfius defines a plane, "a surface, from every point of whose perimeter, a right line may be drawn to every other point in the same."

As the right line is the shortest extent from one point to another, so is a plane the shortest extension between one line and another.

Planes are frequently used in astronomy, &c., for imaginary surfaces, supposed to cut, and pass through, solid bodies; and on this foundation is constructed the whole doctrine of conic sections.

When a plane cuts a cone parallel to one of its sides, it makes a parabola; when it cuts the cone parallel to its base, it makes a circle. *See* Circle and Parabola.

The sphere is wholly explained by planes, imagined to cut the celestial luminaries, and to fill the areas or circumferences of the orbits; and they are differently inclined to each other; and by us, the inhabitants of the earth, the plane of whose orbit is the plane of the ecliptic, their inclination is estimated with regard to this plane.

Plane, *Geometrical*, in perspective, a plane parallel to the horizon, whereon the object to be delineated is supposed to be placed. This plane is usually at right angles with the perspective plane. *See* Perspective.

Plane, *Horizontal*, a plane passing through the spectator's eye, parallel to the horizon, cutting the perspective plane in a straight line, called *the horizontal line.*

This, according to Brook Taylor's definitions of perspective, may be called *the vanishing plane of the horizon.* *See* Perspective.

Plane, *Inclined*, one that makes an oblique angle with a horizontal plane.

Plane, *Objective*, any plane face, or side, of an original object to be represented in perspective.

Plane, *Perspective*, a plane pellucid surface, ordinarily perpendicular to the horizon, and placed between the spectator's eye and the object he views; through which the optic rays, emitted from the several points of the object, are supposed to pass to the eye, and, in their passage, to leave marks that represent them on the said plane.

Plane, *Vertical*, a plane passing through the spectator's eye, perpendicular to the geometrical plane, and at right angles to the perspective plane. *See* Perspective.

Plane Table, a rectangular board, with a plane face, for finding the position and distance of a point, or of any number of points, situated in the same plane. By this mean the plan of horizontal objects, whether straight or crooked can very easily be ascertained by only one distance being given

PLANIMETRY, (from Latin, *planus*, plain, and Greek, *μετρεω*, to measure,) that part of geometry which considers lines and plane figures; without reference to heights or depths.

Planimetry is particularly restrained to the mensuration of planes or surfaces, in opposition to *stereometry*, or the mensuration of solids.

Planimetry, or the art of measuring the surfaces and planes of bodies, is performed with the squares of long measures, as square inches, square feet, square yards, square perches, &c.; that is, by squares whose sides are an inch, a foot, a yard, a perch, &c.; so that the area or contents of any surface is said to be found, when we know how many such square inches, feet, yards, &c., it contains.

PLANING MACHINE, a machine used to diminish the great manual labour of planing the surfaces of planks and boards of wood: in strictness, those alone should be termed planing machines, which reduce the surface of the wood to a true and smooth plane, by means of planes, or instruments of a similar nature, though actuated by the power of machinery instead of the strength of a man's arm; but custom has denominated those machines which cut flat surfaces in a different manner from planes, by the same name.

These machines are of modern invention; the first, we believe, was projected by General Bentham, who obtained a patent for it in 1791. It consisted of a plane, to be put in motion by means of a crank turned by a mill, to give it a reciprocating motion; or, on a smaller scale, it might be worked by hand in the usual manner, but the plane was so formed as to require none of the skill and attention necessary in the ordinary method of operating. The plane is made the full width of the boards intended to be planed, and on each side of it fillets, or cheeks, are fixed, which project beneath the face of the plane just as much as the thickness the board is to be reduced to: these cheeks, therefore, guide the plane sideways in passing along the board, and gauge it in thickness; because, when the board is reduced to the quantity that the cheeks are beneath the surface of the plane, the cheeks rest upon the bench, or surface, on which the board lies, and bear off the plane, so that it can cut no longer. The plane is kept down by its own weight, which is increased, when necessary, by loading it with weights, and these are contrived to be capable of shifting their position from one end of the plane to the other during the time it is making the stroke; because, at first, the pressure is required at the fore end to enter the cut, but, at the conclusion, it must be greatest at the hinder end, to prevent the fore end tripping down the instant it leaves the board. By another contrivance, the plane is caused to rise up sufficiently to clear the cutting edge from the wood when the plane is on its return. It is by a piece, which acts as a handle to the plane, and to which the power is applied, that it is fixed in the manner of a lever upon an axis extending across the width of the plane, and carrying at each side thereof a short lever, provided with rollers in their extremities; the handle projects upwards from the plane, which being forced forwards by it, assumes an inclined position, as do also the short levers, and their rollers then rise above the cheeks of the plane; but when the plane is drawn back, its handle is first drawn back into an erect position, and the levers moving with it, their rollers project beneath the cheeks of the plane, and raise it off the bench, the plane being in its return borne by them.

The bench for supporting the board during the operation, was also of a peculiar construction, in order to confine the work steady upon it. In cases when the boards to be planed are winding or irregular on the lower side, so that they cannot lie flat upon the bench, it is provided with two sides, which can be brought to close upon the edges of the board, and hold it steady between them, being furnished with one or more rows of flat teeth, to penetrate the wood and retain it; these sides are contrived to rise or fall upon the bench, to accommodate the different thicknesses of the boards. When a very thin board is to be planed, it might be liable to spring up to the iron, so as to be reduced even after the plane came to rest with its cheeks upon the bench; to avoid this, the edges of the board are to be held by the sides to the bench before-mentioned, but as it would still be liable to spring up in the middle part, heavy rollers, or rollers loaded with weights, are fitted in apertures made in the plane as near as possible to the cutting-edge, and these will keep the board down close upon the bench. For planing pieces of greater thickness at one end than the other, the cheeks of the plane are to be borne upon rulers of wood laid on the bench on each side, the wood being as much thicker at one end as the board is intended to be thinner at that end; therefore, when the plane has reduced the wood, the cheeks come to bear upon these rulers, and cause it to move not parallel to the bench, but inclined, according as they are thicker at one end than the other; in like manner, by using them of different thicknesses at the different sides, the boards may be made feather-edged.

Mr. Bramah invented a planing machine, which he used very advantageously for planing all kinds of timber flat, at a very trifling expense. In 1802, he took out a patent for the invention, which he describes, in his specification, to consist in the following particulars. "The cutting tools employed to reduce the wood, instead of being worked by hand, are to be fixed on frames, some of which are moved in a rotatory direction round an upright shaft, and others have a shaft lying in a horizontal position, like a common lathe. In other instances, the tools are fixed on frames, which slide in stationed grooves to be driven also by machinery. The principal points on which the merits of the invention rest are, 1. The materials to be wrought are made to slide in contact with the tool, instead of the tool being carried by the hand over the work in the usual way. 2. The tool is made to travel across the work in a square or oblique direction, except in cases where it may be necessary to fix the tool in an immovable station, and cause the work to fall in contact with it by a motion. 3. Instead of common tools, bent knives, spoke-shaves, or deep cutting gouges, are used for cutting off the roughest parts, and planes of various shapes and constructions, as the work may require, are applied to follow the former in succession, under the same operation, and which latter I call *finishers*. 4. These are fixed on frames which move in cases, like those on which the saws are fixed in a sawing-mill; and in other instances, these frames are fixed on a rotatory upright shaft turning on a step, and carrying the frame round in a direction similar to the upper mill-stone for grinding corn; and sometimes the frames turn on a horizontal shaft, resembling the mandrel of a common turning lathe. The different planes, tools, &c., are fixed in the frames, so as to fall successively in contact with the wood or other materials to be cut, so that the cutter or tool calculated to take the rough and prominent part, operates first, and those that follow must be so regulated as to reduce the material down to the line intended for the surface. These cutter frames must also have the property of being regulated by a screw or otherwise, so as to approach nearer the work, or recede, at pleasure, in order that a deeper or shallower cut may be taken at discretion, or that the machine may repeat its action, without raising or depressing the material on which they act. 5. When an upright shaft is used the pivot is to turn in oil, and it may be raised or depressed at pleasure, by means of a greater or less quantity of the said fluid being confined between the end of the shaft and the bottom of the step. 6. The materials to be cut must be firmly fixed on a frame, similar to those in sawing-mills, on which the timber is carried to the saws. These frames must be moved in a steady progressive manner as the cutter frame turns round, either by the same power which moves the latter, or otherwise, as may be found to answer best in practice. 7. The motion of the cutter frames must be under the control of a regulator, so that the velocity of the tool, in passing over the work, may be made quicker or slower, as such work may respectively require, to cause the cutter to act properly to the best advantage." For this purpose, Mr. Bramah proposes to use what he calls *an universal regulator of velocity*, and which he describes as follows: "I take any number of cog-wheels, of different diameters, with teeth that will exactly fit each other through the whole; suppose ten, or any other number, but, for an example, say ten, the smallest of which shall not exceed one inch in diameter, and the largest suppose ten inches in diameter, and all the rest to mount by regular gradations in their diameters, from one to ten. I fix these ten wheels, fast and immovable, on an axis perfectly true, so as to form a cone of wheels; I then take ten other wheels, exactly the same in all respects as the former, and fix them on another axis, also perfectly true, and the wheels in perfect gradation also; but these latter wheels I do not fix fast on their axes, like the former, but leave them all loose, so as to turn on the said axes, contrary to the former, which are all fixed. All these latter wheels I have the power of locking, by a pin or otherwise, so that I can, at discretion, lock or unite any single wheel at pleasure to the axis. I then place the two axes parallel to each other, with the wheels which form the two cones, as above described, in reverse position, so that the large wheel at one end of the cone may lock its teeth into the smallest one in the cone opposite, and likewise *vice versa.* Then suppose the axis, on which the wheels are permanently fixed, to be turned about, all the wheels on the other axis will be carried round with velocities correspondent to their diameters and those of the former, but their axis will not move. Then lock the largest wheel on the loose axis, and, by turning about the fastened axis, as before, it must take ten revolutions, while the opposite wheel performs but one; then by unlocking the largest wheel, and locking the smallest one at the contrary end of the cone in its stead, and turning as before, the fastened axis will then turn the opposite ten times, while itself only revolves once. Thus the axes or shafts of these cones, or conical combinations of wheels, may turn each other reciprocally, as one to ten, and ten to one, which collectively produces a change in velocity, under a uniform action of the *primum mobile*, as ten to a hundred; for when the small wheel on the loose axis is locked, and the fast one makes ten revolutions, the former will make one hundred; and by adding to the number of those wheels and extending the cones, which may be done *ad infinitum*, velocities may be likewise infinitely varied by this simple contrivance: A may turn B with a speed equal to thousands or millions of times its own motion; and by changing a pin and locking a different wheel, as above described, B will turn A in the same proportion, and their power will be transferred to each other, in proportion as their velocities, reciprocally. Here is a universal regulator at once for both power and velocity. In some instances I produce a like effect, by the same necessary number of wheels made to correspond in conical order, but, instead of being all constantly mounted on the axes or shafts, as above described, they will reciprocally be changed from one axis to the other, in single pairs, to match according to the speed or power wanted, just as in the former instance. This method will have, in all respects, the same effect, but not so convenient as when the wheels are all fixed."

In 1803, Mr. Bevans obtained a patent for a machine for planing, (or *sticking*, as the joiners term it,) all kinds of mouldings or rebates, and ploughing grooves, as well as forming flat surfaces of small breadth, which it does with very little labour: in this machine, the operations are performed by the planes commonly used for similar purposes, with only such alterations as are necessary to adapt them to the machinery by which they are put in motion with mechanical power instead of human labour; they are to be used either singly, or combined together in any number, according to the width of the boards to be worked at once, and the nature of the work to be done, so as to plane up, at one operation, such moulding as joiners work up, by using several planes successively for the different parts; this is effected by a kind of frame, or box, which admits of fixing any number of planes in it, side by side, and at any distance asunder, to form the compound moulding required. The work is fixed fast on a bench, and the box of planes is made to pass over it, in the direction of its length, by a connecting rod communicating at one end with the box or frame containing the planes, and, at the other end, with machinery capable of affording a reciprocating motion.

This machinery consists of a crank, whose radius must be nearly half the length of the required stroke, and must be regulated accordingly: this regulation is effected by the arm of the crank passing through a mortise in a strong box, fixed on an axis, and sliding in the said box to any required length, where it must be fixed by strong screws, the axis being turned by manual exertion, by horses, steam, water or any other power, and having its motion regulated by a fly-wheel.

The planes are loaded, to keep them in contact with their work, by a long beam of wood, set up on end upon the sides of the box, and connected therewith by being divided into two cheeks, which, at the lower sides, are formed to an arc of a circle, and united to the box by chains, in the same manner as the beams of steam-engines are connected with their piston-rods. The upper part of the beam is made to pass always through one point, by sliding between friction-wheels, or otherwise, in a tube hung on two pivots, perpendicularly over the centre of the work, and at such heights as may be most convenient for the length of the stroke required: the connecting-rod, from the crank before mentioned, is jointed to the upright beam, near its lower end, and by this means the motion is given to the box of planes, the chains and arches at the bottom allowing it, in all positions, to preserve the plane horizontal. To guide the box of planes in a rectilinear motion, and also to bear them off when the plank has been reduced to the depth required, fences are used, which are irons sliding perpendicularly in tubes or sockets, in the box or frame, and clipping a tongue or ruler, fixed in the direction of the required stroke, in the frame supporting the bench.

PLANISPHERE, (from Latin, *planus*, and Greek, σφαιρα,) a projection of the sphere, and the several circles thereof, on a plane; as upon paper, or the like. In this sense, maps of the heavens and the earth, in which are exhibited the meridians, and other circles of the sphere, are called planispheres. *See* PROJECTION.

In all planispheres, the eye is supposed to be a point viewing all the circles of the sphere, and referring them t

a plane on which the sphere is, as it were, flattened. This plane is called the *plane of the projection.*

A perspective plane is only a plane of projection placed between the eye and the object, so as to contain all the points which the several rays, drawn from the object to the eye, impress thereon. But in planispheres or astrolabes, the plane of the projection is placed beyond the object, which is the sphere. The plane of the projection is always one of the circles of the sphere.

Among the infinite number of planispheres which the different planes of projection, and the different positions of the eye, would furnish, there are two or three that have been preferred to the rest. Such are that of Ptolemy, where the plane of projection is parallel to the equator; that of Gemma Frisius, where the plane of projection is the colure, or solstitial meridian, and the eye the pole of the meridian; that of John de Royas, a Spaniard, whose plane of projection is a meridian, and the eye placed in the axis of that meridian, at an infinite distance. This last is called the *analemma.* The common defect of all these projections is, that they distort and alter the figure of the constellations, so that it is not easy to compare them with the heavens; and that the degrees in some places are so small, that they afford no room for operation.

All these faults M. de la Hire provided against in a new projection, or planisphere; where it is proposed the eye shall be so placed, as that the divisions of the circles projected shall be sensibly equal in every part of the instrument. The plane of his projection is that of a meridian.

PLANK, (from the French, *planche*) a general name for all timber, excepting fir, which is from one inch and a half to four inches thick: if of less dimensions it is called a *board.*

Plank-Hook, a pole with an iron hook at its end, with which navigators shift their runs, or wheeling-planks, as occasion requires.

Plank-Sheers, or, Plan-Sheers, the pieces of plank wrought horizontally over the heads of the timbers of the forecastle, quarter-deck, and round-house, for the purpose of covering the top of the side; hence, sometimes called *covering-boards.*

PLANTING, in architecture, denotes the laying the first courses of stone on the foundation, according to the measures, with all the exactness possible.

PLASTER, (from πλαζω) in building, a composition of lime, sometimes with hair, sometimes with sand, &c. to parget or cover the nudities of a building.

Plaster of Paris, a fossile stone, serving many purposes in building; and used likewise in sculpture, to mould and make statues, basso-relievos, and other decorations in architecture.

It is dug out of quarries, in several parts of the neighbourhood of Paris; whence its name. The finest is that of Montmartre. *See* Gypsum.

Plaster of Paris, amongst our workmen, is of two kinds, viz., *crude,* or in the stone, and *burnt,* or beaten.

The *crude* is the native plaster, as it comes out of the quarry; in which state it is used as shards in the foundations of buildings.

The *burnt* plaster is a preparation of the former, by calcining it like lime in a kiln or furnace, and then beating it into powder, and diluting and working it. In this state it is used as mortar, or cement, in building.

This, when well sifted, and reduced into an impalpable powder, is used also to make figures, and other works of sculpture; and is, besides, of some use in taking out spots of grease, &c. in stuffs and silks.

The method of representing a face truly in plaster of Paris is this: the person, whose figure is designed to be taken, is laid on his back, with any convenient thing to keep off the hair. Into each nostril is conveyed a conical piece of stiff paper, open at both ends, to allow respiration. These tubes, being anointed with oil, are supportod by the hand of an assistant; then the face is lightly oiled over, and the eyes being kept shut, alabaster fresh calcined, and tempered to a thinnish consistence with water, is, by spoonfuls, nimbly thrown all over the face, till it lies near the thickness of an inch. This matter grows sensibly hot, and, in about a quarter of an hour, hardens into a kind of stony concretion; which, being gently taken off, represents, on its concave surface, the minutest parts of the original face. In this a head of good clay may be moulded, and therein the eyes are to be opened, and other necessary amendments made. This second face being anointed with oil, a second mould of calcined alabaster is made, consisting of two parts joined lengthwise along the ridge of the nose; and herein may be cast, with the same matter, a face extremely like the original.

If finely powdered alabaster, or plaster of Paris, be put into a bason over a fire, it will, when hot, assume the appearance of a fluid, by rolling in waves, yielding to the touch, steaming, &c., all which properties it again loses on the departure of the heat; and being thrown upon paper, will not at all wet it, but immediately discover itself to be as motionless as before it was set over the fire; whereby it appears, that a heap of such little bodies as are neither spherical, nor otherwise regularly shaped, nor small enough to be below the discernment of the eye, may, without fusion, be made fluid, barely by a sufficiently strong and various agitation of the particles which compose it; and, moreover, lose its fluidity immediately upon the cessation thereof.

Two or three spoonfuls of burnt alabaster mixed up thin with water, in a short time coagulate, at the bottom of a vessel full of water, into a hard lump, notwithstanding the water that surrounded it. Artificers observe, that the coagulating property of burnt alabaster will be very much impaired, or lost, if the powder be kept too long, especially if in the open air, before it is made use of; and when it hath been once tempered with water, and suffered to grow hard, they cannot, by any powdering of it again, make it serviceable for their purpose as before.

This matter, when wrought into vessels, &c., is still of so loose and spongy a texture, that the air has easy passage through it. Mr. Boyle gives an account, among his experiments with the air-pump, of his preparing a tube of this plaster, closed at one end and open at the other, and, on applying the open end to the cement, as is usually done with the receivers, it was found utterly impossible to exhaust all the air out of it; for fresh air, from without, pressed in as fast as the other, or internal air, was exhausted, though the sides of the tube were of considerable thickness. A tube of iron was then put on the machine; so that being filled with water, the tube of plaster of Paris was covered with it; and, on using the pump, it was immediately seen, that the water passed through into it as easily as the air had done, when that was the ambient fluid. After this, trying it with Venice turpentine instead of water, the thing succeeded very well; and the tube might be perfectly exhausted, and would remain in that state several hours. After this, on pouring some hot oil upon the turpentine, the case was much altered; for, the turpentine melting, it became a thinner fluid, and, in this state, capable of passing like water into the pores of the plaster. On taking away the tube after this, it was remarked that the turpentine, which had pervaded and filled its pores, rendered it transparent, in the manner that water gives transparency to that singular stone called *oculus mundi.* In this manner the weight of air, under proper management, will be capable of making several sorts of glues penetrate plaster of Paris; and not only this, but baked earth, wood, and all other bodies porous enough to admit water on this occasion.

Plaster of Paris, diluted with water into the consistence of a soft or thin paste, quickly sets or grows firm, and, at the instant of its setting, has its bulk increased; for Mr. Boyle has found, that a glass vessel, filled with the fluid mixture, and closely stopped, bursts while the mixture sets, and sometimes a quantity of water issues through the cracks.

This expansion of the plaster, in passing from a soft to a firm state, is one of its valuable properties, rendering it an excellent matter for filling cavities in sundry works, where other earthy mixtures would shrink and leave vacuities, or entirely separate from the adjoining parts.

It is probable, also, that this expansion of the plaster might be made to contribute to the elegance of the impressions it receives from medals, &c., by properly confining the soft matter, that its expansion may force it into the minutest traces of the figure; the expansion of the matter doing the same office as the pressure by which the wax is forced into the cavities of a seal.

Plaster of Paris promotes the fusion of forged iron.

This substance is commonly used for taking casts and impressions from figures, busts, medals, &c., as it is adapted to the double use of making both casts and moulds for forming them.

There is also a plaster of a coarser sort than the plaster of Paris, which is sometimes used in this country for floors in gentlemen's houses, and for corn-granaries: it is made of a blueish stone, taken out of quarries, which are generally at the side of a hill, much like the stone of which Dutch terras is made; the stone is burnt like lime, becomes white by burning, and, when mixed with water, does not ferment like lime: when cold, it is beat into a fine powder; and, when used, the quantity of about a bushel is put into a tub, and water applied to it till it becomes liquid: in this state it is well stirred with a stick, and used immediately; for, in less than a quarter of an hour, it becomes hard and good for nothing, as it will not bear being mixed a second time, like lime.

Plaster Floors, such floors as are constituted of plaster, prepared from such lime as possesses a strong binding property. They are highly useful in cottages and farm-houses, as affording much security against fire. In constructing them, the joists are laid in the usual manner, and on them is nailed a sort of strong reed, found in Huntingdonshire, upon which the plaster is applied; but in order to save it, there is frequently a thin coat of common lime laid on first, to fill up the crevices and inequalities. On this the plaster is then spread out, to the thickness of about two inches, being laid on with as much expedition as possible. The plaster is sold at the kilns in the midland districts, at 6*d.* the bushel; and the expense of laying it on, if burnt and prepared, is 5*d.* the square yard; but if to be burnt and prepared by the workmen, about as much more. These floors are said to be excellent and cheap. Where reeds cannot be procured, laths may be made use of, but they come much higher. Floors of this sort are much in use in Nottinghamshire, as well as in Rutlandshire, where the upper floors of the farm-houses are made of it.

These kinds of floors should be more attended to in constructing small houses, both of the cottage and other kinds, as being cheap, readily laid, and at the same time secure.

PLASTERER, a workman to whom the decorative part of architecture owes a considerable portion of its effect, and whose art is required in every department of building. In ordinary edifices, he lays the ceilings, and covers the walls with a smooth coat, to render them sightly, and prevent the obtrusion of air through any crevices left by the bricklayer and carpenter, or occasioned by settling. In buildings of greater importance, in addition to this service, he also furnishes mouldings, ornamental as well as plain, and covers the exterior walls with stucco, imitative of stone.

The tools of a plasterer consist of *a spade*, or shovel, of the usual description; *a rake*, with two or three prongs, bent downwards from the line of the handle, for mixing the hair and mortar together; *trowels* of two kinds, and various sizes; *stopping* and *picking-out tools*; rules called *straight-edges*; and wood *models*.

Plasterer's *trowels* are more neatly made than the tools of the same name used by other artificers; they are of two sorts, viz., the *laying and smoothing tool*, which consists of a flat piece of hardened iron, about ten inches in length, and two inches and a half wide, very thin, and ground to a semicircular shape at one end, but left square at the other: on the back of the plate, near the square end, is riveted a small iron rod, with two legs, one of which is fixed to the plate; and, to the other, a round wooden handle is adapted; with this tool, all the first coats of plastering are laid on, as are also the last, or the *setting*, as it is technically denominated. The other kind of trowels, which are made of three or four sizes, are for *gauging* the fine stuff and plaster used in forming cornices, mouldings, &c. The longest size of these is about seven inches in length on the plate, which is of polished steel, and two inches and three-quarters broad at the heel, diverging gradually to a point; to the heel, or broad end, a handle is adapted, commonly of mahagony, with a deep brass ferule. The smaller trowels are fitted up in a similar manner, only they gradually vary in size downwards to the length of two or three inches.

The *stopping and picking-out tools* are of polished steel, of various sizes, though most generally about seven or eight inches in length, and half an inch in breadth, flattened at both ends, and ground away to somewhat of a round. These tools are used in modelling and finishing mitres and returns to cornices, as likewise in filling up and perfecting the ornaments at their joinings.

The *straight-edges* are used for keeping the work in an even or perpendicular line; and the *models* or *moulds* are for running plain mouldings, cornices, &c. Of these last the plasterer requires a great number, as very little of his *finishing* can be completed without them. With a good mould, an adept in his profession may execute most exquisite mouldings, possessing a sharpness and breadth unequalled by any other method now practised.

Good workmen keep their tools very clean; after being used, they are wiped free from the plaster that cleaves to them, before they are put away, and they are daily polished by the hawk-boys.

Plasterers have technical divisions of their work, by which its quality is designated, and from which its value is ascertained; as, *lathing; laying; pricking-up; lathing, laying and set: lathing, floating, and set; screed; set or putty rendering and set*, or *rendering, floated, and set; trowelled stucco*, &c., each of which will be found fully described in the next article. *See* Plastering.

Plasterers' work is measured and valued by persons known in the trade as *measurers*, though popularly denominated *surveyors*. All common plastering is measured by the square yard of nine feet; this includes the partitions, walls, and ceilings of rooms, inside and exterior stuccoing, &c. Cornices are measured by the foot superficial, their numbers being girt to obtain their width; while their length is taken at that of the cornice. Running measures consist of beads, quirks, arrises, and small mouldings. Ornamental cornices are frequently valued by the foot run.

As the labour on plasterer's work is frequently a greater consideration than the materials used, it is necessary for the master to be attentive to the noting down the time occupied by his men in executing their several pieces of plastering; otherwise he will be unable to put an adequate value on his work.

PLASTERING, the art of covering the walls and ceilings of a house, or other edifice, with a composition, of which the ground-work is lime and hair-mortar, finished with a coating of finer materials. It is of various kinds; as white lime and hair mortar on bare walls; the same on laths, as in partitioning and plain ceiling; renewing the insides of walls, or double-partition walls; rough-casting on heart-laths; plastering on brick-work, with finishing-mortar, in imitation of stone-work, and the like upon heart-laths; modelling and casting ornamental and plain mouldings; and making and polishing the scagliola for columns of wood or brick and their antæ.

In all the operations of plastering, lime forms an extensive article, as it pervades the whole; and for its nature, properties, and preparation, the reader is referred to the word Lime; suffice it here to remark, that most of the lime used in London is prepared from chalk, and is brought thither from Purfleet, in Kent; but for stuccoing, and other work requiring strength and permanency, that which is made at Dorking, in Surrey, has a decided pre-eminence.

Next to lime, the plasterer depends much on what is called *plaster of Paris* (see that article); for this alone enables him to give the required form and finish to all the superior parts of his business. With this he makes his ornaments and cornices; and he also mixes it with the lime for filling up the concluding coat to the walls and ceilings of rooms. The name of this composition is derived from the circumstance of its abounding in the hills of Montmartre, in the environs of the French capital; but what is chiefly used in London is prepared from a sulphate of lime dug in Derbyshire.

Cements used by plasterers for inside work are of two or three kinds; the first is called *lime and hair*, or *coarse stuff*, and is prepared as common mortar, only with the addition of hair from the tan-yards being mixed with it. The mortar is first mixed with the requisite quantity of sand, and then the hair is worked in by the labourer with the rake.

Next to this is *fine stuff*, consisting of pure lime slaked with a small quantity of water, and then, without any extraneous addition, supersaturated with water, and put into a tub in a half-fluid state, where it remains till the water is evaporated. In particular cases, a small portion of hair is sometimes worked into this fine stuff, before it is laid on.

For inside walls, this fine stuff is mixed with very fine washed sand, in the proportion of one part sand to three parts of *fine stuff*, and then it obtains the name of *troweled*, or *bastard stucco*, with which all walls intended to be painted are finished. *Gauge-stuff* consists of three-fifths of fine-stuff and one-fifth of plaster of Paris, mixed together with water, in small quantities at a time, to render it more ready to set, or fix itself. This cement is mostly used in forming cornices and mouldings run with a wooden model. When great expedition is requisite, plasterers gauge all their mortars with plaster of Paris, which enables them to proceed with their work, because it sets as soon as laid on.

Next to the materials, the technical divisions of the plasterers' work claim attention, and are as follow:—

1. *Lathing:* this operation consists in nailing laths on the ceiling or partition. If the laths be of oak, they will require wrought-iron nails; but if of deal, cast-iron nails may be used. Those mostly used in London are of fir, imported from the Baltic and America, in pieces called *staves*. Laths are made in three-foot and four-foot lengths; and, with respect to their thickness and strength, are either single, lath-and-half, or double. The single are the thinnest and cheapest; those called *lath-and-half* are supposed to be one-third thicker than the single; and the double laths are twice their thickness. In lathing ceilings, the plasterer should use both the lengths alluded to; and, in nailing them up, he should so dispose them that the joints may be as much broken as possible, that they may have the stronger key, or tie, and thereby strengthen the plastering with which they are to be covered. The thinnest laths are used in partitions, and the strongest for ceilings. *See* Lath.

Having nailed the laths in their appropriate order, the next business is to cover them with the plaster, in doing which, the most simple and common operation is that of,

2. *Laying:* this consists in spreading a single coat of lime and hair all over a ceiling, or partition; carefully observing to keep it even and smooth in every direction. This is the cheapest kind of plastering.

3. *Pricking-up* is performed in the same manner as the foregoing, but it is only a preliminary to a more perfect kind of work. After the plaster is laid on, it is crossed all over with the end of a lath, to give it a key, or tie, for the coat that is to be laid upon it.

4. *Lathing, laying, and set*, is when the work, after being lathed, is covered with one coat of lime and hair, and, when that is sufficiently dry, a thin and smooth coat is spread over it, consisting of lime only, or, as the workmen call it, *putty* or *set*. This coat is spread with the smoothing-trowel, which the workman uses with his right hand, while in his left hand he is furnished with a large flat brush of hog's bristles. As he lays on the putty, or set, with the trowel, he draws the brush, dipped in water, backwards and forwards over it, and thus produces a surface tolerably even for cheap work.

5. *Lathing, floating, and set*, differs from the foregoing, in having the first coat pricked up to receive the set, which is here called the *floating*. In performing this last operation, the plasterer is provided with a substantial straight-edge, frequently from ten to twelve feet in length, which must be handled by two workmen. All the parts to be floated are then tried by a plumb-line, to ascertain whether they are perfectly flat and level; and wherever any deficiency appears, the hollow is filled up with a trowel-full, or more, of lime and hair only; this is termed *filling-out;* and when these preliminaries are settled, the *screeds* are begun to be formed.

6. A *screed* signifies a style of lime and hair, about seven or eight inches in width, gauged quite true by drawing the straight-edge over it till it is so. These screeds are made at the distance of about three or four feet from each other, in a vertical direction all round the partitions and walls of a room. When they are all formed, the intervals are filled up with lime and hair, called by the workman *stuff*, till they are flush with the face of the screeds. The straight-edge is then worked horizontally over the screeds, by which all the superfluous stuff, projecting beyond them in the intervals, is removed, and a plain surface is produced. This operation is termed *floating*, and may be applied to ceilings as well as partitions or upright walls, by first forming the screeds, in the direction of the breadth of the apartment, and filling up the intervals as above described. As great care is requisite

in this kind of work, to render the plaster sound and even, none but skilful workmen should be employed upon it.

7. The *set* to floated work is performed in a mode similar to that already prescribed for *laying;* only, as it is employed for best rooms, it is done with more care. There is also added to it about one-sixth of plaster of Paris, to make it set more expeditiously, and give it a closer and more compact appearance, as well as to render it more firm, and better calculated to receive the white-wash, or colour, when dry. For floated stucco work, the pricking-up coat cannot be too dry; but, if the floating that is to receive the setting coat be too dry before the set is laid on, there will be danger of its peeling off, or of its assuming the appearance of little cracks, or shells, which would disfigure the work. Particular attention is therefore to be paid to have the under-coats in a due state of dryness when the exterior surface is laid on. And here it may also be remarked, that cracks and other unpleasant appearances in ceilings are more frequently the effect of weakness in the laths, covered with too much plaster; or, on the contrary, of too little plaster upon strong laths, than of any sagging, or other inadequacy in the timbers of the building. If the laths be properly attended to, and the plastering laid on by a judicious careful workman, no cracks are likely to appear.

8. *Rendering, and set*, or *rendering floated, and set*, combines both the foregoing processes, only it requires no lathing. *Rendering* is to be understood of a wall, whether of brick or stone, being covered with a coat of lime and hair; and by *set* is denoted a superficial coat, upon the rendering of fine stuff or putty. These operations are similar to those described for setting of ceilings and partitions; and the *floated and set* is laid on the rendering in the same manner as on partitions, &c., as above explained for the best kind of work.

9. *Troweled stucco*, which is a very neat kind of work, used in dining-rooms, halls, &c., when the walls are proposed to be painted, must be worked upon a floated ground, and the floating should be as dry as possible before the stucco is applied. In this process, the plasterer is provided with a wooden tool, called *a float*, consisting of a piece of half-inch deal, about nine inches long and three wide, planed smooth, with its lower edges a little rounded off, and having a handle on the upper surface. The stucco is prepared as described above, and afterwards well beaten and tempered, with clean water, for use. The ground intended to be stuccoed is first prepared with the large trowel, and made as smooth and level as possible; and when the stucco has been spread upon it, to the extent of four or five feet square, the workman, with the float in his right hand, and a brush in his left, begins to rub it smooth with the former, having first sprinkled it with water from the latter: this he does in small portions at a time, and proceeds, alternately sprinkling and rubbing the face of the stucco, till the whole is reduced to a fine even surface. He then prepares another square of the ground, and proceeds as before, till the whole is completed. The water has the effect of hardening the face of the stucco, and, when the floating is well performed, it will feel as smooth as glass.

Rough-casting, or *rough-walling*, is an exterior finishing, much cheaper than stucco, and therefore more frequently employed on cottages, farm-houses, &c., than on buildings of a higher class. The wall intended to be rough-cast is first pricked-up with a coat of lime and hair; and when this is tolerably dry, a second coat is laid on, of the same materials as the first, but as smooth as it can possibly be spread. As fast as the workman finishes this surface, he is followed by another, with a pail-full of rough-cast, with which he bespatters the new plastering, and the whole dries together. The rough-cast is composed of fine gravel, clean washed from all earthy particles, and mixed with pure lime and water, till the whole is of a semi-fluid consistency. This is thrown from the pail, upon the wall, with a wooden float, about five or six inches long, and as many wide, made of half-inch deal, and fitted with a round deal handle. While, with this tool, the plasterer throws on the rough-cast with his right hand, he holds in his left a common whitewasher's brush, dipped in the rough-cast also, with which he brushes and colours the mortar, and the rough-cast he has already spread, to give them, when finished, a regular uniform colour and appearance.

Cornices.—These are either plain or ornamented; and sometimes they embrace a portion of both classes. The first thing here to be attended to, is to examine the drawings, and measure the projections of the members: if they project more than seven or eight inches, bracketing must be resorted to. This consists in fixing up pieces of wood, at the distance of about eleven or twelve inches from each other, all round the place proposed for the cornice, nailing laths to them, and covering the whole with a coat of plaster, allowing in the brackets for the stuff necessary to form the cornice: in general, about one inch and a quarter is sufficient. A beech mould is next to be made of the profile of the intended cornice, by the carpenter, of about a quarter of an inch in thickness, with the quirks, or small sinkings, of brass. All the sharp edges are to be carefully removed by the plasterer, who must also open, with his knife, all the points that he finds incompetent to receive the plaster freely. These preliminaries being adjusted, two workmen, provided with a tub of putty, and a quantity of plaster of Paris, proceed to run the cornice. Before they begin, however, to use the mould, they gauge a screed upon the wall and ceiling, of putty and plaster, covering so much of each as will correspond with the top and bottom of the intended cornice. On this screed, one or two slight deal straight-edges are nailed, adapted to as many notches, or chases, made in the mould, for it to work upon. The putty is then to be mixed with about one-third of plaster of Paris, and brought to a semi-fluid state by the addition of clean water. One of the workmen, with two or three trowelfuls of this composition upon his *hawk*, which he holds in his left hand, begins to plaster over the surface intended for the cornice, with his trowel, while his partner applies the mould, to ascertain the parts where more or less may be wanted. When a sufficient quantity of plaster has been laid on, the workman with the mould, holding it steadily and firmly against both the ceiling and the wall, moves it backwards and forwards, which removes the superfluous stuff, and leaves an exact impression of the mould upon the plaster. This is not indeed effected at once, but while he works the mould to and fro, the other workman takes notice of any deficiencies, and fills them up, by adding fresh supplies of plaster. In this manner, a cornice of from ten to twelve feet in length, may be formed in a very short time; indeed, expedition is essentially requisite, as the plaster of Paris occasions a very great tendency in the putty to set; and to prevent this taking place too rapidly, it is necessary to sprinkle the composition frequently with water from a brush; as they generally endeavour to finish all the lengths, or pieces, between any two breaks, or projections, at one time, to secure the truth and correctness of the cornice. In cornices of very large proportions, and in cases where the orders of architecture are to be applied, three or four moulds are requisite, which are applied in the same manner, till all the parts are formed. Internal and external mitres, and small returns, or breaks, are afterwards modelled and filled up by hand; an operation upon which a dexterous plasterer much piques himself.

When cornices are to be charged with ornaments, the plasterer leaves certain indentions, or sinkings, in the mould, in which the casts are laid. These ornaments were formerly made by hand, by artists called *ornament-plasterers;* but now they are cast in plaster of Paris, which has almost superseded that branch of art; at least, the few professors of it who remain, are limited in their labours to the modelling and forming of moulds to cast from. Ornaments, to be cast in plaster of Paris, are previously modelled in clay from the design. When the clay model is finished, and has acquired some degree of firmness from the action of the atmosphere, a wooden frame is adapted to it, and after it has been retouched, and finished, the frame is filled up with melted wax, which, when cool, on the mould being turned upside-down, drops off, and presents an exact cameo, or counterpart, of the model, in which the most enriched and curiously-wrought mouldings may be cast by the common plasterer. These wax models are contrived to cast about a foot in length of the ornament at once; such lengths being most easily got out from the cameo. The casts are made of the finest and purest plaster of Paris, saturated with water; the wax mould being oiled previously to its being poured in. When first taken from the mould, the casts, or intaglios, are not very firm; but after they have been suffered to dry a little, either in the open air or in an oven, they become hard, and are scraped and cleaned up for the workmen.

Friezes and basso-relievos are executed in a similar manner, only the wax mould is so contrived that the cast may have a back ground of plaster, at least half an inch thick: this is cast to the ornament, or figure, so that it strengthens and secures their proportions, at the same time that it promotes their general effect.

Nor is the process different for capitals to columns, except that they require a number of moulds to complete them. To make a good mould, however, requires the utmost skill of the modeller. The Corinthian capital requires a shaft, or bell, to be first made, on which are afterwards to be fixed the foliage and volutes; all which, as well as the other details, require distinct cameos.

In forming cornices that are to be charged with ornaments, the plasterer takes care to have proper projections in the running mould, so as to leave a groove or indention in the cornice, into which the cast ornament is laid, and secured in its place, by spreading a small quantity of liquid plaster of Paris on its back. Friezes, likewise, are prepared for in the cornice in a similar manner, by leaving a projection in the running mould, at the part where they are intended to be inserted, and they are fixed in their places by liquid plaster. Detached ornaments, designed for a ceiling, or other part, where no running mould has been employed, are cast in pieces, corresponding with the design, and fixed upon the ceiling, &c. with white-lead, or the composition known under the name of *iron cement.*

Good plastering is known by its exquisite appearance, both as to regularity and correctness, and its solid effect having no cracks, nor indications of them, visible.

The making and working of stucco has, for a considerable time past, occupied the attention of chemists, physicians, architects, and plasterers; but the only beneficial result has been a more extensive knowledge of the materials used in it: indeed, our climate, from its great moisture, prevents its being brought to superlative perfection, though, among the various compositions that have been proposed and tried, some are comparatively excellent. The common stucco now in use for external work, is known, among plasterers, by the name of *Bailey's compo;* it consists of Thames sand cleanly washed, and ground Dorking lime, mixed dry, in the proportion of three of the latter to one of the former, which when well incorporated together, should be secured from the air in good tight casks, till the moment it is wanted for use. Walls intended to be covered with this composition, must be first prepared, by raking the mortar from the joints, and picking the bricks, or stones, till the whole wall is properly indented. The part must then be clean brushed of all dust and other extraneous matter, and well soaked with clean water. The stucco is then to be supersaturated with water, till it bears the appearance and consistence of ordinary whitewash: in which state it is to be rubbed over the wall with a flat brush of hogs' bristles, and then left to become tolerably dry and hard, which is ascertained by its becoming more white and transparent than when at first laid on. This process is called *roughing in.* Screeds are next to be formed upon the wall, with fresh stucco from the cask, tempered with water to a proper consistency, and spread on the upper part of the wall about eight or nine inches wide, and against the two ends, beginning at the top, and proceeding downwards to the bottom. In this operation, two workmen are required; one to supply the stucco, the other to use and try the plumb-rule and straight-edge. When these are truly formed, other screeds must be made, vertically, about four or five feet apart, unless apertures in the wall should prevent it, in which case they must be formed as near together as possible. When the screeding is all done, more *compo* must be prepared, and in larger quantities than was done for the former process; and, when ready, both the workmen begin to spread it with their trowels over the wall in the space left between each pair of screeds that are nearest together. When this is done the straight-edge is to be applied across both, and dragged from the top to the bottom, so as to remove whatever superfluous stucco may project above the screeds. Should any hollow places appear, fresh stucco must be applied, and the straight-edge again drawn over the spot, till the *compo* is brought even to the face of the screeds, and the whole is level with the edge of the rule. The workmen then fill up another interval; and thus they proceed, till the whole of the wall is covered. The wall is then to be finished, by floating, or hardening the surface, by rubbing it with the common wood float, and sprinkling it with water, an operation that is performed, as above directed, for troweled stucco; always remembering to begin the floating on the part first filled up.

This kind of compo, or stucco, is frequently used by plasterers for cornices and mouldings, in the same manner that has already been described in common plastering. But here, the workman finds requisite to add a small portion of plaster of Paris, to make it fix better while running or working the mould. Such addition, however, is not calculated to give strength to the stucco; and is only made through the necessity of having a quick set.

Some years ago, the patent stucco of Dr. B. Higgins, was in great repute, and employed by the founders of the Adelphi, in the Strand, with considerable success. It consisted of 14lb. or 15lb. of good stone lime, 14lb. of bone-ashes, finely powdered, and 98lb. of clean sand, coarse or fine, according to the intended nature of the building: these were mixed up into mortar as quickly as possible with lime-water, and used as soon as made.

The various suggestions and modes of forming the same materials into stucco, amount to about forty in number, only varying the proportions; but few of them have been found to remain tolerably entire in this climate for thirty years together. In 1796, Mr. Parker obtained a patent for a cement that is impervious to water, and may be successfully employed in ice-houses, cisterns, tanks, &c. (*See* CEMENT, and MORTAR.) In his specification, Mr. Parker observes, "nodules of clay, or argillaceous stone, generally contain water in their centre, surrounded by calcareous crystals, and having veins of calcareous matter. They are formed in clay, and are of a brown colour, like the clay." These nodules, he directs, should be burned, after being broke into small pieces, in a kiln, with a heat nearly sufficient to vitrify them; after which they are to be reduced to powder. Two measures of water added to five of this powder, produces *tarras;* lime and other matters may be added or withheld at pleasure: and the proportion of water may be varied. The term of the patent being now expired, there are many other manufactures of this cement, which are found to be of equal goodness as to quality, and some of them of rather a better colour than the original; a recommendation, or rather improvement, of considerable importance, since the fresco-painting, or whitewash, laid upon Mr. Parker's composition, when applied to the fronts of houses, is soon taken off by the rains, and leaves the walls of a dingy and unpleasant appearance.

An allusion has been made above, to the fresco-painting, or staining, laid upon walls plastered with this cement; this is done to give them an appearance of stone-buildings, and is performed by diluting sulphuric acid (oil of vitriol) with water, and adding the fluid ochres, &c., to give the required tint. When the stucco is washed over with this kind of paint, the affinity existing in the iron of the cement ceases, the acid and colour suspended in and upon the stucco is fixed, and the surface assumes, when dexterously managed, the appearance of an ashlar bond of masonry.

Columns, &c. done in Scagliola, is a distinct branch of plastering, discovered or invented in Italy, where it has been much used, and thence introduced into France, where, having fascinated all the cognoscenti, it obtained the title of *scagliola.* The late Henry Holland, who first brought it to England, engaged the artists from Paris to execute it; some of whom, finding a demand here for their labour, remained in the country, and instructed our own workmen in the art. Columns and pilasters are executed in this branch of plastering, in the following manner. A wooden cradle, composed of thin strips of deal, or other wood, is made to represent the column designed, but about $2\frac{1}{2}$ inches less in diameter than the shaft is intended to be when finished. This cradle is lathed round, as for common plastering, and then covered with a pricking-up coat of lime and hair: when this is quite dry, the artists in scagliola commence their operations, and, by an imitation of the most rare and precious marbles, produce a most astonishing and delusive effect; for, nothing short of actual fracture can discover the counterfeit: and any stone, partaking of the quality of marble, may be exactly imitated by it; the imitation taking as high a polish, and feeling to the touch as cold and solid, as the most compact and solid marble. The workmen select the purest gypsum they can obtain, which, after breaking it into small pieces, they calcine. As soon as the largest fragments lose their brilliancy, the fire is withdrawn; the calcined powder is passed through a very fine sieve, and mixed up as it is to be used with a solution of Flanders glue, isinglass, &c. In this solution the colours required in the marble to be imitated are also diffused: but when the work is to be of various colours, each colour is separately prepared, and they are afterwards mingled and combined, nearly in the same manner that a painter mixes the primitive colours on his palette, to compose his different tints. When the powdered gypsum is prepared and mingled for the work, it is laid on the shaft of the column, &c. over the pricked-up coat of lime and hair, and then it is floated with moulds of wood, made to the requisite size, the artist using the colours necessary for the imitation during the floating, by which means they become mingled and incorporated with the surface. To give the work the requisite polish, or glossy lustre, so much admired in works of marble, the workman rubs it with a pumice-stone with one hand, while with the other he cleans it with a wet sponge. He then polishes it with tripoli and charcoal and fine soft linen; and after going over it with a piece of felt dipped in a mixture of oil and tripoli, he finishes the process by the application of pure oil.

This imitation is the most complete that could be conceived; and, when the bases and capitals are made of real marble, as is the common practice, the deception is beyond discovery. When not exposed to the weather, it is also little inferior to real marble in point of durability, retains its lustre full as long, and is not one-eighth of the expense of the cheapest imported.

There is another species of plastering, though done by a distinct set of persons, known to the public by the name of *composition ornament,* used not only for the decorative parts of architecture, but also for the frames of pictures, looking-glasses, &c. This composition, which is very strong when quite dry, and of a brownish colour, consists of the proportion of two pounds of powdered whiting, one pound of glue in solution, and half a pound of linseed-oil, mixed together in a copper, heated, and stirred with a spatula till the whole is incorporated. After being suffered to stand to settle and cool, it is laid upon a stone, covered with powdered whiting, and beaten till it assumes a tough and firm consistence; after which it is put by for use, and covered with wet cloths to keep it fresh. The ornaments to be cast in this composition are modelled in clay, as for common plastering, and afterwards a cameo, or mould, is carved in a block of box-wood. This carving requires to be done with the utmost neatness and truth, otherwise the symmetry of the ornament to be cast from it will be spoiled. When the composition is to be used, it is cut with a knife into pieces adapted to the size of the mould, and forced with the hand closely into every part. It is then placed in a press worked by an iron screw, by which it is farther compressed into every crevice: after being removed from the press, the mould is turned upside-down, with a smart tap on a board, which dislodges the composition, and the mould leaves it with its face upwards. One foot in length is as much as is usually cast at one time, and when the ornament first drops from the mould, all the superfluous composition is pared away with a knife, and thrown into the copper towards a fresh supply for the next cast. The ornaments, when formed, are glued upon wooden, or other grounds, or they are affixed by means of white-lead, &c., after which they are painted or gilt, according to the purpose for which they are intended. This composition is at least 80 per cent. cheaper than carving, and in most cases is equally well calculated to answer all the purposes of that art.

It were much to be wished, that the art of plastering could be again brought to its ancient perfection. In our best buildings, the plastered walls and ceilings crack and fly, and, in a little time, grow damp, or moulder to decay.

The Romans had an art of rendering their work of this kind much more firm and durable; and there is no reason to despair of reviving this art by proper trials.

The ancient plastering of these people, preserved to this time, where it has not met with violent blows, or injuries from accidents, is still found as firm and solid, as free from cracks or crevices, and as smooth and polished on the surface, as if made of marble. The bottoms and sides of the

Roman aqueducts were lined with this plastering, and endured many ages without hurt, unless by accidents: witness that whereof some yards are still to be found on the top of the Pont de Gard, near Nismes, for the support of which that celebrated bridge was built to carry water to the said town. The roofs of houses, and the floors of rooms, at Venice, are covered with a sort of plaster, of later date, and yet strong enough to endure the sun and weather for several ages, without cracking or spoiling, and without much injury from being trod upon.

The secret of preparing this Venetian plaster is not among us; but it would be worth while to try whether such a substance might not be made by boiling the powder of gypsum dry over the fire (for it will boil in the manner of water); and when this boiling or recalcining is over, mixing with it resin, or pitch, or both together, with common sulphur, and the powder of sea-shells. If these were all mixed together, the water added to it hot, and the matter all kept upon the fire till the instant of its being used, so that it might be laid on hot, it is possible this secret might be hit upon.

Wax and oil of turpentine may be also tried as additions; these being the common ingredients in such cements that we have accounts of as the firmest. Strong ale-wort is, by some, directed to be used instead of water, to make mortar of limestone of a more than ordinary strength. It is possible that the addition of this tenacious liquor to the powdered ingredients of this proposed plaster, might greatly add to their solidity and firmness. *See* Cement, Mortar, and Stucco.

PLATBAND, any flat square moulding, whose height much exceeds its projecture. Such are the faces, or fasciæ, of an architrave, and the platbands of the modillions of a cornice.

The platband is signified, in Vitruvius and others, by the words *fascia*, *tænia*, and *corsa*.

Platband of a Door or Window, is used for the lintel, where that is made square, or not much arched. These platbands are usually crossed with bars of iron, when they have a great bearing; but it is much better to ease them by arches of discharge built over them.

Platbands of Flutings, are the lists, or fillets, between the flutings of columns.

PLATE, a term applied generally to those horizontal timbers bedded in brick, or other walls, for the purpose of sustaining other timbers, &c.: thus we have *wall-plate*, *gutter-plate*, &c.

PLATE-GLASS, *see* Glass.

PLATES, *Ground*, *see* Ground-sill.

PLATFOND, the same as soffit. *See* Soffit.

PLATFORM, a row of beams, which support the timber-work of a roof, and lie at the top of the wall where the entablature ought to be raised.

Platform is also used for a kind of terrace, or broad, smooth, open walk, at the top of a building, whence a fair prospect of the adjacent country may be taken. Hence an edifice is said to be covered with a platform, when it is flat at top, and has no ridge. Most of the Oriental buildings are thus covered, as were all those of the ancients. Cæsar was the first among the Romans who procured leave to build his house with a ridge or pinnacle.

PLINTH (from πλινθος, *a brick*), a flat square member, in form of a brick: sometimes, also, called *the slipper*.

It is used as the foot, or foundation of columns; being that flat square table, under the mouldings of the base and pedestal, at the bottom of the whole order; seeming, if we follow the notion of Vitruvius, to have been originally intended to keep the bottom of the primitive wooden pillars from rotting.

The plinth is also called the *orle* or *orlo*. And Vitruvius calls the Tuscan abacus, *plinth*, from its resembling a square brick.

Plinth of a Statue, &c., a base or stand, flat, round, or square, serving to support a statue, &c.

Plinth of a Wall, a term for two or three rows of bricks advancing out from the wall; or, in general, for any flat high moulding, serving in a front wall to mark the floors, or to sustain the eaves of a wall, and the larmier of a chimney.

PLOTTING, among surveyors, the art of describing, or laying down on paper, &c., the several angles and lines of a tract of ground surveyed by a theodolite, or like instrument, and a chain.

In surveying with the plain-table, the plotting is needless; the several angles and distances being laid down on the spot, as fast as they are taken. But in working with the theodolite, semicircle, or circumferentor, the angles are taken in degrees, and the distances in chains and links; so that there remains a subsequent operation, to reduce those numbers into lines, and thence to form a draught, plan, or map. This operation is called *plotting*.

Plotting is performed by means of two instruments, the protractor and plotting-scale. By the first, the several angles observed in the field with a theodolite, or the like, and entered down in degrees in the field-book, are protracted on paper in their just quantity. By the latter, the several distances measured with the chain, and entered down, in like manner, in the field-book, are laid down in their just proportion.

Plotting-scale, a mathematical instrument, used in plotting grounds, usually of box-wood, sometimes of brass, ivory, or silver, either a foot or half a foot long, and about an inch and a half broad.

On one side of the instrument are seven several scales or lines, divided into equal parts. The first division of the first scale is subdivided into ten equal parts, to which is prefixed the number 10, signifying that ten of those subdivisions make an inch; or that the division of that scale are decimals of inches.

The first division of the second scale is likewise subdivided into 10, to which is prefixed the number 16, denoting that sixteen of those subdivisions make an inch. The first division of the third scale is subdivided, in like manner, into 10, to which is prefixed the number 20. To that of the fourth scale is prefixed the number 24; to that of the fifth, 30; that of the sixth, 40; and that of the seventh, 48; denoting the number of subdivisions equal to an inch, in each respectively. The two last scales are broken off before the end, to give room for two lines of chords, marked by the letters c c.

On the other side of the instrument is a diagonal scale, the first of whose divisions, which is an inch long, if the scale be a foot, and half an inch, if half a foot, is subdivided diagonally into 100 equal parts; and at the other end of the scale is another diagonal subdivision, of half the length of the former, into the same number of parts, viz., 100.

Next the scales is a line divided into hundredth-parts of a foot, numbered 10, 20, 30, &c., and a line of inches subdivided into tenths, marked 1, 2, 3, &c.

PLUG AND FEATHER, or Key and Feather, a method of dividing hard stones, described at length in the article Eddystone Lighthouse.

PLUGS, pieces of timber driven perpendicularly into a wall, with the projecting part sawn away, so as to be flush with the face.

PLUMBER, (from the French *plombier*, derived from the

Latin *plumbum*, lead), an artist who works in lead, and to whom is confided the pump-work, as well as the making and forming of cisterns and reservoirs, large or small, water-closets, &c., for the purposes of domestic economy. The plumber does not use a great variety of working tools, because the ductility of the metal upon which he operates does not require them. They consist of an iron *hammer*, rather heavier than a carpenter's, and with a short thick handle; two or three wooden *mallets*, of different sizes; and a *dressing and flatting tool.* This last is of beech, about 18 inches long and $2\frac{1}{2}$ inches square, planed smooth and flat on the under surface, rounded on the upper, and one of its ends tapered off round, as a handle. With this tool the plumber stretches out and flattens the sheet-lead, or dresses it to the shape required, using first the flat side, and then the round one, as occasion may suit. The plumber has also occasion for a *jack* and a *trying* plane, similar to those of the carpenter (see PLANE), with which he reduces the edges of sheet-lead to a straight line, when the purposes to which it is to be applied require it. He should also be provided with a *chalk-line*, wound upon a roller, for marking out the lead into such breadths as he may want. His cutting-tools consist of a variety of *chisels* and *gouges*, as well as *knives;* the latter of which are used for cutting the sheet-lead into slips and pieces, after it has been marked out by the chalk-line. *Files* of different sizes are requisite for the plumber, in various operations. In soldering, *ladles* of three or four sizes, for melting the solder; and iron instruments, called *grozing-irons*, are used by the plumber. These grozing-irons are of several sizes, and commonly about 12 inches in length, tapering at both ends, the handle-end being turned quite round, to allow of its being firmly held while in use. The other end is a bulb, of a spindle-shape, or sometimes spherical, of a size proportioned to the soldering intended to be executed. They are heated to redness, when wanted for use.

A plumber's *measuring rule* is two feet in length, divided into three equal parts of eight inches each. Two of its legs are of box-wood, and duodecimally divided; the third leg consists of a piece of slow-tempered steel, attached to one of the box-legs, by a pivot, on which it turns, and falls, when not in use, into a groove cut in such leg for its reception. This steel leg will pass into places that the others could not enter, and is also useful for occasionally removing the oxide, or any other extraneous matter, from the surface of his heated metal.

Scales and weights are also necessary to the master plumber, as he cannot charge for anything till it has been weighed. He must also be supplied with *centre-bits* of all sizes, and a *stock*, to work them in, for the purpose of making perforations in lead or wood, through which he may want to insert pipes, &c. He also has occasional recourse to compasses, to strike circular pieces of lead, to line or cover figures of that shape. Plumbers charge their sheet-lead by the hundred-weight.

PLUMBERY, or PLUMBING, (from the Latin *plumbum*, lead), the art of casting and working in lead, and using it in building. As this metal is very easily fusible, it is cast into figures of any kind, with great facility, by running it in proper moulds of clay, plaster, &c., but the chief articles in plumbery are sheets and pipes of lead; which form the basis of the plumber's work.

Lead is obtained from the mines, and, from its being generally combined with sulphur, it has been denominated a *sulphuret.* After the ore has been taken from its bed, it is smelted, first being picked, in order to separate the unctuous and rich, or genuine ore, from the stony matrix and other impurities; the picked ore is then pounded under stampers, actuated by machinery, and afterwards washed to carry off the remainder of the matrix, that could not be separated in picking. It is next put into a reverberatory furnace to be *roasted*, as the workmen call it, during which operation it is repeatedly stirred to facilitate the evaporation of the sulphur. When the surface begins to assume the appearance of a paste, it is covered with charcoal, and well shaken together: the fire is then increased, and the purified lead flows down on all sides into the basin of the furnace, whence it runs off into moulds prepared for its reception. The moulds are capable of receiving 154lb. of lead each; and their contents, when cool, are called *pigs* in the commercial world.

The natural colour of lead is a bluish white; when newly melted, or cut, it is very bright; but is soon tarnished on exposure to the atmosphere; assuming first a dirty gray colour, which afterwards becomes white. It is capable of being hammered into very thin plates, and may be drawn into wire; but its tenacity is very inferior to that of other metals; for a leaden wire the hundred-and-twentieth part of an inch in diameter is only capable of supporting 18.4lb. without breaking. Lead melts at the temperature of 612° of Fahrenheit's thermometer; and, if a stronger heat be applied, it boils and evaporates. If cooled slowly, it crystallizes. The change of its external colour is owing to its gradual combination with oxygen, which converts its exterior surface into an oxide: this outward crust, however, preserves the rest of the metal for a long time, as the air can penetrate it but very slowly. Lead is not acted upon immediately by water, though that element greatly facilitates the action of the air upon it; for it is known, that when lead is exposed to the atmosphere, and kept constantly wet, the process of oxidation takes place much more rapidly than it does under other circumstances: hence the white crust, that is to be observed upon the sides of leaden vessels containing water, just at the place where the surface of the water terminates. For other particulars relative to this metal, *see* LEAD.

Plumbers purchase lead in *pigs*, and reduce it themselves into sheets, or pipes, as they have occasion. Of sheet-lead, they have two kinds, cast and milled; the former is used for covering flat roofs of buildings, laying of terraces, forming gutters, lining reservoirs, &c.; the latter, which is very thin, for covering the hips and ridges of roofs: this last they do not manufacture themselves, but purchase it ready prepared of the lead merchants, as it comes from the ore and roasting furnaces.

In casting sheet lead, a copper is provided, well fixed in masonry at the upper end of the workshop, near the mould, or casting-table, which consists of strong deal boards, well jointed together, and bound with bars of iron at the ends. The sides of this table, of which the shape is a parallelogram, varying in size from 4 to 6 feet in width, and from 16 to 18 feet and upwards in length, are guarded by a frame or edging of wood, 3 inches thick, and 4 or 5 inches higher than the interior surface, called the *shafts*; the table is fixed upon firm legs, strongly framed together, about 6 or 7 inches lower than the top of the copper; at the upper end of the mould, nearest the copper, a box, called *the pan*, is adapted in its length to the breadth of the table, having at its bottom a long horizontal slit, from which the heated metal is to issue, after it has been poured in from the copper. This box moves upon rollers along the surface of the rim of the table, and is put in motion by means of ropes and pulleys fixed to beams above. While the metal is melting, the surface of the mould, or table, is prepared by covering it with a stratum of dry and clean sand, regularly smoothed over with a kind of rake, called *a strike*, which consists of a board, about 5 inches broad, and rather longer than the inside of the mould, so that its ends, which are notched about two inches deep, may ride upon the shafts; this, being passed down the whole length of the table, reduces the sand to a uniform surface. When this is done, the pan is brought to the head of the table, close to the copper, its side having been previously guarded by a coat of moistened sand, to prevent its firing from the heat of the metal, which is now emptied in with ladles from the copper. These pans, or boxes, it must be observed, are made, as to their contents, equal to the quantity of melted lead requiredto cast a whole sheet at one time; and the slit in the bottom is so adjusted as to let out, during its progress along the table, just as much as will completely cover it, of the thickness and weight per foot required. Everything being thus prepared, the slit is opened, and the box is moved along the table, dispersing its contents from the top to the bottom, and leaving in its progress a sheet of lead of the desired thickness. When cool, the sheet is rolled up and removed from the table, and other sheets are cast, till all the metal in the copper is exhausted. The sheets so formed are rolled up, and weighed, it being by weight that the public is charged for sheet lead.

In some places, instead of having a square box, upon wheels, with a slit in the bottom, the pan consists of a kind of trough, being composed of two planks nailed together at right angles in their length, with two triangular pieces fitted in between them at their ends. The length of this pan, as well as that of the box, is equal to the whole breadth of the mould: it stands with its bottom, which is a sharp edge, on a bench at the head of the table, leaning with one side against it: and on the opposite side is a handle to lift it up by, in order to pour out the liquid metal. On the side of the pan next the mould, are two iron hooks to hold it to the table, and prevent it from slipping, while the metal is pouring out of it into the mould. The mould, as well as the pan, is spread over, about two inches thick, with sand sifted and moistened, which is rendered perfectly level by moving over it the strike, and smoothing it down with a plane of polished brass, about a quarter of an inch thick, and nine inches square, turned up on all the four edges, and with a handle fitted to the upper, or concave side. Before they begin to cast, the strike is made ready, by tacking two pieces of old hat on the notches, or by covering them with leather cases, so as to raise the under side of the strike about the eighth of an inch, or more, above the sand, according to the proposed thickness of the sheet: the face, or under surface of the strike is then smeared with tallow, and laid across the breadth of the mould, with its ends resting on the shafts. The melted lead is then put into the pan with ladles, and, when a sufficient quantity has been put in, the scum is swept off with a piece of board to the edge of the pan, and is suffered to settle on the coat of sand, to prevent its falling into the mould when the metal is poured out. It generally happens, that the lead, when first taken from the copper, is too hot for casting; it is therefore suffered to cool in the pan, till it begins to stand with a shell or wall on the sand with which the pan is lined. Two men then take the pan by the handle, or one man takes it by means of a bar and chain fixed to a beam in the ceiling, and, turning it down, the metal runs into the mould: another man stands ready with the strike, and as soon as all the metal is poured in, he sweeps it forward, and draws the residue into a trough at the bottom prepared to receive the refuse. The sheet is then rolled up, as before. In this mode of operation, the table inclines in its length about an inch, or an inch and a half, in the length of 16 or 17 feet, or more, according to the required thickness of the sheets; the thinner the sheet the greater the declivity, and *vice versa;* the lower end of the mould is also left open, to admit of the superfluous metal being thrown off.

When it is intended to cast a cistern, the size of the four sides is measured out; and the dimensions of the front having been taken, long slips of wood, on which the mouldings are carved, are pressed upon the sand, and leave their impression; and figures of birds, beasts, &c. are likewise stamped in the internal area, by means of leaden moulds: whatever of the sand has been disturbed in doing this, is then made smooth, and the process of casting goes on as for plain sheets; only, instead of rolling up the lead when cast, it is bent into four sides, so that the two ends may be joined at the back, where they are soldered together; and afterwards the bottom is soldered up.

The lead that lines the Chinese tea-boxes, is reduced to a degree of thinness, to which European plumbers cannot, it is said, approach. The following account of the process by which these plates are formed, was communicated to a writer in the *Gentleman's Magazine*, by an intelligent mate of an East-Indiaman: The caster sits by a pot, containing the melted metal, and has two large stones, the lower one fixed, and the upper moveable, having their surfaces of contact ground to each other, directly before him. He raises the upper stone by pressing his foot upon its side, and with an iron ladle pours into the opening a proper quantity of the fluid metal. He then lets fall the upper stone, and thus forms the lead into an extremely thin irregular plate, which is afterwards cut into a proper shape.

Cast sheet lead, used for architectural purposes, is technically divided into lead of 5lb. 5½lb. 6lb. 6½lb. 7lb. 7½lb. 8lb. and 8½lb. by which is understood that every superficial foot is to contain those respective weights, according to the price agreed upon.

The milled lead used by plumbers is very thin, seldom containing more than 4lb. to the foot. It is by no means adapted to gutters or terraces, nor indeed to any part of a building that is much exposed either to great wear, or to the effects of the sun's rays: in the former case it soon wears away; in the latter it expands and cracks. It is laminated in sheets of about the same size as those of cast lead, by means of a roller, or flatting-mill.

To cast pipes without soldering, a kind of mill, furnished with arms, or levers, to turn it by, is used. The moulds, which are of brass, consist of two pieces, which open and shut by hooks and hinges; their inward calibre, or diameter, being according to the size of the intended pipe, and usually about two feet and a half in length. In the middle is a core, or round piece of brass, or iron, rather longer than the mould, and of the thickness of the proposed inward diameter of the pipe. This core passes through two copper rundles, one at each end of the mould, which they serve to close; and to this is joined a small copper tube, about two inches long, of the intended thickness of the leaden pipe. These small tubes retain the core in the centre of the cavity of the mould. The core being in the mould, with the rundles at its two ends, and the lead melted in the furnace, the metal is taken up in a ladle and poured into the mould through a small aperture, in the shape of a funnel, at one end. When the mould is full, a hook is passed into the end of the core, which, by turning the mill, is drawn out; the mould is then opened, and the pipe itself is taken away. If it be desired to have the pipe lengthened, one end of it is put in the lower part of the mould, with the extremity of the core passed into it: the mould is then shut, and the upper rundle and tube applied as before; the pipe serving for rundle and tube at the other end. Fresh metal is then poured in, which unites itself with the former length of pipe; and the operation being repeated, a pipe of any required length may be obtained.

Pipes are made of sheet-lead, by beating it round wooden cylinders of the length and thickness required; and then soldering up the edges.

Both these methods are now superseded, by the use of a machine, worked by steam, which produces a much neater article, of almost any length, and at considerably less expense.

Solder is used by plumbers to secure the joints of lead-work, where other means would be improper, or impossible. It is a rule, that solder should be easier of fusion than the metal intended to be soldered; and that it should be as nearly as possible of the same colour. The plumber, therefore, uses what is technically called *soft solder*, which is a compound of equal parts of tin and lead, fused together, and run into moulds, not much unlike, in shape, to a gridiron: in which state it is sold to the manufacturer by the pound. In the operation of soldering, the surfaces, or edges, intended to be united are scraped very clean, and brought close up to each other, in which state they are secured by an assistant, while the plumber lays a little resin, or borax, upon the joint, to prevent an oxidation of the metal. The heated solder is then brought in a ladle and poured on the joint, after which it is smoothed and finished, by rubbing it about with a red-hot grozing iron; and, when completed, it is made smooth by filing.

For the method of laying embossed figures upon a leaden ground, see the article Lead.

In covering terraces, or flats, with sheet-lead, a bottom, as level as possible, should be first laid of plaster, or of boards; if the latter, they should be of sufficient substance to prevent their warping, or flying upwards; for if this be not attended to, the lead will soon become unsightly, and be liable to crack. As the sheets of lead never exceed in their breadth above six feet, it becomes necessary, in covering large surfaces, to have joints, which are managed several ways; but, in all, the main object is to have them water-tight. The preferable mode is by forming *laps* or *roll-joints*, which is done by having a *roll*, or strip of wood, about two inches square, but rounded on its upper side, nailed under the joint of the sheets, where the edges lap over each other; one of these edges is to be dressed up over the roll on the inside, and the other is to be dressed over them both on the outside, by which means the water is prevented from penetrating. No other fastening is required than what is acquired from the hammering of the sheets together down upon the flat; nor should any other be resorted to, where sheet-lead is exposed to the vicissitudes of the weather, because they occasion it to expand and shrink, which, if prevented by too much fastening, would cause it to crack, and be quickly good for nothing but the melting-pot. Circumstances sometimes occur, that preclude the use of rolls, and then the method by *seams* is resorted to: this consists in simply bending the approximate edges of the lead, up and again over each other, and then dressing them down close to the flat, throughout their length. But this is not equal to the roll, either for neatness or security. Soldering is also sometimes had recourse to, for securing the joints; but this is not to be recommended, as lead so fixed will be sure to leak after an exposure to the sunshine of a single summer. Leaden flats and gutters should be always laid with a current, to keep them dry. A fall from back to front, or in the direction of the length of the sheet, is the general rule. A quarter of an inch to the foot run is a sufficient inclination: but the fall, or *current*, as it is called, is generally agreed upon between the carpenter and plumber, while the former is preparing the ground, or platform, on which the lead is to be laid.

In making gutters, &c., pieces of milled lead, called *flashings*, about eight or nine inches wide, are fixed in the walls all round the edges of the sheet-lead, with which the flat is covered, and are suffered to hang down over them, so as to prevent the passage of rain through the interstice between the raised edge and the wall. If the walls have been previously built, the mortar is raked out of the joint of the bricks next above the edge of the sheet, and the flashings are not only inserted into the crack at the upper sides, but their lower edges are likewise dressed over those of the lead in the flat or gutter. And when neither of these modes can be resorted to, the flashings are fastened by wall-hooks, and their lower edges are dressed down, as before.

Drips in flats, or gutters, are formed by raising one part above another, and dressing the lead as already described, for covering the rolls. They are resorted to when the gutter, or flat, exceeds the length of the sheet; or sometimes for convenience. They are also an useful expedient to avoid soldering the joints.

Reservoirs are generally made of wood, or masonry, for their exterior, and lined with cast sheet-lead, soldered at the joints. As these conveniences are rarely in places subject to material change of temperature, the soldering may be resorted to, without fear of its occasioning damage to the work, by promoting a disposition in the lead to crack.

The plumber's employment in pumps is confined generally to two or three kinds, required for domestic purposes, of which the suction and lifting pumps are the chief; these, as well as water-closets, are manufactured by a particular set of workmen, and sold to the plumber, who furnishes the lead pipes, and fixes them in their places.

Plumber's work is commonly estimated by the pound or hundred-weight; but the weight may be discovered by the measure of it, in the manner below stated. Sheet-lead used in roofing, guttering, &c., is commonly between seven and twelve pounds weight to the square foot; but the following table shows the particular weight of a square foot for each of the several thicknesses.

Thickness.	Pounds to a Square Foot.	Thickness.	Pounds to a Square Foot.
.10	5.899	.15	8.848
.11	6.489	.16	9.438
$\frac{1}{9}$	6.554	$\frac{1}{6}$	9.831
.12	7.078	.17	10.028
$\frac{1}{8}$	7.373	.18	10.618
.13	7.668	.19	11.207
.14	8.258	$\frac{1}{5}$	11.797
$\frac{1}{7}$	8.427	.21	12.387

In this table the thickness is set down in tenths and hundredths, &c. of an inch; and the annexed corresponding numbers are the weights in avoirdupois pounds, and thousandth-parts of pound. So the weight of a square foot of $\frac{1}{10}$ of an inch thick, or $\frac{10}{100}$, is 5 pounds, and 899 thousandth-parts of a pound; and the weight of a square foot to $\frac{1}{9}$ of an inch thickness, is 6 pounds and $\frac{554}{1000}$ of a pound. Leaden pipe of an inch bore is commonly 13 or 14 pounds to the yard in length.

The plate exhibits the various forms of joining the lead at the concourse of an external angle made by a flat at the top, and one of the sloping sides of the roof; also, the method of joining the sheets between opposite extremities to which the joints or seams run parallel.

Figure 1. No. 1.—The first part of the operation of joining two sheets both in the same flat or plane. D A and E G are supposed to be portions of the flat joining together at A G, where each is bent to a right angle, D A B and E G F; the part, A B, which rises upwards, exceeds the part G F, in contact by C D, which is about one-third.

No. 2 explains the second step of this operation, exhibiting the part, G F, bent over the end D, perpendicular to the horizon.

No. 3 is the third step, and shows the part, D F, No. 2, bent so as to be parallel to the horizon, and consequently coincident with the surface, C D, of the upper part; and, so far as this operation has gone, it is the same as the first.

No. 4 exhibits the entire finish or last step of the operation.

The other method is by a roll of wood fixed over the upright part, which descends downwards to cover the slates, and is exhibited in *Figure* 3, Nos. 1, 2, 3, 4, 5, 6, which are sufficiently plain to inspection, from what has been explained of *Figures* 1 and 2.

PLUMMET, Plumb-Rule, or Plumb-Line, an instrument used by masons, carpenters, &c. to draw perpendiculars, in order to judge whether walls, &c. be upright, planes horizontal, and the like.

Its name is derived from a piece of lead, *plumbum*, fastened to the end of a thread or chord, which usually constitutes this instrument.

Sometimes the string descends along a ruler of wood or metal raised perpendicularly on another; in which case it becomes a level.

At sea, a plummet is used by the pilot to sound the depth of the water.

PLUTEUS, the wall which sometimes closes the intervals between the columns of a building. The term is also applied to the podium intervening between two orders of columns placed one above another.

PLYERS, in fortification a kind of balance used in raising or letting down a draw-bridge. They consist of two timber levers, about twice the length of the bridge they lift, joined together by other timbers framed in the form of a St. Andrew's cross, which serve as a counterpoise. They are supported by two upright jambs, on which they swing; and the bridge is raised or let down by means of chains joining the ends of the plyers and bridge.

PLYMOUTH MARBLE, a sort of marble dug in great plenty about Plymouth, and in some parts of Devonshire, where it lies in very thick strata, from whence it is carried to London in large quantities; and, when wrought, looks little less beautiful than some of the Italian marble.

It is very hard and firm, and of a beautiful texture; its ground is of blueish-white, and its variegations are principally a pale red, and in smaller quantities brown and yellow: these lie in very orderly beds, and there is often a very agreeable glow of a faint red diffused through the whole substance. It is remarkably even in its whole structure, and is therefore capable of a more than ordinarily elegant polish.

PODIUM (Latin), a continued pedestal, or plinth, serving to support a colonnade: it consists of a plinth, base, die, and corona. It is sometimes made to break forward under each column, such projection being distinguished by the name of *stylobate.* Also, in the theatre of the ancients, the wall that separated the orchestra from the scene.

POINT (from *punctum*, formed from *pungere, to prick*), a term in various arts.

Point, *Accidental*, a term used by the old writers on perspective, instead of *the vanishing point*, adopted by Brook Taylor. Accidental points were the vanishing points in the horizontal line, and were thus found:—The representation of two original points being obtained, a line was drawn through them both, and produced to meet the vanishing line of the horizon, and the intersecting point was called *the accidental point*, which served to draw all other lines, whose originals were parallel to the first. The method given by Dr. Brook Taylor is, however, much more direct; as the vanishing point is found by a geometrical process, viz., by drawing a straight line through the eye, parallel to an original line, which serves likewise for the vanishing point of all its parallels.

Point, in geometry, according to Euclid, is a quantity which has no parts, or which is indivisible. Wolfius defines it, that which terminates itself on every side; or which has no terms or boundaries distinct from itself. This is what we otherwise call *the mathematical point*, and is only conceived by the imagination; yet it is in this that all magnitude begins and ends, the flux or motion of the point generating a line, that of a line a surface, &c. Hence, some define a point to be the inceptive of magnitude. Hobbes defines a point to be a body whose magnitude is not considered; but his false notions of a point, line, and surface, have led him into many errors. Monsieur de Crouzas also has supposed a line to be composed of points in his *Geometry*, and in his comment on the *Analyse des Infiniment Petits.* One line can cut another only in a point. Any three points being given out of a right line, a circle, or part of a circle, may be drawn, that shall pass through them all.

Point, in perspective, a term used for various parts, or places, with regard to the perspective plane.

Point, in physics, the smallest or least sensible object of sight, marked with a pen, point of a compass, or the like.

This is what we popularly call *a physical point*, which, in reality, has parts, though those parts are not here regarded. Of such points does all physical magnitude consist.

This physical point coincides with what Mr. Locke calls *the point sensible*, and which he defines to be the least particle of matter, or space, we can discern. He adds, that, to the sharpest eye, this is seldom less than thirty seconds of a circle, of which the eye is the centre.

Point, *Conjugate*, is used for that point into which the conjugate oval, belonging to some kinds of curves, vanishes.

Point, *Objective*, a point on a geometrical plane, whose representation is required on the perspective plane.

Point of Contrary Flexures, in the higher geometry, the point of a curve wherein it is inflected to a part contrary to that to which it originally tended.

Point of Distance, in perspective ,the distance of the picture, transferred upon the vanishing line from the centre, or from the point where the principal ray meets it; and thus it is generally understood to be on the vanishing line of the horizon.

Point of Reflection, in geometry, is commonly used instead of *point of retrogradation*, or *retrogression.*

Point of Sight, the place of the eye whence the picture is viewed, according to the definition of Dr. Brook Taylor; but, according to the old writers on perspective, the point of sight is what Brook Taylor denominates *the centre of the picture.*

Point of View (the same as *the point of sight*) is the situation of the eye of the spectator when viewing an object to be represented in a picture.

Point, *Visual*, see Visual.

POINTED ARCH, an arch pointed at the top, resembling the point of a lance. *See* Architecture.

POINTED ARCHITECTURE, that style of architecture which originated in the substitution of the pointed for the semicircular arch, and which began to be employed in the early part of the twelfth century. The pointed arch is formed by the intersection of two segments, which in the earlier examples are very flat, and form very acute arches; but in the later periods are of quicker curvature, and the arches in consequence proportionately depressed. The pointed arch, however, although the main feature in the style, does not form its only peculiarity; but in principle as well as in matters of detail, the style is peculiar and distinct from every other. This subject has been fully discussed under the article Gothic Architecture, a name which the style has assumed in common with the above and many others. It is our intention in this place to consider only the origin of the style and the manner of its development. On this subject we are left almost entirely to our own resources, no manuscripts being known to exist which give us any information respecting it, nor are we acquainted with even the names which the Gothic architects employed to designate the different divisions of their style. As regards the architects themselves, too, and the precise date of the buildings erected by them, we are left much in the dark; and whatever conclusions may have been arrived at, have been founded on little better than conjecture. Many archæologists, architects, and others interested in the question, have treated upon the subject, and have eliminated a great deal of useful information by their researches, although not one of them can be said to have come to a conclusive or satisfactory result regarding the question immediately before them. Many theories have been broached by different writers, some of which are plausible, and others little better than ridiculous; none are so perfect as to obtain universal assent, nor is it to be expected under the circumstances that they should be so. It is perhaps owing to the uncertainty necessarily attending the research, that the subject has been so fashionable amongst antiquaries; but however unsatisfactory their inquiries may have been as regards the matter in dispute, we must not forget that it is in all probability to such inquiries we owe our present knowledge on the subject, and the present appreciation of the style. Our very want of information as to its origin has probably been rather an advantage than otherwise, for we have been compelled thereby to search into the matter, and seek knowledge from every quarter; whereas had the question been easy of decision, all the information which we have obtained in this manner might have been lost to us.

Of the many theories which have been started, we shall here take notice of some of the more prominent, commencing with such as require but little comment, and proceeding in those which seem entitled to some further consideration. Bishop Warburton, one of the writers on the subject, discovers the prototype of a Gothic cathedral in a grove of trees, such an imitation having been employed, as he supposes, from the circumstance of the Celts being accustomed to worship in such places, and from their early associations having introduced the same forms in their constructed temples. The trunks of the trees are supposed to be represented by the pillars, and the overhanging branches by the ribs of the vaulting. The same opinion is said to have been entertained by Raphael d'Urbino; but we venture to say that the resemblance between a Gothic aisle and an avenue of trees is not at first sight very striking, and that the idea is rather in accordance with the imagination of the poet than the researches of the antiquary. It makes somewhat against this theory, that all evidence goes against the introduction of the Pointed style by the Goths, and also that the closest resemblance is to be found in the later, and not in the earlier examples. It is not improbable that Warburton himself felt dissatisfied with this notion, for it is not known to exist in more than one edition of his commentary on Pope's works, though later editions were published during his lifetime.

Similar to the preceding is the opinion entertained by Sir James Hall, who, with equal felicity of imagination, refers us to interlaced wicker-work as the undoubted prototype of the Pointed style in all its parts—its groined roofs, clustered pillars, and traceried windows; and thus Gothic churches become representations of the primitive churches in this island. Sir James has taken upon himself no inconsiderable amount of labour in his endeavour to prove his theory the correct one, and has profusely illustrated his book to show how precise is the imitation; but his illustrations, as well as his argument, go to prove the converse of his proposition, not that Gothic architecture took its origin from interlaced twigs and branches, but only that wicker-work may be made to assume the forms frequent in that style. The same argument respecting the similarity being most conspicuous in the later examples, exists also in this instance.

Mr. Murphy, well known by his publications on the architecture of Spain, refers us to the pyramids of Egypt as the grand type of the style; and in his splendid work on the church of Batalha, after having stated the tendency of every ornament to the general pyramidal form, says—"It appears evident from this instance, that the pyramidal form actually exists throughout the several component parts, and the general disposition of the edifice approaches as near to it at least as the ordonnance of an historical painting which is said to be pyramidally grouped. Hence we may comprehend the reason why the arch was made pointed, as no other forms could have been introduced with equal propriety in a pyramidal figure, to answer the different purposes of uniformity, fitness, and strength; it is in vain, therefore, that we seek its origin in the branches of trees, or in the intersection of Saxon or Grecian circles, or in the perspective of arches, or in any other accidental or fortuitous circumstances. The idea of the pointed arch seems clearly to have been suggested by the pyramid, and its origin must consequently not be attributed to accident but to ordination." That there may be some truth in this theory as regards the pyramidal grouping of these buildings we are not prepared to deny; but neither are we prepared to assert that the principles of Pointed architecture were therefore derived from the pyramids of Egypt. A contemporary has given the following somewhat amusing critique or illustration of the arguments brought forward by Mr. Murphy. "The pyramids of the Egyptians are tombs; the dead are buried in churches, and on their towers pyramidal forms are placed; consequently the pyramids of the towers indicate that there are graves in the churches; and as the pyramidal form constitutes the essence of the Pointed-arch style, and the pyramids of the towers are imitations of the Egyptian pyramids, the pointed arch is derived from the latter."

Some authors are anxious to discover the prototype in a framed timber building, but in what the resemblance exists it is somewhat difficult to determine. The late Mr. Barry attributes the Gothic style to the corruption of Greek and Roman art; Mr. Dallaway, to the desire of novelty and the caprice of the Italians. Lord Orford perceives the prototype in shrines for reliques, and observes, "it was a most natural transition for piety to render a whole church as it were one shrine:" he adds, "the Gothic style seems to bespeak an amplification of the minute, not a diminution of the great." Of the first two, Mr. Barry and Mr. Dallaway, we are inclined to think that both are, to a certain extent, correct, that Pointed architecture was a gradual development of the principle of the arch, and that taking it as a whole it does owe its origin to the Romanesque or Debased Roman, in a similar manner as the Roman was, in a degree, an imitation of the Grecian orders. That it owes its existence also—at least partially—to a desire for novelty, we are not in a position to contradict; but that it originated in Italy, we consider a matter of very great improbability. Dr. Whittaker, with whom Mr. Whewell somewhat agrees, is of opinion that pointed arches were known to, and practised by, the Romans during the empire, and originated in the intersection of cross-vaulting, examples of which are to be seen in the palace of Diocletian, at Spalatro. This suggestion is very worthy of consideration, and is, at least, a method by which the pointed arch was constructed, and that, too, accidentally, as it were, and in regular course. Vaulting, we know, was employed by the Romans, and, as a matter of necessity, cross-vaulting succeeded; and in some cases, by such a system, the pointed arch was described in the process. It is not unlikely that this circumstance should have been noted, and turned to practical advantage.

In connection with this should be considered an hypothesis, which has been held by Dr. Milner, Mr. Bentham, and several others, and which has met with a considerable share of public favour. Their supposition is that the pointed arch has been suggested by the intersection of semicircular arches. That interlaced arches were largely employed in Norman architecture as a means of decoration, there can be no question, and that, too, previous to the introduction of the pointed arch. That pointed arches were thus formed by the intersection is equally certain; nor is it at all improbable that the idea may have suggested itself thereby. Still this solution of the question is not unattended with difficulty or objection. In the first place, Dr. Milner is evidently incorrect in attributing its invention to Henry of Winchester, for it is known that the abbey of Clugny, in France, where he himself had been monk, was constructed with pointed arches; and therefore it is more reasonable to suppose that he had copied the idea from that building, rather than have invented it from his observation of the form in the intersection of semicircular arches. But laying aside this objection, which applies only to a peculiar and individual instance, and considering the theory simply on its own merits, we cannot consider it perfectly satisfactory; for it is somewhat improbable that the leading feature of the style should have had its origin in an accidental and unessential matter of detail; that a grand principle of construction should have been eliminated from a mere method of decoration.

Some authors have asserted that the style was invented by the Goths; whether the term Gothic formed the principal ground for such an assertion, it is not easy to determine; but it is very certain that no reason can be assigned for it which would have much greater weight than even this; for as regards this people, we have no reason to suppose that they possessed any style of architecture of their own, but rather the reverse; and although their king, Theodoric, did erect some buildings, they were constructed in the same style as the structures already existing in the country. It is true that Gibbon, in his Fall of the Roman Empire, states that the representation of Theodoric's palace at Verona, still extant on a coin, supplies the oldest and most authentic model of Gothic architecture; but in the work to which he refers for an engraving of this coin, we find none, indeed, of a coin, but one of a seal; the building represented on which is in a totally dissimilar style. One conclusive argument, however, against this theory, consists in the fact, that no building of this style has ever been known to exist which can claim so great an antiquity as that desired to be established by this statement; and, moreover, that the Gothic style was not introduced into Italy till a comparatively late period, when the Goths had been long since forgotten, and, indeed, never obtained a permanent footing in that country.

Other writers, with greater show of reason, have derived our knowledge of this style from the Saracens, supposing it to have been brought over by the Crusaders; nor is such an opinion taken up without good grounds, as it meets some grand difficulties which others are subject to, and yet is in many points unsatisfactory. As regards its chronology, this theory is fortunate; for it certainly was about the time of the Crusades that the style became prevalent; while yet, on the other hand, there is good evidence to suppose that one or two buildings of the kind existed in Europe before any of the Crusades had taken place. Another circumstance in its favour is, that it is the only supposition which will account satisfactorily for the simultaneous adoption of the style throughout Europe; a circumstance which, in all the other ideas which have been broached, forms an insurmountable objection to their acceptance. Whether the pointed arch was common in Saracenic buildings of the time, has been a matter of endless discussion; nor does it seem to have ever been satisfactorily proved or disproved, owing to a want of accurate information, and uncertainty as to the date of existing examples. There seems reason to believe that the pointed arch did exist, but was not so prevalent as some would have us suppose, or at least not in that form in which we find it in Europe; but whether pointed arches were to be found or not, is not a matter of such consequence as some would make it; nor does it of necessity prove anything; for we know that this form is to be found occasionally in ancient buildings of other countries, from which no one has attempted to deduce its introduction into Europe. But even supposing the styles to assimilate as regards the pointed arch, they agree in no other principle; in the buildings of the Saracens, we find neither cross-vaulted roofs nor arcades forming nave and aisles, nor clustered columns, nor crocketed pinnacles, nor towers, nor spires: their mosques are mostly square on plan, and are conspicuous chiefly for their bulbous domes, the nearest approach to the Gothic spire being found in the minarets. The idea of Gothic window-tracery is said to have been derived from the perforated fret-work of Arabian architecture; but if so, it must be recollected that such tracery is only to be found in the later examples when the style was fully developed; and, moreover, that we have a more satisfactory mode of accounting for its introduction. The above theory is supported by Warburton, Warton, Whittington, Lord Aberdeen, and Sir Christopher Wren; the last author, however, seems to prefer the supposition of the introduction of the arch into Europe by the Moors of Spain, but for this opinion there does not appear to be anything like the amount of evidence which may be produced in favour of the former. Other writers prefer to give the honour to the Visi-Goths of Spain, rather than to their Arabian invaders, but apparently with little better reason.

We have now taken a cursory glance at most of the leading theories respecting the introduction of the pointed style into Europe; but, as we have seen, not one of them is free from objections of considerable importance. One main objection, which affects nearly all of them, is this, that instead of the resemblance to the supposed prototype being, as it ought to be, the closest and most exact in the first stages of the style said to be derived from it, the resemblance is there least of all discernible. There is another objection, which touches every one of them—they all seem to rest satisfied when they have found, or thought they have found, the origin of the pointed arch, forgetting that this does not comprise the entire question at issue; their only inquiry appears to have been as to who were the inventors of the pointed arch, and not of pointed architecture. Now, there is a vast difference between the two questions, for the former embraces but a fractional part of the latter: a pointed arch is but a component part, and does not of itself constitute absolute Gothic architecture, although it is one and a very important characteristic of it. At the same time there are other peculiarities little less important; such are its principle of verticality; its lofty towers and spires; its cross-vaulting; its light and clustered pillars, with their slender shafts; its tracery, mullions, &c.; these are all necessary to make up a complete whole, and each and all ought to be considered in determining the origin of the style.

With such conflicting opinions as to the origin of the style, it is not to be expected that there should be any agreement as to what European country was the first to adopt it. The honour has been claimed for England, France, and Germany: the claim has been made for England by Sir Henry Englefield and Horace Walpole; but although the buildings of the style are to be found in this country in great number and variety, and are, on the whole, of greater purity, and in our opinion, of superior excellence, to those on the continent, still more satisfactory evidence has been elicited in favour of the latter. The late Mr. Hope, in his historical Essay on Architecture, has produced much able argument in favour of Germany; whilst Wetter, a writer of that country, contends that priority of date, as regards the adoption and development of the style, properly belongs to France. The claim has been made for Italy, but there seems to be little evidence to favour such an opinion; and Mr. Gally Knight, in his elaborate work on the ecclesiastical architecture of that country, gives good reason for disregarding it.

Notwithstanding the variety and antagonism of the opinions which have been started upon the subject, it is possible that more than one of them may be partially correct, because a variety of circumstances may have contributed more or less towards the same end; but we must confess that the change of style has not as yet been sufficiently accounted for. Whether the question will ever be determined beyond dispute, may fairly be questioned; nor do we know that any substantial advantage would be gained thereby. It is true, we are every day advancing to a more perfect knowledge of the style, and, in the course of our inquiries, some unexpected light may be thrown upon the subject; but be this as it may, it is certain that it will be much more advantageous to continue our practical study of the style, than to turn aside for the mere purpose of speculating on its origin.

POINTS, *Proportion of Mathematical.* It is a current maxim, that all infinities, whether infinitely great or infinitely small, are equal; yet is the maxim false in both cases. Dr. Halley shows several infinite quantities, which are in a finite proportion to each other; and some infinitely greater than others.

The like, the honourable Mr. Roberts shows of infinitely small quantities, viz., mathematical points. He demonstrates, for instance, that the points of contact between circles and their tangents, are in a subduplicate proportion to the diameters of the circles; that the point of contact between a sphere and a plane is infinitely greater than that between a circle and a tangent; and that the point of contact in spheres of different magnitudes are to each other as the diameters of the spheres.

POLISHING, the art of giving a gloss or lustre to a thing; particularly a precious stone, marble, glass, a mirror, or the like.

For grinding and polishing steel, the grindstones used are made to revolve, either vertically or horizontally, with a velocity so great as to describe sometimes as much as sixty feet in a second. The steel is also, in some cases, drawn backwards and forwards horizontally on a circular surface; and in order that the action may be equally distributed throughout the surface, it is allowed to revolve on an axis by means of the friction; its motion being confined to one direction by the action of a catch. Various substances, chiefly of mineral origin, are also used, on account of their hardness, as intermediate materials, for grinding and polishing others. These are diamond-dust, corundum, emery, tripoli, putty, glass, sand, flint, red oxyde of iron, or crocus martis, and prepared chalk. These are sometimes applied in loose powder, and sometimes fixed on wood, leather, or paper. Cuttle-fish bone and seal-skin are furnished by the animal kingdom; and Dutch rushes by the vegetable; these are employed chiefly in polishing wood or ivory. Marble is made smooth by rubbing one piece on another, with the interposition of sand; the polishing-blocks are sometimes caused to revolve by machinery in a trough, in which the marble is placed under water, and are drawn at the same time gradually to and from the centre; or the slab itself, with the frame on which in rests, is drawn slowly backwards and forwards, while the blocks are working in it. Granite is polished with iron rubbers, by means of sand, emery, and putty; but it is necessary to take care, during the operation, that the water, which trickles down from the rubbers, and carries with it some of the iron, may not collect below the columns, and stain them; an inconvenience which may be wholly avoided by employing rubbers of glass.

POLLARD, in planting, a term applied to a tree that has been frequently polled or lopped, and its top taken off, or headed down to the stem, for the purpose of fire-wood, or small poles for hurdle-wood, and other similar uses, as well as for hop-poles, &c. It is a term most commonly in use in the southern and eastern districts of the kingdom. But though much wood of this small sort may be provided in this way, the practice has been highly reprobated, not only as being destructive of good timber, but as a barbarous system which disfigures, and renders the appearance of the country disagreeable.

POLYCLETUS, a celebrated sculptor of antiquity, a native of Sicyon, who flourished about the year 430 B.C. He was supposed to have carried the art to the highest degree of perfection, at least as far as the excellence of single figures could go. One of his figures, representing a life-guard of the king of Persia, was performed in such exact proportions that it was called *the rule*, and artists came to study it as a model. He made the statue of a boy, which was estimated at a hundred talents (nearly 20,000*l.* sterling). The emperor Titus had two naked boys playing at a game, by his hand, which was considered as a perfect performance. It was peculiar to him, that he formed almost all his figures supported on one thigh, which made them appear deficient in variety.

POLYCHROMY (Greek πογυς and χρῶμα, colour), the art of painting in positive colours, either on flat surfaces or sculptured figures. It was much used by the Egyptians in their edifices, and they were probably the first to introduce such ornament. The Greeks adopted the same method of decoration, and improved upon it; as also did the Romans. There are still existing many specimens of the application of this art in the ruins of Herculaneum and Pompeii, the colours still retaining their brilliancy. The Arabs excelled in this art, as is evidenced by their edifices, which owe much of their peculiar beauties to the aid of colour. The interiors of their edifices are completely covered with polychromatic decoration, such parts of the walls as were not covered with actual painting being lined with coloured and glazed tiles. Polychrome was also in general use amongst our mediæval architects, and the grand effect of their buildings was considerably heightened by such ornamentation. We regret that even in the present day any prejudices should be found to prevail against its introduction into our ecclesiastical buildings; we have, however, more than one of our recent churches in which such assistance has not been despised; and we feel sure that the contrast between such and the cold bare walls of the majority, will at length prevail against every prejudice. We are glad to be able to allude, also, to the restoration of this art to its proper position, in the instance of a public building such as the British Museum, and we trust that its success there will lead to its general adoption.

POLYFOIL, an ornament prevalent in Gothic architecture, formed of a moulding, disposed in a number of segments of circles, producing projecting points at their intersections, termed cusps: thus we have *trefoil*, consisting of three cusps; *quatrefoil*, of four; and *polyfoil*, of any number above four.

POLYGON (from πολυγωνος, formed from πολυς, *many*, and γωνια, *angle*) a multilateral figure, or one whose perimeter consists of more than four sides and angles.

If the sides and angles be equal, the figure is called a *regular polygon*. For *similar polygons* see SIMILAR.

Polygons are distinguished according to the number of their sides. Those of five sides are called *pentagons;* those of six, *hexagons;* those of seven, *heptagons*; those of eight, *octagons*, &c.

POLYGONS, *General properties of.* Euclid demonstrates the following:—1. That every polygon may be divided into as many triangles as it hath sides. 2. The angles of any polygon, taken together, make twice as many right angles, abating four, as the figure hath sides. Thus, if the polygon hath five sides, the double of that is ten; whence, subtracting four, there remains six right angles. 3. Every polygon, circumscribed about a circle, is equal to a right-angled triangle, one of whose legs is the radius of the circle, and the other the perimeter, or sum of all the sides of the polygon. Hence every regular polygon is equal to a right-angled-triangle, one of whose legs is the perimeter of the polygon; and the other a perpendicular, drawn from the centre to one of the sides of the polygon.

Hence, also, every polygon circumscribed about a circle is larger than it; and every polygon inscribed is less than the circle. The same likewise appears hence, that the thing containing is ever greater than the thing contained. Hence, again, the perimeter of every polygon circumscribed about a circle, is greater than the circumference of that circle; and the perimeter of every polygon inscribed, less; whence it follows, that a circle is equal to a right-angled triangle, whose base is the circumference of the circle, and its height the radius; since this triangle is less than any polygon circumscribed, and greater than any inscribed.

Nothing therefore is wanting to the quadrature of the circle, but to find a right line equal to the circumference of a circle.

The subjoined table gives the areas of polygons and their perpendiculars from the centre to one of the sides, the side being supposed equal to unity.

Number of sides.	Area.	Perpendiculars.
3	.433013	.2886751
4	1.000000	.5000000
5	1.720477	.6881910
6	2.598076	.8660254
7	3.633912	1.0382617
8	4.828427	1.2071068
9	6.181824	1.3737387
10	7.694209	1.5388418
11	9.365640	1.7028437
12	11.196152	1.8660254

To apply this rule generally, multiply the square of the side of the given polygon by the number found in the table of areas for a polygon, having the same number of sides as that whose area is required.

POLYGRAM, (Greek, πολυς, and γραμμα,) in geometry, a figure consisting of many lines.

POLYHEDRON, or POLYEDRON (from πολυεδρον, formed from πολυς, *many*, and ἑδρα, *side*,) a body comprehended under many rectilinear sides, or planes.

If the sides of the polyhedron be regular polygons, all similar and equal, the polyhedron becomes a regular body, and may be inscribed in a sphere; that is, a sphere may be drawn round it, so that its surface shall touch all the solid angles of the body.

POLYHEDROUS FIGURE, a solid contained under, or consisting of, many sides. *See* POLYHEDRON.

POLYSTYLE, (Greek, πολυς, *many*, and στυλον, *a column*,) a term applied to buildings which are surrounded by a multitude of columns.

POMEL, a boss or knob terminating a conical or dome-shaped roof.

POMPEII, an ancient city of Naples, overwhelmed in the first century by the same disastrous catastrophe which destroyed *Herculaneum.* It is said to owe its name to the triumphant pomp in which Hercules led his captives along the coast after his conquest of Spain; it was probably situate on an arm of the sea, and served as a port for the inland towns; which inlet of the sea has been filled up by successive eruptions, besides that which destroyed the town. It is about fourteen miles from Naples, on the road to Nocera. From Naples to Torre del Greco, the highway is almost a street, so close are the villas, villages, and towns to each other. As the road runs along the coast, and at the foot of Vesuvius, every break gives on one side a view of the bay, on the other of the mountain. Torre del Greco still presents, in its shattered houses, half-buried churches, and streets almost choked up with lava, a melancholy instance of the ravages of the eruption. The depth of the destructive torrent is, in some places, twenty-five feet, so that the entrance into several houses is in the second story, and into one church through the great window over the western door. Some edifices were entirely destroyed: others were surrounded, incrusted, and filled with lava, and may perhaps give a very accurate idea of the state of Herculaneum at the time of its destruction. The town of Torre del Greco was supposed, by Cluverius, to occupy the site of Herculaneum, because the distances nearly corresponded; and inscriptions have been found that seem to corroborate this conjecture. In fact, making allowances for the extent of the ancient town, there is little more than three-fourths of a mile difference, so that its name and jurisdiction extended probably much farther. In the vicinity of this place are the ruins of ancient barracks, which were the quarters of a legion of Roman soldiers, and behind the barracks are two theatres, one small, and supposed to have been covered, the other large; both these edifices were lined with marble, beautifully paved, and in every respect highly-finished. These theatres are exactly of the same form as the Teatro Olimpico of Palladio at Verona; having, like it, a narrow proscenium, and three entrances, one large and the other two less, to the stage, from the scenery behind. These theatres, when discovered, were nearly entire, but though they have been stripped of all their decorations, they still retain all their great characteristic features. Behind the little theatre is a temple of Isis, occupying an angle formed by two streets. Some have supposed that oracles were issued from this temple, and have declaimed against the priestcraft that was practised here; but it does not appear that oracles were ever given at Pompeii, as this was a privilege reserved to the ancient and more renowned temples; besides, oracles had everywhere ceased before this edifice, or temple, if it may be so called, was erected; and, moreover, the entrances into it are too public, and the whole contrivance too gross to dupe the dullest peasant, much less the polished inhabitants of Pompeii. In this building there are niches, where various statues of Venus, Priapus, &c., were found, which, with the furniture, marble, and pictures, were transported to Portici. Behind this temple, on one side, is a court surrounded with a portico, supported by sixteen Doric pillars, and, from a sort of pulpit on one side, it may be inferred, that it was intended for some public assembly. Another court follows with a similar portico, and communicates with the grand portico of the theatre supported by more than sixty stone pillars of the Doric order, but, in proportion, bordering upon Tuscan. Near this portico lie several fragments of columns of a much larger size, and of bolder proportion; which, perhaps, belonged to the temple of Neptune, and may have been thrown down and laid in their present situation by the earthquake, which nearly destroyed this city a few years previous to the eruption that buried it finally. The most perfect and most curious object that has yet been discovered is a villa at a little distance from the town. It consists of three courts; in the first and largest is a pond, and in the centre an ædicula, or little temple: there are numerous apartments of every description, paved in mosaic, coloured and adorned with various paintings on the walls, all in a very beautiful style. The baths in this villa seem to have been objects of particular attention.

Cicero's Pompeianum stood in the neighbourhood of this town, and possibly on this very spot. It was a favourite retreat, much frequented by Cicero and his friends. The houses at Pompeii are on a small scale, generally of one, sometimes of two stories; the principal apartments are always behind, enclosing a court, with a portico round it, and a marble cistern in the middle; two had glass windows, in the others shutters only were used; the pavements are all mosaic, and the walls are stained with mild colours; the decorations are bassorelievos in stucco, and paintings in medallions. Marble seems to have been common. An extent of about 500 feet of the town wall has been completely cleared. It is from eighteen to twenty feet high, twelve thick, and fortified at short distances with square towers. In the main street, passing in front of the temple of Isis, has been discovered the portico of the theatre. Near the same spot, ten feet below the level of the street, was found a human skeleton, and immediately beneath it a large collection of gold and silver medals in the finest preservation, chiefly of the reign of Domitian. Under a superb portico, in the quarter of the tombs, a number of skeletons have been discovered, and among them those of a female and several children. Three finger-rings and several ear-rings were found among the bones. Among the vases discovered, there were two which were full of water, with a small quantity of ashes at the bottom. In one the water was limpid and odourless; in the other it was of a brownish tinge, and had the taste of lye.

POMPEION, a stately edifice at Athens, in which were kept the sacred utensils made use of at festivals, and where all things necessary for the solemn processions were prepared. It stood at the entrance of the old city, which looked towards Phalerum, and was adorned with many statues of the Athenian heroes. This word was likewise used for any utensils employed on these occasions.

POMPEY'S PILLAR. *See* PILLAR.

POPPY HEAD, a carved ornament used as a terminating ornament at the top of the standards of ancient church-benches. The designs of such ornaments are not confined to one particular form, as the name might appear to signify, but were most frequently in the form of a finial composed of foliage of various kinds, grotesque figures, crests, and various other devices.

PORCH, (from the Latin, *porticus*) a kind of vestibule, supported by columns, much used at the entrance of the ancient temples, halls, churches, and many other buildings. *See* ATRIUM.

In the ancient architecture, a porch was a vestibule, or a disposition of insulated columns, usually crowned with a pediment, forming a covert place before the principal door of a temple, or court of justice.

When it had four columns in front, it was called a *tetrastyle;* when six, *hexastyle;* when eight, *octostyle;* when ten, *decastyle*, &c. Vitruvius calls it *pronas;* Pollux *προδομος*, *prodomos:* when finer than ordinary, the ancients call it, also, *propyleum.*

Porches are almost universal in churches, and are usually on the south side, and in the second bay from the west, but the position is frequently determined by the circumstances of the locality.

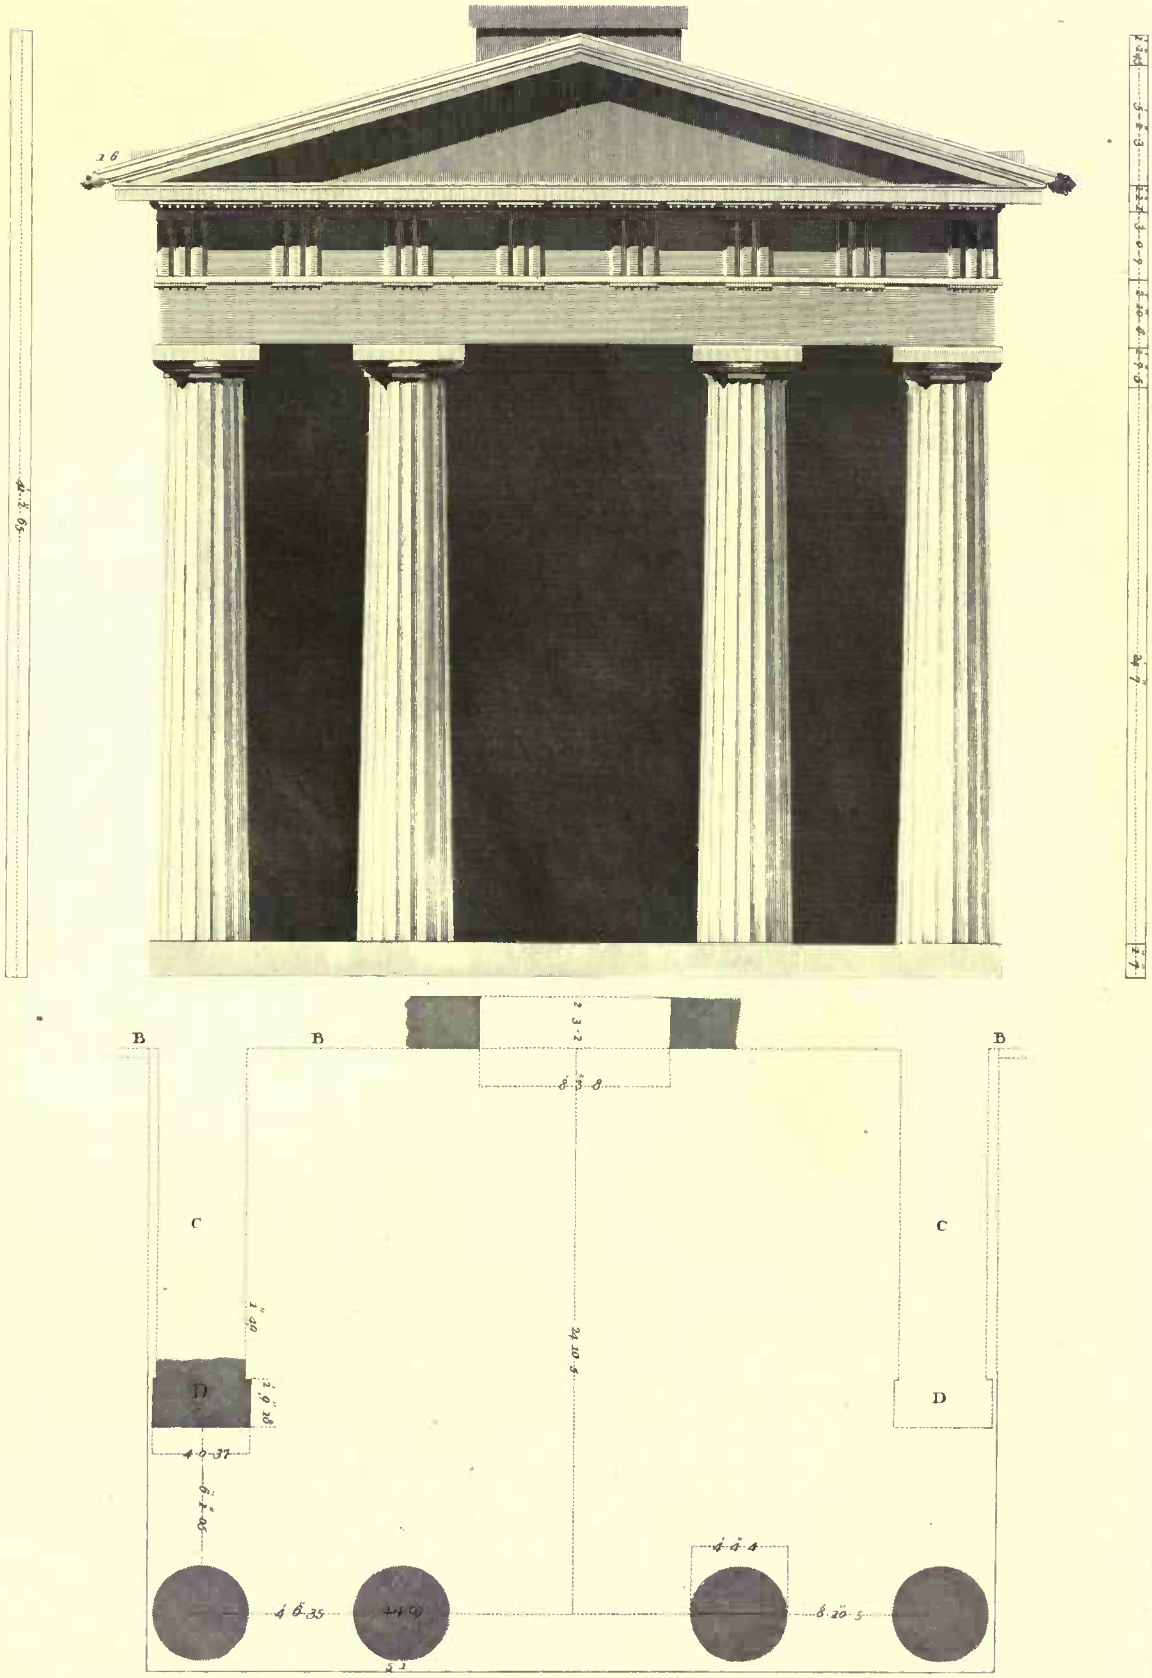
Norman porches are frequently of large dimension, and highly enriched with the ornament peculiar to that period; many such have been preserved in buildings which in other respects have been entirely rebuilt in a later style. Many fine porches of this kind are to be found at Malmesbury, Sherbourne, and Southwell, the last having a room over it; there is also a very fine one at the Temple Church, London. Early English specimens occur at Wells, Salisbury, Lincoln, and Westminster; and the examples in this as well as in the Norman style, are almost invariably of stone. Decorated and Perpendicular porches are frequently of wood, sometimes entirely closed at the sides, but more often of open work, and with ornamental barge boards at the end of the roof; many very beautiful specimens are to be found of both styles.

A few Galilee porches exist in some of our cathedrals. *See* GALILEE, and CATHEDRAL, also CHURCH.

PORPHYRY, (from *πορφυρος*, *purple*) a denomination that distinguishes a large class of primitive rocks, composed of one substance, in the form of grains, or crystals, imbedded in another, consisting most commonly of a compact paste, as its basis. The base is clay-stone, horn-stone, compact felspar, pitch-stone, pearl-stone, or obsidian; the implanted grains, or crystals, are of quartz, or felspar. Of porphyry there appear to be two formations; the most ancient consists principally of horn-stone and felspar porphyry, and the most recent are of clay, pitch-stone, pearl-stone, and obsidian porphyry. The porphyritic formation is not very distinctly separated from the other rock formations which accompany it, nor is its rank among the primitive mountains, with regard to antiquity, very clearly ascertained. The mountains of porphyry are not stratified, and never enclose beds of other substances. Its texture is commonly compact, but it occasionally occurs in schist-stone. It is not very rich in mineral veins; the clay porphyry is the most rich. The mines of Schweitz, in Hungary, which are of this description, are found in this species of rock.

Some writers have reckoned five species of rocks belonging to the proper porphyritic formation, which are as follows: viz., 1, *Horn-stone porphyry*, the base of which, being horn-stone, is generally red or green, with a conchoidal, or splintery fracture; and enclosing crystals of quartz and felspar. This is also distinguished, says Kirwan, by its hardness, slight transparency, and want of lustre; it is fusible without difficulty. Sometimes the felspar is decayed, and sometimes

PORTICO.



PORTICO.

The Ionic Temple on the Ilissus.

Drawn . by. P. Nicholson . Eng.d by. R . Thew.

also the horn-stone, whilst the quartz and hornblende remain entire: the whole thus acquires the appearance of indurated volcanic ashes, though the quartz might prove the contrary: if the felspar alone be decayed, the horn-stone will appear porous, and may be taken for lava. Its transitions are into granite and sand-stone. 2. *Felspar porphyry*, the base of which is commonly red compact felspar, enclosing crystals of felspar and quartz. 3. *Sienitic porphyry*, which differs from the preceding in containing crystals of hornblende in addition to the other ingredients. 4. *Pitch-stone porphyry*, the base of which is pitch-stone, either red, green, brown, gray, black, or yellow, of various shades, having generally many colours at once in the same specimen. According to Kirwan, this porphyry has the following characters: lustre, greasy, 2.1: transparency, 2.1: fracture, imperfectly conchoidal: hardness, 8, 9, 10: the felspar often blue: the fracture of some is slaty, and colour yellowish-gray: lustre, scarcely 1; transparency, 1; hardness, scarcely 9; specific gravity, 2.452. 5. *Clay porphyry*, the base of which is indurated clay, passing into horn-stone; generally of a reddish colour, and containing crystals of quartz and felspar. The colour of this porphyry, belonging to Kirwan's argillaceous porphyries, is generally some shade of gray, or greenish-gray, or brown, or blackish or reddish-brown, or isabella-yellow. Lustre and transparency, 0; fracture, earthy; hardness, from 5 to 7; sometimes adhering to the tongue.

PORTABLE BRIDGE. *See* Bridge.

PORTAIL, the face or frontispiece of a church, viewed on the side in which is the great door. Also, the great door, or gate itself, of a palace, castle, &c.

PORTAL, (perhaps a diminutive of the French, *porte*, door, gate,) a term used for a little square corner of a room, cut off from the rest of the room by the wainscot; frequent in ancient buildings, but now disused.

Portal is sometimes also used for a little gate, *portella*; where there are two gates of a different size: also, a kind of arch of joiner's work before a door.

PORT-CRAYON, (French) a pencil-case, an instrument serving to enclose a pencil, and occasionally also used as a handle for holding it. It is usually four or five inches long, and contrived so that the pencil may be slid up and down by means of a spring and button. Its outside is filed into eight sides or faces, on which are sometimes drawn the sector lines: its inside is round; sometimes it is made round or cylindrical, both without and within, and has its length divided into inches and parts of inches.

PORTCULLIS, (from the French *portecoulisse*) called also *herse* and *sarrasin*, an assemblage of several great pieces of wood, laid or joined, across one another, like a harrow, and each pointed at the bottom with iron.

These were formerly hung over the gateways of fortified places, to be let down in case of a surprise, when the enemy should come so quick as not to allow time to shut the gates. But now the orgues are more generally used, as being formed to answer the purpose better.

PORTICI, a small town of Italy, about six miles from Naples, on the sea-shore, at the foot of Vesuvius. Its principal ornament is a royal palace. Under this town and palace lies buried, at the depth of 70 feet under accumulated beds of lava, the city of Herculaneum, the first victim of the fires of Vesuvius. The Prince d'Elbœuf, after the first discovery was made by accident, purchased the spot, and continuing the excavations that had been begun, discovered various statues, pillars, and even a whole temple of the finest marble, adorned with statues. Upon the interposition of the Neapolitan government, the work was stopped for twenty years; however, the excavations were occasionally continued, and a basilica, two temples, and a theatre, were successively discovered, and stripped of their numerous pillars and statues. Streets were observed, that were paved and flagged on the sides, and private houses, and even monuments, explored. A prodigious number of statues of bronze, of different sizes, pillars of marble and alabaster, and paintings and mosaics, many of them entire and in high preservation, others fractured and damaged, have been drawn from the edifices of this subterraneous city, and give a high idea of its opulence; to these we may add many species of ornaments used in dress, of weapons and armour, of kitchen utensils and domestic furniture, of agricultural and chirurgical instruments. The theatre is at present the only part open to inspection. Of all the articles drawn from Herculaneum, the most curious and valuable are the MSS. Of these many dissolved into dust as soon as they were exposed to the air: while others, though scorched, or rather burnt, resist the action of that element. The number of the latter, it is conjectured, may be about 1800.

PORTICO, (from the Latin *porticus*, a gate) a kind of gallery on the ground; or a piazza encompassed with arches supported by columns. The roof is usually vaulted, sometimes flat. The ancients called it *lacunar*. *See* Lacunaris.

The most celebrated porticos of antiquity were those of Solomon's temple, which formed the atrium, or court, and encompassed the sanctuary: that of Athens, built for the people to divert themselves in, and where the philosophers held their disputes and conversations; which occasioned the disciples of Zeno to be called *stoics*, from the Greek *ϛοα, porticus*; and that of Pompey at Rome, consisting of several rows of columns.

Plate I.—Plan and elevation of the Doric portico at Athens.

Plate II.—Portico of the Ionic temple, on the Ilissus, at Athens.

Porticos were numerous buildings in Rome for the convenience of the public in sultry or inclement weather; distinguished from those which formed the vestibules, or which decorated the entrance of temples. Some of the principal were the *porticus duplex*, so called from its double row of pillars, erected by Cneius Octavius, near the Circus Flaminius, after the defeat of Perses; it was of the Corinthian order, and ornamented with brazen capitals; the walls were decorated with paintings representing the achievements of the founder. The *portico of Pompey*, annexed to his theatre, was supported by 100 marble columns; opened on both sides into groves of plane-trees, was refreshed by fountains and streams, and, in summer time, was the favourite resort of the young, the gay, and the gallant. Augustus erected several porticos; and, prompted by his example, many of his most distinguished and opulent friends vied with each other in similar works of magnificence. Among the former were the porticos of Caius and Lucius, with a basilica annexed to it; that of Octavia, which rose near the theatre of Marcellus, and contributed not a little to its beauty as well as convenience; that of Livia, near the Roman Forum. This latter was ornamented with a collection of ancient pictures, and shaded by a vine of prodigious luxuriance. Ovid alludes to it in his usual lively manner. But this, and every edifice of the kind prior to this æra, was eclipsed by the splendour of the *Palatine* portico, dedicated to Apollo. It was supported by pillars of Numidian marble, enlivened with exquisite paintings and statues, and emblazoned with brass and gold. It enclosed the library and temple of Apollo, so often alluded to by the writers of the Augustan age, and was deservedly ranked among the wonders of the city. It is described by Propertius, lib. xi. 81. Another portico, erected by this emperor, was called *Ad Nationes*, from the statues with which it was furnished, representing various nations in their respective habits. It was, perhaps, still more remarkable for a statue of Hercules, lying neglected on the ground, though it had been brought from Carthage, and was that to which the Carthaginians were accustomed to offer human victims. The *Porticus Septorum* was finished, or repaired, by Agrippa, as Pliny says, and enclosed not the *Septa Tribata Comitii*, where the people assembled to vote, but *Diribitorium*, or place where the legions were mustered and paid. These edifices were all of marble, and the latter, in particular, unusually magnificent. Agrippa also built and gave his name to another portico, which, as some suppose, was connected with the present portico of the Pantheon, and carried around it. But as he had erected *Thermæ*, and other noble fabrics near that edifice, it is more probable that his portico enclosed the whole, and united them together in one grand circumference. That it was extensive, is evident from Horace, who represents it as a public walk, much frequented. The materials were, as in all Agrippa's works, rich marbles, and the ornaments, paintings and statues. The portico of *Hercules*, or of *Philippus*, was so called because it was rebuilt by the latter at the instigation of Augustus, and dedicated to Hercules, whose temple it enclosed, under the appellation of *Musagetos*, a leader of the Muses. It was erected solely for the ornament of the city, and of course was decorated with an unusual profusion of splendid objects; the paintings of Apelles, Zeuxis, and Antiphilus, forming part of its furniture. Several porticos took their names from the temples to which they were annexed, and seem to have formed either vast squares or courts before, or immense galleries round their respective temples, thus detaching them from ordinary buildings, and giving them a distinguished and solitary grandeur. The porticos of *Quirinus* and *Europa*, are mentioned by Martial as fashionable places of resort, and must consequently have been very spacious. That of *Isis* was remarkable, not only for paintings but mosaics.

The approach to the curiæ, the basilicæ, and the forums, were generally by porticos; several ranges of porticos led to the capitol, and lined the sides of the declivity; the Campus Martius was surrounded by an uninterrupted colonnade; almost every emperor distinguished himself by the erection of a new edifice of the kind; and Nero is said, by Suetonius, to have lined the streets of Rome (those probably which he himself had rebuilt) with a continued portico. Several porticos were erected by later emperors, of astonishing extent; such were that of Gallienus, extending nearly two miles along the Via Flaminia; and that of Gordian in the Campus Martius, which was a mile in length, and formed of one range of pilasters and four of columns, opening upon plantations of box, cedar, and myrtle.

PORTLAND STONE, (*Saxum Arenarium Portlandicum*, of Da Costa, and *Psadurium Hebes*, *Albidum*, *Laxius*, of Hill), an alkaline sand-stone, of a dull whitish colour, heavy, moderately hard, of a somewhat flat texture, and composed of a large roundish grit, cemented together by an earthy spar, and intermixed with numerous glittering spangles of pure spar; the grit splits in the cutting of the stone, so that it is capable of being brought to a surface very smooth and equal; it will not strike fire with steel, and burns to a slight ashen hue. The Portland stone belongs to the third variety of the compact limestone, under the calcareous genus, whose fracture is earthy, according to Kirwan's arrangement. Its specific gravity is 2.461. There are vast quarries of it in the island of Portland, in Dorsetshire, whence its name. It is brought from thence in large quantities to London, and is much used in building. This and all similar sorts of stone, composed of granules, and not of a laminated texture, will cut and rive in any direction, as well in a perpendicular, or in a diagonal, as horizontally and parallel to the site of the strata. For this reason they have obtained the name of *free-stone*. This stone is very soft when it comes out of the quarry, works very easily, but becomes in time very hard and durable.

POSITION, in architecture, the situation of a building with regard to the points of the horizon. Vitruvius directs the position of a building to be such, that the four corners may point directly to the four winds.

Position, in geometry, a term sometimes used in contradistinction to *magnitude*. Thus a line is said to be *given in position* (*positione data*) when its situation, bearing, or direction, with regard to some other line, is given: on the contrary, a line is *given in magnitude*, when its length is given, but not its situation.

Sir Isaac Newton shows how to find a point, from which three lines, perpendicularly let fall, to three other lines given in position, have any given ratio, &c.

POST, in building, a large piece of timber, placed upright in houses, &c. The corner posts are called the *principal*, or *fencing* posts; the posts framed between the principal posts for strengthening the roof of a house are called the *queen-posts*. An excellent method to preserve posts from rotting, is to burn the outside of the ends that are to be set in the ground to a coal.

Post, *Crown*, or King-Post. *See* Crown-Post.

Post and Paling, a kind of close wooden fence, constructed by means of posts set into the ground, and pales nailed to rails between them.

This sort of fence can seldom be had recourse to for common farm-purposes, except about the buildings or home-stalls. The only circumstances concerning it, which seem to require any notice in this place, are, that the posts, whether of rough or sawn timber, should be charred, or burnt, in a superficial manner, in the parts which are designed to be set in, or nearly on a level with the surface of the ground, in order to prevent their decay in these places. The posts should also be well and firmly put into the earth; and the sawn rails, whether for close or open paling, should be cut triangular-wise, by slitting square scantlings diagonally. The pales of open paling should be cut in the same manner; the broadest sides of the pales being firmly nailed against the broad flat sides of the rails, at such distances from each other, and of such height and strength, as the given purpose may stand in need of, or require.

Post and Railing, another sort of open wooden fence, often used for protecting young quick-hedges, consisting of posts and rails, &c.

These sorts of fences, or protections, should likewise have constantly the parts which are set into the ground, and the rails, prepared in the same manner as directed above.

POSTERN, a small doorway in the rear of a building, more particularly applied to those of castles, which were reserved for private communication with the exterior.

POSTICUM, the postern-gate, or back-door, of any fabric, for private entrance.

POSTIQUE (from the Italian *posticcio*, *added*;) an ornament of sculpture is said to be *postique*, when it is superadded after the work itself is done. A table of marble, or other matter, is also said to be *postique*, when it is incrustated in a decoration of architecture, &c.

POSTSCENIUM, or Parascenium, among the Romans, was a place behind the theatre, where the actors withdrew to dress, undress, &c.

POT-METAL, that kind of stained glass into which the colours are incorporated while in a state of fusion.

POWDERINGS, a term sometimes used for devices serving to fill up vacant spaces in carved works; as also in escutcheons, writings, &c.

POWER, in mechanics, a force, which, being applied to a machine, tends to produce motion; whether it actually produces it or not. In the former case, it is called a *moving* power; in the latter, a *sustaining* power. If the power be a man, or a brute, it is called an *animate* power; if the air, water, fire, gravity, or elasticity, an *inanimate* power. *See* FORCE.

POWER, is also used for any of the six simple machines, viz., the *lever*, *balance*, *screw*, *axis in peritrochio*, *wedge*, and *pulley;* which are particularly called the *mechanical powers.*

POZZOLANA. *See* PUZZOLANA.

PRACTICE. See CROSS MULTIPLICATION.

PRAXITELES, a celebrated sculptor of antiquity, born in Magna Græcia, who flourished about the year 364 B. C. He excelled particularly in the working of marble, and was the author of some of the most famous statues noticed by ancient writers; among these were two of Venus, one clothed and the other naked. The first was purchased by the Coans, who preferred it as the most decent. The Cnidians took the other, which was so exquisitely beautiful, that many persons took a voyage to the island for the sole purpose of seeing it. Praxiteles was deeply enamoured of the famous courtezan Phryne, of whom he made several statues, one of which was erected at Delphi. Many of his performances were in the Ceramicus at Athens; among the rest the statues of Harmodius and Aristogiton, which Xerxes carried away, and Alexander afterwards restored. Many were extant at a later period in Rome. His most noted works were in marble, but he cast many statues in metal, which, as well as those of marble, were greatly admired. He had a son, Cephissodorus, who inherited his skill and fame.

PREACHING CROSS, a cross erected in the highway for the purpose of preaching, as implied by the adjective.

PRECEPTORY, a subordinate or branch establishment of Knights' Templars, under the management of a *preceptor;* the same as the *commandery* of the Knights' Hospitallers.

PREPARATION, (from the Latin, *præparatio*), in mathematics, one of the parts or branches of a demonstration.

If it be a proposition in geometry that is to be demonstrated, the preparation consists in certain lines to be drawn in the figure: if a proposition in arithmetic, in some computation to be made, to obtain more easily the demonstration.

PRESBYTERY, that part of the church in the chancel set apart for the officiating priests.

PRESERVING OF TIMBER. *See* TIMBER.

PRICE BOOK, a book containing the prices of labour and materials, of the various articles employed in building. See *The Universal Price Book*, with regard to labour only, under the articles Carpentry and Joinery.

PRICK-POST, or QUEEN-POST. *See* Post.

PRIME FIGURE, in geometry, one that cannot be divided into any other figures more simple than itself.

Such is a triangle among planes; and the pyramids in solids. For all planes are made of the first, and all bodies, or solids, are compounded of the second.

PRIMING, among painters, the laying on of the first colour.

PRINCIPAL BRACE, a brace immediately under the principal rafters or parallel to them, in a state of compression, assisting with the principals to support the timbers of the roof.

PRINCIPAL POINT, a point in the perspective plane, upon which a line drawn from the eye, perpendicular to the plane, falls. This point is in the intersection of the horizontal and vertical plane; and is also called the *point of sight*, and *point of the eye. See* PERSPECTIVE.

PRINCIPAL RAFTERS, two inclined timbers in a roof, either meeting each other in the middle, or the ends of a beam in the middle of the roof, the lower ends resting on the ends of the tie-beam: their office is to support the roof.

PRINCIPAL RAY, that which passes perpendicularly from the spectator's eye to the perspective plane, or picture. Whence the point where this ray falls on the plane is, by some, called *the principal point*, which other writers call *the centre of the picture*, and *the point of concurrence.*

PRIORY denotes a society of religious, the superior of which was denominated a prior, or prioress; and of these there were two sorts; as where the prior was chief governor, as fully as any abbot in his abbey, and was chosen by the convent; such were the cathedral priors, and most of the Austin order, and where the priory was a cell subordinate to some great abbey, and the prior was placed and displaced at the will of the abbot.

PRISM, (from πρίσμα, something sawn, or cut off) in geometry, an oblong, or solid body, contained under more than four planes, and whose bases are equal, parallel, and alike situate.

PRISMOID, (formed of πρίσμα and εἶδος) a solid figure, having for its two ends any dissimilar parallel plane figures of the same number of sides, and all the upright sides of the solid trapezoids. If the ends of the prismoid be bounded by dissimilar curves, it is sometimes called a *cylindroid.*

To find the solidity of a prismoid, the general rule is: To the sum of the areas of the two ends, add four times the area of a section parallel to, and equally distant from both ends: multiply the last sum by the height, and one-sixth of the product will be the solidity. Or, if the basis be dissimilar rectangles, take two corresponding dimensions, and multiply each by the sum of double the other dimension of the same end, and the dimension of the other end corresponding to this last dimension: then multiply the sum of the products by the height, and one-sixth of the last product will be the solidity.

PRISON, an edifice erected for the confinement of debtors and criminals, until they be discharged or convicted. The principal properties in the construction of a prison, are those of strength and convenience. Strength is of the utmost consequence, in order to prevent the escape of the prisoners; and convenience, to promote their health; to have the apartments of their due size and arrangement, according to the different species of criminals, and to be handy in respect of the keeper.

Before the philanthropic labours of the celebrated Howard had made known to the world the dreadful condition of the public prisons of that day, such places were hardly fitted for the habitations even of the lowest animals, much less for the confinement of human beings. But his exertions having called public attention to the subject, a gradual amelioration has taken place, not only in the construction but in the whole system of prison discipline; until it may be doubted whether modern philanthropy is not running into the opposite extreme, and rendering abodes intended for the punishment of the vicious, superior to those attainable by the unfortunate and the poor.

It would be impossible to point out with any degree of minuteness the successive steps in prison improvement; nor is it, perhaps, strictly within the objects of this work to do so; it will be sufficient to describe one or two modern buildings adapted for the confinement of criminals, as specimens of the great advance made within the last few years.

Before doing so, however, it may not be uninteresting to give Mr. Howard's recommendations relative to the situation and arrangements of a prison, by way of showing the ideas entertained at that time on the subject.

"A county gaol," he says, "and indeed every prison, should be built on a spot that is airy, and, if possible, near a river, or brook. I have commonly found prisons situate near a river, the cleanest and most healthy. They generally have not (and, indeed, could not well have) subterraneous dungeons, which have been so fatal to thousands: and, by their nearness to running water, another evil, almost as noxious, is prevented, that is, the stench of sewers.

"I said, a gaol should be near a stream; but I must annex this caution, that it be not so near as that either the house or yard shall be within the reach of floods. This was so little thought of at Appleby, in Westmoreland, when their new gaol was first building, that I saw the walls marked from nine inches to three feet high by floods.

"If it be not practicable to build near a stream, then an eminence should be chosen: for as the wall round a prison should be so high as greatly to obstruct a free circulation of air, this inconvenience should be lessened by rising ground, and the prison should not be surrounded by other buildings, nor built in the middle of a town or city.

"That part of the building which is detached from the walls, and contains the men-felons' ward, may be square, or rectangular, raised on arcades, that it may be more airy, and leave under it a dry walk in wet weather. These wards over arcades are also best for safety; for I have found that escapes have been most commonly effected by undermining cells and dungeons. If felons should find any other means to break out of this raised ward, they will still be stopped by the wall of the court, which is the principal security; and the walls of the wards need not then be of that great thickness they are generally built, whereby the access of light and air is impeded.

"I wish to have so many small rooms, or cabins, that each criminal may sleep alone. These rooms to be ten feet high to the crown of the arch, and have double doors, one of them iron-latticed, for the circulation of air. If it be difficult to prevent their being together in the day-time, they should, by all means, be separated at night. Solitude and silence are favourable to reflection; and may, possibly, lead them to repentance. Privacy and hours of thoughtfulness are necessary for those who must soon leave the world; (yet how contrary to this is our practice! Keepers have assured me, that they have made £5 a day after the condemnation of their prisoners.)—In the Old Newgate there were fifteen cells for persons in this situation, which are still left standing, and are annexed to the new building.

"The separation I am pleading for, especially at night, would prevent escapes, or make them very difficult; for that is the time in which they are generally planned, and effected. This also would prevent their robbing one another in the night. Another reason for separation is, that it would free gaolers from a difficulty of which I have heard them complain: they hardly know where to keep criminals admitted to be evidence for the king: these would be murdered by their accomplices, if put among them; and in more than one prison, I have seen them, for that reason, put in the women's ward.

"Where there are opposite windows, they should have shutters; but these should be open all day. In the men-felons' ward, the windows should be six feet from the floor; there should be no glass; nor should the prisoners be allowed to stop them with straw, &c.

"The women-felons' ward should be quite distinct from that of the men; and the young criminals from old and hardened offenders. Each of these three classes should also have their day-room, or kitchen, with a fire-place; and their court and offices all separate.

"Every court should be paved with flags, or flat stones, for the more convenient washing it; and have a good pump, or water laid on—both, if possible; and the pump and pipes should be repaired as soon as they need it; otherwise the gaols will soon be offensive and unwholesome, as I have always found them to be in such cases. A small stream constantly running in the court is very desirable. In a room, or shed, near the pump, or pipe, there should be a commodious bath, with steps (as there is in some country hospitals) to wash prisoners that come in dirty, and to induce them afterwards to the frequent use of it. It should be filled every morning, and let off in the evening through the sewers into the drains. There should also be a copper in the shed, to heat a quantity of water sufficient to warm that in the bath, for those that are sickly. There should also be an oven: nothing so effectually destroys vermin in clothes and bedding, nor purifies them so thoroughly when tainted with infection, as being a few hours in an oven moderately heated.

"The infirmary, or sick wards, should be in the most airy part of the court, quite detached from the rest of the gaol, and raised on arcades. These rooms should never be without crib beds and bedding. In the middle of the floor of each room there should be a grate of twelve or fourteen inches square, for a current of air, covered with a shutter or hatch at night.

"The sewers, or vaults, of all prisons, should be in the courts, and not in the passages, and (like those in the colleges) close boarded between the seat up to the ceiling, the boards projecting ten inches before each seat.

"The infirmary and sheds will not render the court unsafe, provided the walls have parapets, or small *chevaux de frise.*

"Debtors and felons should have wards totally separate; the peace, the cleanliness, the health, and morals of debtors, cannot be secured otherwise.

"The ward for men-debtors should also be over arcades, and placed on one side of the gaoler's house. This house should be in or near the middle of the gaol, with windows to the felons' and the debtors' courts. This would be a check on the prisoners, to keep them in order; and would engage the gaoler to be attentive to cleanliness and constant washing, to prevent his own apartments from being offensive.

"A chapel is necessary in a gaol. I have chosen for it what seems to me a proper situation. It should have a gallery for debtors, or women; for the latter should be out of sight of all the other prisoners, and the rest may be separated below. Bibles and prayer-books should be chained at convenient distances on each side: those who tear, or otherwise damage them, should be punished."

The introduction of the separate system of confining prisoners, led to great alterations in the mode of constructing prisons; and the penitentiary at Millbank was built for the purpose of carrying this plan of prison-discipline into effect. It was completed in the year 1821, and is calculated for the reception of twelve hundred convicts. The outer walls inclosed not less than eighteen acres. The principal entrance on Millbank is a stone-fronted lodge, with a Gothic arch, and false portcullis over the gates. At the top, "Penitentiary" is written in large characters. The cells for solitary confinement are arranged within the quadrangular building, which stands a considerable distance from the outer wall. At each angle of the structure there is a tower or bastion to form water-closets, to communicate with the different ranges of cells. Each side has three tiers of windows (twenty-seven in a tier) strongly grated with iron. The bastions are also pierced for loop-holes, to give light and air. Projections, or out-works, are built for various departments, and the space between the building and the wall is laid out as gardens.

The model prison at Pentonville was planned with a view to embrace every improvement that modern science could suggest. It is placed in an elevated and airy situation, well adapted for such a building, and for securing the health of the prisoners. The following description will show the general principle adopted in its construction.

The boundary-wall is of a height above the ground sufficient to preclude all chance of escape by climbing, and the foundation of such a depth as to prevent undermining in the course of a single night. It presents an even, smooth surface on both sides. A clear space is preserved on the outside of the boundary, that no erection may be made against it, and that the exterior may be open to inspection; and in like manner the prison-wings are not connected with it, but a clear space preserved round the interior. There is only one gateway in this external boundary, which is placed immediately opposite the entrance-door, opening into an enclosed court-yard. The gate being retired a little, it is deemed will be of advantage in affording the means of defending it through loop-holes made in the side-walls, should attempts be made to force it during riots or popular excitement. Accommodation is afforded within the prison walls for officers, in detached houses. The prison is entered by a broad passage, leading through the entrance-building to the central hall, on the sides of which are convenient apartments for turnkey, male and female superintendents, and surgeon, and a mess-room for the officers, together with a room for the magistrates, and an office for the governor. These last rooms look into a central-hall, and command a view of the interior of the prison; there are likewise staircases leading to the basement, infirmary, and chapel. The basement of the entrance-building contains reception-cells, a cleansing-room for males, a fumigating oven for disinfecting prisoners, clothes; store-rooms for clothing; and prison stores, such as bedding, &c.; water-closet; and a room for the steward or prison-officer employed about the kitchen and store departments. A portion of the upper part of this entrance-building is appropriated as a chapel, and the remainder as an infirmary, or convalescent-rooms—the former entering into the central hall, and the latter entirely detached from the rest of the prison by a partition-wall, being a separate staircase from the passage below. The central hall, as before explained, opens from the floor to the roof, and is used as the principal station of the officers engaged in carrying on the discipline of the prison. A gallery—which is a continuation of that into which the prison-rooms or cells open—runs round the central hall, about ten feet above the floor, affording access to the chapel and all the wings, staircases being placed in convenient situations communicating with it. The windows of the hall overlook the airing-yards, and the greater part of the space within the boundary wall. The general kitchen of the prison, the bread-room, scullery, coal-cellar, and an apparatus for cooking, and for ventilating and warming the entrance-building, are situated in the basement under the central hall, and a small portion of the adjacent wings. The prison-wings, as before explained, radiate from the central hall, an open passage or corridor being designed to run longitudinally through the centre of each; and the prison-rooms, or cells, open into the corridor; these being ranged in three stories. The lower range is on the level of the floor of the corridor and hall; the upper ranges open upon a narrow gallery attached to the wall, which is continued round the central hall, as already explained. At the farther extremity of each prison-wing, a flight of steps, covered by a trap-door, lead to the punishment cells, which are placed in the basement. In the centre of each wing, a circular iron staircase is designed to communicate with the galleries, and continued into the store-rooms below. In addition to the stores and ventilating apparatus, placed in the basement, under the centre of each prison-wing is a large bath, the use of which is essentially conducive to the health of the prisoners. The general dimensions of the cells are about 13 feet long by 7 broad; 9 or 10 feet high to the under side of the arched ceiling. It is deemed desirable that the length should greatly exceed the breadth, as this affords a better opportunity of taking exercise, and facilitates the unobserved inspection of the interior. The partitions between the cells are not less than 18 inches in thickness, thereby precluding, as much as possible the transmission of sound between adjoining cells. The external walls are two bricks and a half thick, or two feet of stone; the internal walls next the corridor or passage, two bricks thick, or 18 inches of stone; the flues are 12 by 5 inches, and are worked in the corridor-wall and the external wall for ventilation. The windows of the cells are placed close under the arch, and have stone sills. The iron window-frame is a fixture let into a groove, with proper rebates for the glass, which is unpolished. The general dimensions of the windows are about 3 feet 6 inches long, and not exceeding 11 inches in breadth. For additional security, a strong wrought-iron bar is placed outside the window-frame, in the direction of its length, so as to divide the opening into two portions of about 5 inches each. The cells have single doors, the frame of which is of oak, 6 inches by 5; the doors, 2 inches thick, of deal, framed flush on both sides; the edges covered with felt, to prevent noise in the transmission of sound; a strong iron plating is on the side next the cell, riveted through, and the doors are hung with strong 4½-inch butt hinges, and fastened with a spring lock and latch; a bevelled aperture is cut for the inspection slide; and a trap-door, 6 by 9, is fixed in the door for passing provisions through, and which is hung on two centres, so as to form a shelf when let down; it is fitted with a strong bottom thumb-bolt, to secure it in its place. The outer door next the corridor is hung with 4½-inch butt hinges, working on centres, the object being that the door may be opened without noise, for inspection; the edge is covered with felt, and shuts into a rebate in the door frame, flush with the wall. For every cell there are suitable means provided for a constant supply of fresh water, and for necessary relief, without entailing unwholesome smells. The exercise of prisoners in the open air, without compromising individual separation, is thus obtained. The airing-yards radiate from a central point, round which is placed a dark passage, affording an inspection into each yard. The advantage of a dark passage is, that it facilitates close and unobserved inspection. The yards have open railings at both extremities, in order to allow a free circulation of air; and they are so constructed that no two prisoners can see each other. A small roof is attached to the division-walls, to afford shelter when necessary: and the position of the yards with reference to the doors in the centre of the prison-wings, gives a ready means of access from the cells.

The chapel is fitted up with separate stalls or sittings; the sides of each stall, and the doors, which form the continuation of those sides, and shut up the general passage to each row, radiate upon the pulpit, so that each prisoner can see, and be seen, by the chaplain. The back of each row of seats is made of such a height as to intercept the communication between the rows, when the prisoners are standing up, and yet not so high as to conceal them from the observation of the prison-officers when sitting down. A double passage is made down the centre of the chapel, opening into and communicating with the gallery surrounding the central hall, and thus affording two points of access to it. A staircase leads from the gallery to a door on a convenient level for entering, near the upper row of seats, from whence a succession of steps, arranged in pairs, communicate downwards with each row in front. The ceiling of the chapel is coved, and ventilators are introduced into it; the roof and the bearers supporting the seats being made of iron. For the ventilation of the cells, an apparatus is placed in the centre of the basement-story of each wing, the object of which is to secure a more complete ventilation than could be obtained, if the system had been extended from either extremity. The apparatus consists of a proportion of large tubes or pipes for hot water, and in connection with it there is a large cold-air flue communicating with a shaft out of doors, which serves for two wings. The fresh air introduced through the flue, is brought in contact with and passes through the tubes of the apparatus, and may therefore be warmed or left at its natural temperature, as may be desirable. The air thus brought from without, then passes to the right and left along the flue which runs horizontally under the floor of the corridor, from whence a communication is established by lateral small flues, separately with each cell, both on the lower and upper floors.

The means whereby foul air is extracted from the flues are these: a grating is placed close to the door of each cell, on the side next to the outer wall, and diagonally opposite to where the fresh air is introduced. This grate opens into a flue which passes down the outer wall, and communicates with a main foul-air flue placed under the floor of the basement. These main foul-air flues terminate in a chimney-shaft rising above the top of the building. With a view to obstruct the transmission of sound, and prevent that communication which might be attempted by means of the flues, the main foul-air flues are divided into three compartments, one for each range of cells. By means of the system of flues which has been described, a communication is established—first, from the outer-air, and then from the floor of each cell back again through the extracting or foul-air flues or chimney into the outer air. In order to regulate the quantity of air admitted into each cell, which, with apertures of equal size, would differ in proportion to the distance from the apparatus, a valve or damper may be placed in the extracting flues, close to the outer door of each cell in the corridor, so constructed as not to close it up entirely, but to leave sufficient range to operate upon the circulation; the damper being at the command of the superintending officer, he is enabled to regulate the quantity according to circumstances. By the application of this system of ventilation, it has been found that a circulation of air of from six to eight cubic feet per minute, may be kept up through all the cells, at all times of the year, and under all possible circumstances, when the doors and windows of each are perfectly closed.—*Fourth Report of the Inspectors of Prisons.*

In September, 1847, a number of gentlemen taking an active part in the management of prisons, assembled at Brussels under the title of a "Penitentiary Congress;" for the purpose of discussing various questions connected with prison discipline. In this "Congress," colonel Jebb commissioned by the secretary of state (for England), Mr. B. Rotch (the Middlesex magistrate), and Mr. Charles Pearson, took a distinguished part.

"Foremost amongst the subjects of debate was *the mode of constructing cellular prisons*; and, as this is a matter which greatly concerns architects and others of our readers, we deem it right to record the results.

"Colonel Jebb rightly remarked, that there was an intimate connection between the construction and the discipline of a prison. He was impressed with the necessity of having the various departments and the various offices of the establishment kept quite distinct one from the other, with a convenient mode of access to the centre and the cells. It was also essential that the families of the officers should not live in the prisons; that the latter should come to their employment at a certain hour during the day, and attend alternately at night. He saw by a paragraph in the programme, that it was proposed not to construct prisons with more than three stories, including the ground-floor. He thought, however, when the number of prisoners amounted to 700 or 800, it would be more convenient to have four stories, than very long wings. With respect to the attending of divine worship, a mode existed in Pentonville and other places, by which all the prisoners might proceed separately to the church or chapel, and hear and see the person officiating, without being seen by any one, except by him. The time occupied in proceeding to and departing from divine service, was seven minutes respectively. With respect to the size of the cells, he thought that, as a general rule, they should be about 13 feet long, 7 broad, and from 8 to 9 feet high. Of course it would be necessary sometimes to make larger cells for special purposes."

The following are some of the propositions, which were agreed to *nem. con.*

"The buildings and exercise-ground should be disposed so as to receive the rays of the sun, and be sheltered from rain and the north wind. 2nd. The destination of a prison must in some sort determine its internal arrangement. If it is to be a penal prison, none but convicts of one sex should be placed in each, and the number should never surpass the maximum of 500, although the congress were of opinion that a less number would be better. If it is to be a preventive establishment, different wings and sections should be parted off for the different categories of prisoners. The two sexes at any rate must be kept distinct. 3rd. The number of stories should not be more than three, including the ground-floor. The parts of the prison specially destined for persons undergoing their sentences, should be disposed in such a manner as, 1st, to allow of a complete separation by day as well as by night; 2nd, to give them the means of open-air exercise; 3rd, to enable them to be suitably employed, to receive instruction, and to assist at divine service and religious exercises, without infringing the rule of separation. 4th. To facilitate the mode of superintendence of the prisoners, and of frequent communication with them."

The following propositions were read and discussed:—

"*Central Observatory.*—The various parts of the building should be connected with a central point of inspection, from which the head of the establishment may inspect, without being under the necessity of moving all the essential branches of the service. Regard must be had to the internal distribution of the localities, to the arrangement of the galleries, and to the choice of the materials of construction, in order that no material obstacle may thwart that inspection.

"*Cells.*—In the disposition and arrangement of the cells, regard must be had to the following conditions:—1. The cells must be large enough to allow of the prisoners taking exercise, carrying on trades, and enjoying sufficient space and air for the preservation of their health: the space should vary from 28 to 35 cubic metres. 2. They should be lighted up, ventilated, and heated in a suitable manner. 3. Their construction should be such as to allow no communication between their inmates. 4. They should be furnished with bed and bedding, with a fixed wash-hand basin with a tap; with a water-closet, and with other necessary articles. The prisoners should also have the means of giving the alarm to the attendants, in case of illness or accident, or under any circumstances in which their presence might be necessary. The prisoners should be subjected to an easy, but unperceived inspection.

"*Special Cells.*—In penal prisons, it is necessary to have a certain number of special cells for the infirmary, for special punishments, for the different callings, and for prisoners on their first arrival. The cells for infirmaries, chiefly reserved for patients who cannot be suitably attended to in the ordinary cells, should be more spacious than the former, and should be disposed in such a manner as to allow of the access of the attendants. One cell of that kind for every forty or fifty prisoners would possibly be sufficient. Cells for punishment should be stronger than others, and should be built in such a manner as to be easily darkened, if necessary. One such cell would be sufficient for about 100 prisoners. The dimensions of the cells for the exercise of certain trades should correspond with the use to which they are put: they should be situated in preference on the lower stories, and their number must depend on the nature of the trades carried on in the prison. In prisons where prisoners are constantly arriving, a certain number of cells should be made, in which each prisoner may be placed temporarily, previous to being seen by the surgeon: and such cells might be of smaller dimensions than others.

"*Heating and Ventilation.*—Whatever the system of ventilating by heating may be, its result should be the following: —A sufficiency to each cell of fresh air, or, if necessary, of air tempered for each prisoner, without the inconvenience of draughts. The extraction from each cell of a quantity of foul air equivalent to the quantity of pure air introduced, and of the carrying on of the heating and ventilating without facilitating the means of communication, whether of sound or otherwise, between the different cells.

"Mr. Rotch said, that excellent as the Pentonville prison was, he could not help saying that many things were wanting to render that establishment perfect. All the medical men to whom he had spoken on the subject were of opinion, that the temperature should be lowered at night-time. The mode of ventilation was not good in Pentonville: and he would just observe, that if people were satisfied with what was simply good, they would never have better. The question of ventilation was a most important one, particularly for nations which, unlike England, had no colonies to which criminals might be transported, and which were, therefore, under the necessity of detaining the criminals for a long time in prison. It must not be said that there was no way of bringing the fresh air into prisons conducted on the cellular system; but rather urge architects *to find out a plan to that effect before the next congress was held.* The system of ventilation in Clerkenwell prison had been lately changed, because it was found to be a bad one. Mr. Rotch here showed the meeting a plan for procuring ventilation: the principle appearing to be, that fresh air should be applied from the lower parts of the building, whilst the foul air should escape from the roof of the house. He would just state one fact, to show that at Pentonville some improvements were required. About three weeks ago, he had been informed by one of the furnace or oven men of that prison, that it required thirty-six hours to lower the temperature.

"Colonel Jebb admitted that it would be better to admit air into the prison by means of open windows; but then such windows would admit of communication between the cells. He did not think that the present system at Pentonville could be well changed at present, without endangering the health of the inmates. Should the medical men, however, decide otherwise, alterations would be made. He thought that the present mode of ventilation would not act prejudicially on the health of the inmates during the eighteen months or so they remained in the model prison.

"The article in favour of the establishment of a central observatory of inspection was adopted; as was also one relating to cells, with the exception of a sentence which fixed their space at from 28 to 35 cubic metres."

The congress also adopted the following propositions:—

"*Chapels.*—The chapel should be so disposed as that each prisoner should join in the exercise of worship—seeing and hearing the minister officiate, without being himself seen; regard being had, at the same time, to the fundamental principle of the separation of prisoners amongst themselves.

"*Parlours.*—A certain number of cell-parlours should be made, for the use of prisoners not authorized to meet their relations or friends in their own cells.

"*Domestic Service—Administration—Lodging of persons employed in Prisons.*—Whatever plan may be adopted, independent of the localities above mentioned, each prison on the cellular system should contain a bath-room, with a number of separate baths in proportion to the number of inmates; a kitchen, with its accessories; a baking-house; and a wash-house: a certain number of magazines for provisions, fuel, clothes, general stores, and manufactured goods, according to the destination of the prison; a clerk's office; and a meeting-room for the committee of surveillance; lodgings for the director or chief officer, the guards, or watchers; and, in penal prisons, for the sub-director, the superintendent of works, the almoner, the doctor or his assistant, and of such other persons as may be placed in each prison by the administration."—*Builder October* 9, 1847.

In the new prison which has been built at Holloway, for the Corporation of London, it has been endeavoured to carry out these ideas. It is constructed upon the radiating principle, having four wings diverging from one centre, with two other wings in front of the former: one of these wings is for juvenile offenders, with school-rooms attached; the other for females, with work-rooms and laundry; the other four radiating wings constitute the male adult prison. These have large work-rooms attached, and an apparatus for lifting water. The wings are twelve cells in length, or about 100 feet, and 3 stories high. The corridors are 16 feet wide, and are open up to the arched ceiling, with galleries leading to the upper cells. The cells are 13 feet by 7 feet, fitted up with water-closets, wash-hand basin, cupboard, table, stool, &c: these are warmed by means of hot-water pipes laid under the corridor-floor, the air passing over them and through the flues provided in the thickness of the wall, and entering the cell over the door. The ventilation is to be effected by means of a shaft, 146 feet high, of large dimensions. Inside this shaft is a tube of boiler-plate the whole height of the shaft, 5 feet diameter at bottom and 3 feet at top. In addition to a furnace at the bottom of the tube, the smoke from the various chimneys, together with the spare heat from the kitchen boilers, is conveyed into it, and will necessarily raise the temperature of the column of air in the shaft, and make it pass off with great rapidity. The theory is, that as no air can enter the shaft without previously passing through the cell, a constant supply of fresh air will thereby be conveyed to the prisoners.

The chapel is a spacious room 70 feet by 40, and 48 feet to the ridge of the roof, with two deep recesses for the females and juveniles, and will contain sittings for 380 prisoners. Provision is made for having a constant supply of fresh air passing through the chapel to the ventilating shaft. The arrangements for taking the prisoners from the various cells to the chapel, have been well considered. The females and juveniles enter by separate doors near the altar, while the male prisoners enter by four different passages at the opposite end. The kitchen is of ample dimensions, and being close to the base of the ventilating shaft, the steam and smell from the victuals will be readily carried off. The well-house is to be fitted with one of Mr. Bessemer's disc pumps, and to be worked like a capstan, in a building 30 feet diameter. The shaft is 217 feet deep, bore 102 feet, making a total depth of 319 feet. The depth to the water is 153 feet. The tanks, to contain 14,000 gallons, are placed over the front towers at a great elevation, from which the cells and other places are supplied: the whole depth of bore is in chalk.

The whole extent of frontage next the Camden-road is of Kentish rag, with Caen-stone dressings. The style is castellated Gothic. The sides of the chapel building, and the back wings, are of brick; the windows to the cells have Parkspring-stone sills, with splayed brick reveals. The whole of the parapets are coped with Caen-stone. The roofs are flat, covered with asphalte, upon plain tiles and iron rafters. As the extracting flues for ventilation are immediately under the roof-covering, two thicknesses of plain tiles have been put 6 inches apart, to prevent the atmosphere acting in any way against the free current of air passing through them.

The porter's lodge, which stands about 66 feet in front of the entrance-building, is also of rag, with Caen-stone dressings, and contains accommodation for two families. Between the last-named building and the road, stand the two houses intended for the governor and chaplain, with large gardens attached.

The accommodation afforded in the prison is as follows—

Females	60	
Juveniles	61	
Male adults	283	
		404
Reception cells		14
Punishment ditto		18
		436

with fourteen work-rooms, equal to ninety-six cells; offices for the governor, chaplain, surgeon, steward, clerks, &c.; apartments for the surgeon and deputy-governor, and for master and two turnkeys in juvenile wing, matron and two turnkeys in female wing. The ground, consisting of ten acres, is surrounded by a brick wall 18 feet high with a strip of land 20 feet broad round its exterior.

The prison is built upon land originally purchased by the City for the purposes of a cemetery during the raging of the cholera in 1832. It is a little to the westward of the Holloway-road, upon the side of a hill, having a declivity of 4 feet in 100. Previous to the commencement of the works, the City authorities entered into an arrangement with the commissioners of sewers, who built a new sewer for the purpose of securing good drainage for the prison.

The building has been erected from the design and under the able superintendence of Mr. Bunning, the City architect. Mr. Jay is the contractor employed; Mr Lawrie, the clerk of the works.

The original estimate for the building was £92,293; but the committee considered that sum too large, and orders were given to cut it down. The pruning knife was applied, and it was reduced to the extent of £14,635. The contract now stands as follows:—Buildings, £77,655; warming, ventilating, water-pipes, gas fittings, locks, bells, cooking apparatus, laundry fittings, forming the grounds, fittings and furniture, about £14,000; so that, after allowing for any additions the corporation may think proper to make, the expense of the whole may be called something under £100,000.

Prison-discipline is a problem the wisest of our legislators have not been able to solve. When Pentonville prison was erected, it was thought that complete separation, by its severity, would lessen crime. The result, however, has scarcely justified the belief. The government have had ample opportunity of forming an opinion upon the merits of the separate system; consequently, within the last twelve months, some relaxation has been made, and about 10 per cent, as we understand, are now in association.

With so many perplexing opinions before them, the City authorities were at a loss upon what principle to arrange their prison, but they adopted a middle course, and they have now the means of confining the vicious in separate cells; and have a sufficient number of work-rooms for classified association.

It is expected that this prison will be ready for occupation in the early part of the year 1852. *Builder*, 1851.

PROBLEM, (from πρόβλημα) in geometry, a proposition in which some operation, or construction, is required; as to divide a line, to make an angle, to draw a circle through three points not in a right line, &c.

Messieurs, of the Port Royal, define a *geometrical* problem, a proposition given to be demonstrated, in which something is required to be done; and what is done, to be proved to be the thing required.

A problem, according to Wolfius, consists of three parts: the proposition, which expresses what is to be done; the resolution or solution, wherein the several steps, by which the thing required is to be effected, are orderly rehearsed; the demonstration, in which is shown, that by doing the several things prescribed in the resolution, the thing required is obtained.

Accordingly, the general tenor of all problems is this: the things prescribed in the resolution being done, the thing required is done.

PRODUCING, in geometry, the continuing a right line, or drawing it out to any assigned length.

PROFILE, (French) in architecture, the figure or draught of a building, fortification, or the like; in which are expressed the several heights, widths, and thicknesses, such as they would appear, were the building cut down perpendicularly from the roof to the foundation. Hence the profile is also called the *section*, sometimes the *orthographical section;* and by Vitruvius, also the *sciagraphy.*

Profile in this sense, amounts to the same with *elevation;* and stands opposed to *a plan*, or ichnography.

Profile is also used for the contour, or outline of a figure, building, member of architecture, or the like; as a base, a cornice, &c.

Hence, *profiling* is sometimes used for designing, or describing the member with rule, compass, &c.

PROJECTION, the art of forming the representation of a body upon a plane, by drawing straight lines through a given point, or parallel from the contour, and from the intermediate lines of the body, if any, so as to cut the plane; then colouring the respective compartments according to the degree of light, shade, and line of each surface.

If the projection be made by drawing straight lines from a point, it is called *a perspective representation ;* but if formed by parallel lines, it is called an *orthographical representation.*

The projections of points, lines, and plane figures, are found by placing the originals in a given original plane, in a certain position to the intersection of such plane with the plane of projection: and thence the projections of the faces of solids are easily discovered, either by finding the intersection of their planes with the plane of projection, or by finding the representation of one of the planes, and the representation of lines making any given angle with the original of the plane to be represented; and thus the seat, inclination, and length of the original line must be known. Each of these methods has its advantage: but that in which the representations are obtained, by finding the intersections of the different planes forming each of the solid angles, having the inclinations of their planes, is the most natural, as well as the most universal in its application; though the other method, where the objects to be represented are prisms, is more expeditious; since, if the representation of one of the ends be found, the whole solid may be also obtained by finding the representation of one of the arrises, or edges, of the planes which form the sides; or, in the case of a cylinder or cylindroid, by finding the representation of the axis, then drawing lines from all points of the base, or from a sufficient number of points in the base, parallel and equal in length to the axis, and completing the other end equal and similar to the one projected, will complete the representation of the whole solid.

Every solid, whose properties are known, may be projected in any given position to the plane of projection; and no other method offers such ready means of projecting points or lines in space, which have a relation to a given or original plane, where the original plane and the plane of projection are given in position.

In the doctrine of shadows, nothing can be more easy, or more convenient, than the methods furnished by this principle; the universality of the rules is such, that they apply equally to perspective and to orthographical representations, and are much more convenient than the method of finding the vanishing lines of their planes and those of the planes of shade.

Definition 1.—The plane on which the object is represented, is called *the plane of projection.*

In orthographical projection, the rays by which the projection is formed, are here understood to be perpendicular to the plane of projection.

Definition 2.—If the projection be made on a plane parallel to the horizon, or on a plane representing the horizon, it is called *the plane of the object.*

Definition 3.—If the projection be made on a plane perpendicular to the horizon, or on a plane representing a vertical plane, it is called *the elevation of the object.*

Definition 4.—The *plane of position of an inclined line and a plane*, is another plane passing along the line perpendicular to the plane.

Definition 5.—The *inclination of a line to a plane*, is the angle on the plane of position comprehended between the line and the plane.

Definition 6.—The plane on which any object is given, is called *the primary plane.*

Definition 7.—A *point on a plane* is said to be *given*, when its situation is known in respect of some given line, relatively to some fixed point in that plane.

Definition 8.—The *position of a line to a plane* is said to be *given*, when the seat of the line is given upon the plane, and when the angle which the line makes with its seat is known.

Definition 9.—In the representation of figures, in planes inclined to the plane of projection, the situation of the figure, in respect to the intersection of its plane with the plane of projection, is supposed to be known. The intersection is therefore given on the plane of projection, and the space on the one side is to be considered as *the original plane*, while that on the other is *the plane of projection.*

Axiom.—If any point, line, or plane, coincide with the plane of projection, that point, line, or plane, so coincident, is both the original and the projection of that point, line, or plane.

Proposition I.—The projection of a point is in a straight line drawn from the original point perpendicular to the intersection.

For, suppose a plane to pass through the original point, perpendicular to the primary plane and to the plane of projection, its intersection with each of them will be perpendicular to that of the primary plane and the plane of projection; but lines perpendicular to the same straight line, drawn from the same point, are in the same straight line, and therefore the projection of a point is in a straight line drawn from the original point perpendicular to the plane of projection.

Proposition II.—The orthography, or projection of a straight line, is also a straight line. Thus, let a plane pass through the original straight line perpendicular to, and intersecting the plane of projection; here, as the intersection of one plane with another is a straight line, the orthographic representation must be so likewise.

Proposition III.—All original parallel straight lines are represented by parallel straight lines; because the intersection of one plane with another is a straight line; and, when a plane cuts several parallel planes, the intersections of these planes with the cutting plane, are parallels.

Proposition IV.—The orthographical representation of a line parallel to the plane of projection, is a line equal and parallel to its original.

Proposition V.—The orthographical representation of a line parallel to the intersection, is a line equal and parallel to the original.

Proposition VI.—The orthographical representation of a plane figure parallel to the plane of projection, is a figure equal and similar to the original.

Proposition VII.—All planes perpendicular to the plane of projection, are described as straight lines.

Proposition VIII.—All straight lines in the primary plane perpendicular to the intersection, have their representations also perpendicular to the intersection.

Proposition IX.—Every straight line in a plane perpendicular to the plane of projection, is represented by the intersection, or a part of the intersection, of that plane.

Proposition X.—The intersecting point of every line in any original plane is that point in the intersecting line of the original plane, which is cut by producing the original line to the intersecting line of the plane.

Proposition XI.—If, through any point in the original plane, a plane be drawn perpendicular to the intersection, so as to meet, or intersect, the plane of projection, the representation of the point will be in the line of section where it is cut by a perpendicular to such line, in the plane perpendicular to the intersection.

Proposition XII.—If two points in the intersection of one plane with another be found, or known, the intersecting line of the first plane in the second, is the line which joins the two points.

Proposition XIII.—If the intersecting lines of two planes, inclined to each other, be given, or found, upon a third plane, the point of concourse of the two intersecting lines will be a point in the intersection of the two first planes.

Proposition XIV.—If two points be given in the projection of a straight line, the whole line is given in position.

PROBLEM I.—*Given a point on a plane, inclined to the plane of projection, to find the orthography, or projection of the point.*

Plate I. *Figure* 1.—Let I N be the given intersection of the inclined plane; and let A be the given point thereon; draw A *a* perpendicular to the intersection, I N, cutting it in B; make *a* B C equal to the inclination of the original plane to the plane of projection; make B C equal to B A, and draw C *a* perpendicular to A *a*; then will *a* be the projection of the point A.

Demonstration.—Conceive the triangle *a* B C to be turned up on the base B *a*, perpendicular to the plane of projection; also conceive the original plane, with the point A, to be turned on the line I N, as a hinge; and the line B A will always be in a vertical plane, whose intersection is A *a*; and since B C is equal to B A, and B C is also in the same vertical plane when turned up, B A may be made to coincide with B C; therefore let B A coincide with B C; and, because B C is equal to B A, the point A will fall upon C: but, because C *a* is perpendicular to B *a*, and the plane *a* B C is by supposition perpendicular to the plane of projection, therefore *a* C is perpendicular to the plane of projection; consequently *a* is the projection of the point A.

Corollary.—Hence the projection of a line may be obtained by finding the projection of two points in that line, and then joining the two projected points.

PROBLEM II.—*To find the projection of a straight line in the original plane.*

Figure 2.—Let A B be the given straight line; produce A B to its intersecting point, C; by PROBLEM I. find *a*, the representation of A; join *a* C; draw B *b* perpendicular to I N, cutting *a* C at *b*; then *a b* is the projection of the line required.

PROBLEM III.—*To find the orthographical projection of an angle.*

Figures 3 and 4.—Let A B C be the given angle; find *b*, the projection of the point B; produce A B and C B to their intersecting points, D and E; join E *b* and D *b*, and produce them to *a* and *c*, if necessary, as in *Figure* 3 (*Figure* 4 does not require it); then *a b c* is the projection of the angle required.

PROBLEM IV.—*The indefinite projection of a straight line being given; to find the projection of any original point therein.*

Figure 2.—Let *a* C be the indefinite projection of A B, and let it be required to find the projection of the point B, in the original line A B. Draw B *b* perpendicular to I N, cutting *a* C in *b*; and *b* will be the projection of the point B.

PROBLEM V.—*To find the projection of a given triangle.*

Figure 5.—Let A B C be the triangle given; find the projection, *a b c*, of the angle A B C; by Problem III. and by Problem IV. find the points *a* and *c*, the projections of the points A and C; join *a c*, and *a b c* will be the projection required.

PROBLEM VI.—*To find the projection of a parallelogram.*

First, when the sides are obliquely situate.

Figure 6. Let A B C D be the given parallelogram; find *a b c*, the representation of the angle A B C (being any one of the three angles that is most convenient) by Problem III. and the representations *a* and *c*, of the points A and C, by Problem IV.: draw *a d* parallel to *b c*, and *c d* parallel to *b a*; and the parallelogram *a b c d* will be the representation of the original parallelogram A B C D.

2. When the parallelogram is a rectangle, with its sides parallel and perpendicular to the intersecting line.

Plate II. *Figure* 1.—Find the representation of the points C, D in one of the sides, C D perpendicular to the intersection, by Problem I.; draw *d a* and *c b* parallel to the intersection I N; draw B *a* parallel to D *d*, cutting *c b* at *b*; then the rectangle *a b c d* will be the representation of the rectangle A B C D. as required.

3. When two of the sides are parallel and two oblique.

Figure 2.—Find the representation *a*, of the point A, by Problem I.; produce the side A B to its intersecting point, E; join the intersecting point E and the point *a*; draw B *b* perpendicular to the intersecting line, cutting E *a* at *b*; draw *b c* parallel to I N; draw C *c* parallel to B *b*; draw *c d* parallel to *b a*, and *a d* parallel to *b c*; and the parallelogram, *a b c d*, will be the representation of the original parallelogram A B C D, as required.

Note. Both of these might have been included in one problem; they are thus particularized, in order to give the reader a clear view of the subject.

PROBLEM VII.—*To find the representation of a regular pentagon.*

Figure 3.—Find *a*, the representation of the point A, by Problem I.; produce A E and A B to their intersecting points, and join each of those points with the point *a*; find the projections, *b* and *c*, of the points B and E, by Problem IV.; produce the diagonals, A C and A D, to their intersecting points, and find the representations, *c* and *d*, of C and D, by Problem IV.; join *c d*; and *a b c d* will be the representation required.

PROBLEM VIII.—*Given the intersecting line, and the projection of one of the angles of a pentagon, and the projected length of one of the sides: to project the whole figure.*

Figure 4.—Let *b a e* be the projection of one of the angles of a pentagon, say the most remote; produce *a b* and *a e* to F and G, their intersecting points; then, upon F G, describe the segment, F A G, of a circle, to contain the angle of a pentagon, that is, $\frac{3}{5}$ of two right angles; draw *a* A perpendicular to F G, to cut the segment in A; join A F and A G: let *a b* be the projected side given; draw *b* B perpendicular to F G, cutting A F at B; upon A B describe the regular pentagon A B C D E; and project the other parts, *b c*, *c d*, *d e*, as in the preceding example.

PROBLEM IX.—*To find the projection of a circle.*

Plate III. *Figure* 1.—Draw the diameter B D parallel, and the diameter C E perpendicular to the intersecting line; find *a*, the projection of the point A; and draw the diameter, *b d*, parallel to the intersecting line; find *b*, the projection of the point B; join B E, and produce it to f; join *b* f, cutting *a* A at *c*; then, with half the major axis, *a b*, and half the minor axis, *a e*, describe the ellipsis, *b c d e*, the projection required.

PROBLEM X.—*To find the projection of the segment,* B C D E B, *of a circle.*

Figure 2.—Through the centre, A, draw the diameter, C F, parallel to I N; complete the semi-circumference, C D F; find the axis *a c* and *a d*, as in the last problem; produce the chord B E, to meet the intersecting line, I N, in f; find the representation of the point *g*; join f *g*, and produce it to *b*; then, with the semi-axis *a c* and *a d*, describe an ellipsis, or so much of it as may be necessary; and the part, *b c d e b*, will be the representation of the segment, B C D E B, as required.

PROBLEM XI.—*To find the projection of an ellipsis,* B C D E B; B D *and* C E *being the two axes cutting each other at* A.

Figure 3.—Find the representations, *b d* and *c e*, of the axes; then with the diameters, *b d* and *c e*, describe the

ellipsis *b c d e*. This may be done as in Problem I., Method V. of the article Ellipsis (Vol. I., page 365), or by finding the two axes, as in Method I, (page 365), of the same article.

Problem XII.—*Any two conjugate diameters,* B D *and* E C, *of an ellipsis, being given; to find the representation of the ellipsis.*

Figure 4.—Find the representations. *b d* and *e c*, of the diameters B D and E C; and *b d* and *e c* will also be conjugate diameters; then, by Problem I., Method I., of the article Ellipsis (Vol. I., page 365), describe the ellipsis *b c d e b*, which will be the representation of B C D E B, as required.

Problem XIII.—*To find the projection of any point in space, upon a plane given in position; and to determine the distance of the point from the plane.*

Figure 5.—Make choice of any three points, A, B, C, on the plane; measure the distance of the point in space from each of the points A, B, C, and the distance of the points A, B, C, from each other; then the projection may be found on paper, thus: let Q R be a scale, representing feet and inches; let A B be measured 1 foot $4\frac{1}{2}$ inches, B C 1 foot $1\frac{1}{2}$ inch, and C A 1 foot 2 inches; describe the triangle, A B C, according to these dimensions from the scale; let the distance of the point in space from A be 1 foot 4 inches; with the centre, A, and distance of 1 foot 4 inches, describe an arc at D; let the distance of the point in space from B be measured 1 foot 3 inches; then, with the centre, B, and distance of 1 foot 3 inches, describe an arc cutting the former at D, and join A D and B D; with the same distance, from B, describe an arc at E; let the distance of the point in space from C be measured 1 foot; then, with the centre C, and distance of 1 foot, describe an arc, cutting the former at E, and join B E and C E; draw D *p* perpendicular to A B, and E *p* perpendicular to B C; and *p* will be the projection of the point in space.

To find the altitude of the point in space.—Let D *p* cut A B at F; draw *p* H perpendicular to F *p*; with the centre F, and distance F D, describe an arc, cutting *p* H at H; and *p* H will be the height of the point required.

Problem XIV.—*Supposing a tetraedral, or three-sided solid angle to be placed with one of its sides upon the plane of projection, and one of the other two sides, and the two inclinations adjoining that side, with the intersection of that side, to be given; to find the projection of the given side; and the intersection of the remaining side, upon the plane of projection.*

This problem is the same as if one of the sides, and the two adjoining inclinations, of a tatraedral, were given; to find the projection of the given side on one of the others, and also to find the side of the solid on which the projection is made.

Figure 6.—Let A B C be the given side, and A B the edge which intersects or meets the plane of projection in I N; from any point, C in B C, draw C D perpendicular to I N, cutting I N at A; find B D, the projection of B C; that is, make D A L equal to the inclination of the given plane towards the plane of projection; make A L equal to A C; draw L D perpendicular to C D; join D B; and D B A will be the projection of A B C, as required.

To find the intersection of the other side, with the plane of projection.

In B C, take any point, G; and draw G F perpendicular to B C, cutting A B at F; draw F I perpendicular to B D, cutting B D at H; with the centre F, and distance, F G, describe an arc, cutting B D at K; join F K; make the angle, F K I, equal to the other inclination; join B I; and B I will be the intersection of the other side, as required.

Problem XV.—*Given the representation, a, of a point, situate in a plane, whose original is given: to find the representation of a line from the original point, perpendicular to the original plane.*

Plate IV. *Figures* 1, 2.—Draw O K perpendicular to the intersecting line, and make O K L equal to the inclination of the plane to that of projection, if not already made; draw *a* L perpendicular to O K, and L M perpendicular to K L; make L M equal to the line; draw *a b* parallel to O K, and M *b* parallel to L *a*; then *a b* will be the projection required.

Problem XVI.—*Given the representation, a, of the intersection of a line with the original plane, and the seat in, and inclination of, the line, to the original plane; to find the representation of the line.*

Figures 3, 4.—Draw O K perpendicular to I N; make the angle O K L equal to the inclination of the plane to that of projection, and produce K L to M, if necessary; draw A *a* perpendicular to I N, and C *b* parallel to A *a*; make K M equal to C D; draw M P perpendicular to K L: make M P equal to the tangent of the seat, A C, made radius; draw C *b* parallel to A *a*, and P *b* perpendicular to A *a;* then join *a b*, and *a b* will be the representation of the line required.

Problem XVII.—*Given the representation, a b c d, of one side of a parallelopiped, with the inclination of the plane, and the other dimension perpendicular to the original of that plane; to find the representation of the whole solid, supposing the planes of the original solid at right angles to each other.*

Figure 5.—Find the representation, *a f*, of a line perpendicular to the original of the plane represented, by Problem XV., and complete the parallelograms *a f g d* and *a b e f*, which will form the representation of the whole solid.

Problem XVIII.—*To find the inclination of two adjoining planes of the regular solids.*

Plate V. *Figures* 1, 2, 3, 5.—Draw the base, A B C, A B C D, or A B C D E of the pyramid which forms one of the solid angles; draw the triangle B G C, the development of one of the sides of the pyramid; draw G F perpendicular to B C; bisect the angle A B C, and let the bisecting line meet O F in F, their point of concourse; draw F H perpendicular to B F; from B, with the radius B G, describe an arc, cutting F H at H; draw F I perpendicular to B H, cutting B H at I; in F B make F L equal to F I; let F H and B C meet in M; also let F H and B A meet in K; join M L and K L; then will K L M be the angle of the planes as required.

As the sides of the tetraedron are equilateral triangles, and as three of the triangles form each solid angle, both the base of the pyramid, A B C, and the developed side, B G C, will be equilateral triangles in *Figure* 1.

In the construction for *Figure* 2, as the sides of the hexaedron are squares, and as each solid angle is formed by three of the right angles, the base of the pyramid will be an equilateral triangle, and the vertical angle of the developed side will be a right angle.

In the construction for the octaedron, *Figure* 3, as each side is an equilateral triangle, and as four of the angles of the triangle form the sides of the solid angle, the base of the pyramid will be a square, and the developed side will be an equilateral triangle.

In the construction for the dodecaedron, *Figure* 4, No. 2, as each solid angle is formed by three planes, and as each of the planes is a pentagon, the base of the pyramid will be an equilateral triangle, and the vertical angle of the developed side will be equal to the angle formed by the two sides of a pentagon.

In the construction for the icosaedron, *Figure* 5, as each solid angle is composed of five sides, and as all the sides of the solid are equilateral triangles, the base of the pyramid is a pentagon, and the developed side an equilateral triangle.

In the construction for the dodecaedron, *Figure* 4, the angle of the pentagon was found by dividing a circle into five equal parts, and joining the chords of two adjoining parts, as A B, B C, *Figure* 4, No. 1. Then, to obtain the vertical angle, draw A C as a base; bisect the angle A B C, which will also bisect the straight line A C in E; make E F equal to the half of B C, No. 2, and draw F G parallel to B C, cutting B D at G; make E G, No. 2, equal to E G, No. 1; and in No. 2 join G B and G C, which will give the vertical angle B G C.

PROBLEM XIX. *To project the dodecaedron.*

Figure 6.—Find *a b c d e*, the orthography of one of the planes, by Problem VII.; find the angle which two contiguous planes of the solid make with each other, by Problem XVIII.; find the intersection of each of the planes adjoining to the plane whose projection is found, by Problem XIV., and thus three of the arrises of the solid will be projected; then, to project the planes adjoining the extremities of the arrises, or edges, *a b*, *a e*, *a h*, suppose that contiguous to *a b*, produce *b c* to meet the intersecting line X Z in *o*, and produce *b f* to meet X Y in *p*; join *o*, *p*; then, having the projection of the angle *c b f*, and the projected lengths, *c b* or *b f*, of one of the sides, and the intersecting line, *o p*, of the plane of that side, find the orthography, *c b f m l*, of the whole figure, by Problem VIII. In like manner, find the orthography of the figures *g h i q r*, *k s t d c*, and the representation of the solid will be completed.

PROBLEM XX.—*To divide the representation of a circle into parts representing the original circle divided into equal parts.*

Plate VI. *Figure* 1.—Let A B C D be the original circle, and let *a b c d* be its orthographic representation. Suppose the first part of the original circle to commence at the given point, E; let E F, F G, G H, &c. be the equal parts in the original circle, and let O be its centre; join E O, F O, G O, H O, &c.; let the diameter, B D, be perpendicular to the intersecting line, I N, and let A C be parallel to I N; then *b d* and *a c* being the representations of B D and A C, draw *b a* and B A, and let B A cut the radii E O, F O, G O, H O, &c. in the points K L M N, &c.; draw K *k*, L *l*, M *m*, N *n*, &c. cutting the representative chord, *a b*, at *k l m n*, &c. Let *o* be the representative centre; draw *o k*, *o l*, *o m*, *o n*, &c., and produce *o k*, *o l*, *o m*, *o n*, &c. to meet the circumference of the representative circle in *e*, *f*, *g*, *h*, &c.; then will *e f*, *f g*, *g h*, &c. be the representations of the equal parts E F, F G, G H, &c. of the original circle: and if the representative radii, *e o*, *f o*, *g o*, *h o*, &c. be produced to meet the opposite parts of the curves at *e'*, *f'*, *g'*, *h'*, &c., *e' f'*, *f' g*, *g' h*, &c. will also represent equal parts.

In the same manner, if B C, and its representation, *b c*, be joined, the other two representative quadrants may be divided, so as to represent equal parts in the original quadrants remaining; and thus the whole representative circle will be orthographically divided into parts, representing the whole of the original circle divided into equal parts.

To find the orthographical representation of a water-wheel.

Figure 2.—Let No. 1 be the face of the wheel, or its section, perpendicular to the axis: let I N be the intersecting line: draw the ellipsis *a b c d*, representing the original circle, A B C D, divided into equal parts, as in the preceding problem: through the points of division draw the portions of the radii, as intercepted between the orthographic circumferences: draw the ellipsis *e f g*, which will give the orthography of the opposite outer circle: then draw the edges of the boards perpendicular to the intersecting line, I N, so as to be terminated by the orthographic circles *e f g* and *c d a*; then, two of the sides of the float-boards being thus found, the other two may be completed by parallel lines.

The ring which supports the float-boards is represented in the same manner as the orthographic circles, which contain the representations of the float-boards themselves. The radiating pieces, to which the float-boards are attached, are made to tend to the centre, on the side that adjoins the float-boards, and the opposite face is tapered off; and, to accomplish this regularly, it is made to touch the representation of a circle in the same plane.

To project a straight line in a plane, supposing the plane which contains the line to be wrapped round the surface of a cylinder.

Plate XIII. *Figure* 1.—Let A B C D be a cylinder orthographically projected; and let B A be continued to G, so that A G may be equal to the semi-circumference of the cylinder; also let F E be the line to be projected, the point E being in the line A D, and the position of E F to A G being supposed to be given.

Continue the axis of the cylinder to any convenient distance beyond the base A B: at any convenient point in the axis thus produced, describe a circle equal to the radius of the cylinder; draw the diameter H J parallel to A B: divide the semi-circumference H I J into any number of equal parts, as 8; also divide A G into the same number of equal parts; from the points of division in the semi-circumference H I J, draw lines parallel to the axis of the cylinder through the projection A B C D.

Again, from the points of division A G, draw lines perpendicular to the said line A G, to cut the line E F in as many points as A G; from the points of section in E F, draw lines parallel to A B, to cut the former lines drawn parallel to the axis; then the line E F of contrary flexure, is the projection required.

In the same manner the concave line D E, *Figure* 2, is projected from the surface of a cylinder upon a plane into the line D *e*.

To project any line upon the surface of a cone.

Figure 3.—Let A B C be the orthographical projection of the cone on a plane parallel to the axis, and let A B E be the development of the projected surface: then any line B F on this development, will be projected from the conic surface in the following manner:

On B C describe a semicircle B D C, and divide the arc B D C into any number of equal parts; from the divisions of the arc B D C, draw lines perpendicular to B C, to meet it in as many points of section as there are divisions in B D C; from the points of section in the base B C, draw lines to A; from the points of section in the base B E of the development, draw straight lines to A, to cut the line B F intended to be projected; from the points of section in B E, describe arcs from the centre A to cut A B in as many points of section as the number in B F; from every point of section in A B draw lines parallel to B C, to cut each former line respectively; through the corresponding points, draw a curve, as shown by the dark line, and this will be the projection of the line on the conic surface.

Corollary.—Hence the projection may be found according to any given fanciful form, as in *Figure* 4, where *f g* is the projection of F G.

Not only architectural designs, but mechanical drawings, depend upon orthographical representation; it enables the architect, engineer, or mechanic, to construct the object intended to be executed. As drawings of every kind are greatly facilitated by a knowledge of the formation of bodies, so, in drawing machines, it is necessary to know the methods of representing any system of lines upon cylindric and conic surfaces, as this knowledge will determine whether the lines represented are parallel to each other or tend to a point.

In drawing machinery, as in other kinds of orthographical

representations, the object is represented upon two planes, one parallel, and the other perpendicular to the horizon.

As the faces of the different parts of a machine are generally in vertical planes parallel to each other, the elevation is also made on a vertical plane parallel to the faces of the work, or to the greatest number of faces, in order to facilitate the execution, as this position not only gives the altitude of the parts, but is also convenient in ascertaining the magnitude of lines in every direction in these planes, and the angles which the lines form with each other; for if the faces of the work stand at oblique angles with the projecting plane, there can be only one direction, namely, that of measuring in a vertical line, in which the true dimensions can be ascertained; every other will be fore-shortened, and the angles formed by the lines of representation will also vary from the original angles of the object.

As the axes of wheels are sometimes obliquely situate, it becomes necessary to represent them in various positions. The several kinds of representations are sections through the principal parts (as through the axis of a wheel), plane or horizontal projections, and elevations.

Though a plan and elevation are sufficient to construct any machine with proper attention, yet from the greater facility of comprehending the nature of the design, and applying the measures to practice, two elevations are sometimes given, particularly in a complex machine. One of these elevations expresses the parts in the longest horizontal dimension of the work, and the other represents the parts comprehended in its breadth, or horizontal extension.

In the representation of a machine, the wheel-work is the most difficult of any part, except when the whole of the surfaces of the wheel are planes, with two or more faces parallel to the projecting plane, and all the other surfaces perpendicular to it, as in this case the boundaries of the parallel planes are represented by figures similar to the original faces, and the whole of the other surfaces are projected into straight lines or circles. This is so very simple, as not to require any directions; but if the wheel, or its faces, have an oblique position to the projecting plane, several considerations are necessary to effect a true representation. A ground section through the axis of the wheel, placed at the required angle, with the intersection of the plane of elevation, and an elevation of the wheel on a plane parallel to the faces, will be required. It is likewise necessary to observe, that, in this oblique projection, all the parallel arrises of any original object are represented by parallel lines, and all equal distances in the original object are represented by other distances equal among themselves; also, all straight lines whatever in the original plane, divided into parts, are represented by a series of parts respectively in the same proportion. The proportion of any line is to its original, as radius to the cosine of the inclination of the original line and the plane of projection. The representation of an original circle is an ellipsis; and as the plane of projection is vertical, the elevation of an ellipsis will be represented with its greater axis perpendicular to the intersecting line.

Problem XXI.—*Given the seat and altitude of a line on plane, and the intersection of the plane with another plane a given angle, to find the sun's seat on such plane, as also angle of altitude.*

Plate VIII. *Figure* 1.—Let A C, No. 1 and 2, be the seat the line; A B the intersection of the last named plane. A C take any point, C; draw C D perpendicular to A C; draw C E perpendicular to A B, cutting A B at B. In No. 2, draw C H perpendicular to B C; make C H equal to C D, and angle C B G equal to M L K, No. 3, the inclination of the planes; draw H G perpendicular to B G; make B E equal to B G, and join A E; then A E will be the seat of the sun's rays on the plane, as required. Draw E F perpendicular to A E; make E F equal to G H, and join A F; then E A F will be the angle of altitude of the line on the same plane.

In No. 1, the two planes are at right angles to each other; in this case, the problem may be constructed without the quadrilateral B C H G; thus, having drawn C E perpendicular to A B, cutting A B at B; make B E equal to C D, and complete the triangle A E F, as in No. 2; then A E will be the seat of the line, and E A F the angle of altitude, as before.

This may easily be conceived, by supposing, that upon the triangle A B C, No. 2, the triangle A C D, and the quadrilateral B C H G, are raised perpendicularly; then C H and C D will coincide, and the point H will coincide with the point D; turn the triangle A B E upon A B, and the side B E, being perpendicular to A B, will describe a plane upon B E, perpendicular to the plane A B C; and because B C and B E are in the same straight line, B C will be in that plane; and because the plane B C H G, is supposed to be raised perpendicular to the plane A B C upon B C, the plane supposed to be described by B E will be in the same plane with B C H G, when raised perpendicularly to the plane A B C; therefore, move the plane A B E till B E coincide with B G, supposed to be raised with the plane B C H G; the planes A C D, B C H G, and A B E, being thus supposed to be raised, turn A E F round A E, till E F falls upon G H; then the point F will fall upon H; and the straight line A F will also be coincident with A D; for the triangle A E F will be at a right angle with the triangle A E B; therefore E F will be at right angles to the plane A B E.

Problem XXII.—*Given the seat and altitude of the sun's rays on a plane, and the angle which the seat of a line parallel to the plane of projection makes with the seat of the sun's rays; to determine the inclination of the plane of shade obstructed by the original line towards the plane of projection.*

Figure 2.—Let A C be the seat of the sun's rays given upon the plane of representation; make C A D equal to the altitude of the sun's rays; draw C D perpendicular to A C; make C A B equal to the angles made by the seat of the sun's rays with the seat of the original line, which occasions a plane of shade; from C draw C B perpendicular to A B, and C E perpendicular to C B; make C E equal to C D, and join B E; then C B E will be the inclination of the plane required. Produce C B to F; make B F equal to B E, and join A F; then let the triangles C A D, C B E, B A F, be turned up, and A F and A D will coincide; and the triangle C B E will measure the inclination of the plane A B F to C B A. This problem is of the utmost use in finding the shadows of parallel lines to planes in various positions; as also in finding the shadows of cylinders where the axis is parallel to the plane of projection; and in determining the points and lines of light and shade in cylinders and cylindric rings.

Problem XXIII.—*Given the seat and altitude of a line and the seat and altitude of the sun's rays; to determine the shadow of the line on that plane.*

Figure 3.—Let H E be the seat of the line; make the angle, E H I, equal to the altitude of the line, viz., of A B C, No. 1; E being any point in H E; draw E I perpendicular to H E; draw E F parallel to the seat of the sun's rays; and draw E G perpendicular to E F; make E G equal to E I; make the angle E G F equal to the complement of the sun's altitude, and join H F, which will be the shadow of the line required.

This problem will be of great use in finding the shadows of objects upon inclined planes.

Problem XXIV.—*Given the inclination of a line to two planes at right angles to each other; to find the seat of the line on each of the planes, and the intersection of the planes.*

Figure 4.—Let A B C, No. 2, be the inclination, or angle, made by the line with one of the planes, and D E F, No. 3, the angle it makes with the other.

From the angular point, B, No. 2, take B C, of any length, and from the angular point, E, No. 3, take E F equal to B C; in No. 2, draw C A perpendicular to A B; and, in No. 3, draw F D perpendicular to E D; in No. 1, draw any line G K; and through G, any point in G K, draw H I perpendicular to G K; make G H equal to the sine, D F, of one of the angles of No. 3, and G I equal to the sine, A C, of the other, No. 2; from H, with the radius, A B, No. 2, describe an arc, cutting G K at K; and join H K and K I; then G K will be the intersection of the planes, and K H and K I will be the seats of the line on each of them.

In the following problems, respecting shadows, two planes of projection are always supposed to be given, viz., the seat of the rays of light on each of the planes, and the intersection of the planes, unless otherwise announced.

Practical examples of shadows.

Example 1.—*To find the shadow of a rectangular prism attached to a wall, one of the sides of the prism coinciding with the surface of the wall.*

Figure 5.—Let H I K L M N be the plan, the straight line, H I M N, that of the wall, and I K L M that of the prism; let A B C D be the elevation of the prism, and V W the intersection of the plane of elevation with that of the ichnography, parallel to H N, and K L in the plan.

To find the shadow of any point, B, *on the elevation, corresponding to* L *on the plan.* Draw the ichnography, L N, of a ray of light; also, from B, draw B F, the elevation of the ray, at any given angle with the intersection V W; join B L; draw F N parallel to B L; and the point F will be the shadow of the point B on the elevation.

In the same manner, find E and G, the shadows of the points A and C; join E F and F G; and A B C G F E A will be the shadow required.

Or, find the shadow, F, of the point B, as before; draw the indefinite representations, A E and C G, of the extreme rays; then, because the arrises, or edges, of the prism are parallel to the wall, or to the surface on which the shadows are thrown, the representations of the edges of the shadows will be parallel to the representations of the arrises on the plane of elevation; therefore draw F E parallel to A B, and F G parallel to B C; and A E F G C will be the edge of the shadow, as before.

Example 2. *Plate* IX.—The shadow of *Figure* 1 is found in the same manner as in the last example; the body which throws the shadow being a prism, with its planes parallel and perpendicular to the surface on which the shadow is thrown; A N M L C is therefore the outline of the shadow thrown by a prism, represented by F G H I on the plan, and by A B C D on the elevation. The figure here introduced represents a cantiliver projecting from a wall.

Example 3.—*To find the shadow of a cantiliver, formed as in the last example, the plane of elevation being placed obliquely to the surface on which the shadow is thrown.*

Figure 5.—Let E F I K be the representation of the surface on which the shadow is projected, placed obliquely to the line V W, the intersection of the orthographic planes; let F G H I be the plan of the cantiliver, and A B C D its elevation, the points A and D on the elevation corresponding with the point H on the plan, and the points B and C corresponding with the point F. The end of the cantiliver is represented by D *e f* A, and the root by C *g h* B; the point I, on the plan being represented by *g* and *h* on the elevation, and the point F, on the plan, by B and C on the elevation. To find the shadow of any corresponding lines, F G and B *h;* draw G L the parallel of the seat of the sun's rays on the plan, meeting the shadowed surface, E K, in L; draw L *m* perpendicular to V W; from *h*, the corresponding point of G, draw *h m*, the elevation of the ray; join B *m;* draw *g o* parallel to B *m*, draw *m n* parallel to A B, and *n o* parallel to A D; then *h m n o g* will be the shadow required: for the representation of the two edges of the shadows are parallel to the representation of the two edges of the end of the cantiliver.

Example 4. *Figure* 3.—Let A B D E be the intersection of any vertical surface on which a shadow is to be thrown; also let B C D be the plan of a triangular prism projecting from that surface; and G H I F its elevation; find *p n*, the shadow of the perpendicular line, as before; and join *n* G; then will *p n* G be the shadow of the prism, as required.

Example 5. *Figure* 4.—G H I K L is the elevation of several rectangular prisms joined to each other in the form of a pediment; O H I K L is the outline, and *l m n* the inner line, forming the tympanum; A B E F is the plan of the surface on which the shadow is to be thrown, parallel to the intersecting line, V W; B C D E is the plan of the pediment, of which the line C D, representing the face, is parallel to A F. Draw G O, H P, I G, and *n r*, the elevation of the rays; also, draw the ray D *v* on the plan, meeting A F at *v*; *v* P G perpendicular to the intersecting line, cutting the rays, H P and I G, of elevation, at P and G: draw P O parallel to G H; then O O P O I will be the extremity of the shadow, as in Example 1. To find the shadows from the inner edges, *l m* and *n m*, make *n r* equal to G O, or H P, or I O, as each of the points, G, H, I, *r*, is equally distant from the surface; draw *r s* parallel to *n l*, and *r t* parallel to *n m;* then will *s r t* represent the shadow from the under arrises of the inclined parts.

Example 6.—*Figure* 5, is the shadow of several rectangular prisms crossing each other at equal angles; one of the faces of each is parallel to the plane on which the shadow is thrown, and also to the plane of elevation; the opposite, or parallel faces, are attached to the plane on which the shadow is thrown, and, therefore, the other faces are perpendicular to such plane. The shadows are to be found as in the last example, viz., by drawing indefinite rays from all the angular points on the elevation, and finding the length of one of them; then the rest will be completed by parallel lines from the termination.

Example 7.—*To find the shadow of a rectangular ring.*

Figure 6.—Find the point, *l*, the shadow of the centre, *k;* through *l* draw O P perpendicular to *k l;* then, with the radius of the interior circle, describe the arc, W X U, meeting the said inner circle in W and U; also, from *l*, with the radius of the exterior circle, describe the semicircle, O Q P; draw O M and P N parallel to *l k*, and these lines will touch the circle in M and N; then M O Q P N will represent the exterior shadow required.

Problem XXV.—*Given the sun's seat and inclination on the plane of the horizon, and the intersection of two planes at right angles with each other, and perpendicular to the horizon; to find the representation of the sun's rays on each of the vertical planes.*

Plate X. *Figure* 1.—Let A D and D B be the intersection of the two vertical planes, and A B the seat of the sun's rays on the horizon; make the angle, A B C, equal to the angle of the sun's altitude; draw A C perpendicular to A B and A E perpendicular to A D: make A E equal to A C, and join E D, which will represent the ray of the sun, on the plane of which the intersection is A D: produce A D to G; make D G

equal to A C, and join G B; and G D will represent the sun's ray, on the plane of which the intersection is D B.

This problem is necessary in the three preceding examples, when the seat and inclination of the sun is given on the horizon, in order to find the orthography of the ray upon both elevations, viz., upon the front and end.

PROBLEM XXVI.—*To find the representation of the shadow on a prismatic solid, by a plane cutting the prism perpendicular to its arrises; given the elevation of the prism on a plane parallel to its arrises, and parallel to one of its sides: as also the figure of the plane which throws the shadow, with the section of the surfaces of the prism on that plane, and likewise the sun's rays, both on the plane and on the elevation.*

Place the figure of the plane and the elevation so that any two of their corresponding points, or parts, may be in a line perpendicular to the intersection. Draw the representation of the rays from all the angular points on the figure of the plane, to meet the sectional line of the prism; draw the corresponding representations of the rays on the elevation, and from the points where the representation from the angles of the plane meet the section, draw lines parallel to the representations of the arrises of the prism to cut the corresponding rays on the elevation; then, by joining the successive points, the shadow required will be determined.

Example 1. *Figure* 2.—Let A B C D be the plane, and E F, F G, the intersection of two other planes at right angles to A B C D; let K L N O be the elevation of the prism; the lines O N, R M, and K L, representing the arrises corresponding to the angular points, G, F, E, on the section,—that is to say, the point G is in the same straight line with O N, the point F with R M, and the point E with K L; also, let K L M R represent the plane parallel to the plane of elevation, and let K P represent the line of intersection; make K U equal to the breadth of the shadow at the bottom; draw the ray, D I, on the figure of the plane, and D T perpendicular to K P, cutting K P at T; and T will represent the point which throws the shadow on the elevation; draw T Q, the ray of the sun, on the elevation; I Q parallel to D T, and U S parallel to K P, cutting R M at S; join S Q; then K U S Q V O will be the representation of the shadow required.

Example 2.—*Figure* 3 shows the shadow of a chimney-shaft upon the roof of a house, the sides of the shaft being parallel and perpendicular to the front.

Example 3.—*Figure* 4 shows the shadow of a chimney-shaft upon a roof, which has two inclinations; the sides of the shaft being situate as in *Example* 2. The principles of performing these two examples are the same as in the preceding problem, *Example* 2.

PROBLEM XXVII.—*To find the indefinite shadow of a line perpendicular to the horizon on an inclined plane: given the inclination of the plane to the horizon, and the seat of the sun's rays: the intersection of the inclined plane with the horizon being parallel to the intersection of the plane of representation and the horizon.*

Plate XI. *Figure* 2, No. 3.—Draw any straight line, A B C; make A B to A C, as the sine is to the cosine of the plane's inclination; make the angle, C A D, equal to that of the seat of the sun's rays, with a line perpendicular to the intersection of the horizon and the plane of representation; draw C D perpendicular to A C, and join B D; and B D will be the indefinite representation required.

PROBLEM XXVIII.—*To find the shadow of a plane rectilinear figure intersecting another plane figure: a point through which the shadow is to pass on the plane which receives the shadow, and the orthography of the rays of the luminary, being given.*

If the line which throws the shadow meets the intersection of the planes, draw a straight line from the point of concourse through the given point, and the line thus drawn will be the indefinite representation of the shadow. But if the line which throws the shadow does not meet the intersection of the planes, continue the line or the intersection of the plane, or both of them, as the case may require, to meet each other, and draw a straight line from the point of concourse through the given point, as before; and the line thus drawn will be the shadow required.

PROBLEM XXIX.—*Given the orthography of a determinate line, and the indefinite representation of its shadow, also, the orthography of the sun's rays, to find the limits of the shadow.*

From one, or either of the terminations of the line, as the case may require, draw the orthography of a ray to cut or meet the indefinite shadow of the line, and the length comprehended between the point, or points, thus found in the shadow, will be the extremity, or will terminate the length, as required.

Example 1.—*To find the shadow of a chimney-shaft on the roof of a house.*

Plate XI. *Figure* 1.—Find the indefinite shadow of the vertical line, F L, No. 2, thus: let A C, No. 3, be parallel to F L: find B D, as in PROBLEM XXVII: draw F O, No. 2, parallel to B D, No. 3: now let the parallel of the orthography of the sun's rays be given: from L draw L O, the orthography of the sun's rays, and the point O is the termination of the shadow, F O; produce F G and L M to meet each other in N; draw O N, and it will give an indefinite representation of the shadow of the edge, L M, of the top; draw the orthography, M Q, of the ray, parallel to L O, cutting O N at Q; continue the intersection, G H, and the edge M L, of the top, to meet each other in P; draw Q P, and it will give the indefinite representation of the edge of the top, and of the other vertical plane not seen; draw H R parallel to F O, and F O Q R H will represent the shadow required.

Example 2.—*Figure* 2, is the shadow of a dormer window with a rectangular front, and the top inclined towards the front: find the indefinite shadow, A G, as in the last example, and the orthography, F G, of the sun's rays; join B G, and A G B will represent the shadow, as required.

Example 3.—*Figure* 3, is the shadow of a dormer window, with a pediment top: find A G, the shadow of A E, as before; then D E being the next line that projects a shadow, A B is the intersection of the plane, A B C D E; therefore, produce D E and B A to meet in F; join F G, which produce to H; find the termination, H, by the rays, H; and A G H E will represent the shadow, as required.

Note.—If the lines D E, E G, had been in the same straight line, or had formed a salient angle, instead of a re-entrant one, the upper side of the shadow would have been the same as in the last example.

Example 4.—*Figure* 4, exhibits the shadow of a dormer window with a semicircular head: find the shadow, A I of the perpendicular line A F; let O be the centre of the semicircular head; draw D L to touch the head of the window at D, parallel to the orthography of the sun's rays; draw O D perpendicular to D L, and D will be the point of contact.—Now, let it be required to find the shadow of any intermediate point, E, of the arc of the circle: A B is the intersection of the plane A B C D E F; therefore draw the chord, E F, and produce A B and E F to meet each other in H; produce H I to K; and draw the orthography, E K; and the point K will represent the shadow of the point E. In like manner, draw the chord D E, and produce D E and B A to meet each other in G; join G K; produce G K to L; and L will represent the shadow of the point D: draw a curve from the point I, through K to L, touching the straight line A J and D L at the points I and L; and A I K L D will represent the shadow, as required.

Example 5.—*Figure* 5, exhibits the shadow of a dormer window with a kirb-roof top; find the shadows, M, K, I, of the points E, F, G, as in the last example; and A I K M E F G A will represent the shadow required.

It is hardly possible to conceive a method more expeditious, than the foregoing, of finding the indefinite representation of the shadow, by producing the line which throws it, and the intersection of the plane, till they meet each other in the plane in which the shadow is thrown.

Example 6.—*Plate* XII. *Figure* 1, No. 1, is the elevation of a prismatic object, as the walls of a building, which form two prisms attached to each other; the lower prism is terminated with an inclined plane, in the manner of a roof. The plan, No. 2, shows the end of the higher prism, to which the lower prism is attached, to be at an obtuse angle with the plane of the front.

Let the ray, B F, No. 2, be drawn on the plan from the corner B, to meet the side C D at F; then F is the projected point of B on the plan; draw *f g*, the elevation of the point F, cutting the top of the lower wall at *g;* draw *l m*, the elevation of the sun's ray, as in the preceding examples; produce the intersection, *h i*, of the inclined plane to meet the line, *b l*, which projects the shadow in *k;* through the points, *k* and *g*, draw *k g m*, meeting the elevation of the sun's rays at *m.* Now, as the line, *l o*, of the top of the end of the prism projects the next shadow, produce *l o*, and the intersection, *i h*, to meet each other in *n;* draw *m n*, cutting the upper termination, *h q*, of the inclined plane at *r;* and *f g m r h i e f* will represent the shadow required.

Example 7, *Figure* 2, No. 1, is a plane figure, representing the gable of a house, of which B A is the base; F G, G H, H U, are the intersections of several planes; F G, parallel to B C, is the intersection of a vertical plane, as the face of a wall; G H and H U are the intersections of two inclined planes, forming two sides of a kirb-roof. Now, to find the shadow, by the intersecting points of the lines which project the shadow with the plane on which the shadow is thrown, it is evident that the line, B C, will project a shadow on the plane, whose intersection is F G, parallel to F G; and as B C, No. 2, represents B C, No. 1, draw *p q* parallel to B C, cutting the lower inclined plane at *q*. Then, supposing the side, B C, also to throw a shadow upon the lower inclined plane, produce its intersection, H G, No. 1, and the line, B C, which throws the shadow, to meet in K; produce C B, No. 2, to *k*, and draw *k k* parallel to B A; then through the points, *k* and *q*, draw *k q r;* draw C C from C, No. 1, to C, No. 2, parallel to B A, No. 1; from the point, C, No. 2, draw the elevation, C *r*, of the sun's rays. C D, No. 1, is the next line, which throws the shadow still upon the lower inclined plane; therefore, produce C D and G H to meet each other in M; draw M *m* parallel to B A, cutting B C at *m;* draw also the indefinite shadow, *r m*, cutting the intersection of the two inclined planes at *s*, No. 2; then the line, C D, will also project a shadow upon the upper inclined plane; therefore, produce H U and C D, No. 1, to meet each other in N; draw N *n* parallel to B A, cutting B C at *n;* draw the indefinite shadow, *s n;* then *d*, No. 2, being the corresponding point of D, No 1, draw the elevation of the ray, *d t*, No. 2; and the point, *t*, No. 2, will be the shadow of D, No. 1. D E, No. 1, is the next line that projects a shadow, and U is the intersection of D E and H U, and *u* the corresponding point to U, No. 1; therefore join *t u* and B *p q r s t u* will represent the shadow required.

Example 8, *Figure* 3, represents an example, similar to *Figure* 1, but with two inclined planes; the plan is here omitted, as being only used in the projection of the first ray; the ray, G L, parallel to A B, is drawn at pleasure at any distance from F H, to meet the intersection, H P, of the two adjoining planes in L; produce J H to meet the line A B, which throws the shadow in D; draw D L, and produce D L to S; draw the elevation of the ray B S; then B C is the next line which throws the shadow; produce B C and H J to meet each other in E; draw the indefinite shadow, S E, to cut the intersection, I Q, of the two inclined planes at M; then B C will also project a shadow upon the upper plane; therefore, produce B C, and the intersection, J K, of the upper plane, to meet each other in T; draw the indefinite shadow, M T, cutting the top, K R, at N; then F G L S M N K will represent the projection of the shadow by the edges A B, B C, of the plane, A B C, as required.

This figure may either represent the vertical plane, A B C, or perpendicular to the first vertical plane, F O P H, according as the sides are parallel or oblique to the plane of representation.

Example 9. *Figure* 4.—Let A B C D E, be the figure of a gable; K L M N the upright of a wall; A B the base of the gable; N M the base of the wall; and suppose that the edge, B C, is joined to N K at any given angle, so that the point B may coincide with the point N. Now, let it be required to find the shadow of the gable, A B C D E, upon the wall, K L M N, the side, B C, of the gable being placed parallel to the edge, N K, of the wall: as the vertical sides, A E and B C, of the gable are parallel, the shadow thrown upon the plane, K L M N, will also be parallel to the edge, N K; therefore, taking N *g* at pleasure, draw *g h* parallel to N K; then, *e* being the corresponding point of E, draw *e h*, the elevation of a ray of the sun, and the point *h* will be the shadow of the point E. E D being the next line that projects the shadow, produce E D and B C, the intersection of the plane, to meet in F; find *f*, the corresponding point of F, and draw the indefinite shadow, *h f;* find *d*, the corresponding point of D, and draw the elevation, *d i*, of a ray, cutting *h f* at *i;* C being the concourse of the line which throws the shadow with the intersection, B C, of the plane, find *c*, the corresponding point of C, and join *c i;* then *c i g h* will represent the shadow of the lines A E, E D, and D C.

Example 10. *Figure* 5.—A B C D E represents the gable of a building, as in the preceding example; S T U V the upright wall and inclined side of a roof; F G and G I the respective intersections of the wall and the roof; then supposing the edge, E D, of the gable to be attached to S *b*, it is required to find the form of the shadow; the intersection, F G, of the plane being parallel to A B, the breadth of the shadow will also be parallel; therefore, taking the distance, S *n*, upon S V at pleasure, draw *n o* parallel to S T; then, *b* being the corresponding point of B, draw the elevation, *b o*, of the ray: B C being the next line which projects the shadow, produce the intersection, F G, to meet B O in L; find *l*, the corresponding point of L, and draw the indefinite shadow, *o l*, cutting *b* W at *p;* B C now projects the shadow upon the inclined plane; therefore, produce the intersection, G I, and the edge, B C, that throws the shadow, to meet in K; find *k*, the corresponding point of K; through *k* and *p* draw the indefinite shadow *k p q;* *c* being the corresponding point of C, draw the elevation, *c q*, of a ray: find *i*, the corresponding point of I; and join *i q*, which completes the shadow on both planes.

Problem XXX.—*A cylinder being capped with a square abacus, jutting alike over each of the sides, to find the representation of the shadow; the elevation and plan being given, as also the plan and elevation of the sun's rays.*

Plate XIII. *Figure* 1, No. 1.—Let A B C D be half the plan of the abacus, E F G half the plan of the cylinder, H I J K the elevation of the same, and L M N O that of the abacus; to project the shadow of any point, p', in the elevation of the abacus, p being its corresponding place on the plan; draw the plan of the ray, $p\ q$, meeting the semi-circumference E F G at q; also from p' draw $p'\ q'$ the indefinite elevation of the ray; and draw $q\ q'$ parallel to I J, or H K, and q' will represent the shadow of the point p'. Find as many other points as may be necessary, in the same manner; then, through all the points thus found, draw a curve, which will be the shadow required.

If the ray, R T, be drawn to touch the circle in V, on the plan, and if V′ V″, the elevation of V, be drawn, then V′ V″ will be the line of separation of light and shade.

If the rays of the sun be in two planes, one perpendicular to the plane of representation, but inclined 45 degrees to the horizon, and the other equally inclined to the horizon and to the plane of representation; that is to say, making 45 degrees with each; then all the points, q', will be in the circumference of a circle, whose diameter is equal to the diameter of the cylinder.

No. 2, shows the elevation completely shadowed.

Problem XXXI.—*A cylinder being capped with another concentric cylinder, to find the representation of the shadow.*

Figure 2, No. 1.—Proceed to find all the points, q', as in the last problem, and a curve being traced through them will give the shadow required. The point p', on the elevation, corresponding to p, on the plan, may be thus found: draw B R parallel to A C, and A R perpendicular to A C; draw p S parallel to A R, cutting B R at S. In L M make L p' equal to R S, and p' will be the corresponding point of p. No. 2 shows the elevation completely shadowed.

Projection, *Stereographical.* See Stereography.

Projection of Shadows, *see* Shadows.

PROJECTURE, in architecture, the out-jettings, or prominence, which the mouldings and members have, beyond the plane, or naked, of the wall, column, &c. They are called by the Greeks, *ecphoræ;* by the Italians, *sporti;* by the French, *saillés;* by our workmen frequently, *sailings over;* and by the Latins, *projecta*, from *projicio, I cast forward;* whence the English, *projecture.*

Vitruvius gives it as a general rule, that all the projecting members in buildings have their projectures equal to their heights: but this is not to be understood of the particular members, or mouldings, as dentils, coronas, the fasciæ of architraves, the abacus of the Tuscan and Doric capital, &c., but only of the projectures of entire cornices, &c. The great point of building, according to some modern architects, consists in knowing how to vary the proportions of projectures, &c., agreeably to the circumstances of the building.

Thus, say they, the nearness and remoteness, making a difference in the view, require different projectures; but it is evident the ancients had no such intention.

The projecture of the base and cornice of pedestals, M. Perrault observes, is greater in the antique than in modern buildings, by one-third; which seems to follow, in good measure, from the ancients proportioning this projecture to the height of the pedestals; whereas the moderns make the projecture the very same in all the orders, though the height of the pedestal be very different. The reason of this change, which the moderns have made of the antique, the same author refers to a view of the appearance of solidity.

PROLATE (from the Latin *prolatus*, flat) an epithet applied to a spheroid produced by the revolution of a semi-ellipsis about its longer diameter. If the solid be formed by the revolution of a semi-ellipsis about its shorter diameter, it is called an *oblate spheroid;* of which figure is the earth we inhabit, and, perhaps, all the planets too; having their equatorial diameter longer than the polar.

PRONAOS, (from προναος) in ancient architecture, a porch in front of a temple, church, palace, or other spacious building.

PROPORTION, (French) the just magnitude of the members of each part of a building, and the relation of the several parts to the whole; *e. gr.* of the dimensions of a column, &c., with regard to the ordonnance of the whole building.

One of the greatest differences among architects, M. Perrault observes, is in the proportions of the heights of entablatures with respect to the thickness of the columns, to which they are always to be accommodated. *See* Entablature. There is scarcely any work, either of the ancients or moderns, in which this proportion is not different; some entablatures are even nearly twice as high as others: yet it is certain, that this proportion ought, of all others, to be most regulated: none being of greater importance, as there is none in which a defect is sooner observed, nor any in which it is more shocking.

Proportion is likewise understood of the magnitudes of the members of architecture, statues, or the like, with regard to the distance whence they are to be viewed.

The most celebrated architects are much divided in their opinions on this subject; some will have it, that the parts ought to be enlarged in proportion to their elevation; and others, that they ought to remain in their natural dimensions.

PROPORTIONAL COMPASSES, an instrument consisting of two equal and narrow slips of metal, terminating at each extremity in a point, the slips being connected together by a cylindric pin, which, when they are made to coincide, is moveable along a slit through both pieces: so that the axis, or centre of the pin, and the two extreme points of each piece, may be in the same straight line, and fixed at any point which will keep its situation in each of the pieces, whether the instrument be opened at any angle, or shut.

The two surfaces of the instrument which appear when it is shut are called *the sides.*

The four parts of the instrument, from the centre of motion, are called *legs.*

It is evident from the definition given, that two legs will be equal to each other, and of the same invariable length, whatever angle these legs make with each other; and that the two which include the opposite angle will also be equal to each other, and their length also invariable at any angle formed by them.

The application of the proportional compass with regard to the division of lines, and the circumferences of circles into any number of equal parts, has already been shown under the articles Compasses and Instruments. In this place it is proposed to treat of its application to perspective, and some other branches of geometry and architecture.

Problem 1.—*To set the proportional compasses in the ratio of a line divided into any two parts.*

Figure 1.—Take a line equal to the length of the instrument, and divide it in the ratio required; then apply the shorter or longer part of the line thus divided on the length of the instrument when shut, from the extremity of the longer or shorter legs to an intermediate point, to which bring the axis of the pin, and the compasses will be set in the ratio required. Thus, let A D, be a straight line, divided in E; make A B equal to the length of the instrument; join D B, and draw E C parallel to D B, cutting A B at C; shut the instrument; take either distance, C A or C B, say the shorter, C B, and apply it from the shorter end of the instrument; push the slider along the slit until the centre of the pin coincides with the other extremity, and the instrument will be set in the ratio required.

As this problem is essential to most of the following, the reader is requested to understand it thoroughly before he proceeds farther.

PROBLEM II. *Figure* 2.—*Given any number of lines*, A B, C D, E F, G H, *&c., to find a series of other lines, which will have the same ratio in every two corresponding lines, given one line* a b, *of the series required, corresponding to* A B *of the series given.*

Set the proportional compasses in the ratio of A B to *a b* by Problem I.; then if A B be greater than *a b*, take the distance, C D, with the remote extremities, and make *c d* equal to the distance contained between the near extremities, and *a b* will have the same ratio to *c d*, which A B has to C D: in like manner, take the distance, E F, with the remote extremities, and make *e f* equal to the distance contained between the points of the near extremities, and *c d* will have the same ratio to *e f*, that C D has to E F; or *a b* will have the same ratio to *e f*, that A B has to E F, and thus the remaining lines, *g h*, &c., will be found in the same manner; but if the line, A B, in the given series, be less than *a b*, in the given line of the series required, the lengths, C D, E F, &c., must be taken with the shorter ends of the compasses, and the lines, *c d*, *e f*, &c., made respectively equal to the corresponding distances contained between the extremities of the longer ends.

PROBLEM III.—*To divide a given line in the same proportion as another given line is divided.*

Figure 3.—Let A X be a given line, divided into the parts, A B, B C, C D, D X, and let it be required to divide the line, *a e*, in the same proportion.

Set the compasses in the ratio of the whole lines A X and *a e*, then take the distances, A B, B C, C D, D E, with the same legs which were applied in taking the distance A X, and with the other legs corresponding to the distance *a e*, make *a b*, *b c*, *c d*, *d e*, respectively equal to the distance between the points of these legs, and *a b*, *b c*, *c d*, *d e*, will have the same ratio to each other, that A B, B C, C D, D X, have to each other.

PROBLEM IV.—*To divide a straight line*, A X, No. 2, *in continued proportion; given the extreme part*, A B.

Set the compasses in the ratio of A X to B X by Problem I.; contract the points of the longer legs to B X, then, with the shorter legs, cut off the distance X C; again contract the distance between the points of the longer legs to X C, thus found, and with the shorter legs cut off the distance X D; and thus, by setting the distance between the points of the longer legs to the last distance found, the shorter legs will give the succeeding part by transferring the distance between the shorter legs from X towards A. By continuing this operation, as many points may be found as are necessary for the purpose required; then A B : B C : C D : D E : E F : F G, &c; that is, A B : B C : : B C : C D; and B C : C D : : C D : D E, &c.

Any question in the rule of three may be resolved by the proportional compasses and a plane scale. Thus, suppose three articles of the same kind to cost two shillings; what will eight cost? Set the compasses in the ratio of 2 to 3 by Problem I.; extend the points of the shorter legs to 8 on the scale: then apply the longer legs to the scale, and 12, the measure indicated, will be the fourth proportional, as required.

Where there is a great disproportion in the terms of the ratio, it would be more eligible to use two scales; thus, suppose it were required to find a fourth proportional to the numbers 30, 3, and 45, take any convenient scale for the antecedents, 30 and 45, and any convenient larger scale for the consequents, 3; then, by Problem I. set the compasses in the ratio of the distance 30, on the scale of the antecedents, to the distance 3 in the scale of the consequents; then take 45 from the scale of the antecedents with the legs first applied to the same scale, and the other legs will give the distance 4.5, or $4\frac{1}{2}$, the answer as required, by applying the distance between their points on the scale of the consequents.

By this, any proportion, whether in lines or numbers, may be resolved.

PROBLEM V. *Figure* 4.—*Given two straight lines*, A B *and* C D, *tending to an inaccessible point, and a point*, E, *in position, to draw a straight line through the last-named point, so that all the three straight lines*, A B, C D, *and that which is required to pass through the given point, may have the same point of concourse.*

Through the given point, E, draw F G, meeting A B at F, and C D at G; draw H I parallel to F G, cutting A B at H, and C D at I: set the proportional compasses in the ratio of the two straight lines, F G and H I; then, F G being greater than H I, take the distance G E, with the longer legs, and make I K equal to the distance between the points of the shorter legs; draw a straight line through the points E and K; then if the straight lines A B, C D, and E K, be produced, they would have one common point of concourse.

Corollary. Figure 5.—Hence, if A B and C D be two straight lines, and if E, G, I, L, be several points in a straight line, P O, meeting A B in P, and C D in O; then drawing any line, R S, parallel to P O, cutting A B at R, and C D at S, and setting the proportional compasses in the ratio of P O to R S; (P O being longer than R S,) take the distance O E, O G, O I, O L, with the longer legs, and apply the distances contained between the points of the shorter legs respectively from S to F, from S to H, from S to K, and from S to M; and drawing the lines, E F, G H, I K, L M, they would all have one common point of concourse, if produced with A B and C D.

Figure 12 shows the application of this problem and its corollary, in drawing the representations of the horizontal lines which regulate the heights of doors and windows in the perspective representation of a building, when the vanishing points of the sides, A *k* and A *h*, are not in the picture, and when all the points, through which these lines pass, are in the corner of the building, or any other convenient line.

PROBLEM VI. *Figure* 6.—*Given two straight lines*, A B *and* C D, *tending to an inaccessible point, and any number of points*, E, G, I, *in position, not in a straight line; to draw a right line through each of the points* E, G, I, *tending to the same point with* A B *and* C D.

Through the point E, draw any line, A C; through the point G, draw L M, parallel to A C, cutting A B at L, and C D at M; and through the point I, draw N O, also parallel to A C, cutting A B at N, and C D at O; draw any line, I Q, parallel to A C; set the proportional compasses in the ratio of A C to I Q; take the distance C M, C O, with the longer legs, and make Q R, Q S, respectively equal to the distances contained between the points of the shorter ends; draw R T, S U, parallel to P Q, cutting A B in T, U; make Q *e*, R *g*, S *i*, respectively equal to C E, M G, O I; and draw the straight lines, E *e*, I *i*, G *g*, which will tend to the same point with A B and C D.

Figure 7 is added to show the great use of these problems in perspective, and completely exemplifies this problem by showing, that if any section of the original object made by the plane of the picture be obtained, such as the mouldings on the face of a building, it will be very easy to draw lines from all the points of such a section that will tend to the proper vanishing point, two lines tending to the same point being given.

PROBLEM VII. *Figure* 8.—*Given the representation*, $a'' b'' e'' d'' e'' f''$, *of the end of a right cylinder*, (*the original* *having its axis parallel to the picture,) and the vanishing line, u z, of the plane of that end; through a given point, a, in any perpendicular, a'' a, to u z, to draw the representation of the other end of the cylinder.*

Let *a'' a* cut the vanishing line, *u z*, at *u*; draw *b'' b*, *c'' c*, *d'' d*, *e'' e*, *f'' f*, parallel to *a'' a*, cutting *u z* respectively at *v*, *w*, *x*, *y*, *z*; set the proportional compasses in the ratio of *u a''* to *u a*; then *u a''* being greater than *u a*, take the distance, *v b''*, with the longer legs, and make *v b* equal to the distance contained between the points of the shorter ends; find the remaining points, *c*, *d*, *e*, *f*, in the same manner, and through the points, *a*, *b*, *c*, *d*, *e*, *f*, draw a curve, which will be the representation of the other, or lower, end of the cylinder.

Or, if the base, *a*, *b*, *c*, *d*, *e*, *f*, were given, the top would be found in the same manner, by making the ratio of the shorter legs to the longer legs, as *u a* to *u a''*, and taking *v b* with the nearer extremities, and making *v b''* equal to the distance of the remote extremities, and finding the remaining points, *c''*, *d''*, *e''*, *f''*, in the same way. In like manner, any section, *a'*, *b'*, *c'*, *d'*, *e'*, *f'*, may be found.

This application of the proportional compasses is exceedingly useful in the representation of bows, when required in the fronts of buildings, as is shown by *Figure* 9, which exhibits the elementary lines of the perspective of a house. Here the horizontal terminations of the apertures are readily represented, by only drawing perpendicular lines, which may be the vertical terminations of such apertures, and would therefore be required at all events. The same description of words applies to this figure, as in *Figure* 8, to which the problem refers.

Problem VIII.—*Given the representation of any point on the picture, and the intersecting and vanishing lines of the plane it is in, to find the height of a representative line, the original of which is parallel to the picture.*

Set the proportional compasses in the ratio of the distance between the intersecting and the vanishing lines, and the distance of the point from the vanishing line, then take the length of the original line with the longer legs, and the opposite points will give the height of the line required.

Example.—Suppose the distance between the vanishing and intersecting lines to be three inches, and the distance between the representation of the point or foot of the line to be two inches, and the height of the original line to be six inches, required the perspective height of the same. Set the proportional compasses in the ratio of 3 to 2; extend the longer legs of the compasses to six inches, and the extent between the opposite shorter legs will be the height of the line required, which, in this case, will be four inches.

Scholium.—By this method all the heights of the representation of a solid may be found without any additional lines; but, in order to expedite the work, when the original object is of different heights in the same plane parallel to the picture, or where the same height is required to be found upon two or more points, it will be eligible to draw a straight line through one of the points, cutting the one or more lines on which the heights are to be found; and the same setting of the compasses will do for as many heights as are to be raised upon the line so drawn.

Example.—Suppose a cylinder to be represented, its base is an ellipsis, to find any two points in the height of the cylinder; draw a straight line, parallel to the vanishing line, to cut the representation of the base of the cylinder in two points; upon each point of section draw a perpendicular; set the proportional compasses in the ratio of the distance between the intersecting and vanishing lines, and either point and the vanishing line; then take the height of the cylinder between the points of the long legs, and the distance between the opposite points will give the perspective height upon each perpendicular from its respective foot.

In the application hitherto made of the proportional compasses, the sides of the instrument have not required any gradations of parts; but as these are necessary to the perfection of the instrument, the construction of the scales for this purpose is as follows.

Problem IX.—*To construct the scales of sines for the proportional compasses.*

Figure 10.—Let A C be a scale of sines found in the usual manner; and let C A be produced to R, making A R equal to the radius; draw R D at any convenient angle with R C; make R D equal to the length of the proportional compasses, and join C D; draw A 9 parallel to C D, and as 9 at the point C is the chord of 90°, the point 9, in R D, will be the point for the index of the slider to be set to; then if the legs of the compasses be set to any angle, the distance between the points corresponding to D will be to the distance between the points corresponding to R, as the sine of 90° is to radius. In like manner, join D 8, the next point, 8, in the line A C, and draw A 8 parallel to D 8, cutting R D in 8; then the point, 8 in R D, will be the point for the index of the slider to be set to; then, if the ends of the proportional compasses, corresponding to R, be opened to any radius, the extent of the ends corresponding to D is the sine of 80 degrees corresponding to that radius: in like manner, the points 6, 5, 4, 3, 2, 1, will be found in R D, so that 1, 2, 3, 4, 5, 6, 7, 8, 9, in R D, are the gradations on the side of the proportional compasses corresponding to 10°, 20°, 30°, 40°, 50°, 60°, 70°, 80°, 90°; hence if the index be set to any of these numbers, and the points corresponding to R be extended to the radius, the distance between the opposite points will be the sine of that number of degrees. The cosines have the same divisions as the sines, but are numbered the contrary way.

In the same manner, by placing the radius in the same straight line with a common scale of sines or tangents from zero on A, so as to lengthen the line A C, of tangents, by adding the said radius, A R, and forming the extension, R C, drawing R D at any convenient angle with R C and dividing R D as in the problem; then R D will contain the gradations of a scale of tangents, to be inserted on the side of the proportional compasses: so that when the index, or mark, upon the slider is brought to any of these numbers, the end corresponding to R being opened to the radius, the end corresponding to D will be the sine or tangent of the angle corresponding to that number. See the *Figure*.

Figure 11 shows the application of the method to a scale of tangents.

Example 1. *Figure* 13.—To make an angle of 30° at a given point, A, in the straight line A B.

With any convenient radius, A B, describe an arc, B C; set the index to 30° on the line of chords; then extend the points of the instrument corresponding to R, to the radius A B, and with the opposite points set off the distance B C, on the arc, and join C A; then C A B is the angle required.

Example 2.—To find the tangent of 40° to any given radius within the limits of the points corresponding to R.

Set the index to 40° on the line of tangents, and extend the points R to the radius; then the extent between the opposite points will be the tangent of 40°, as required.

Example 3.—To find the sine of 20° to any given radius within the limits of the points corresponding to B.

Set the index to 20° on the line of sines, then extend the points corresponding to R to the radius given, and the extent between the opposite points will be the sine of the angle, as required.

Example 4.—To find the cosine of 50°, the radius being given within the limits of the instrument.

Set the index to 50° on the line of cosines; extend the points corresponding to R to the radius, and the opposite points will be the cosine of the angle required.

Example 5.—The chord, sine, cosine, or tangent, of any number of degrees being given, to find the radius.

Extend the points corresponding to D to the chord, sine, cosine, or tangent, and the opposite points corresponding to R will be the radius of the circle required.

PROBLEM X.— *To draw the representation of a house, by making the centre of the picture the dividing point, having the dimensions of the building given.*

Figure 12.—Let V L be the vanishing line, *h k*, the intersecting line, and c, the centre of the picture; and let the building touch the intersecting line in A; also, let the vanishing points of the sides be supposed to be given.

Set the proportional compasses to the cosine of the angle which the one side of the building (viz., say that on the right) makes with the intersecting line by *Example* 4, Problem IX., say 30°; then, with the ends of the instrument corresponding to R, take the original measure from a plan; or, if the measures are known in feet, &c., take them from a scale, without being at the trouble of drawing a plan; take the distance of the corner of the building, and the nearest side (say 3 feet 6 inches) from the scale, with the remote points, and with the opposite points set off the distance A b on the intersecting line; take the breadth of the window from the scale (say 3 feet) with the remote points, and with the opposite points set off the distance b c, on the intersecting line; take the breadth of the next pier from the scale (say 4 feet) with the remote points, and with the opposite points set off the distance c d: proceed in this manner to h, so that the whole extent, A h, will represent a distance of 24 feet. Next proceed to the end of the building, which is supposed to be on the left hand; here, as the angle of the building is supposed to be a right angle, and as the right-hand side was supposed to make an angle of 30° with the intersecting line, the left-hand side will therefore make an angle of 60°; set the index of the proportional compasses to 60° in the line of cosines; then, from the scale, take the breadth of the end (say 20 feet) with the remote ends, and with the opposite ends set off the distance, A k; set the breadth of the piers from k to j, and from A to i, in the same manner, draw the lines A h and A k to the vanishing points of the sides.

From the points, b, c, d, e, f, g, h, as also from i, j, k, draw lines to c, cutting A *h* at *b*, *c*, *d*, *e*, *f*, *g*, *h*, and A *k* at *i*, *j*, *k*: from the points of section draw perpendiculars to V L; set the heights of the apertures, and the height of the building itself, upon the corner A A′; say that the sills of the lower windows are three feet high, the windows six feet, the space between the lower windows and the upper, four feet, the upper windows four feet also, and the distance to the parapet three feet; therefore make A *l* equal to three feet, *l m* equal to six feet, *m n* equal to four feet, *n o* equal to four feet, and *o* A′ equal to three feet, exactly to the scale or natural measures of the building: from these points of section draw lines to the vanishing points, and complete the whole representation. In setting up the heights, common dividers may be used. By the last setting of the proportional compasses, if the thickness of the walls are taken from the scale by the remote ends, marked R, and the distance of the two opposite points be set upon the intersecting line from the points, c, e, g, towards A; and if, from the points of section, lines be drawn to c, the centre of the picture, to cut the representative base line, A *h*, of the building, and perpendiculars be drawn from the points of section in A *h*, these perpendiculars will give the reveals of the windows; that is, they will show the thickness of the walls on the sides of the windows.

PROBLEM XI.—*Given the vanishing line of a plane, its centre and distance, and the inclination of a line in that plane to the intersection; to find the vanishing point of the line without drawing any lines in the vanishing plane, in order to find the vanishing points of the original line, as given in position to the intersecting line.*

Figure 14.—Let the angle made by the original line with the intersection be 30°; subtract 30° from 90°, and 60° will remain; bring the index of the proportional compasses to 60° on the line of tangents; extend the extremities of the compasses, marked R, to the radius; then set the distance of the opposite extremities from c to *v*, on the vanishing line, V L, and *v* will be the vanishing point of the line, as required.

The proportional compasses will answer to any distance of the eye from the vanishing line, however great, by taking one-half, one-third, one-fourth, &c. of the distance of the vanishing line, as most convenient, with the extremities marked R; then repeating the distance between the points of the opposite extremities, twice, three times, four times, &c., accordingly.

By this method, the vanishing point of every original line, of any plane figure, may be found without having the point of sight placed in a perpendicular to the vanishing line from the centre of the picture. This will be very convenient, as the extension is entirely confined to the vanishing line, and thus it requires the paper to be of no greater breadth than what is sufficient for the picture intended.

Example.—Let it be required to find the vanishing points of a rectangle, supposing the right-hand side to be placed at 40° with the intersecting line.

Subtract 40° from 90°, the number contained in a right angle, and the remainder, 50°, will give the angle made by the primary, or shortest radial, and the radial of the right-hand side, or the angle made by the original side of the rectangle on the right-hand, and a perpendicular in the original plane to the intersecting line; then the angle contained between the primary radial and the radial of the left-hand side of the rectangle will be 40°. Now, suppose the length of the picture to be 12 inches, and the spectator to stand at 2 feet, or 24 inches, from the centre of the vanishing line; and suppose the proportional compasses to be $6\frac{1}{2}$ inches, which is the usual length: divide 24 into 6 equal parts, each of which, in this instance, will contain 4 inches; slide the index of the instrument to 50° on the line of tangents; then with the legs R, take the extent of 4 inches, or the sixth part of 2 feet, and repeat the distance of the opposite points on the vanishing line, from the centre, c, of the picture, towards the right-hand, six times, to *v*, and *v* will give the vanishing point. To find the vanishing-point of the left-hand side: as the radial of this side makes 40° with the primary radial, slide the index of the instrument to 40° on the line of tangents; then, with the legs marked R, take the extent of 4 inches, or the sixth of 2 feet; repeat the distance between the points of the opposite ends from the centre of the picture towards the left hand, six times to v, and v will be the vanishing point on the left-hand side of the rectangle.

The vanishing points of all lines whatever may be found in this manner, having the angle formed by the intersecting line and the original: for this is always equal to the angle formed by the radial and the parallel of the eye; and because the distance of a vanishing point from the centre of the picture is the tangent of the angle made by the primary radial and the radial of the line, the primary radial being radius, the proportional compasses, being set as above, will give the true vanishing point.

Scholium.—None of the lines on the proportional compasses, except the tangents, require the slit to be less than half the length of the shank, deducting that part of the slide from the centre of the pin; the tangents, therefore, cannot be inserted higher than 45°; and, indeed, the higher tangential numbers would be of little use, as the radius would be shortened by every such increase: and it would be attended with greater inaccuracy and more labour. If the gradations, however, do not exceed 45°, the distance of the extremities of the compasses may still be extended to six inches: but, in order to find the tangent of any greater number of degrees than 45, we have only to subtract that number of degrees from 90, and the remainder is the complement of the angle; then it will be as the tangent of the complement is to radius, so is radius to the tangent itself.

From these observations it will be very easy to find the vanishing point of any line, whatever number of degrees the radial of that line forms with the primary radial, as may be seen in the following problem.

Problem XII.—*To find the vanishing point of a line, the radial of which makes a greater angle with the primary radial than* 45°, *the vanishing line and its centre being given, as also the primary radial.*

Subtract the given angle from 90°; set the index of the compasses to the tangent of the remaining angle; take a convenient aliquot part of the distance of the eye from the vanishing lines, and set the legs marked R, to that distance; upon any imaginary straight line, A E, with the ends R, set off the distance A B; take the distance A B, with the opposite ends, and set off the distance A D; then let V L be the vanishing line, and C its centre; and, according as the original line, or its radial, is on the right or left, the distance, A D, must be set to the right or left of the centre of the picture, as often as the radial is supposed to contain the distance of the points upon the legs marked R.

Example.—Suppose the radial of the line to make an angle of 50° with the primary radial, and the length of the primary radial to be three feet; to find the distance of the vanishing point from the centre of the picture.

Subtract 50° from 90°, and the remainder is 40°; set the index to the tangent of 40°; take the ninth part of the primary radial, or 4 inches, and extend the ends opposite to those marked R, to 4 inches, or the ninth part of the distance, and repeat the distance of the legs marked R, on the vanishing line, nine times from the centre to the right or left hand accordingly; and the extremity of the distance so repeated from C, is the vanishing point required.

The reason of this operation is evident; since the radius is a mean proportional between the tangent of the angle and the tangent of its complement, and, therefore, as the tangent of the complemental angle is to the radius, so is the radius to the tangent itself.

If the object to be drawn be a rectangle, making unequal angles with the intersecting line, the angles made by the radials of the sides and the primary radial, being equal to the angles made by the sides of the rectangle and the intersecting line, or a line drawn through the outer corner parallel to the intersecting line; set the proportional compasses to the tangent of the least angle; extend the legs marked R to the distance, or to any part of the distance that the compasses will admit of; set the distance of the opposite legs, or repeat that distance as often as the primary radial contains parts, from the centre to the right or left, and the point of extension will give the vanishing point of that side of the rectangle; extend the ends opposite to R to the primary radial, or that portion of it before-mentioned, that the compasses will admit of, and the extension between the extremities of the legs marked R, being set from the centre on the other side of the vanishing line, or repeated according to the number of parts into which the primary radial is divided, will give the vanishing point of the other side of the rectangle, viz., of that side which makes the greatest angle with a line perpendicular to the intersection; and therefore the vanishing point so found must be upon the same side of the centre of the picture that the angle itself is upon, being nothing more than the tangent of that angle.

Scholium.—The vanishing points of a rectangular building may be found arithmetically upon the foregoing principles, viz., as the tangent of the angle made by the radial of one side and the primary radial is to the primary radial itself, so is the primary radial to the tangent of the angle made by the radial of the other side and the primary radial. Now, admitting the shortest tangent to be to the primary radial as 2 to 3, and the length of the primary radial 3 feet 6 inches, or 42 inches; to find the vanishing points, it will be

```
3 : 2 : : 42
             2
           ---
       3 ) 84
           ---
           28 inches, the distance of
```

the vanishing point of the least angle.

```
And again, 2 : 3 : : 42
                      3
                    ----
                2 ) 126
                    ----
                    63 inches, the distance of
```

the vanishing point of the greater angle.

Or, because the distance is a mean proportional between the two tangents, it will be

```

        ---       as before.
         84
         84
```

When the distance of the vanishing points is required, the square root of the sum of the squares of each tangent, and the primary radial, will give the distance from each respective vanishing point; but if the vanishing points be inaccessible, subtract each tangent from the respective distance so found, and set the remainder on each side of the centre of the picture.

This method of finding the distance would be thought by many artists very troublesome; but the following, by the proportional compasses, is very easy: Suppose one radial to make an angle of 30°, the other will be 60° with the primary radial; add 30° to 90°, the sum will be 120°; take the half of 120, which is 60; then 30 from 60, there remains 30; the tangent of 30°, set upon the other side of the primary radial, will give the distance of the vanishing point. Again, add 60 to 90, the sum is 150, the half is 75°; subtract 60 from 75, and the remainder is 15°; then the tangent of 15°, set from the centre of the picture on the other side of the angle of 60°, will give the distance of the vanishing point of the line that makes 30° with the intersection.

Again, suppose one of the angles to be 40°, the other will be 50°; add 40 to 90, the sum is 130; the half of 130 is 65; subtract 40 from 65, and the remainder is 25°; then the tangent of 25°, set on the other side of 40 from the centre of the picture, will give the distance of the vanishing point of the line, the radial of which makes 40° with the primary radial. Again, add 50 to 90, the sum is 140, the half is 70; subtract 50 from 70, and the remainder is 20°; then, the tangent of 20° being set from the centre of the picture upon the other side of the angle formed by the primary radial, the other radial, containing 50°, will give its distance.

In general, suppose the lesser angle to be called v, and the greater w; then $\frac{v + 90}{2} - v = \frac{90 -}{2} = 45 - \frac{v}{2}$, and the tangent of this angle, set upon the other side, will give its vanishing point.

Again, $\frac{w + 90}{2} - w = \frac{90 - w}{2} = 45 - \frac{w}{2}$, gives the distance of the other vanishing point, set on the contrary side of the centre; thus, if $w = 60$, then $45 - \frac{w}{2} = 15$, therefore set the tangent of 15° as directed; and thus the tangent of the remainder of half the angle contained by the primary radial and the radial from 45°, gives the vanishing point; or, take the tangent of half the complement of the said angle, and set it on the vanishing line from the centre of the picture on the other side, and it will give the vanishing point.

Problem XIII.—*Given the angle made by the radials of any two original lines with each other, and the angle which one of them makes with the primary radial; to find a dividing point common to the same measures or scale, so as to cut off a portion from the indefinite representation of each line, such that the portions may be the representations of the two original lines.*

Note.—When one of the angles which the primary radial makes with the one radial is given, that made by the primary radial with the other may be found by subtracting the one given from the whole angle contained by the radials. This being obtained, proceed as follows:—Subtract the lesser angle formed by the one radial and the primary radial from half the angle contained by the radials of the original lines; then, if the tangent of the remaining angle be set on the vanishing line, on the side of the primary radial which has the greatest angle, it will give the dividing point required.

Thus, call the whole angle A; the half is $\frac{A}{2}$; call the lesser angle made by the primary radial with one radial, B, then $\frac{A}{2} - B$ is the difference; find the tangent of $\frac{A}{2} - B$; then the greater angle made by the primary radial with the other radial being $A - B$, set the tangent of $\frac{A}{2} - B$ from C, on the vanishing line on the side of $A - B$, and the extremity of the distance will give the dividing point required.

Example 1.—Suppose the angle contained between the two radials to be 100°, and the lesser angle to be 40°, then the greater will be 60: now the half of 100 is 50: subtract 40°, the lesser angle, from 50, there remains 10: set the index of the proportional compasses to 10° on the line of tangents; take the length of the primary radial with the legs marked R, and set off the distance contained by the opposite points from the centre of the picture on the vanishing line, on the side of the primary which has the angle of 60°, and the extremity of the distance is the dividing point.

Example 2.—Suppose the angle contained by the radials to be 80°, the lesser angle to be 30°, and consequently the greater 50°; the half of 80° is 40°; subtract 30° from 40 and 10° remain. Set the index of the proportional compasses to the tangent of 10°; take the length of the radial with the legs marked R, and set the distance of the point contained by the opposite legs from C on the vanishing line, on the side of the angle of 50°, and the extremity will give the dividing point.

Problem XIV.—*Given the sun's altitude on a plane, the height of a line, and the length of its shadow on that plane, the orthographical representation of a cornice, with a section of the same, also the seat of the sun's rays; to find the shadow of the cornice.*

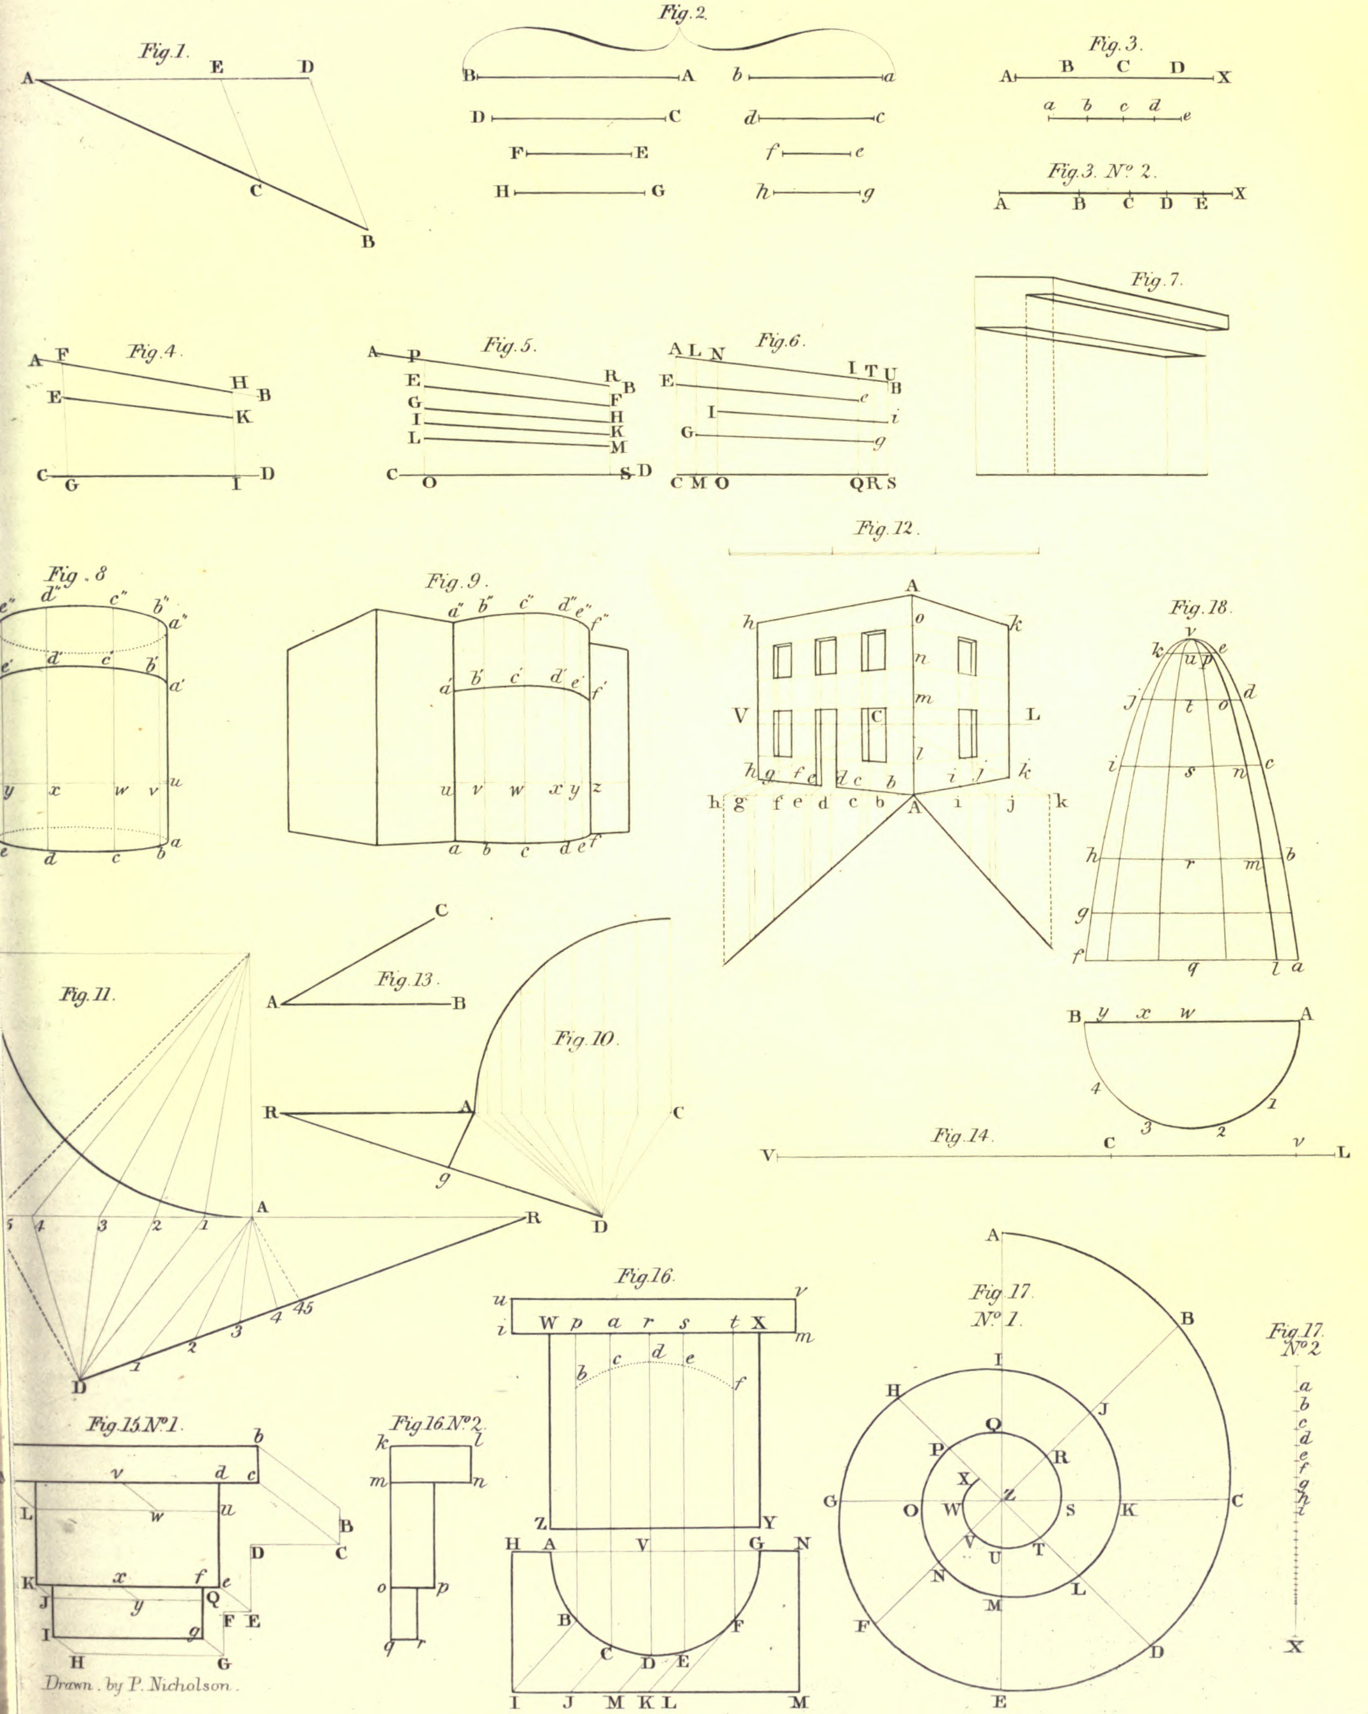
Figure 15.—Let No. 1 be the cornice or architrave, and No. 2 a profile, or section, perpendicular to the arrises, or edges of the mouldings; draw *b* B for the indefinite representation of the shadow of a line represented by the point *b*, No. 1, and let *b* B be the distance that the shadow is thrown from the point *b*, so that B will be the shadow of *b*; from all the external angles draw *c* C, *e* E, *g* G, I H. Now *k l*, No. 2, is the length of the line represented by the point *b*, No. 1, set the proportional compasses in the ratio of *k l*, No. 1, to *b* B No. 2: make *c* C equal to *b* B: take *o p*, No. 2, with the shorter ends, and make *e* E, No. 1, equal to the distance between the points of the remote ends; take *q r*, No. 2, with the shorter legs, and make *g* G, No. 1, equal to the distance between the points of the remote ends; join B C; draw C D parallel to M *c*, and draw E D parallel to *e d*; draw E F parallel to *e* K, and G F parallel to *g f*; draw G H parallel to *g* I and *b* B C D E F G H I will be the shadow from one side: draw the lines M L, K J, parallel to *b* B, *c* C, &c., to meet K *h* and I at L and J; then will M L and K J be the shadows upon the other side. To find the shadows upon the planes of the faces in the representation, *c* M, of the arris line, take any point, *v*, and draw *v w* parallel to *b* B, or *c* C, &c.; also, in the representation, *e* K, of the next arris line, take any point, *x*, and draw *x y* parallel to *b* B or *c* C; take the distance *d c*, with the shorter ends of the proportional compasses, and make *v w* equal to the distance between the points of the longer legs; also, take the projection, *f e*, with the shorter legs, and make *x y* equal to the distance contained between the points of the remote ends; through the points *w* and *y* draw L *u* and J *t* parallel to M *c*, which will terminate the breadth of the shadow upon the face.

The reason of this operation is evident, since the distance that a shadow will be thrown by a line perpendicular to a plane, is as the length of the line: and the shadow of a line parallel to a plane will be projected on the plane parallel to the line which projects the shadow; and every two parallel lines in the original object are also represented by parallel lines.

Problem XV.—*The representation of a cylinder with a square abacus, or cap, being given, to find the shadow of the cap upon the cylindric surface, the axis of the cylinder being parallel to the plane of projection; also, the shadow of a line perpendicular to the axis of the cylinder, and in a plane passing along the said axis, and through the luminary.*

Figure 16.—Let A B C D E F G be the plan of the semi-cylinder, and H I M N that of the cap; let W X Y Z be the elevation of the semi-cylinder, and *i m v u* that of the cap; let I B be the projection, or representation, of a ray on the plan from the corner of the abacus at I, cutting the plan of the cylinder at B; draw L F parallel to I B, to touch the semicircle in F, and cutting I M at L; draw F V perpendicular to L F, V being the centre of the semicircle; and F will be the point of contact: in I M take any number of intermediate points J, M, K, and draw J C, M D, K E, parallel to I B, cutting the

PROPORTIONAL COMPASSES.



Drawn. by P. Nicholson.

semicircle in C, D, E; draw B p, C a, D r, E s, F t, parallel to the axis of the cylinder, cutting the under edge, $i\ m$, of the abacus in p, a, r, s, t; set the proportional compasses in the ratio to the distance to which I B will throw the shadow, and suppose I B to be greater than the length of its shadow; take the distance, I B, with the longer legs; make $p\ b$ equal to the distance contained between the points of the opposite ends; take the distance, J C, with the longer legs, and make $a\ c$ equal to the distance contained between the shorter legs; take the distance, M D, with the longer legs, and make $r\ d$ equal to the distance contained between the opposite points; and the points, b, c, d, will be obtained. In the same manner, the points e and f will be found; through the points, b, c, d, e, f, draw a curve, which will be the shadow of the lower edge of the abacus; the sun's rays will be in a tangent plane to the cylinder surface at F f: and the part of the edge of the shadow which falls upon the representation of the cylindric surface, from i to b, will be straight.

In the same manner, if the representation of a cylinder capped with a cylindric abacus, having the same axis with the cylinder, be given, and the representation of the sun's rays on the plan, supposing the axis of the cylinder perpendicular to the plane of projection, the shadow of the abacus may be found upon the cylindric surface; and thus for every other prismatic object.

PROBLEM XVI.—*To describe the logarithmic spiral by a series of points found in the curve; the centre, and two opposite points in a straight line passing through the centre, being given in the curve.*

Figure 17.—Let Z, No. 1, be the centre; let the straight line, A E, pass through Z; let A and E be two opposite points, the one, A, on the one side, and the other, E, on the other side of the centre, Z; through Z draw G C at right angles to A E; bisect the angle A Z C, by the straight line B F; also bisect the angle E Z C, by the straight line D H; find Z C, a mean proportional between Z A and Z E; also find Z B, a mean proportional between Z A and Z C; draw any straight line, Z X, No. 2, and set the proportional compasses in the ratio of Z A to Z B; take the distance, Z A, with the points of the longer legs, and set that distance from X to a, No. 2, and make X b equal to the distance contained between the shorter legs; contract the points of the longer legs to X b, and with the shorter legs set off the distance X c; contract the distance between the points of the longer legs to X c, and make X d equal to the distance contained between the points of the shorter legs; and the parts, $a\ b$, $b\ c$, $c\ d$, of the straight line, X a, will be in geometrical progression. In the same manner, the points e, f, g, h, i, &c., may be found, which will continue the series of parts as far as there may be occasion; make Z A, No. 1, equal to X a, No. 2, Z B equal to X b, Z C equal to X c. In the same manner, the points, D, E, F, G, H, I, &c., may be continued through any number of revolutions; and a curve drawn through all the points will give the spiral required.

Scholium.—As the tracing of the curve depends very much on the eye of the person who performs this operation, by the following method a curve may be drawn with a pair of compasses, provided the points do not approach very rapidly to the centre. To describe any quadrant, take the length of the radius that bisects it from one extremity of the curve, describe an arc, and with the same radius from the other extremity describe another arc cutting the former; then, from the point of intersection with the same distance, describe an arc between the two extremities, and it will pass through the middle point, very nearly; thus, take the distance Z B as a radius; from the extremity A, of the arc A B C, describe an arc near the centre; from the point C, with the same radius, describe another arc, cutting the former near the centre Z; then, from the point of intersection, describe the arc A C, which will pass through the point B, very nearly. In the same manner the successive arcs, C E, E G, G I, &c. may be described; and the curve thus formed will be so near as not to be detected by the eye.

PROBLEM XVII.—*To draw the representation of the meridians of a solid of revolution upon a plane parallel to the axis of the solid; given an axal section, that is, a section of the solid, passing along the axis, upon a plane parallel to the said axis.*

Figure 18.—Let $a\ b\ c\ d\ e\ v\ k\ j\ i\ h\ g\ f$ be the axal section, $q\ v$ the axis itself, and $a\ f$ the base perpendicular to $q\ v$; in $q\ v$ take any number of points, r, s, t, u; through these draw $b\ h$, $c\ i$, $d\ j$, and $e\ k$, perpendicular to $q\ v$, meeting the curve on the one side at b, c, d, e, and on the other at h, i, j, k; then it is obvious that the lines $b\ h$, $c\ i$, $d\ j$, $e\ k$, will be bisected; now, supposing the meridians to be formed on the surface of the solid by the intersection of five planes at equal angles round the axis, and that one of these planes is parallel to the plane of projection, and let $a\ v\ f\ a$ be the representation of that plane; draw A B parallel to $a\ f$; produce $v\ q$ to meet A B at w; from w as a centre, with the radius $q\ a$, or $q\ f$, describe the semicircle A 1 2 3 4 B; divide the semicircle into five equal parts by the points of section 1, 2, 3, 4; draw 3 x and 4 y perpendicular to A B, cutting A B at x and y; make $q\ l$ equal to $w\ y$; set the proportional compasses in the ratio of $q\ a$ to $q\ l$; take the distance $r\ b$, with the longer legs, and with the opposite legs set off the distance $r\ m$; take the distance $s\ c$, with the longer legs, and with the opposite points set off the distance $s\ n$; take the distance $t\ d$, with the longer legs, and with the shorter legs set off the distance $t\ o$; lastly, take the distance $u\ e$, with the longer legs, and with the shorter legs set off the distance $u\ p$; then draw the curve $l\ m\ n\ o\ p\ v$, which will be one of the meridians, as required. In the same manner all the others may be found.

Besides the uses of the proportional compasses, which have already been shown, they may be applied to trigonometry in finding the sides and angles of triangles; suppose, in a right-angled triangle, that the two legs were given, to find the angles; the analogy is, as the one side is to the other, so is radius to the tangent of the angle opposite the latter side; set the proportional compasses in the ratio of the two sides containing the right angle; then the index will show the tangent of the angle on the line of tangents.

Again, suppose the hypothenuse and one of the legs were given, to find the angles; the analogy in this will be, as the hypothenuse is to the given leg, so is radius to the sine of the angle opposite to that leg; set the proportional compasses in the ratio of the hypothenuse to the given leg, and the index will be against the sine of the angle.

Lastly, suppose the angles and the hypothenuse to be given: the method of proceeding in this case is exactly the reverse of the last; thus, set the proportional compasses to the sine of the angle, then extend the longer legs to the hypothenuse of the angle, and the shorter legs will contain the length of the leg required.

In the same manner, if the angles and one of the legs were given, to find the other leg; set the proportional compasses to the tangent of the leg required, then take the length of the given leg with the longer legs, and the distance between the points of the shorter legs will be the leg of the triangle, as required.

PROPYLÆA, (Greek προ, before or in front of, and πυλον a gate) the entrance to a temple or other large building, consisting mostly of a gateway flanked by towers or other erections. The Egyptian temples were universally adorned with magnificent propylæa, which consisted of lofty truncated pyramids of solid masonry, covered on the faces with hieroglyphics.

The term is also particularly applied to the entrance of the acropolis of Athens, which was erected by Pericles, and was of unusual magnificence.

PROPYLON, an entrance or vestibule.

PROSCENIUM, (Greek) in the ancient theatre, an eminence on which the actors performed their parts. The proscenium answered to our stage. It consisted of two parts among the Greeks; one, particularly so called, where the actors performed; the other was the *logeion*, where the singers and the mimics acted their parts. Among the Romans, the proscenium and pulpitum were the same.

PROSTYLE, (from the Greek προςυλος, formed from προ *before*, and ςυλος, *column*) in the ancient architecture, a range of columns in the front of a temple.

PROSTYPA (from προστυπα) images carved in such a manner as to be only half raised above the ground, or plain, on which they are formed. They seem to adhere to it, and have only one side exposed to view. To *prostypa* is opposed *ectypa*.

PROTHYRIS, (Greek) in ancient architecture, a word sometimes used for a cross-beam, or over-thwart rafter; as likewise, for a quoin or corner of a wall; otherwise called *anco*. *See* CONSOLE.

PROTHYRUM, (from προθυρον) a porch at the outer door of a house, or portal.

PROTRACTOR, (from the Latin *protractus*, to draw out) an instrument used in surveying, by which the angles taken in the field with a theodolite, circumferentor, or the like, are plotted, or laid down, on paper.

This protractor consists of a semicircular limb of brass, silver, horn, or the like, divided into 180°, and subtended by a diameter, in the middle of which is a little notch, or lip, called the *centre of the protractor.*

For the convenience of reckoning both ways, the degrees are numbered from the left hand towards the right, and from the right hand towards the left.

But this instrument is made much more commodious by transferring the divisions on the same circumference to the edge of a ruler, whose side is parallel to the diameter, which is easily done by laying a ruler on the centre, and the several divisions on the semi-circumference, and marking the intersections of that ruler on the line: so that a ruler with these divisions marked on three of its sides, and numbered both ways, as in the protractor (the fourth, or blank side representing the diameter of the circle) is of the same use as a protractor, and much better adapted to a case.

On the limb of the protractor are sometimes also placed numbers, denoting the angles at the centres of regular polygons: thus, against the number 5, denoting the sides of a pentagon, is found 72, the angle at the centre of a pentagon, &c.

The uses of this instrument are, 1. *To lay down an angle of any given quantity, or number of degrees, at any point, and with any given line.*

Example.—Lay the centre of the protractor on the given point, and the diameter of the protractor on the given line: make a mark against the given degree (say 50) on the limb of the protractor; through which, from the given point, draw a line, and it will give the angle required.

2. *To find the quantity of a given angle.*—Lay the centre of the protractor on the point of the angle, and the diameter on one of the lines forming it. The degree of the limb cut by the other line (*viz.* 50) is the number of degrees of the angle required.

3. *To inscribe any given regular polygon (a pentagon for example) in a circle.*—Lay the centre and diameter of the circle, and make a dot against the number of degrees of the angle at the centre, *viz.* 72.. Through this dot and the centre of the circle draw a line, cutting the circumference of the circle. To the point of intersection, from the point where the diameter cuts the circumference, draw a right line; this line will be a side of the pentagon, which, being taken in the compasses, and set off as often as it will go in the circumference, will give points, which, being connected by lines, will form the pentagon required.

4. *To describe any regular polygon* (e. gr. *an octagon*) *on a given line.*—Subtract the angle at the centre, which the protractor gives (say 45°) from 180; and the remainder, 135, will be the angle included between two sides of the octagon, one-half of which is 67½. Applying then the diameter of the protractor over the given line, with the centre over one extreme; make a dot against 67½, to which, from the centre, draw a line: apply the protractor to the other end of the line, with the centre over the extreme, and there set off another angle of 67½°. From the point where the two lines thus drawn intersect, as a centre, describe a circle with the interval of the given line. The given line will be one side of the octagon; and this set off as often as it will go in the circumference thus drawn, will give points, which, being connected, will form the octagon required.

PROTRACTOR, *Improved*, an instrument much like the former, but furnished with a little more apparatus, so that an angle may be set off to a minute; which is impracticable on the other.

The chief addition is an index fitted on the centre, and moveable on it, so as to play freely and steadily over the limb.

Beyond the limb, the index is divided, on both edges, into sixty equal parts of the portions of circles, intercepted by two other right lines drawn from the centre, so that each makes an angle of one degree with lines drawn to the assumed points from the centre.

To set off an angle of any number of degrees and minutes with this protractor, move the index, so that one of the lines drawn on the limb, from one of the fore-mentioned points, may fall upon the number of degrees given; and prick off as many of the equal parts on the proper edge of the index as there are minutes given; thus, by drawing a line from the centre to the point so pricked off, an angle is obtained with the diameter of the protractor, of the proposed number of degrees and minutes.

PSEUDO-DIPTERAL, (from ψευδο-διπτερος) a temple with eight columns in front, and a single row of columns all round.

The word signifies *false* or *imperfect* diptere; and is used to distinguish this from the diptere, which was surrounded with a double row.

PSEUDO-PERIPTERAL, (Greek, ψευδο-περιπτερος, *false peripteral*,) a term applied to temples in which the columns at the sides are engaged in the wall, instead of being detached from it, as in the true peripteral buildings, the walls of the cella being carried forward to the inter-columniations of the portico.

PTEROMA, the space between the walls of the cella of a temple, and the columns of the peristyle; called also *ambulatio*.

PUDDLING, the method of backing a wall with clay rammed into a compact mass, by means of a beater.

PUG-PILING, the same with *dove-tailed* or *pile planking*.

PUGGING, a coarse kind of mortar laid upon the sound-boarding between joists, in order to prevent sound reaching from one apartment to another.

PULLEY, (from the French, *poulie*) one of the five mechanical powers; consisting of a wheel, or rundle, having a channel around it, and turning on an axis, serving; by means of a rope which slides in its channel, for the raising of weights.

The Latins call it *trochlea;* and the seamen, when fitted with a rope, a *tackle.* An assemblage of several pulleys is called *a system of pulleys,* or *polyspaston:* some of which are in a block, or case, which is fixed; and others in a block which is moveable, and rises with the weight. The moveable wheel, or rundle, is called the *shieve* or *shiver;* the axis on which it turns, the *gudgeon;* and the fixed piece of wood, or iron, into which it is put, the *block.*

The common methods of arranging pulleys in their blocks, may be reduced to two. The first consists in placing them one by the side of another, upon the same pin; the other, in placing them directly under each other, upon separate pins. Each of these methods is liable to inconvenience. Mr. Smeaton, in order to avoid the impediments to which these combinations are subject, proposes to combine these two methods in one. Accordingly, the pulleys are placed in each block, in two tiers; several being upon the same pin, as in the first method, and every one having another under it, as in the second; so that, when the tackle is in use, the two tiers that are the most remote from each other, are so much larger in diameter than those that are nearest, as to allow the lines of the former to go over the lines of the latter, without rubbing. From this construction arises a new method of reviving the line upon the shieves; for here, whatever be the number of shieves, the fall of the tackle will be always upon the middle shieves, or on that next to the middle, according as the number of pulleys in each pin is odd or even. To do this, the line is fixed to some convenient part of the upper block, and brought round the middle shieve of the larger tier of the under block, from thence round one of the same sort next the centre one of the upper block, and so on, till the line comes to the outside shieve, where the last line of the larger tier falls upon the first shieve of the smaller, and being reeved round those, till it comes at the opposite side, the line from the last shieve of the smaller tier again rises to the first of the larger, whence it is conducted round, till it ends on the middle shieve of the upper block on the larger tier.

As a system of pulleys is of no great weight, and lies in a small compass, it is easily carried about, and can be applied, in many cases, for raising weights, where other engines cannot be used. But they have a great deal of friction; because the diameters of their axes bear a very considerable proportion to their own diameters; and because, in working, they are apt to rub against each other, or against the sides of the block, to say nothing of the stiffness of the rope that goes over and under them.

PULLEY, *Doctrine of the.* 1. If the equal weights W and P hang by the cord B B upon the pulley A, whose block, *b*, is fixed to the beam H I, they will counterpoise each other, just in the same manner as if the cord were cut in the middle, and its two ends hung upon the hooks fixed in the pulley, at A and A, equally distant from its centre.

Hence, a single pulley, if the lines of direction of the power and the weight be tangents to the periphery, neither assists nor impedes the power, but only changes its direction.

The use of the pulley, therefore, is when the vertical direction of a power is to be changed into a horizontal one; or an ascending direction into a descending one; and on the contrary.

This is found a good provision for the safety of the workmen employed in drawing with the pulley.

The change of direction by the means of a pulley has this farther advantage; that if any power can exert more force in one direction than in another, we are here able to employ it in its greatest force. For instance, a horse cannot draw in a vertical direction, but draws with all its advantage in a horizontal one. By changing the vertical draught, therefore, into a horizontal one, a horse becomes qualified to raise a weight.

But the grand use of the pulley is, where several of them are combined; thus forming what Vitruvius, and others after him, call *polyspasta;* the advantages of which are, that the machine takes up but little room, is easily removed, and raises a very great weight with a moderate force.

2. If a weight, W hangs at the lower end of the moveable block, *p*, of the pulley D, and the cord, G F, goes under the pulley, it is plain that the half, G, of the cord, bears one half of the weight, W, and the half, F, the other; for they bear the whole between them. Therefore, whatever holds the upper end of either rope, sustains one-half of the weight; and if the cord at F be drawn up so as to raise the pulley D to C, the cord will then be extended to its whole length, except that part which goes under the pulley; and consequently, the power that draws the cord will have moved twice as far as the pulley D, with its weight W, rises; on which account, a power whose intensity is equal to one half of the weight, will be able to support it, because, if the power moves (by means of a small addition) its velocity will be double the velocity of the weight; as may be seen by putting the cord over the fixed pulley C (which only changes the direction of the power, without giving any advantage to it) and hanging on the weight P, which is equal only to one-half of the weight W; in which case there will be an equilibrium, and a little addition to P will cause it to descend, and raise W through a space equal to one-half of that through which P descends. Hence, the advantage gained will be always equal to twice the number of pulleys in the moveable or undermost block. So that, when the upper or fixed block, *u*, contains two pulleys, which only turn on their axes, and the lower or moveable block, U, contains two pulleys, which not only turn upon their axes, but also rise with the block and weight, the advantage gained by this is as four to the working power. Thus, if one end of the rope, K M O Q, be fixed to a hook at I, and the rope passes over the pulleys N and R, and under the pulleys L and P, and has a weight, T, of one pound, hung to its other end, at T; this weight will balance and support a weight, W, of four pounds, hanging by a hook at the moveable block U, allowing the said block as a part of the weight. And if as much more power be added, as is sufficient to overcome the friction of the pulleys, the power will descend with four times as much velocity as the weight rises, and, consequently, through four times as much space. The two pulleys in the fixed block, X, and the two in the moveable block, Y, are in the same case with those last mentioned; and those in the lower block give the same advantage to the power.

It is necessary to observe, that if the lower pulleys do not rise all together in one block with the weight, as in the cases just recited, but act upon each other, and the weight is only fastened to the lowest of them, the force of the power is very much increased, each pulley doubling it. Thus, a power, whose intensity is equal to 8 lb. applied at *a*, will, by means of the lower pulley, A, sustain 10 lb.; a power equal to 4 lb. at *b*, will, by means of a lower pulley, B, sustain the power of 8 lb. acting at *a;* a third power, equal to 3 lb. at *c*, will, by means of the pulley C, sustain the power of 4 lb. at *b;* a fourth power of 1 lb. at *d*, will, by means of the pulley D, sustain the power of 2 lb. at *c;* and this is not altered by having its rope carried over the upper pulley, or roller, E.

In the former cases, the force of the power is augmented in an arithmetical proportion of the number of ropes or pulleys; but in this, in a geometrical proportion.

3. If a power move a weight by means of several pulleys, the space passed over by the power will be to the space passed over by the weight, as the weight, to the power.

Hence, the smaller the force that sustains a weight by means of pulleys is, the slower is the weight raised; so that what is saved in force, is spent in time.

Pulley mortise, a longitudinal mortise of considerable length, parallel and near to the under side of the bonding joists, in order to insert the ceiling joists.

PULPIT, an elevated stage or desk, from which orations are pronounced, applied more especially to those employed in churches. They are for the most part of wood, but sometimes of stone, of which an early and beautiful example exists at Beaulieu, Hants. The greater number of examples are of Perpendicular work, and these principally of wood, and polygonal in plan; sometimes with a canopy above. Pulpits are sometimes found outside of buildings, as at Magdalen College, Oxford, and in many instances abroad, where also are pulpits of great size and magnificence, capable of containing more than one person.

PULPITUM, (Latin) among the Romans, a part of the theatre, called also *proscenium*, or what we now call the *stage*, on which the actors trod. Though some say it was properly an eminence on the stage for the music; or a suggestum, whence declamations, &c. were spoken.

The French use the word pulpit, *pupitre*, for a reading-desk in a church, library, or the like; those large ones in churches they properly called *lutrins*.

PULVINARIA, (Latin,) cushions upon which the statues of the gods were laid in the temples, at the time when thanks were given for some signal victory.

PULVINATED, (from the Latin, *pulvinatus*,) in ancient architecture, a term applied to a frieze, which swells, or bulges out, in manner of a pillow, *pulvinus:* whence the name.

PUNCHION, or Puncheon, (from the French, *poinçon*,) a little block or piece of steel, on one end of which is some figure, letter, or mark, engraven either in creux, or in relievo; impressions of which are taken in metal, or some other matter, by striking it with a hammer. There are various kinds of these puncheons used in the mechanical arts. Such, for instance, are those of the goldsmiths, cutlers, pewterers, &c.

Punchion, is also a common name for all the iron instruments used by the stone-cutters, sculptors, locksmiths, &c., for the cutting, inciding, or piercing their several matters.

Those of sculptors and statuaries serve for the repairing of statues, when they are taken out of moulds.

The locksmiths use the greatest variety of punchions; some for piercing hot, others for piercing cold; some flat, some square, some round, others oval; each to pierce holes of its respective figure in several parts of locks.

Punchion, or Punchin, in carpentry, a piece of timber placed upright between two posts, whose bearing is too great, serving, together with them, to sustain some heavy weight.

The punchion is usually lower and slighter than either prick-posts or principal posts, and is joined by a brace, or the like, of iron. *See* Post. Those on each side of a door are called *door punchions.*

Punchion is also a piece of timber raised upright under the ridge of a building, in which the little forces, &c., are jointed. Vitruvius calls the punchion *columen.*

Punchion, is also used for the arbor or principal part of a machine, on which it turns vertically; as that of a crane, &c.

PUNT, a sort of oblong flat-bottomed boat, with a square head and stern, whose floor resembles the platform of a floating stage; used by shipwrights for breaming, caulking, or repairing a ship's bottom. It is also used in some canals.

PURBECK STONE, (the *saxum arenarium cinereum Purbecense* of Da Costa, and *psadurium friabile albido fuscum* of Hill,) an alkaline sand-stone, harsh and rough, of a disagreeable ash-colour, very heavy, and moderately hard; of a texture not very compact, but somewhat porous, and composed of an angular grit, cemented together by an earthy spar: it cuts freely, and with a tolerably even or smooth surface. It will not strike fire with steel, and burns to a white colour. The quarries of this stone are in the island of Purbeck, in Dorsetshire, whence it is brought to London in great quantities, and there used in building, and for pavements. Its specific gravity is 2.68. There is also another kind of Purbeck stone, the *saxum fusco-albidum* of Da Costa, and the *sympexium durissimum splendidum albido-fuscum* of Hill, which is alkaline, of a dull disagreeable pale-brownish white colour, and cuts to a very smooth surface: it is of a fine, close, compact texture, not quite destitute of brightness, but full of sparks of pure spar, and intimately mixed with vast quantities of small pectunculi, which are often saturated and filled with the same substance; is very heavy and hard, and water does not pervade its texture; it does not strike fire with steel, and when burnt acquires a clear ashen colour. This stone is brought from Purbeck, and used in building, pavements, &c. Hill informs us, that it is likewise found in many other parts of the kingdom, and that there are large strata of it in Yorkshire.

PURFLED, (from the French, *pourfiler*, to embroider,) ornamental work, whether in stone or other materials, representing drapery, embroidery, or lace-work.

PURLINS, pieces of timber lying across the rafters on the inside, to keep them from sinking in the middle of their length.

Purlins are supported by the principals. The strongest method is to make bridges over, as in the present practice of the construction of roofs.

PUTEAL, (from the Latin, *puteolus*, a well,) among the Romans, a small kind of edifice raised in the place where a thunder-bolt had fallen.

PUTLOGS, or Putlocks, short pieces of timber, about seven feet long, used in building scaffolds. They lie at right angles to the wall, with one of their ends bearing upon it, and the other upon the ledges or poles which stand parallel to the side of the wall of the building.

PUTTY, (from the French, *potee*,) a kind of paste, compounded of whiting, with or without a little white-lead, and linseed oil, beaten together to the consistence of a tough dough; used by glaziers for fastening the squares of glass in sash-windows, &c., and by painters, to stop up the crevices and clefts in timber and wainscot, to prevent the wet from getting in and ruining the work.

PUZZOLANA, or Pozzolana, a kind of substance formed of volcanic ashes, more or less compacted together, so called from Pozzuolo, as also *pulvis Puteolanus*, from Puteoli, situate near mount Vesuvius, from which these ashes are ejected, and in the vicinity of which it abounds. It occurs of various colours, white, red, or black, reddish, or reddish-brown, gray or grayish-black; that of Naples is generally gray; that of Civita Vecchia is more generally reddish, or reddish-brown. The red variety is the proper puzzolana; the black and the white sorts are called, in Italy, *lapillo*, or *rapillo*. The ashes which overwhelmed Pompeii now form an immense bed of white puzzolana. The surface of this substance is rough, uneven, and of a baked appearance. It comes to us in pieces, from the size of a nut to that of an egg. It is wholly destitute of internal lustre and transparency. It is easily frangible, and its fracture is uneven or earthy, and porous; commonly filled with particles of pumice, quartz, scoriæ, &c. Hardness, 3. Very brittle. Specific gravity from 2.570, which is that of the black, to 2.785, rarely 2.8. Its smell is earthy. It is not diffusible in cold-water; but in boiling-water it gradually deposits a fine earth. It does not effervesce with acids. Heated, it assumes a darker colour, and easily melts into a black slag, or, with borax, into a yellowish-green glass. Before it is heated, it is magnetic, but not afterwards. By Mr. Bergman's analysis, it contains from 55 to 60 per cent. of siliceous earth, 19 to 20 of argillaceous earth, 5 or 6 of calcareous earth, and from 15 to 20 of iron. When mixed with a small proportion of lime, it quickly hardens; and this induration takes place even under water. This singular property proceeds, as Mr. Kirwan supposes, from the magnetic state of the iron it contains; for this iron, being unoxygenated, subtilly divided, and dispersed through the whole mass, and thus offering a large surface, quickly decomposes the water with which it is mixed, when made into mortar, and forms a hard substance, analogous to the specular iron-ore, as it does in the iron tubes, in which water is decomposed, in the experiments of M. Lavoisier and Dr. Priestly; for in these the iron swells and increases in bulk; and so does puzzolana, when formed into mortar, as we learn from Higgins *on Cements*. One principal use of lime seems to be to heat the water, as, while it is hot, it cannot pervade the caked argil that invests the ferruginous particles; yet, in time, even cold water may pervade it, and produce hardness; and hence, as M. Dolomieu has observed, lavas become harder when moistened. If the mortar be long exposed to the atmosphere, fixed air, as well as pure air, will unite to the iron, rust will be produced, and the mortar will not then harden, as Dr. Higgins has noticed. Clay, over which lava has flowed, is frequently converted into puzzolana; but volcanic scoriæ never afford it; either because they are much calcined, or retain sulphur, or its acid. The ancients were well acquainted with this substance and its properties: and, among them, its principal use, as it has been also in modern times, was that of mixing it with their cements for buildings sunk into the sea. As it hardens and petrifies in water, it is of particular service in making moles and other buildings in maritime places.

PYCNOSTYLE, (from πυκνοςυλος, formed from πυκνος, *close*, and ςυλος, *column*,) in the ancient architecture, a building where the columns stand very close to each other; one diameter and a half of the column being allowed for the intercolumniation.

The pycnostyle is the smallest of all the intercolumniations mentioned by Vitruvius. Some make it the same with *systyle*; others distinguish the latter by its allowing half a module more in the Corinthian intercolumniation.

The pycnostyle, Mr. Evelyn observes, chiefly belonged to the Composite order, and was used before the most magnificent buildings; as, at present, in the peristyle of St. Peter's at Rome, consisting of nearly three hundred columns; and such as yet remain of the ancients among the lately-discovered ruins of Palmyra.

PYRAMID, (from the Greek, πυραμις—derived from πυρ, fire) a solid standing on a square, triangular, or polygonal basis, and terminating at top in a point; or a body whose base is a regular rectilinear figure, and whose sides are plain triangles; their several verticals meeting together in one point.

Euclid defines it a solid figure, consisting of several triangles, whose bases are all in the same plane, and have one common vertex.

The pyramid is said to be *triangular*, *quadrangular*, *quinquangular*, &c., according as the base is triangular, quadrangular, &c. The pyramid may be called a square, triangular, &c. cone; or the cone may be denominated a round pyramid. When very narrow at bottom, i. e. their base very small, they are called *obelisks* and *needles*.

Some derive the word from πυρος, *wheat*, and αμαω, *colligo*; pretending that the first pyramids were built by the patriarch Joseph, for granaries. But Villalpandus and Bryant, with much better reason, derive the word from πυρ, *fire*; because of their ending in a point like flame; whence the latter writer conceives them to have been originally altars dedicated to the sun.

Wilkins, conversant with the Coptic tongue, suggests another derivation from that language, in which *pouro* signifies a king, and *miri*, a race or generation; and he says, the pyramids were thus called, because they were erected to preserve the memories of the Egyptian kings and their families; and that those who descended from them had recourse to these pillars in order to prove their pedigree: but this supposition can have very little weight, when it is recollected that the memory of the founder of the largest of the Egyptian pyramids was lost long before the days of Herodotus. And as to their having been erected for granaries, their internal capacity is so limited, that the nation could have derived no just benefit from them. We therefore prefer the idea of Villalpandus and Bryant as to the derivation of the term.

Pyramids are now, sometimes, erected to preserve the memory of singular events, or to transmit to posterity the glory and magnificence of princes; but, as they are the symbols of immortality, they are more commonly used as funeral monuments. Such is that of Cestius at Rome, the mausoleum of that distinguished Roman, who was one of the seven officers called *Epulones*, and is said to have lived under Augustus; it was repaired in 1673 by Pope Alexander VII.

The pyramids of Egypt, comprehending the great and small, are very numerous; of these there are about twenty of the largest size. The most remarkable are the three pyramids of Memphis, or, as they are now called, of Gheisa, Geeza, or Gizé. The dimensions of the greatest of these have been differently stated both by ancient and modern writers. Herodotus (lib. ii.) makes the base of it to be 800 Grecian feet long; Diodorus (lib. i.) 700; Strabo (lib. xvii.) less than 600; and Pliny (lib. xxvi. c. 12.) 883 feet. Among the moderns, Sandys found it to be 300 paces; Bellonius, 324; Greaves, 693 English feet; Le Bruyn, 704 French feet, or 750 English feet; Prosper Alpinus, 750 French feet; Thevenot, 682; Niebuhr, 710; Chazelles, 704.80 English feet. In order to reconcile these differences, Dr Shaw observes that none of the sides of this pyramid are exactly upon a level; so that it is difficult to find a true horizontal base; besides, it is impossible to say how much the drifts of sand, to which it is exposed, may have been accumulated above the foundation of it; and, therefore, all calculations depending upon the time and circumstances of the situation, when they were made, must be exceedingly precarious. The perpendicular altitude of it, according to Greaves, is 499 feet; but its oblique height is equal to the breadth of the base, or 693 feet. The whole area of the base contains 480,249 square feet, or $11\frac{10889}{43560}$ English acres. The height, according to Herodotus, is 800 French feet; according to Strabo, 625; according to Diodorus Siculus, 600 and a fraction; as stated by Le Bruyn, 616; by Prosper Alpinus, 625; by Thevenot, 520; by Niebuhr, 440. The ascent to the top of this pyramid is by steps, the lowermost being nearly four feet high and three broad; the second, of the same dimensions, but retiring inward from the first about three feet; and in the same manner the third row is placed upon the second, and the rest in the same order, to the top, which terminates in a small flat or square; and they are so disposed, that a line stretched from the bottom to the top would touch the angle of every step. These steps are called by Herodotus little altars, on account of their form; and their number has been variously assigned: Greaves states them at 207; Maillet at 208; Pococke at 212; Belon at 250; Thevenot at 208, and Chazelles at 498.222 English feet.

This pyramid is situate on a rocky hill, in the sandy desert of Libya, about a quarter of a mile from the plains of Egypt, above which the rock rises 100 feet or more, with a gentle and easy ascent. Upon this advantageous elevation, and solid basis, the pyramid is erected: the height of situation adding to the beauty of the work, and the solidity of the rock affording it a stable support.

We may here observe, that the sides of this pyramid stand exactly facing the four cardinal points, and consequently mark the true meridian of the place: which precise position could not have been well owing to chance, but was, probably, the effect of design and art. We may hence infer that the Egyptians had made an early progress in astronomy.

The entrance is nearly in the centre, and a passage descending at an angle of 27° terminates in an unfinished chamber, below the level of the ground. About 100 feet from the entrance, this passage is joined by an upper one, which ascends at the same angle to the great gallery, where it runs horizontally into what is now called the Queen's Chamber. But the gallery itself, continuing at an angle of 27°, leads to a larger room, called the King's Chamber, in which is a sarcophagus of red granite, 7 feet 4 inches by 3 feet, being only 3 inches less than the width of the door by which it was admitted. At the bottom of the great gallery is the well; and it was by this that the workmen descended, after they had closed the lower end of the upper passage, which was done with blocks of granite. And having gone down by the well, and reached the lower passage, they followed it upwards to the mouth, which they also closed.

Several other chambers and passages, hitherto undiscovered, no doubt exist in the upper part of the pyramid, and one seems to be connected with the summit of the great gallery. It appears to run upwards in a contrary direction to the north, from that end which is above the well; where a block, apparently of granite, projects at the complement of the usual angle of these passages. It probably turns afterwards, and extends in a southerly direction over the great gallery. Above what is called the King's Chamber, is a low room, which should support another similar chamber, and the stone at the south-west corner of it, has probably been let in after the workmen had closed the above-mentioned passage; so that this room served also as an outlet from the upper apartments, as the well from those about the great gallery.

The second pyramid stands at about a bow-shot from the first, towards the south. Herodotus says, after having measured both, that it falls short of the other in magnitude; that it has no subterraneous chambers, and that the Nile is not conveyed into it by a channel, as into the former, but that it is of equal altitude. Diodorus says it resembles the first in architecture, but is inferior in magnitude; each side of the base containing a stadium, or 600 Grecian feet, in length, so that by his computation each side is less than that of the former in length by 100 feet. Pliny makes the difference to be greater by 46 feet. Thevenot makes it but 631 feet square. Strabo supposes these pyramids to be equal; and Greaves assures us, that the basis of both are alike, and that the height of the second is not inferior to that of the first. This pyramid is built of white stones, not near so large as those of the first: the sides do not rise with gradations, but are smooth and equal, and the whole fabric, except on the south side, is quite entire. On the North and West sides of this second pyramid are two very stately and elaborate pieces of architecture, about 33 feet in depth, and about 1,400 in length, cut out of the rock in a perpendicular direction, and squared by a chisel; supposed to be designed for the lodgings of the Egyptian priests. The entrance to the interior is on the north front.

The first passage is built of granite, the rest are cut out of the natural sandstone rock, which rises above the level of the basis of the pyramid. This passage is 104 feet long, 4 feet high, and 3 feet 6 inches wide; descending at an angle of 26°, at the bottom is a portcullis, beyond which is a horizontal passage of the same height as the first, and at the distance of 22 feet, it descends in a different direction, leading to some passages below. Hence it re-ascends towards the centre of the pyramid, by a gallery 84 feet long, 6 feet high and 3.6 feet wide, leading to a chamber also cut out of the solid rock. The chamber is 46 feet in length, 16 feet wide, and 23.6 feet high, and contained a sarcophagus of granite, 8 feet long, 3.6 feet wide, and 2.3 feet deep in the inside. Returning from the chamber to the bottom of the gallery, a passage descends at an angle of 26° to the extent of 48.6 feet, when it takes a horizontal direction for a length of 55 feet; it then ascends at the same angle, and proceeds to the base of the pyramid, where another entrance is formed from the outside.

About the middle of the horizontal passage, there is a descent into another chamber, which is 32 feet long, 10 feet wide, and 8 feet 6 inches high.

The third pyramid stands at about the distance of a furlong from the second, on an advantageous rising of the rock, so that at a distance it appears equal to the former, though it is really much less and lower. Herodotus says it is 300 feet on every side, and to the middle, built of Ethiopic marble. Diodorus gives the same dimensions of its base, and adds, that the walls were raised fifteen stories with black stone, like Thebaic marble, and the rest finished with such materials as the other pyramids are built with; that this piece of work, though exceeded by the two former in magnitude, yet far excels them in respect to the structure, art, and magnificence of the marble; and that on the side towards the north, the name of Mycerinus, the founder, is engraved; but this inscription has been defaced by time. Pliny writes to the same effect, except that he makes this pyramid 363 feet between the angles.

Dr. Shaw apprehends, that neither of these pyramids was ever finished, supposing that the steps already mentioned should have been filled up with prismatical stones, so that each side of the pyramid might be smooth and level, like that of Cestius at Rome.

But, from the description of Maillet and Savary, the first pyramid appears to have been covered with a coating of marble, and thus finished on the outside, but closed; and that it has been since forcibly opened, and the stones which shut the passage, and were of an enormous size, have been removed. This passage was composed of marble, and the stones which form its four sides are of the finest white and hardest marble.

The ancients inform us, that the stones of the pyramids were brought from the mountains of Arabia; and Herodotus (lib. ii. c. 124.) has described the manner in which they were conveyed; but Dr. Shaw imagines, that they were taken from the spot where they were employed; and he observes, that the greatest of them, especially, is not an entire heap of hewn stones, because that portion of it which lies below the horizontal section of the entrance, may probably be no more than an incrustation of the natural rock on which it is founded. Mr. Bryant conjectures that, like the sphynx, which stands directly in the front of the second pyramid, they were immense rocks which stood upon the brow of the mountain; that the Egyptians cased them over with large stones, and brought them, by these means, to a degree of symmetry and proportion. At the same time, they filled up the unnecessary interstices with rubbish and mortar, and made chambers and apartments, as the intervals in the rock allowed, being obliged to humour the indirect turns and openings in the original mass, to execute what they proposed. This he infers from the narrowness and unnecessary sloping of the passages, which are often very close and steep, and also from the fewness of the rooms in a work of so immense a structure. That the pyramids were built upon a rock, in the place where they now stand, was suggested by Mr. Hooke.

The pyramids of Saccara, which are as many as 20 in number, vary in form, dimensions, and construction. They extend five miles to the north and south of the village of Saccara. Some of them are rounded at the top, and resemble hillocks cased with stone. One is constructed with steps, like that of Cheops. They are six in number, each 25 feet high, and 11 feet wide. The height of one in the group is 150 feet. Another, built also in steps, is supposed to be as high as that of Cheops. The stones whereof they are composed are much decayed, and more crumbling than those of Gizeh, hence they are considered older. One of them is formed of unburnt bricks, containing shells, gravel, and chopped straw.

The general opinion, with regard to the intention and use of pyramids, is, that they were sepulchres and monuments of the dead, particularly of kings. This is expressly affirmed by Diodorus, (lib. i.) and Strabo (lib. xvii.); and the opinion is confirmed by the writings of the Arabians. And the reason, says Greaves, of their erecting these magnificent structures is founded on the theology of the Egyptians, who, as Servius shows, in his *Comment upon Virgil* (Æneid, lib. iii.) where he describes the funeral of Polydorus—*Animamque sepulchro condimus*—believed, that as long as the body endured, so long the soul continued with it; and this was also the opinion of the Stoics. The reason of their building their sepulchres in the form of pyramids, was either from a notion that this was the most permanent form of structure, or because they hereby intended to represent some of their gods; particularly, as Greaves conjectures, Osiris, or the sun with many rays; for, under this form, the statues of the gods were frequently exhibited, and the gods themselves worshipped.

Among the Egyptians, the pyramid is said to have been a symbol of human life; the beginning of which is represented by the base, and the end by the apex; on which account it was that they used to erect them on sepulchres.

The tomb of Porsenna, king of Etruria, at Clusium, in Italy, is an ancient monument of square stone, each side of which is 300 feet broad, and 50 feet high. Within the square base, says Pliny, quoting from Varro, there is an inextricable labyrinth; upon this square stand five pyramids, four in the angles, and one in the middle, 75 feet broad at the bottom, and 150 feet high, and terminating in a point; at top, they are covered with a brass circle, from which are suspended bells, which are put in motion by the wind, so that their sound may be heard at a great distance. Upon this circle are four other pyramids, each 100 feet high; above which, upon one plane, are five other pyramids.

Pyramids are found in various parts of the world; indeed, the form of structure seems to have been not uncommon. Pyramidal tombs are found in Abyssinia, and even in Mexico, and the same form is observable in the constructed temples and pagodas of India and China. *See* EGYPTIAN and MEXICAN ARCHITECTURE.

PYRAMID, *Properties of the.* 1. All pyramids and cones standing on the same base, and having the same altitude, are demonstrated to be equal.

2. A triangular pyramid is the third part of a prism, standing on the same base, and of the same altitude.

3. Hence, since every multangular may be divided into triangulars, every pyramid is the third part of a prism, standing on the same basis, and of the same altitude.

4. If a pyramid be cut by a plane parallel to its base, the section will be similar to the base.

5. All pyramids, prisms, cylinders, &c., are in a ratio compounded of their bases and altitudes: the bases, therefore, being equal, they are in proportion to their altitudes; and the altitudes being equal, they are in proportion to their bases.

6. Similar pyramids, prisms, cylinders, cones, &c., are in a triplicate ratio of their homologous sides.

7. Equal pyramids, &c. reciprocate their bases and altitudes: i. e. the altitude of the one is to that of the other, as the base of one is to the base of the other.

8. A sphere is equal to a pyramid whose base is equal to the surface, and its height to the radius of the sphere.

PYRAMID, *to measure the surface and solidity of a:* Find the solidity of a prism that has the same base and height with the given pyramid: divide this by three; and the quotient will be the solidity of the pyramid. Or, multiply the base by the perpendicular height; and one-third of the product will be the content.

The surface of a pyramid is obtained, by finding the areas of the base and of the lateral triangles. The sum of these is the area of the pyramid. The external surface of a right pyramid, standing on a regular polygonal base, is equal to the altitude of one of the triangles which compose it, multiplied by the circumference of the base of the pyramid.

PYRAMID, *Frustum of a.* *See* FRUSTUM.

PYRAMID, *Truncated.* *See* TRUNCATED.

PYRAMIDOID, a solid generated by the revolution of a pyramid about its base.

Q.

QUADRA, in building, any square border, or frame, encompassing a basso-relievo, panel, painting, or other work.

The word is also used, erroneously, for a frame or border, of any other form; as round, oval, or the like.

QUADRÆ, the fillets on either side of the scotia of the Ionic base. Also the plinth or lower member of the podium.

QUADRANGLE, (from the Latin *quadrantus*, quartered, and *angulus*, a corner) a quadrangular, or quadrilateral figure; or a figure which has four sides, or four angles.

To the class of quadrangles, or quadrangular figures, belong the square, parallelogram, trapezium, rhombus, and rhomboides.

A square, &c. is a regular quadrangle; a trapezium, an irregular one.

Quadrangular figures are not proper for fortifications; the flanks and flanked angles being too small.

QUADRANT, (from the Latin *quadrans*, a fourth part) an arc of a circle, containing 90 degrees, or one-fourth of the entire periphery.

Sometimes, also, the space, or area, included between this arc and two radii, drawn from the centre to each extremity thereof, is called a quadrant, or, more properly, *a quadrantal space;* as being a quarter of the entire circle.

QUADRATURE, (from the Latin, *quadratura*) literally, the finding of a square equal in area to any given figure; which was the method the ancients made use of, when they had in view the determination of the surface of any space; but the term, *quadrature*, has now a more indefinite signification; implying, in general, the determination of the area of a figure, without any reference to the geometrical exhibition of it, in a square or other rectilinear form.

QUADRELS, a kind of artificial stones, perfectly square; whence their name. They are made of a chalky, or whitish and pliable earth, &c., dried in the shade for at least two years.

They were formerly in great request among the Italian architects.

QUADRIFORES, folding-doors which are divided into two in the height, so making four flaps.

QUADRILATERAL, from the Latin, *quatuor*, four, and *latus*, a side) a figure whose perimeter consists of four right lines, making four angles; whence it is also called a quadrangular figure.

If the several angles be right, the figure is a rectangular quadrilateral. If oblique, an oblique-angular quadrilateral.

If the sides of a quadrilateral be equal, and the angles right, the figure is a square.

If the sides be equal, but the angles unequal, the figure is a rhombus.

If the angles be equal, and the sides unequal, the figure is a rectangle.

If only the opposite angles and sides be equal, the quadrilateral is a rhomboides.

If the opposite angles and sides be unequal, the quadrilateral is a trapezium.

If any side of a quadrilateral, inscribed in a circle, be produced out of the circle, the external angle will be equal to the opposite internal angle.

QUADRIPORTICUS, a quadrangle with porticos or ambulatories on each side.

QUARREL, a lozenge-shaped pane of glass; also a tile or other material of the same form; same as QUARRY.

QUARRY, (from the Irish, *carrig*, a stone mine, or place where stones are digged. The methods which are practised in searching for, and ascertaining the presence of different sorts of materials of this nature, are principally those of boring, by means of an auger or borer made for the purpose, into the earth, and digging into it in other ways. In searching for most sorts of mineral substances, coals, and some other matters, the use of the borer is constantly first had recourse to, and not that of sinking a shaft, however favourable the appearances of the place may be for the purpose, and the success of the undertaking. The ground is first tried by this means, and a certainty of success or failure gained, as well as that of the most proper situation for sinking the shaft, or making the opening, or pit, without much expense being incurred, in case of the former. In trying for ochres, marls, and other similar articles, the same implement is also in common use. But in raising and providing lime-stone, free-stone, flags, and slates, &c., in some cases, digging down into, and opening the ground, by spades and other tools, is the mode employed in the first instance, in consequence of such substances being obviously present in sufficient quantities to be wrought with advantage.

Lime-stone is a very general sort of stone, raised from quarries and pits, in many different parts of this country, as in Devonshire, Sussex, Kent, &c., towards the south, where it lies in vast beds, from which it is dug for use; in the more midland counties, as in Gloucestershire, Shropshire, Derbyshire, Staffordshire, and others, where it exists, and is employed to a still greater extent; but by far the most extensively in those farther to the north, as Lancashire, Westmoreland, Yorkshire, Cumberland, and some districts of Scotland. In many parts of the county of Lancaster, it is dug and raised from quarries, where it lies in a stratified manner at no great depth from the surface, being got up without much difficulty or trouble; while, in other places, it is forced from the solid rock with great labour and expense. This is likewise the case in many other districts. Wherever it is met with it is almost constantly a quarry material of great value, and affords much employment to labourers.

In the county of Kent, the banks of some of the large rivers are scooped out into stone quarries in a remarkable manner, some of them worn out and disused, others in the state of being wrought. It has been observed, that this is the nearest stone county into which water-carriage can penetrate from the metropolis; and that the original London was built, as well as the modern one chiefly paved, by materials from this district, such as the rag stone, and the large pebbles gathered on the sea-shores, before the Scottish granite came into use. In the neighbourhood of Maidstone, there are appearances of many abandoned and neglected quarries of this nature; but the most considerable, which were lately wrought in that vicinity, are those of Farleigh and Fant. In each of these, blocks of stones, of different kinds, and of every form and size, are met with, being separated by seams, and large irregular masses of earth of various qualities: among the rest, brick earth of the best quality. In some places, the stones are buried several feet under these earthy materials: in others, the rock rises to the surface. After this, the quarry-men worm their way; following it with irregular windings, leaving behind them refuse in greater quantity than the useful materials which they raise.

The stony surfaces which are principally met with in them are of two very distinct kinds: the one hard and of a strong contexture, provincially denominated *rag or Kentish rag;* the other of a soft crumbly nature, provincially termed *hassock.* The quarrymen are in the practice of dividing the first sort into two kinds; what they call the *common-rag* and the *cork-stone,* the latter being their principal object in these immense works. It has, in its general appearance, much resemblance to the strong gray limestones which are found in different parts of this country; but when minutely examined by means of a glass, its fracture and contexture have the characters of the Devonshire marbles: except that the grain of this sort of stone is somewhat coarser. In colour, too, it differs from those marbles, having a greater resemblance to the Yorkshire limestones. It is used for different purposes; much of it is sent to the neighbourhood of London, where it is burnt into lime for the use of the sugar-bakers; who for some reason or other chiefly employ lime burnt from this material, or stone, instead of that from chalk. It is likewise made use of as a building material; and particularly in pedestals, for the posts of cattle-sheds, and other farm-offices. It is hewn with stone-masons' axes, working with tolerable freedom.

It is very durable, as some part of the basement of Westminster Abbey appears to have been built with the stone from these quarries. In this case, it seems to have been dressed smooth: and the surface still remains with little alteration; having withstood the attacks of time with great firmness; it being, even now, difficult to detect a loosened splinter in the work.

The common rag-stone comprehends all the different kinds which are met with in these quarries, except that of the above, and that which is of the hassocky nature; though the true unmixed rag is a distinct sort, having characters different from any of the others. In colour, it inclines more to the red, or liver colour, than that of the cork-stone, but otherwise resembles it considerably. Viewed with a glass, its grain is finer, and the fracture flint-like.

It has of late years come into very extensive use. Its constituents are—carbonate of lime, with a little magnesia, 92.6; earthy matter, 6.5; oxide of iron, 0.5; and carbonaceous matter, 0.4 = 100.

The hassocky-stone appears, to the naked eye, to be of a soft, white, sandy quality; and its fracture is the same; but under the glass, its grain is fine, its contexture uniform, and so thickly interspersed with small seed like granules, of a dark or black colour, as to give it a gray appearance; sometimes bearing evident impressions of shells. Its texture is loose and brittle, crumbling easily between the fingers into a coarse, sand-like powder. It will not burn into good lime, although it is almost wholly calcareous.

Its principal use is that of forming a loose friable sort of rubbly sub-soil, in some places, where it is admirably suited to the growth of saintfoin, and some other crops of the plant as well as of the fruit-tree kinds.

The quarries in several other counties contain stony materials of all these different kinds, which are wrought and applied to a variety of uses.

Quarries of marble are wrought in several districts in different parts of the country, and afford great advantages in various ways. In Sussex they have a marble, which, when cut into slabs, is used for ornamenting chimney-pieces, and other purposes. It is equal in quality and beauty to most sorts, when highly polished. For square building and paving, it is also a material scarcely to be excelled. By burning, it likewise affords a very valuable manure, equal, and by some thought superior, to chalk, being cheaper to those who are near the places from which it is dug. It is found the most perfect about Kirdford, at the depth of from ten to twenty feet under ground, in flakes nine or ten inches in thickness, and is called *Petworth marble.* It was much employed in building the cathedral at Canterbury; the pillars, monuments, vaults, pavement, &c., being formed of it; and the archbishop's chair is one entire piece of it. Marble is got in some of the counties in the middle of the island, as Derbyshire, Nottinghamshire, &c.

At Beacon-hill, near Newark, a blue stone for hearths is obtained, which approaches to marble, and is capable of burning into lime. And, in the county of Derby, much good marble is raised in different places.—In Lancashire there are quarries of fine black marble, besides stones which approach to, and take on the polish of marbles. In many of the western and northern parts of Yorkshire, marble of various kinds is found, some much resembling, and others superior, in closeness of texture and distinctness of colours, to that which is wrought in Derbyshire. Also a stone, which greatly resembles the marble of that county, and which is capable of receiving much such a polish, and is nearly of the same colour, mixture, and appearance.

In the county of Inverness, likewise, marble of the greatest variety of colours, and of the most beautiful shades, has been met with in Ben-Nevis; and inexhaustible quarries of it lie untouched in the islands which belong to it.

Besides, this sort of material exists in immense quantities in quarries in many other parts of the kingdom.

Chalk is a material which is raised from quarries and pits, mostly in the southern parts of the country, as in Sussex, Surrey, Kent, Essex, Berkshire, Hertfordshire, &c. It exists in vast ranges and tracts in most of these districts, whence it is dug up from quarries, at different depths, according to circumstances, exposed in sheds to dry when wet, and then converted into lime for various uses, by means of fire: or it is employed in its broken and powdery state, without undergoing the above processes, by merely digging it out of such places. In some parts, as in Kent, and the neighbouring districts, it is often dug and raised from considerable depths, from beds of very great thicknesses. And near Reading, in Berkshire, there is a stratum of this substance, which is thirty feet in thickness. It is there used and dug out for manure, and occasionally as a building material; for the latter of which purposes it is very durable. The remains of the abbey of Hurley, and of the ancient chapel, now the parish church, built wholly of chalk, in the reign of William the Conqueror, are still as fresh and sound as if they had been the works of the last century. Chalk, when once indurated by the air, has a remarkable property of resisting the action of the weather.

Granite is a stony substance which is found to exist in some of the southern parts of the country, as well as in those of the north, but it abounds much more in the latter.

In the western parts of Cornwall, it is in great plenty in the districts of Penwith and Kirrier, presenting itself in large slabs on all the rocky hills or tors, as well as in the waste moors and valleys, and appearing in detached spots, even in the shelvy slaty tracts. It is of different colours and textures, being adapted to a great variety of uses and purposes, as those of building, and being wrought into columnar masses, eight or ten feet in length, for supporters to sheds, out-houses, &c., and as gate-posts, and bridges over brooks, rivulets, &c., as well as in the forming of rollers, and malting, salting, and pig-troughs. It is also an article of commerce to different parts. It is supposed to be exactly of the same nature with the original granite; and there are five sorts of it, which are distinguished by their colours, the white, the dusky or dove-coloured, the yellow, the red, and the black, most of which are charged with a brown and bright silvery matter.

The county of Inverness has a great deal of this sort of stone, and there are numerous quarries for raising and working it. The common granite abounds in all the different districts of it. In many places, the whole rocks are composed of this kind, which is uncommonly useful for all ordinary purposes. By natural fissures, which run in straight lines, and generally at right angles, it is formed into all-sized portions and shapes, having uniformly a plain surface; and, by means of cutters or transverse lines, these stones are easily quarried, and found in the greatest plenty everywhere. They are remarkably beautiful, being almost as smooth and regular as hewn stone, and, of course, well suited for various sorts of building-work. The best buildings of the county-town are of a dark kind of granite, which is very hard and durable, but which has few or no fissures. It is generally found in large blocks; and in many of these parts, there is no other material for building or adding ornament with. The manner of giving it the polish it admits of, at the quarries, is by means of small picks or pick-axes, which are, in fact, hammers with sharp points at each end, in the manner of those employed by millers in preparing their grinding-stones. It is a very heavy, compact stone. There is a mixed sort, denominated *peasy granite*, which consists of white, black, and gray spots, that sparkle beautifully in the sun, is very ornamental, and much used for different purposes, as stairs, doors, and windows. Though this is very solid, and almost without natural fissures, it splits very straight, by means of iron wedges, set in a line, and struck alternately with a hammer of great power.

A great deal of this kind of stone is imported into the metropolis, and other large towns, for paving the streets, &c. It is, on the whole, a very advantageous sort of quarry material in various parts of the kingdom.

Quarries of freestone are wrought in a great number of different places. In the more southern parts is found the Portland-stone, which is so famous and useful in building. A sort of this kind of stone, which much approaches to it in quality, is also met with in Cornwall. Some likewise exists in Devonshire and Gloucestershire. The Cotswold quarries, in the latter, afford freestone of an excellent quality, particularly those at Painswick, Lodbury, Lockhampton-hill, &c. It abounds more, however, in Cheshire, Lancashire, Westmoreland, Cumberland, and some of the still more northern districts. Several excellent quarries of freestone are carried on in the first of these, as those at Runcorn, Manley, &c., where much valuable stone of this nature is raised. The second county also affords equally valuable quarries in many different places, from which vast quantities of the stone are raised, and employed, or sent away to a distance. Those about Ormskirk, Up-Holland, and Wigan, as well as those on all the eastern side, are in general of a very good quality; and in the vicinity of Lancaster there are some excellent ones; that on the moor, or common, close to the town, is very extensive, and affords a freestone that admits of a fine polish. In this district, this sort of stone is met with, of a whitish-brown, yellowish and reddish cast, but the first is by much the most esteemed. In the eastern parts of Westmoreland, as about Hutton Roofe, and some other places, a good sort of freestone is dug up from pits and quarries formed for raising it. This sort of stone exists, and is quarried almost all over, the counties of Cumberland and Northumberland; and prevails occasionally in others, where it is wrought to advantage. A grit-stone, somewhat of this nature, is met with in some districts, as in Shropshire, &c., which is raised from quarries, and used as a building material. And a sandstone exists to considerable extent in others, as in Sussex, &c., that is sometimes dug up, and made use of for common buildings, &c. In Cheshire, on the hills near Macclesfield, about Kerridge, a sort of sandstone is met with, which is particularly well suited to the making of flags, and whetting tools, as well as sometimes to the forming of slates, for which it was formerly much employed. Near Pott-Shrigley, also, a fine sandstone is found, that admits of a good polish. The quarry has not, however, been wrought for some late years, as, from the extreme hardness of the stone, the expense of getting it is very considerable. There are several other quarries of excellent freestone wrought in the same neighbourhood.

There has been great abundance of freestone wrought, from time immemorial, in the low parts of the county of Perth, and quarries of a greater or smaller grained stone of this sort appear almost in every place, with the exception of the Carses. In the Lowlands, and near to the eastern sea, the pores and grain of it are coarser; but as the mountains are approached, the pores are less, and the grain finer, by which these stones admit of a smoother polish. The quarry of Tullyalan parish, called Long-annat, affords a stone of a very excellent quality. It is of a white colour, admits of a smooth polish, and resists the influence of the weather. Some of the principal houses in that part of the country, as well as some of the most magnificent public buildings in the capital of Edinburgh, as those of the Exchange, the University, and the Register-office, consist partly of this stone, and those found at hand. And farther, in some instances it has been carried to the continent. But the quarry of Kingoodie, in the Carse of Gowrie, is unquestionably the finest of this kind of any in the country. Astonishing blocks, in great numbers, are raised there, fifty feet in length, sixteen feet in breadth, and three feet in thickness. Such is the demand for this stone, both at home and abroad, that four vessels are employed in exporting it from this quarry.

Flag-stones and quarries for the working and preparing of all sorts of flags, are met with in all those situations where free-stone is found, and where it exists in rather thick strata, or layers, of some depth, which are capable of being separated by hammers, wedges, or other means. In many places in the southern parts of the island, the flags raised from such free-stone quarries are of an extremely good quality, being used in very large quantities for various purposes. Those of Cornwall and Devonshire also, in many cases, afford a good sort of flags. The sandstone quarries of Shropshire as, at Grinsell, near Shrewsbury, about Bridgenorth, and at Corndon-hill, near Bishop's-Castle, as well as in the Swinney mountain, &c., where alternate beds of fine white and red stone of this kind, of very superior quality and thickness, exist; that in the first of these situations, being twenty yards thick, affords flags likewise which are of a very useful nature. Freestone flags, too, of useful sorts, are met with in the quarries of some of the midland counties; and they abound much in many of the freestone quarries of Lancashire, Yorkshire, and some of the other more northern districts of the country.

The quarries of this kind become slate-stone, and furnish the white, gray, and brown slate, wherever the stone lies in thin layers, or strata, which are able to be raised and separated from each other with convenience and facility. They exist in most of the above tracts, and are plentiful in some of them, especially those toward the north. The Lancashire and Yorkshire quarries, in many places, supply the white and gray sorts in great abundance, and of good qualities. Those of Westmoreland, Cumberland, and Northumberland also afford them, in many instances, of a valuable nature; and they are equally good in the still more northern districts. There are numerous quarries of different colours of them in Clydesdale, Perthshire, Argyleshire, and the county of Inverness, from which vast supplies are constantly raised for home and other use. This sort of slate has, however, mostly the disadvantages of being very porous, heavy, less durable, and of requiring more and stronger timber to support it than some other kinds; being only fit for exposed climates and situations.

The quarries of the lighter and thinner kinds of slate, of the blue, green, purple, and other colours, formed from other sorts of stone, only exist in some particular districts, as those of Wales, and the northern part of Lancashire, and the adjoining counties, and in a few places in Scotland. The slate quarries of the Welch districts supply several kinds and colours in large quantities, and of good qualities; but the dark and lighter purples are the most prevalent sorts in most of them. In Lancashire, the quarries of this kind are very numerous in the part to the north of the Sands, as about Gothwaite-common, Kirby-moor, Conistone-hills, and Tilberthwaitefells, &c., and from which very large supplies of the blue, green, and the dark purple sorts of slate are raised, and sent away for exportation, or consumed at home for different purposes. They are wrought, and the slate prepared, in somewhat different manners in different places. The Gothwaite quarries have the slate dug out from the side of the hill, and carried away. But in some on Kirby-moor, a level is driven through the ground from below, the metal being conveyed away by small four-wheeled waggons, on iron railways. Those about Conistone are mostly worked into the hills, and the metal raised and carried out from them. Some of the Tilberthwaite quarries are wrought by blasting the slate-stone, and collecting and carrying it out of them on slanting roads, in small carts, or trucks, constructed for the purpose, of levels being below the hills, but not nearly so low as the bottoms of the quarries. Others are wrought by draught roads from the bottoms of them. One man will raise eighteen or twenty hundred-weight of slate in one day where the metal rises well, but less in other cases. In some, it is dug out by one set of men, split by another, and formed into slates by a third; for which purposes, flat crow-bars, slate-knives, and axes are employed. The slate is divided and distinguished into three sorts, as firsts, seconds, and thirds, or London, country, and toms. In the first, or Gothwaite quarries, the slate has a darkish purple or black cast. In the Conistone quarries, it has a fine blue and green appearance, and is much thinner and lighter than the other sort. The Tilberthwaite slate, in some instances, splits very fine, thin, and light, but does not cover so far as those of the Gothwaite and Kirby quarries. In some quarries a sort of rent is paid per ton, on the slate which is raised; while in others, a certain rent only is paid for the liberty of the royalty, and not a tonnage duty. These rents, or duties, on the workers of these quarries, are probably higher than they will bear, and have enabled the Welsh slate-dealers to undersell those of this county.

Westmoreland and Cumberland, in some instances, afford good blue and green slates. In the latter, some of an excellent quality are obtained in the quarries of Borrowdale, and inferior sorts in some of the neighbouring mountains.

The county of Argyle, in Scotland, in some parts, abounds with slate-quarries, as the tracts about Esdale, from which five millions of slates have for some time been annually sold. Quarries of the same kind are also wrought in many other parts, with great benefit to the inhabitants.

Slate-quarries are found in many parts of the highlands of the county of Perth, but none in the low. The slates in some are of a purple colour, in others of an azure blue, and in a few, of a muddy, sandy, brown complexion along the cutters. It is well known where the different sorts are quarried. The veins of slate-rock seem to run from Drumlane, in the parish of Aberfoil, in a north-east direction, to Dunkeld; and may be traced beyond the limits of the county both ways. The azure coloured are the best metal, and rise of a greater size than any of the other kinds. Many of the buildings in different places are slated with this beautiful covering. Into the lower districts of the county, slates are imported from Esdale, and the other quarries on the west coast of the county of Argyle.

Quarries of gray slate exist in many different parts of the county of Inverness, in which the quality is very good, and well suited to the climate. In some places these slates are much preferred to blue ones, as the latter are more expensive in procuring, and though nailed on the roofs ever so firmly, are apt to be loosened by high winds, unless bedded in lime, which circumstance renders repairs difficult.

Quarry, (from the French, *quarré*, square; or, according to some, a corruption of the English term, *quarrel*) a pane, or piece of glass, cut in a losenge or diamond form.

Quarries, or quarrels of glass, are of two kinds; viz. square and long, each of which is of different sizes, expressed by the number of pieces which make a foot of glass; viz., 8ths, 10ths, 12ths, 15ths, 18ths, and 20ths; but all the sizes are cut to the same angle, the acute angle being 77° 19′ in the square quarries, and 67° 22′ in the long ones.

Quarry-Cart, a name commonly given to that sort of cart which is principally employed in the work of quarries, and which is generally of a low, compact, strong kind, in its nature, form and manner of construction, in order to sustain heavy weights, and receive them without difficulty, or the danger of being destroyed. Carts for this purpose should always be made of well-seasoned wood, well put together, with sufficient strength of timber in those parts where the main stress of the load is placed.

Quarry-Waggon, or Truck, a small carriage of the low truck kind, which is much employed in the business of quarries, especially those of the slate kinds, for the purpose of holding and conveying the rough materials, which have been blown from the large massy rocks, or separated in other ways, out of or from the quarries and pits in which they are situate and contained, to the places where they are to receive their different preparations and shapes.

It is formed and constructed on a frame somewhat similar to that of the common barrow, and mounted on two low light iron-wheels on the fore part, having two feet behind, projecting from the frame, bent something in the manner of the letter S, and of sufficient length to let it stand or rest in a horizontal position while it is in the act of being loaded. These feet are usually made of iron, but they may be formed of other materials. A sort of inclined plane is formed from the bottoms of the quarries or pits, up which it is forced, with great ease and facility, by the workmen, or small animals of the horse kind, after being filled with these sorts of heavy materials.

QUARRYING, the business of directing and conducting the nature and management of sinking the different kinds of quarries, pits, and shafts, as well as of the different sorts of work which are necessary to be undertaken, carried on, and performed in the several different descriptions of them; such as those of separating, getting up, and preparing the various sorts of materials for use in the arts, or in other ways. It is a practice which requires considerable knowledge and experience, to be fully master of it in all its different bearings and intentions. *See* QUARRY, and QUARRYING SLATES AND STONES.

Almost every kind of quarrying-work requires a different kind of management, not only in the opening and sinking the quarries and pits in the ground at first, but afterwards in the methods and practices of working them, and getting up the various sorts of materials from them, as well as in the modes of preparing, trimming, and arranging them, after they have been raised. They are, however, mostly well known and familiar to the quarry-men and pit-men, who are usually engaged in works of the several kinds.

QUARRYING SLATES AND STONES, the methods of preparing them for their different uses and applications at the quarries and pits where they have been raised. The former of these articles, particularly those of the blue, green, and purple or blackish kinds, undergo several different sorts of preparation in the quarrying, according to the purposes to which they are to be afterwards applied. They are separated and divided into very thin pieces, or slates, where light neat coverings are required, or in much demand; but for more strong and heavy coverings, in exposed situations, or other places, they are split into much thicker sheets, layers, or slates, and are, of course, more clumsy in their appearance.

Each sort, in the business of quarrying, is wrought in a separate manner, and packed up by itself; the different sorts having appropriate names, as has been already seen.

The white or brown slates are never divided and prepared in so fine a way as the other kinds, but separated into much thicker flakes or laminæ, in this intention. The blue, green, and purple or darkish sorts, are, for the most part, found capable of being split into very thin laminæ, or sheets; but those of the white, or brownish freestone kinds, can seldom be separated or divided into any very thin slabs, as the layers of the large masses of the stones are of a much thicker nature, they consequently form heavy, strong, thick coverings, proper for buildings in exposed climates and situations, and of the more rough kinds, such as barns, stables, and other sorts of out-houses.

In the different operations and processes of this sort of quarrying, slate-knives, axes, bars, and wedges, are chiefly made use of for the different purposes of splitting and cleaning the slates, they being separated into proper thicknesses by the axe, bar, and wedge, and afterwards chipped into their proper forms and shapes by the knife. All the inequalities which may appear upon any of them, are removed by this last-named implement. In the quarrying of the latter sorts of materials, or those of stones, the work is usually performed in such a manner as to suit the different uses for which they are intended. Where flags are to be formed, they are split or riven into suitable thicknesses, and squared to different sizes, so as to be adapted to different applications. These operations are executed in rather a rough way, as they are afterwards to be finished by the stone-mason. When for steps, they have the proper breadths and depths given to them in a sort of squaring manner, being left to be completed as they may be wanted for particular uses and applications. Gate-posts are, for the most part, quarried so as to have from about a foot to a foot and a half or more in the square. Trough-stones have the quarrying performed so as to be formed into various proper-sized squares or other forms, in a rough manner, being left in these states to be afterwards hewn and hollowed out, in the intended parts, by the stone-masons.

Stones for building purposes are usually raised and quarried out roughly into something of the square shape, being left in that state for the builders, who afterwards fit them so as to suit their own purposes and intentions.

In the quarrying of stones, the quarrymen commonly make use of large hammers, with cutting ends on one side, the other being formed in a plain manner; strong, sharp, crow-bars, and broad, sharp, iron wedges; by which means these matters are, from the constant practice of the men, split and torn into such forms as are wanted, with great ease and facility.

QUARRYING TOOLS, the different sorts of implements made use of in the different works of the quarry. They are principally such as have been noticed in the former article; to which may be added different descriptions of picks, mattocks, and jumpers, or boring implements for the purpose of blasting the various kinds of stone, and other hard materials.

QUARRYINGS, the small pieces that are broken or chipped off from the different sorts of materials found and wrought in quarries while preparing for various uses. These substances where they are of the hard kind, such as those of the blue and lime stone, as well as some other sorts, are extremely well calculated for the purpose of forming and repairing roads, as they are nearly, if not quite, in a state fit for immediate application. Materials of these kinds ought, therefore, where they can be conveniently had, never to be neglected by those who have the care and management of roads, as they will save much expense and trouble, in a great number of instances.

QUARTERINGS, or QUARTERS, slight upright timber-posts framed together, and employed instead of walls for the separation of apartments &c.; they are lathed over in the same manner as ceilings, to receive plastering, but when used for external work they are usually boarded. They are of two kinds, single and double, the scantling of the former being 2 inches by 4 inches, and the latter 4 inches square; they are placed at about 12 or 14 inches apart. The term *quarterings* is especially applied to a series of quarters.

QUARTER-PARTITIONS, a partition composed of quarters.

QUARTER-ROUND, a term used by the workmen for any projecting moulding in general, whose contour is a perfect quadrant, or quarter of a circle, or which approaches near that figure. The architects usually call it *ovolo;* and Vitruvius, the *echinus;* but oval more properly applies to the quadrant of an ellipsis as used in Grecian architecture.

QUATRE-FOIL, (French, *quatre-feuille*), An ornament much used in Gothic architecture, formed by a moulding disposed in four segments of circles, forming four cusps or points at their intersection.

QUEEN-POST, a timber post employed in roofs, for the purpose of suspending the tie-beam. It performs the same office as a king-post, but the term is applied to such suspenders only when there is more than one in a single truss; when there is only one, it is termed a *king-post.*

QUICK-LIME, such lime as is in the caustic or most active state, and which possesses the greatest power of operating upon different substances with which it may come in contact. It is quite the opposite, in its qualities and properties, to that which has fallen down into a powdery state, in consequence of being saturated with water and carbonic acid gas, or fixed air, or which is slaked and become effete.

According to Dr. Anderson, lime is in the best and most fit state for the purpose of cement, when most perfectly caustic, or in the most crystallizing condition. It is remarked, that the powder of lime, when reduced by means of water into a fluid, or thin paste-like form, and then suffered to become dry, concretes into a coherent mass, which fixes to stones and other rough bodies in a very firm manner, and in this way becomes a proper cement for building any sort of walls. And that, after this pasty material has once become firmly dry, it is quite indissoluble in water, and incapable of ever being softened again by the moisture of the atmosphere or other similar causes. Hence it excels many other sorts of cements.

When composed for the purpose of building walls, &c.; it is usually denominated *mortar;* but when formed as an application in the way of a smooth coating upon any plain surface without intermixture with stony matters, it is commonly termed *plaster.*

When made from the lime of the purer sort of lime-stone, it is found to be more soft and crumbly, and to acquire a less degree of hardness, and to be broken with much less force, than where the lime-stone, from which it is made, contains a large proportion of sand; in which case it becomes much more hard, firm and durable.

It has, however, been discovered, that the purest lime may be rendered a firm cement by adding a proper proportion of clean hard sand to it; hence the practice of blending sand with lime, when intended for mortar, has become so universal. This is fully shown to have been very early the case, by the oldest lime-built walls which are now to be met with.

It nevertheless still remains a desideratum to ascertain the due proportion of sand necessary, as both writers and practical masons greatly disagree in opinion on this matter, as well as in their directions about the mode of mixing the materials, and of applying the cement; some of the more modern, especially ascribing extraordinary effects to a small variation in these particulars, while others deny that these circumstances have any sensible effect on the durability and firmness of the cement.

It is conceived that these different and contradictory opinions arise from the imperfect knowledge of the nature of quick-lime, and the variations it may admit of; for these variations are so very great, as to render it impossible to afford any general rules that can possibly apply in all cases. It is, therefore, conceived to behove those who are desirous of acquiring any consistent and satisfactory knowledge on this head, to endeavour to ascertain, in the first place, the circumstances which render calcareous substances *at all* capable of becoming a cement, and then to trace the several changes that may be produced upon it by extraneous causes.

Having explained the circumstances which cause the differences in limestone, and pointed out the different constituent principles of it, as well as various other peculiarities; it is known, that lime which has in any way absorbed its full quantity of air from the atmosphere, and become mild, is altogether unfit for becoming a cement, and that, of course, a great change may be produced upon the quality of any lime, by having allowed less or more of it to be in this state before it is worked up into mortar. And farther, that if a large quantity of water be put to fresh-slaked quick-lime, and beat up with it into a thin sort of paste, the water dissolves a small portion of the lime, which, as it gradually absorbs its air, is converted into crystals; between the particles of which crystals, that part of the lime which was not dissolved, and the other extraneous matters which may have been mixed with it, are entangled, so as to form a firm coherent mass of the whole. And that the pasty substance formed in this manner, is the well-known article mortar; and this heterogeneous, imperfectly semi-crystallized mass, constitutes the common cement employed in building ordinary walls, or other erections. These circumstances, therefore, being known, it is thought that it will not be difficult to comprehend what are the particulars necessary to form the most perfect cement of this nature. That since lime becomes a cement only in consequence of a certain degree of crystallization taking place in the whole mass, it is sufficiently obvious that the firmness and perfection of that cement must depend upon the perfection of the crystals, and the hardness of the matters that are entangled among them; for if the crystals are ever so perfect and hard of themselves, if they be separated from each other by any brittle incoherent medium, it is evident that the whole mass must remain in some degree brittle and incoherent. That as water can only dissolve a very small proportion of lime, even when in its most perfect saline or caustic state, or while it remains deprived of its carbonic acid gas, and, as happens in other similar cases, no more of the lime can be reduced to a crystalline mass than has been actually dissolved in the water; it follows, of course, that if mortar be made of pure lime and water alone, a very small proportion only can be dissolved by that small quantity of water that is added to it; and as this small proportion alone can afterwards be crystallized, all the remaining undissolved particles of the lime will be entangled among the few crystals that are formed. And as the undissolved lime in this mass will in time absorb its air, and be converted into *mild* calcareous earth, without having had a sufficiency of water to allow it to crystallize, it must concrete into a friable mass, exactly resembling chalk; this kind of mortar, therefore, when as dry as it can be made, and in its highest degree of perfection, will always be soft, and easily crumbled into powder. But if, instead of forming the mortar of pure lime alone, a large proportion of sand be added to it, the water will, in this case, dissolve as much of the lime as in the former; and the particles of hard sand, like sticks or threads, when making sugar-candy or other crystals, while surrounded by the watery solution, will help to forward the crystallization, and render it more perfect than it otherwise would have been, so as firmly to cement the particles of sand to each other. And as the granules of sand are perfectly hard of themselves, so as not to admit of being broken down like the particles of chalk, it necessarily follows, that the cement made of these materials must be much more perfect, in every respect, than the former.

After considering a variety of circumstances in regard to the solubility of lime in water, and its crystallization, it is remarked, that when a large quantity of sand is mixed in the mortar, that sand will of course bear a great proportion to the whole mass; so that the water that may be mixed with the mortar will be much greater in proportion to the quantity of lime contained in this mortar, than if the whole had consisted of pure calcareous matter. And that, as the sand absorbs none of that water, the water, now pure, is at liberty to act once more upon those few particles of caustic lime that may still remain in the mortar, which will be dissolved and converted into crystals in their turn. In this way, it may happen, in some circumstances, that a very large proportion of the lime may become crystallized; so that the mortar will consist almost entirely of sand enveloped in crystalline matter, and become in due time as hard as stone itself; whereas mortar, consisting of pure lime, without sand, can hardly ever be much harder than chalk. It is not, however, to be supposed, that in any case this dried mortar will assume that transparent crystalline form, or the compact firmness of some sorts of calcareous matters, such as marble and limestone. In mortar, in spite of the utmost care that can ever be taken, a very considerable quantity of the lime must remain undissolved; which undissolved lime, although it may be so much separated by the sand and crystalline limestone as not much to affect the hardness of the mortar, yet it must still retain its white chalk-like appearance. As marble and limestone are, however, always formed by those particles of lime that have been wholly dissolved in water, and from which they have been gradually separated by a more slow and more perfect mode of crystallization, they have nothing of that opaque calx-like appearance, but assume other colours, and appear more firm, uniform, and compact; the sand and other matters that may be enveloped in them being entirely surrounded with a pure crystalline matter.

But to obtain the most perfect kind of mortar, it is not, however, enough that a large proportion of sand should be employed, and that the sand should be intimately mixed with the lime; it is also of the utmost importance that a large proportion of water be added; for, without this, it is impossible that a large proportion of the lime can be crystallized: and the mortar, in that case, would consist only of a mixture of chalky matter and sand, which could hardly be made to unite at all, and would be little more coherent than sand by itself, and less so than pure chalk. In that case, pure lime alone must afford rather a firmer cement than lime with sand. It is also of very great importance that the water be retained as long in the mortar as possible: for if it be suddenly evaporated, it will not only be prevented from acting a second time upon the lime, after a part of what was first dissolved has been crystallized, but even the few crystals that would be formed when the water was suddenly evaporating, would be of themselves much more imperfect than they otherwise most certainly would have been. In proof of which, instances of the crystallization of common salt, lump-sugar, and sugar-candy, are adduced; after which it is noticed, that every one knows what a difference there is between the firmness of the different substances; and that as great must be the difference between the firmness of that cement which has been slowly dried, and that which has been hastily hardened by the powerful action of a warm air.

It is contended, that it is owing to this circumstance that the lime, which remains all winter in a mortar-tub filled with water, is always found to be much firmer and more coherent than the mortar that was taken from the same tub and used in any work of masonry, although in this case the materials were exactly the same. From the same cause, any work cemented with lime under water, if it has been allowed to remain undisturbed and uninjured until it has once become hard, is always much firmer than that which is above the surface of the water.

In order to render the force of the above reasoning more strong and convincing, lime-cement or mortar is compared to a mass of matter consisting of a congeries of stones closely compacted together, and united by a strong cementing matter, that had, while in a fluid state, pervaded all the interstices between the stones, and afterwards become a solid indissoluble substance. If the cementing matter be exceedingly hard and coherent, and if the stones bedded among it be also very hard and firm, the whole mass will become like a solid rock, without fissures, that can hardly be broken to pieces by the power of man. But, although the cement should be equally firm, if the stone, of which it consists, be of a soft and friable nature, suppose chalk or sand-stone, the whole mass will never be capable of attaining such a degree of firmness as in the former case; for, when any force is applied to break it in pieces, although the cement should keep its hold, the solid matter cemented by it would give way, and the whole would be easily broken to pieces. Whereas, in mortar, the sand that is added to it represents the stones of a solid matter, in the composition, the particles of which are united together by the lime which had been formerly dissolved, and now crystallized, which becomes an exceedingly solid and indissoluble concretion; and as the particles of sand are of themselves exceedingly hard, and the cement by which they are united equally so, it is plain that the whole concretion must be extremely firm, so as to require very great force to disunite any particle of it from the whole mass. But if, instead of employing sand, the only solid body that is entangled among the cementing matter should be chalk, (as in all cases where the mortar consists of pure lime alone,) or any other slightly coherent substance, let the cementing particles of that composition be ever so perfect, it is impossible that the whole can ever attain a great degree of firmness, as these chalky matters will be easily broken asunder.

It is remarked, in addition, that a variety of conjectures have been made about the nature of the lime-cement employed by the ancients. It has been thought that they possessed an art of making mortar which has been long since entirely lost; as the cement in the walls which have been built by them, appears to be, in many cases, much firmer than that which had been made in modern times. Yet, when the mortar of these old buildings is analyzed, it is found to consist of the same materials, and nearly in the same proportions, in which they are now made use of. And it is thought probable, that their only secret consisted in mixing the materials more perfectly than the rapidity or avarice of modern builders will permit; in employing their mortar in a much more fluid state than is done now; and in allowing it to dry more slowly, which the immoderate thickness of many of their walls would naturally produce, without any preconcerted design on their part. Tradition has even handed down to the present times the memory of the most essential of these particulars; as the lower class of people, in every part of the nation, at this moment, invariably suppose and believe that these old walls were composed of a mortar so very thin, as to admit of its being poured, like a fluid, between the stones, after they were laid in the wall: and the appearance of these old walls, when taken down, seems to favour this popular tradition. Nor is it doubted but that this may have been the case. The stones in the outer part of the wall, it is thought, were probably bedded in mortar, nearly as is practised at present; and the heart, after being packed well with irregular stones, might have the interstices between them entirely filled up with fluid mortar, which would insinuate itself into every cranny, and, in time, adhere as firmly as the stones themselves, or even more so, if the stones were of a sandy friable nature. And that, as these walls were usually of very great thickness, it might often happen, that the water in this mortar, by acting successively upon different particles of caustic lime, would at length be entirely absorbed by successive crystallizations, so as to become perfectly dry, without any evaporation at all; in which case, a very large proportion of the original lime must have been regularly crystallized in a slow and tolerably perfect manner, so as to attain a firmness little inferior to limestone, or marble itself.

It is supposed that, upon these principles, it is easy to account for the superior hardness of some old cements, when compared with that of modern times, in which a practice very different is usually followed, without having recourse to any wonderful *arcana* whatever.

There are likewise a few other circumstances that may influence the quality of common lime-mortar. If limestone be sufficiently calcined, it is deprived of all its moisture, and of all its carbonic acid gas, or fixed air. But experience shows, that limestone will fall to powder on the effusion of water upon it, when it is much less perfectly calcined, and while it still retains almost the whole of its fixed air. And that, as masons have hardly any other rule for judging whether limestone be sufficiently calcined, except this single circumstance of its falling to a powder when water is poured upon it, it may thus easily be perceived, that the same lime may be more or less fitted for making good mortar, according to a circumstance that, in a great measure, eludes the observation of operative masons; for if it should happen that all the pieces of lime drawn from a kiln at one time were just sufficiently calcined to make it fall to a powder with water, and no more, that powder would be altogether unfit for making mortar of any kind. This is a case that can seldom happen; but as there are a great many intermediate degrees between that state and perfect calcination, it must often happen that the stone will approach nearer to one of these extremes at one time than at another; so that the mortar may be much more perfect at one time than at another, owing to a variation in this particular.

All those who have written on the subject of lime as a cement, have endeavoured to ascertain what is the due proportion of sand for making the most perfect cement. But a little attention to the matter will show, that all rules which could be prescribed as to this particular, must be so vague and uncertain as to be of little utility to the practical mason; as, besides the variation which may arise from a more or less perfect degree of calcination as above, it is a certain fact, that some kinds of limestone are much more pure, and contain a much smaller proportion of sand, than others do; some being found almost perfectly pure, while others contain eleven-twelfths of sand, and all the intermediate proportions of it. Therefore, it would be absurd to say that pure lime would require as small a proportion of sand, when made into mortar, as that which originally contained in itself a much larger proportion of sand than any writer has ever ventured to propose for being put into mortar.

Besides, there are variations caused by the different nature of the calcination in the several sorts of limestone; from which it may, upon the whole, be concluded, that about one-tenth of *pure* limestone is not enough calcined to admit of being made into mortar; and that of the most impure sorts of limestone, not above one-fourth part of the lime contained in it is so much calcined as to be in a caustic state.

The variation that is produced by these means, in regard to the proportion of sand that will be required to the lime in the one or the other case, is found to be so extremely great as hardly to be conceived. It is, however, stated, that the best mortar that has been seen made was formed of lime which had been found to contain eleven parts of sand to one of lime; to this there was added between twice and thrice its whole bulk of sand by measure, which may be allowed to have been at least three times its quantity *by weight*. Therefore, supposing that every particle of that lime had been so perfectly calcined as to be in a caustic state, there could not be less than forty-seven parts of sand to one of lime. As much may, however, be allowed for the uncaustic part of the lime as is desired, and the calculation made accordingly. But it is hardly possible to suppose that above one-hundredth part of this mass, independent of the water, consisted of pure caustic calcareous earth.

On these considerations it is conceived, that it is impossible to prescribe any determinate proportion of sand to lime, as that must vary according to the nature of the lime, and other incidental circumstances, which would form an infinity of exceptions to any general rule. But it would seem that it might be safely inferred, that the moderns, in general, rather err in giving too little sand than in giving too much. It deserves, however, to be noticed, that the sand, when naturally in the limestone, is more intimately blended with the lime than can possibly be ever effected by any mechanical operation; so that it would be in vain to hope to make good mortar artificially from pure lime, with such a small proportion of caustic calcareous matter as may sometimes be effected when the lime naturally contains a very large proportion of sand. But there seems to be no doubt, that if a much larger proportion of sand were employed, and if that were more carefully blended and expeditiously worked than is common, the mortar would be much more perfect than is usual in modern times, as has been proved by actual trials.

Another circumstance that tends greatly to vary the quality of cement, and to make a greater or smaller proportion of sand necessary, is the mode of preparing lime before it is beaten up into mortar. When for plaster, it is of great importance to have every particle of the limestone slaked before it is worked up; for, as smoothness of the surface is the most material point, if any particles of lime should be beaten up in it, and employed in work before sufficiently fallen, the water still continuing to act on them after it was worked up, would infallibly slake such particles, which, forcibly expanding themselves, would produce those excrescences on the surface of the plaster commonly termed blisters. Consequently, in order to obtain a perfect kind of plaster, that will remain smooth on the surface, and free of blisters, there is an absolute necessity to allow the lime to lie for a considerable time macerating or *souring* in water, before it is worked up. And the same sort of process is necessary for the lime, when intended for use as mortar, though not so absolutely. Great care is, however, required in the management in this respect; the principal things being the getting of well-burnt lime, and the allowing it to macerate or *sour* with the water for only a *very short time* before it is used; but that which is the best burnt will require the maceration of some days in the water before it is sufficiently slaked in the whole mass for this purpose.

It has been almost universally admitted, that the hardest limestone affords a lime that will consolidate into the firmest cement; hence it is generally concluded, that lime made of chalk produces a much weaker cement than what is made of marble or limestone. It would seem, however, that if ever this be the case, it is only incidentally, and not necessarily so. As, from the nature of calcareous matter, every kind of lime is equally fit for becoming a firm cement, if it be first reduced to a proper degree of causticity, and has afterwards a due proportion of sand properly mixed with it, before it be employed in work. Different sorts of lime, without doubt, differ much from each other in the proportion of sand they naturally contain, and, of course, require very different proportions of sand to be added to them before they can be made equally perfect as a cement; which is an economical consideration of no small moment, in some cases, as it may make one sort of lime a great deal cheaper than another on some occasions, and, of course, deserves the attention of builders in general.

The excellencies and defects of other substances, that may be occasionally mixed with lime, in making cement, may be just noticed. Those commonly used as an addition to mortar, besides sand of various denominations, are powdered sandstone, brick-dust, and sea-shells. And, for forming plaster, where closeness rather than hardness is required, they use lime that has been slaked and kept long in a dry place till it has become nearly effete, powdered chalk, or whiting, and gypsum, in various proportions; besides hair and other materials of that nature. But some others have been more lately advised, such as earthy balls, slightly burnt and pounded, powdered and sifted old mortar rubbish, and others of a similar kind. All of which substances are found objectionable, in some respect or other, for this use, sand being the only perfectly suitable material that can be easily met with; on which account, it has been always justly preferred. Pure firm crystallized sand is the best; though all pure sands are not equally proper for this purpose.

It is stated by Sir Humphrey Davy, in his work on *Agricultural Chemistry*, that there are two modes in which lime acts as a cement; in its combination with water, and in its combination with carbonic acid. When quick-lime is rapidly made into a paste with water, it soon loses its softness, and the water and the lime form together a solid coherent mass, which consists of seventeen parts of water, to fifty-five parts of lime. When this hydrate of lime, while it is consolidating, is mixed with red oxyde of iron, alumina, or silica, the mixture becomes harder and more coherent than when lime alone is used; and it appears, that this is owing to a certain degree of chemical attraction between hydrate of lime and these bodies: and they render it less liable to decompose by the action of the carbonic acid in the air, and less soluble in water. It is thought that the basis of all cements that are used for works which are to be covered with water must be formed from hydrate of lime; and that the lime made from impure lime-stones answers this purpose very well. Puzzolana, it is said, is composed principally of silica, alumina, and oxyde of iron; and it is used mixed with lime, to form cements intended to be employed under water. It is stated that Mr. Smeaton, in the construction of the Eddystone lighthouse, used a cement composed of equal parts, by weight, of slaked lime and puzzolana. Puzzolana, it is said, is a decomposed lava. Tarras, which was formerly imported in considerable quantities from Holland, is found to be a mere decomposed basalt: two parts of slaked lime and one part of tarras form the principal part of the mortar used in the great dykes of Holland. It is supposed that substances which will answer all the ends of puzzolana and tarras, are abundant in the British islands. An excellent red tarras may be procured in any quantities from the Giant's Causeway, in the north of Ireland: and decomposing basalt is abundant in many parts of Scotland, and in the north of England where coal is found.

It is observed that Parker's cement, and cements of the same kind, are mixtures of calcined ferruginous, siliceous, and aluminous matter, with hydrate of lime.

It is noticed, that the cements which act by combining with carbonic acid, or the common mortars, are made by mixing together slaked lime and sand. These mortars at first solidify as hydrates, and are slowly converted into carbonate of lime by the action of the carbonic acid of the air. It was found by Mr. Tennant, that a mortar of this kind, in three years and a quarter, had regained sixty-three per cent. of the quantity of carbonic acid gas, which constitutes the definite proportion in carbonate of lime. The hardness of the mortar in very old buildings is also thought to depend upon the perfect conversion of all its parts into carbonate of lime. The purest lime-stones are the best adapted, it is said, for making this kind of mortar. The magnesian lime-stones make excellent water-cements, but act with too little energy upon carbonic acid gas, to make good common mortar. The Romans, on Pliny's authority, made their best mortar a year before it was used; so that it was partially combined with carbonic acid gas before it was employed, it is supposed. See more on this subject under the articles Cement, Lime, Mortar, and Plastering.

QUIRE, the same as Choir.

QUIRK, a piece of ground taken out of any regular ground-plat, or floor. Thus, if the ground-plat were square, or oblong, and a piece be taken out of a corner, to make a court, or yard, &c., the piece is called a *quirk*.

Quirk-Mouldings are the convex parts of Grecian mouldings, where they recede at the top, and form a re-entrant angle with the soffit, or level surface which covers the moulding.

Quirks, in moulding, belong to the ovolo and semi-reversa.

QUOIN, or Coin, (from the French, *coin*, of the Latin, *cuneus*), a wedge. *See* Coin.

Quoins, (from the French *coin*, a corner), the corners of brick or stone walls. The word is particularly used for the stones in the corners of brick buildings. When these stand out beyond the brick-work (their edges being chamfered off) they are called *rustic quoins*.

R.

RABBET, or Rebate, *see* Rebate.

Rabbet-Plane, *see* Plane.

RABBETING, or Rebating, the planing or cutting of channels, or grooves, in boards.

RACK, the case in a stable where the hay is placed for the horses.

RADIUS, in a circle, the right line drawn from the centre to the circumference.

RAFTERS, (Dutch), pieces of timber, which, standing by pairs on the reason-piece, or raising-piece, meet in an angle at the top, and form the roof of a building.

It is a rule in architecture, that rafters should not stand farther than twelve inches asunder.

For the sizes or scantlings of rafters, it is advisable that *principal* rafters from 12 feet 6 inches, to 14 feet 6 inches long, be 5 inches broad at the top, 8 inches at the bottom, and 6 inches thick. Those from 14 feet 6 inches, to 18 feet 6 inches long, to be 9 inches broad at the foot, 7 inches at the top, and 7 inches thick. And those from 18 feet 6 inches, to 21 feet 6 inches, to be 10 inches broad at the foot, 8 inches at the top, and 8 inches thick. Single rafters, 6 feet 6 inches long, must be 4 feet 3 inches in their square.

Rafters, the inclined timbers disposed in the sides of a roof, so that their edges may be in planes parallel to the covering which is supported by them. See the article Roof, Curb-roof; but more particularly Mechanical Carpentry.

RAG-STONE, a kind of limestone much used in building of late. *See* Quarry.

RAIL, (from the German, *riegel*), in *architecture*, is applied variously; particularly to those pieces of timber which lie horizontally between the panels of wainscot, and over and under them. The word is also applied to those pieces of timber which lie over and under balusters in balconies, staircases, &c. Also, to the pieces of timber that lie horizontally from post to post in fences, with pales or without.

Fig. 3.

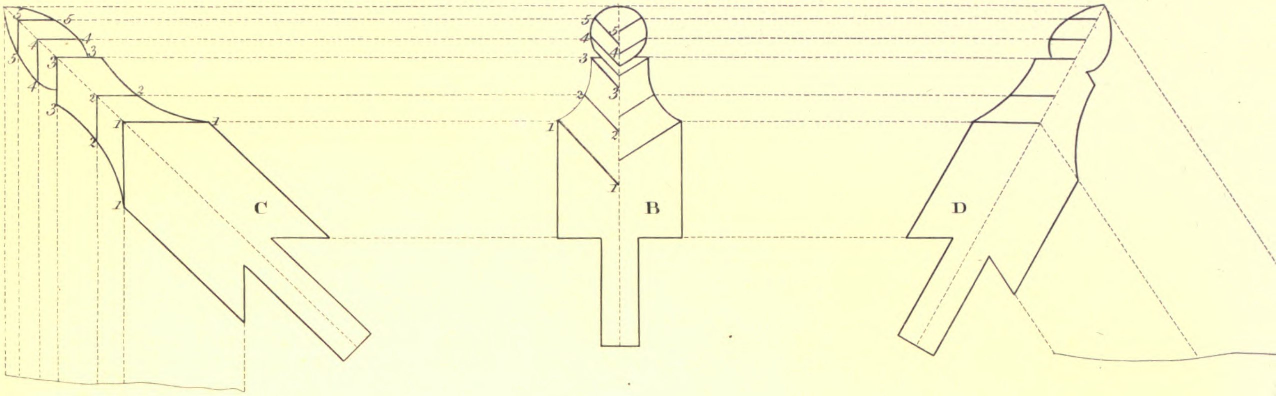


Fig. 2.

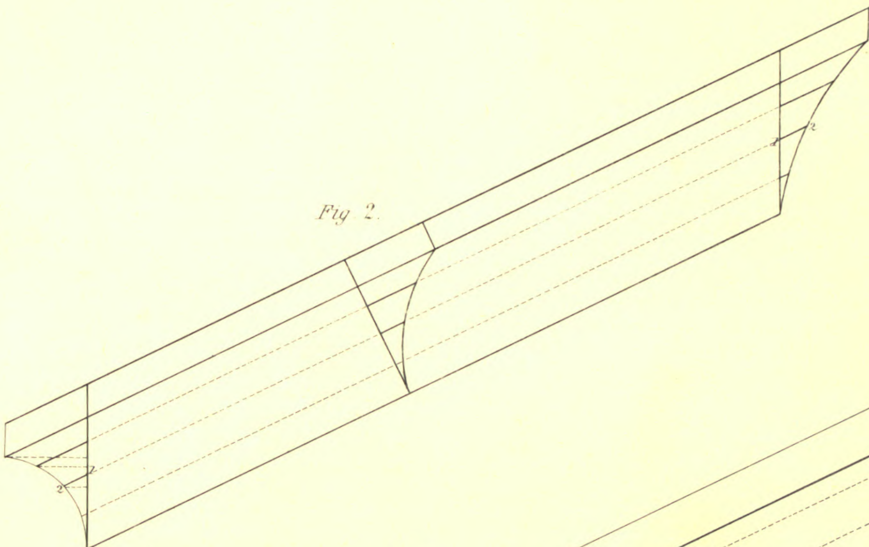

Fig. 1.

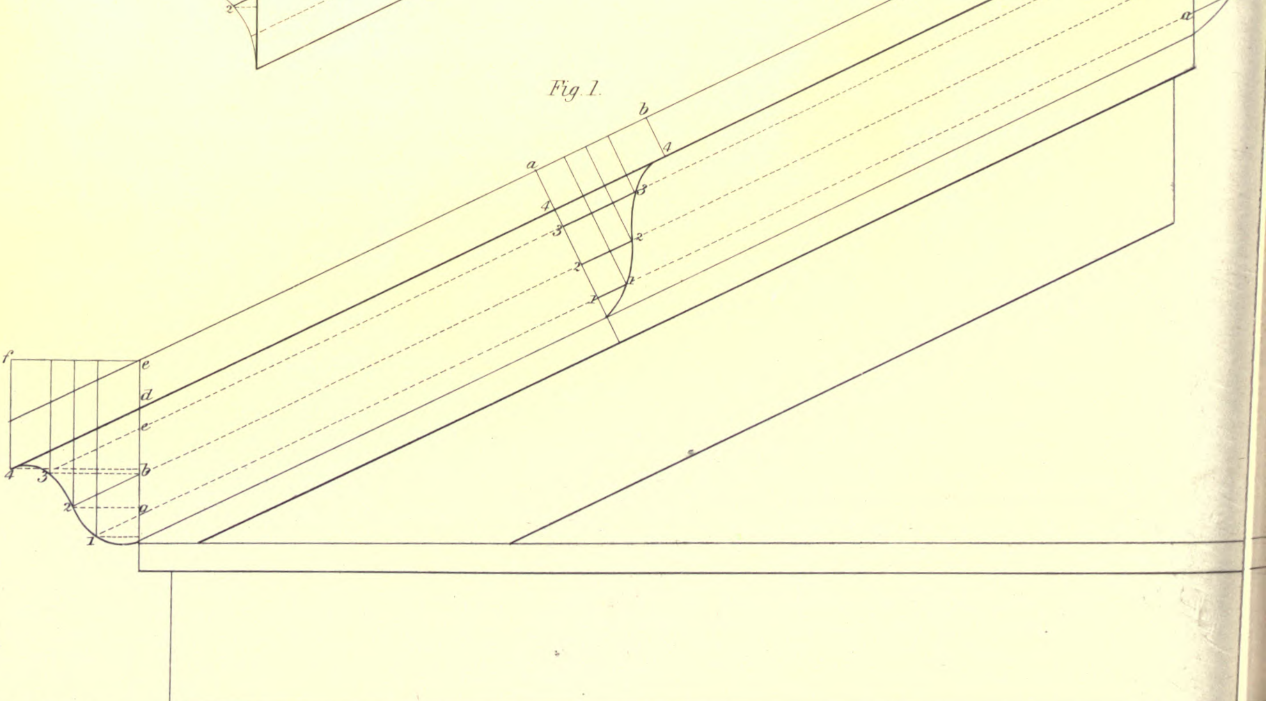

RAILING, in *Rural Economy*, a sort of fence constructed with posts and rails. It is often made use of in protecting young hedge-fences from the cropping of cattle or other animals. Any sort of coarse timber does very well for this last purpose, such as outside planks, and the boughs or loppings of timber plantations.

RAILWAY, or TRAM-ROAD, or DRAM-ROAD, or WAGGON-WAY, a track constructed of iron, stone, timber, or other material, upon the surface of an inclined plane, or other situation, for the purpose of diminishing friction, and thus serving for the easy conveyance of heavy loads of any kind of articles.

Railways were at first solely employed for transporting coals to a moderate distance from the pits, to the places where they could be shipped, and were universally made of wood. By degrees they were, however, carried to a farther extent; when the scarcity of wood, and the expense of their repairs, suggested the idea of employing iron for the purpose of improving these roads. At first, flat rods of bar-iron were nailed upon the original wooden rails, or, as they were technically called, *sleepers;* and this, though an expensive process, was found to be a great improvement.

They were next cast in the form of long narrow plates, with a vertical flanche on one side, so that the section presented the form of the letter L, and thus the wheels of the carriages were retained in the direction of the rails; the flanches on the wheels being dispensed with.

But the longitudinal timbers on which these plate-rails rested, being liable to rot and give way, were at last entirely discarded, and the rails were cast of sufficient depth to sustain the weight passing over them, and of length sufficient to reach from one cross sleeper to the next, to which they were secured by means of chairs; these rails were reduced in width, and the flanche transferred back again to the wheels.

About 1815, malleable bars were introduced, those of cast-iron having been found objectionable on account of their frangibility. The former were simply bars of iron, three or four feet long, and from one to two inches square, but they were found to destroy the wheels, on account of their narrowness: and a return to cast-iron appeared inevitable, until a new method of constructing the malleable rails was patented in 1820 by Mr. Birkinshaw. This improvement consisted in passing the bars, when red-hot, between rollers, which gave the required form to the rails, and by this means the bars were rolled in lengths of from 12 to 15 feet, and of any section required, the depth and breadth being increased in proportion to the distance from the bearings.

The rails are placed in chairs of cast-iron, which are spiked down to transverse timbers or sleepers, as they are termed, laid from 2 feet 6 inches to 3 feet apart. These sleepers are commonly of larch, about 9 feet in length, 9 inches in width, and 6 inches deep, and at either end at the distance apart of 4 feet 8½ inches, are placed the chairs or saddles to receive the ends of the rails, which run parallel to each other; they are generally about 5 inches deep at the centre, 2½ inches wide at the top and bottom, and ⅝ inch thick in the middle vertical rib.

The rails of the broad guage are placed 7 feet apart, and are spiked down to longitudinal timbers, which are kept equidistant by transverse sleepers.

The permanent way consists of a level roadway, properly ballasted with gravel or other suitable ballasting.

RAIN-WATER PIPE, a pipe fixed on the exterior of houses and other buildings, for the purpose of conveying rain-water from the roofs, &c., into a drain.

RAISER, a board set on edge under the foreside of a step, a stair, &c. *See* STAIRCASING.

RAISING-PIECES, or REASON-PIECES, in architecture, pieces that lie under the beams, and over the posts or puncheons.

The term is chiefly employed in buildings constructed of timber frame, where the interstices are filled with clay, or brickwork, called *panels.* In brick or stone buildings, the board or plank placed on the top of the wall is denominated the *wall-plate;* but, in some parts of the country, the wall-plates are denominated *platbands.*

RAKING, a term applied to such members of a building as slope or lie inclined to the horizon.

RAKING-MOULDING, in joinery, a moulding whose arrises are inclined to the horizon in any given angle.

If the raking-moulding has to meet with a horizontal moulding, at a given angle, on the plan; and if the section of the horizontal moulding be given; the following method will show how to find the section of the raking-moulding:

Figure 1.—Let the given moulding be a cima-recta; take any number of points in the curve, and through these points draw straight lines parallel to the rake; then the moulding shown in the middle of the rake, being pricked off from the level lines at the bottom, will give the section to work the raking-moulding.

If the moulding is required to be returned, as shown at the upper part, the inclined lines are continued; the proper projections are set at the top of the moulding, and vertical lines are drawn through the points of section to meet the respective inclined lines; then a curve, being drawn through the points of intersection, will give the horizontal return moulding at the top.

Figure 2.—An inclined cavetto, showing the section of the raking moulding, and also the section of the return level-moulding of the top.

Angle-bars, for shop-fronts, are also ranked among the class of raking mouldings. In *Figure* 3, let B be the common bar, of the same thickness with the angle-bar: take the raking projection, 1, 1, in C, and set the foot of the compasses in 1 at B, and cross the middle of the bar at the other 1; draw the lines 2, 2, 3, 3, &c. parallel to 1, 1, then prick the section at 1 C, from the ordinates so drawn at B, and thus the section of the angle-bar is obtained.

RAMMED-EARTH BUILDINGS, such as are raised with some sort of earthy material, hardened by being rammed into moulds or cases. This mode of building with earthy materials is supposed by some to have been known at a very early period, and has been long practised with success in the southern parts of France, especially about Lyons, though but little understood in any other part of Europe until comparatively lately. *See* PISE.

RAMP, in hand-railing, a concavity on the upper side, formed over risers, or over a half or quarter space, by a sudden rise of the steps above, which frequently occasions a knee above the ramp.

RAMPANT ARCH, one whose abutments spring from an inclined plane.

RAMPART, or RAMPIER, (from the Spanish, *amparo, defence*, or *covering,*) in fortification, a massy bank, or elevation of earth, about the body of a place, to cover it from the direct fire of the enemy, and of sufficient thickness to resist the efforts of the cannon for many days; and formed into bastions, curtains, &c.

Upon the rampart the soldiers continually keep guard, and pieces of artillery are planted there for the defence of the place. Hence, to shelter the guard from the enemy's shot, the outside of the rampart is built higher than the inside, *i. e.*

a parapet is raised upon it with a platform. Hence, also, earth not being capable to be raised perpendicularly, like stone, the rampart is built with a talus, or slope, both on the inner and outer side.

The rampart is sometimes lined, *i. e.* fortified with a stone wall withinside, otherwise it has a berme.

It is encompassed also with a moat, or ditch, out of which the earth that forms the rampart is dug.

The height of the rampart should not exceed three fathoms, this being sufficient to cover the houses from the battery of the cannon: neither ought its thickness to be above ten or twelve, unless more earth be taken out of the ditch than can be otherwise bestowed.

The ramparts of half-moons are the better for being low, that the small fire of the defendants may the better reach the bottom of the ditch; but yet they must be so high as not to be commanded by the covert-way.

Rampart, in civil architecture, is also used for the space left void between the wall of a city and the nearest houses. This is what the Romans call *pomœrium*, in which it was forbid to build, and where they planted rows of trees, for the people to walk and amuse themselves under.

RAMPS, in fortification, gentle slopes made for the cannon to be drawn up and down by, and also for the easy communication of the troops posted in a battery raised above the level of the ground. The rise of these slopes is about two inches, on twelve of base; or the length of the base is six times the height, and this is general for the draught of carriages; but footways need not be of so gentle a slope, as a rise of one foot in three may answer the purpose; or, instead of ramps, stairs may be, and commonly are, used for the passage of the foot. The breadth of a carriage ramp is usually about nine or ten feet; but those for foot-passage only need not be above three or four feet wide. Ramps may either rise on the side of an elevated work, or against a salient angle of that work, or on each side of an entering angle.

RANGE, or Ranging, (from the French, *ranger*, to place in ranks,) a term applied to the edges of a number of bodies, placed in a given surface: thus, if the edges of the ribs of a groin were placed in a cylindric surface, they would be said to *range*. It is also used in speaking of the side of a work that runs straight, without breaking into angles.

RASP, a rough file.

RATE, in architecture, the particular class of a building, under which it is arranged, as to the quantity of ground on which it stands, its height, or destination.

This classification is only used in the neighbourhood of London, in order to modify the construction according to the regulations of the building act. *See* House.

RAVELIN, in fortification, was anciently a flat bastion, placed in the middle of a curtain; but now it is a detached work, composed only of two faces, which make a salient angle, sometimes without, and sometimes with flanks; and raised before the curtain on the counterscarp of the place; serving to cover it and the adjoining flanks from the direct fire of an enemy.

A ravelin is a triangular work, resembling the point of a bastion with the flanks cut off. Its use before a curtain is, to cover the opposite flanks of the two next bastions. It is used also to cover a bridge, or a gate, and is always placed without the moat.

What the engineers call a *ravelin*, the soldiers generally call a *demi-lane*, or *half moon*.

There are also *double* ravelins, which serve to defend each other. They are said to be double when they are joined by a curtain.

READING-DESK, a raised desk in churches, from which the lessons and other parts of the services are read. It is more correctly termed Lettern, or Lectern, and consists usually of one or two sloping-desks of sufficient size to sustain the books raised upon a pedestal or standard; they are mostly made of wood, but frequently of brass or other metal, and is enriched with various degrees of ornamentation. In many cases, the stem or pedestal was surmounted by an eagle with outspread wings, on which the books rested.

REBATE, or Rabbet, (from the French, *rabbattre*, to abate,) a deep groove, or channel, cut longitudinally in a piece of timber, to receive the edge of a plank, or the ends of a number of planks, which are to be securely fastened into it. The depth of this channel is equal to the thickness of the plank, so that, when the end of the latter is let into the rebate, it will be level with the outside of the piece.

RECESS, (from the Latin, *recessus*,) a cavity in a wall, left either for ornament or use, or for both purposes united; for use, when it is to receive some piece of furniture, as a sideboard, or to add to the size of room; and for ornament when made in the form of a niche, to give beauty and variety to the building. When the construction of the edifice requires some of its walls to be of very great thickness, niches are frequently taken out of the wall, to lessen its thickness and give a greater quantity of floor-room; so that utility and ornament are united, and the expense of materials is saved.

RECIPIANGLE, or Recipient-Angle, a mathematical instrument, serving to take the quantity of angles; used especially in the drawing of plans of fortifications.

The recipiangle was formerly a popular instrument among the French, but little known among us; it is usually very simple, in form of a square, or rather a *bevel*; consisting of two arms, or branches, riveted together, but moveable, like a sector, on the centre or rivet.

To take an angle with it, the centre of a protractor is laid to the joint, and the degrees cut by the edge show the quantity of the angle; otherwise the angle made by the two rulers is drawn on paper, and then measured with a protractor.

Sometimes there is a circle divided into degrees added over the centre or rivet, with an index to show the degrees without a protractor. At other times the under branch is divided.

To measure a salient angle with any of the recipiangles, apply the insides to the lines that form the angle; for a re-entering angle, apply the outsides, &c.

RECTANGLE, (from the Latin, *rectangulus*,) called also *oblong*, and *long square*, a quadrilateral rectangular figure, whose opposite sides are equal. Or, a rectangle is a parallelogram, whose angles are right.

RECTANGULAR, a term applied to figures and solids which have one or more angles right. Such are squares, rectangles, and rectangled triangles, among plain figures; cubes, parallelopipeds, &c. among solids.

Solids are also said to be rectangular with respect to their situation: thus, if a cone, cylinder, &c. be perpendicular to the plane of the horizon, it is called a rectangular or right cone, cylinder, &c.

The ancients used the phrase *rectangular section of a cone*, to denote a parabola; that conic section, before Apollonius, being only considered in a cone, whose section by the axis would be a triangle, right-angled at the vertex.

Hence it was that Archimedes entitled his book of the quadrature of the parabola, by the name of *Rectanguli Coni Sectio*.

RECTANGULAR, or RIGHT-ANGLED TRIANGLE, a triangle, one of whose angles is right, or equal to 90 degrees. *See* TRIANGLE.

RECTIFICATION, in geometry, the finding of a right line equal to a proposed curve, or simply finding the length of a curve-line ; a problem which, even in the present advanced state of analysis, is attended, in many cases, with considerable difficulty ; and was, *in all*, totally beyond the reach of the ancient geometers, who were not able to assign the length of any curve-line whatever ; though they could, in a few instances, determine the area of a curvilinear space. The first rectification of a curve-line was effected by Mr. H. Neal, as we are informed by Dr. Wallis, at the conclusion of his *Treatise on the Cissoid.* This curve was the semi-cubical parabola, and Neal's rectification of it was published in July or August, 1657 ; and in 1659, the same was done by Van Haureat, in Holland.

It is, however, to the doctrine of fluxions and differential calculus that we owe the complete rectification of curve-lines, infinite terms, when they admit of it ; and in others, by means of infinite series, circular arcs, logarithms, &c.

RECTILINEAR, or RIGHT-LINED, a term applied to figures whose perimeter consists of right lines.

RECTORY, the official residence of a parish priest, usually in close proximity to the church.

REDANS (French) projections constructed at intervals in walls built on sloping or uneven ground, for the purpose of preserving the same height through its whole length.

REDOUBT, or REDOUBTE (from the Latin *reductus*) in fortification, a small square fort, without any defence but in front, used in trenches, lines of circumvallation, contravallation and approach ; as also for the lodging of corps de garde, and to defend passages. Redoubts are usually figures of three, four, five, or six sides, encompassed with a ditch, and a bank of earth, which consists of two parts called *rampart* and *parapet.* In marshy grounds, redoubts are often made of stone-work for the security of the neighbourhood ; their face consists of from ten to fifteen fathoms ; the ditch round them from eight to nine feet broad and deep : and their parapets, which are cut into embrasures and merlons, have the same thickness.

The inner sides of square redoubts are usually between the limits of twelve and thirty-two yards ; and when they are to be defended by musketry, the number of men necessary to the defence may be thus determined ; half the side squared, gives the number of troops ; and twice the square root of a given number of men, shows the length in yards of the side of a square redoubt proper to contain them.

REDUCTION of a Figure, Design, or Draught, the making a copy of it, either larger or smaller than the original, still preserving the form and proportion.

The great use of the proportional compasses is in the reduction of figures, &c., whence they are also called *compasses of reduction.*

REFECTORY, a dining-hall or refreshment room. The term is especially applied to the dining-halls of monastic or other religious establishments.

REFLEX, or REFLECT, in painting, is understood of those places in a picture which are supposed to be illuminated by a light reflected from some other body represented in the same piece.

Or, reflexes may be defined those places which, beside the general light that illumines the whole piece, receive some particular light from their situation with respect to some more illuminated polished body, that reflects part of the rays it receives upon them.

Reflexes are scarcely sensible, except in the shadowed parts. The management of the reflexes requires great accuracy and skill. All reflected light is supposed to carry with it part of the colour of the body which reflects it : so that those places which receive this light must have their colour mixed or tinged with that colour. But the same place may receive reflexes from different objects, differently coloured, and those, again, receive reflexes from others. The painter, therefore, must have a view to every circumstance of the colour, light, and position of each figure ; he must consider what effect each has on others, and pursue nature through all the variety of mixtures.

REGLET, or RIGLET, (from the French *reglette*), a flat narrow moulding, used chiefly in compartments and panels, to separate the parts, or members, from each other, and to form knots, frets, and other ornaments. The reglet, according to Daviler, differs from the *fillet* and *listel* in that it projects equally, like a ruler.

REGRATING, among masons, &c., taking off the outer surface of an old hewn stone, with the hammer and ripe, in order to whiten and make it look fresh again.

REGULA, a band below the tœnia in the Doric architrave.

REGULAR FIGURE, a figure that is both equilateral and equiangular; *i. e.*, whose sides, and consequently its angles, are all equal.

The equilateral triangle and square are regular figures. All other regular figures, consisting of more than four sides, are called regular *polygons.* Every regular figure may be inscribed in a circle.

REGULAR BODY, called also PLATONIC BODY, a solid terminated on all sides by regular and equal planes, and whose solid angles are all equal.

The regular bodies are five in number, viz., the *cube*, which consists of six equal squares ; the *tetrahedron*, or regular triangular pyramid, having four equal triangular faces ; the *octahedron*, having eight ; the *dodecahedron*, having twelve pentagonal faces ; and the *icosahedron*, having twenty triangular faces.

REGULAR ARCHITECTURE, such as has all its parts disposed in regular symmetry, or that has its parts disposed in counter-parts.

REINS OF A VAULT, *see* VAULT.

REJOINTING, the filling up of the joints of stones in old buildings, &c., when worn hollow by the course of time, or by weather. Rejointing is to be performed with the best mortar, as that of lime and cement ; sometimes also with plaster, as in the joints of vaults, &c.

RELATION, in architecture, between the several parts and members of an edifice, constitutes what is otherwise called *symmetry*.

RELIEVO, RELIEF, or EMBOSSMENT, a term applied to a figure which projects from the ground, or plane, on which it is formed, whether it be cut with the chisel, moulded, or cast. There are three kinds of relievo, viz. *alto*, *basso*, and *demi-relievo.*

Alto-relievo, *haut relief*, or *high relievo*, is when the figure is formed after nature, and projects as much as the life.

Basso-relievo, *bas relief*, or *low relievo*, is when the work is raised but a little from its ground, as in medals, and the frontispieces of buildings, particularly the histories, festoons, foliages, and other ornaments, in friezes. *See* BASSO-RELIEVO.

Demi-relievo is when one half of the figure rises from the plane, *i. e.*, when the body of a figure seems cut in two, and one-half is clapped on a ground. When, in a basso-relievo, some parts stand clear out, detached from the rest, the work is called a *demi-bosse.*

Relievo also denotes the sally, or projecture of any architectural ornament.

This, Daviler observes, is always to be proportioned to the magnitude of the building it adorns, and the distance at which it is to be viewed. If the work be insulate, and terminated on all sides, it is called a *figure in relievo*, or a *round embossment*. Such are statues, acroters, &c.

Relievo, in painting, denotes the degree of force, or boldness, by which a figure seems, at a due distance, to stand out from the ground of the painting, as if really embossed.

The relievo depends much on the depth of the shadow, and the strength of the light; or on the light of the different colours bordering on each other; and particularly on the difference of the colour of the figure from that of the ground.

When the light is well chosen, to make the nearest parts of figures advance; and well diffused on the masses, still diminishing insensibly, and terminating in a large spacious shadow, brought off insensibly; the relievo is said to be *bold*, and the claire obscure *well understood*.

RENAISSANCE, that style which arose in the arts in general, and also in architecture, by the attempt made to revive classic taste upon the decline of the Gothic system. This revival was commenced in Italy in the latter part of the fourteenth century, by Brunelleschi, and still further developed by his successors, amongst whom may be mentioned Alberti, Bramante, Michael Angelo Buonarotti, Palladio, &c. The Gothic style had never been fully developed, nor obtained a secure footing, in Italy; and hence the classic styles were revived without difficulty, and with greater success than in those countries where the Gothic had been fully established; and although even in Italy the latter style does not seem to have disappeared immediately—for we see in many buildings an admixture of the two—still the struggle for pre-eminence was not so great, or of so long continuance, as in other countries. In Italy, the classic principles were at once introduced in the constructive and essential parts of the building, and the Gothic only retained in matters of detail; whereas in other places the contrary practice occurred—that is to say, the change took place gradually by the introduction or substitution of classic details upon buildings essentially Gothic, until at last the classic predominated both in essentials and accessories. *See* Italian and Tudor Architecture.

RELIQUARY, a casket of wood, metal, or stone, frequently enriched with precious stones, &c., for the purpose of preserving reliques.

RENDERING, in building, *see* Pargeting and Plastering.

REPAIRING of large walls, doors, ceilings, coverings, &c., belongs to the proprietor, or landlord: the tenant is only charged with small repairs, or glass windows, locks, &c., by the French called *locative* repairs.

REREDOS, the ornamental screen, or other decorative work, of whatever kind, employed to enrich the wall at the back of the altar.

RESERVOIR (French), a large pond or pen of water, artificially made, in order to retain and collect it for the use of canals, rivers, mills, &c.

In a building, the reservoir is a large bason, usually of wood, lined with lead, where water is kept to supply the occasions of the house. Large reservoirs are frequently constructed of cast-iron.

The reservoir is sometimes, also, a large bason of strong masonry, clayed or paved at the bottom, where the water is reserved to feed *jets d'eau*, or spouting fountains.

RESISTANCE, or Resisting Force, any power that acts in opposition to another, so as to destroy or diminish its effect.

Of resistance there are several kinds, arising from the various natures and properties of the resisting bodies, and governed by various laws: as the resistance of solids, the resistance of fluids, the resistance of the air, &c.

Resistance of Solids, the force with which the quiescent parts of solid bodies oppose the motion of others contiguous to them.

Of this there are two kinds. The first, where the resisting and resisted parts, *i. e.* the moving and quiescent bodies, are only contiguous, and do not cohere; i. e. where they constitute separate bodies or masses.

This is what M. Leibnitz calls *resistance of the surface*; but which is now more commonly denominated *friction*.

The second case of resistance is where the resisting and resisted parts are not only contiguous, but cohere; i. e. are parts of the same continued body or mass.

To which we may also add, the resistance which takes place between surfaces of solids, when completely in contact, though not forming one and the same body; or the resistance they offer to separation.

Resistance of the Fibres of Solid Bodies, *Theory of the.* To form an idea of this resistance or renitency of the parts, suppose a cylindrical body suspended vertically by one end. Here all its parts, being heavy, tend downwards, and endeavour to separate the two contiguous planes, where the body is the weakest; but all the parts resist this separation by the force with which they cohere, or are bound together. Here, then, are two opposite powers; viz., the weight of the cylinder, which tends to break it; and the force of cohesion of the parts, which resists the fracture. If the base of the cylinder be increased, without increasing its length, it is evident the resistance will be increased in the same ratio as the base; but the weight also increases in the same ratio: whence it is evident, that all cylinders of the same matter and length, whatever their bases may be, have an equal resistance, when vertically suspended.

But if the length of the cylinder be increased, without increasing its base, its weight is increased, while the resistance, or strength, remains the same: consequently, it is weakened by its additional length, and has a greater tendency to break.

Hence, to find the greatest length a cylinder of any matter may have to break with its own weight, it is only necessary to know what weight is just sufficient to break another cylinder of the same base and matter: for the length of the required cylinder must be such, that its weight may be equal to the weight of the first cylinder, together with the additional weight that was employed in producing the separation.

If one end of the cylinder were fixed horizontally into a wall, and the rest suspended thence, its weight and resistance would then act in a different manner; and if it be broke by the action of its weight, the rupture would be at the end fixed into the wall. A circle, or plane, contiguous to the wall, and parallel to the base, and consequently vertical, would be detached from the contiguous circle within the plane of the wall, and would descend. All the motion is performed on the lowest extremity of the diameter, which remains immovable, while the upper extremity describes a quadrant of a circle, and till the circle, which before was vertical, become horizontal, *i. e.* till the cylinder be entirely broken.

In the fracture of the cylinder, it is visible, two forces have acted, and the one has overcome the other: the weight of the cylinder, which arose from its whole mass, has overcome the resistance which arose from the largeness of the base; and, as the centres of gravity are points in which all the forces, arising from the weight of the several parts of the same bodies, are conceived to be united, one may conceive the weight of the whole cylinder applied in the centre of gravity of its mass, *i. e.* in a point in the middle of its axis: and the resistance of the cylinder applied in the centre of gravity of its base *i. e.* in the centre of the base; it being the base which resists the fracture.

When the cylinder breaks by its own weight, all the motion is on an immovable extremity of a diameter of the base. This extremity, therefore, is the fixed point of a lever, whose two arms are the radius of the base, and half the axis; and, of consequence, the two opposite forces do not only act of themselves, and by their absolute force, but also by the relative force they derive from their distance with regard to the fixed point of the lever.

Hence it evidently follows, that a cylinder, *e. gr.* of copper, which, vertically suspended, will not break by its own weight, if less than four hundred and eighty fathoms long, will break with a less length in an horizontal situation; because the length, in this latter case, contributes two ways to the fracture; both as it makes it of such a weight, and as it is an arm of a lever to which the weight is applied. Hence, also, the smaller the base is, the less length or weight will suffice to break it; both because the resistance is really less, and because it acts by a less arm of a lever.

If two cylinders of the same matter, having their bases and lengths in the same proportion, be suspended horizontally; it is evident, that the greater has more weight than the lesser, both on account of its length, and of its base. But it has less resistance on account of its length, considered as a longer arm of a lever, and has only more resistance on account of its base; therefore it exceeds the lesser in its bulk and weight more than in resistance, and, consequently, it must break more easily.

Hence we see why, upon making models and machines in small, people are apt to be mistaken as to the resistance and strength of certain horizontal pieces, when they come to execute their designs in large, by observing the same proportion as in the small. Galileo's doctrine of resistance, therefore, is no idle speculation, but becomes applicable in architecture, and other arts.

The weight required to break a body placed horizontally, being always less than that required to break it in a vertical situation; and this weight being greater or less, according to the ratio of the two arms of the lever, the whole theory is always reducible to this: viz. to find what part of the absolute weight the relative weight is to be, supposing the figure of the body known; which indeed is necessary, because it is the figure that determines the two centres of gravity, or the two arms of the lever. For if the body, *e. gr.* were a cone, its centre of gravity would not be in the middle of its axis, as in the cylinder; and, if it were a semi-parabolical solid, neither would its centre of gravity be in the middle of its length or axis, nor the centre of gravity of its base in the middle of the axis of its base. But still, wheresoever these centres fall in the several figures, the two arms of the lever are estimated accordingly.

It may be here observed, that if the base, by which the body is fastened into the wall, be not circular, but, *e. gr.* parabolical, and the vertex of the parabola be at the top, the motion of the fracture will not be on an immovable point, but on a whole immovable line; which may be called the *axis of equilibrium;* and it is with regard to this, that the distances of the centres of gravity are to be determined.

Now, a body horizontally suspended, being supposed such that the smallest addition of weight would break it, there is an equilibrium between its positive and relative weight; and, of consequence, those two opposite powers are to each other reciprocally as the arms of the lever to which they are applied. On the other hand, the resistance of a body is always equal to the greatest weight which it will sustain in a vertical situation without breaking, *i. e.* is equal to its absolute weight. Therefore, substituting the absolute weight for the resistance, it appears that the absolute weight of a body, suspended horizontally, is to its relative weight as the distance of the centre of gravity from the axis of equilibrium is to the distance of the centre of gravity of its base from the same axis.

The discovery of this important truth, at least an equivalent to it, and to which this is reducible, we owe to Galileo. From this fundamental proposition are easily deduced several consequences; as, for instance, that if the distance of the centre of gravity of the base from the axis of equilibrium be half the distance of the centre of gravity of the body, the relative weight will only be half the absolute weight; and that a cylinder of copper, horizontally suspended, whose length is double the diameter, will break, provided it weigh half what a cylinder of the same base, 4801 fathoms long, weighs.

On this theory of resistance, which we owe to Galileo, M. Mariotte made a very ingenious remark, which gave birth to a new system. Galileo supposes, that where the body breaks, all the fibres break at once; so that the body always resists with its whole absolute force, or with the whole force that all its fibres have in the place where it is to be broken. But M. Mariotte, finding that all bodies, even glass itself, bend before they break, shows that fibres are to be considered as so many little bent springs, which never exert their whole force till stretched to a certain point, and never break till entirely unbent. Hence, those nearest the axis of equilibrium, which is an immovable line, are stretched less than those farther off; and, of consequence, employ a less part of their force.

This consideration only takes place in the horizontal situation of the body; in the vertical, the fibres of the base all break at once; so that the absolute weight of the body must exceed the united resistance of all its fibres: a greater weight is therefore required here than in the horizontal situation; that is, a greater weight is required to overcome their united resistance than to overcome their several resistances one after another. The difference between the two situations arises hence, that in the horizontal there is an immoveable point, or line, as a centre of motion, which is not in the vertical.

Varignon has improved on the system of M. Mariotte, and shown, that to Galileo's system it adds the consideration of the centre of percussion. The comparison of the centres of gravity with the centres of percussion afford a fine view, and set the whole doctrine in a most agreeable light.

In each system, the base, by which the body breaks, moves on the axis of equilibrium, which is an immoveable line in the same base; but in the second, the fibres of this base are continually stretching more and more, and that in the same ratio as they recede farther and farther from the axis of equilibrium; and of consequence, are still exerting a greater and greater part of their whole force.

These unequal extensions, like all other forces, must have some common centre where they all meet, and, with regard to which, they make equal efforts on each side; and, as they are precisely in the same proportion as the velocities which the several points of a rod moved circularly would have to each other, the centre of extension of the base, by which the body breaks or tends to break, must be the same with the centre of percussion. Galileo's hypothesis, according to which the fibres are supposed to stretch equally, and break all at once, corresponds to the case of a rod moving parallel to itself, where the centre of extension or percussion does not appear, as being confounded with the centre of gravity.

The base of fraction being a surface, whose particular nature determines its centre of percussion, it is necessary that this should be first known, to find on what point of the vertical axis of that base it is placed, and how far it is from the axis of equilibrium. Indeed, we know in the general, that it always acts with so much the more advantage as it is farther from it; because it acts by a longer arm of a lever; and, of consequence, it is the unequal consistency of the fibres in M. Mariotte's hypothesis which produces the centre of percussion; but this unequal resistance is greater or less, according as the centre of percussion is placed more or less high on the vertical axis of the base, in the different surfaces of the base of the fracture.

To express this unequal resistance, accompanied with all the variation it is capable of, regard must be had to the ratio between the distance of the centre of percussion from the axis of equilibrium, and the length of the vertical axis of the base; in which ratio, the first term, or the numerator, is always less than the second, or the denominator; so that the ratio is always a fraction less than unity; and the unequal resistance of the fibres in M. Mariotte's hypothesis is so much the greater, or, which amounts to the same, approaches so much nearer to the equal resistance in Galileo's hypothesis, as the two terms of the ratio are nearer to an equality.

Hence it follows, that the resistance of bodies in M. Mariotte's system is to that in Galileo's, as the least of the terms in the ratio is to the greatest. Hence, also, the resistance being less than what Galileo imagined, the relative weight must also be less; so that the proportion already mentioned, between the absolute and relative weight, cannot subsist in the new system, without an augmentation of the relative weight, or a diminution of the absolute weight; which diminution is had by multiplying the weight by the ratio, which is always less than unity. This done, we find that the absolute weight, multiplied by the ratio, is to the relative weight as the distance of the centre of gravity of the body from the axis of equilibrium, is to the distance of the centre of gravity of the base of the fracture from the same axis; which is precisely the same thing with the general formula given by M. Varignon for the system of M. Mariotte. In effect, after conceiving the relative weight of a body, and its resistance equal to its absolute weight, as two contrary powers applied to the two arms of a lever, in the hypothesis of Galileo, there needs nothing to convert it into that of M. Mariotte, but to imagine that the resistance, or the absolute weight, is become less, everything else remaining the same. One of the most curious, and perhaps the most useful questions in this research, is to find what figure a body must have, that its resistance may be equal in all its parts, whether it be loaded with an additional weight, or as only sustaining its own weight.

To this end, it is necessary that some part of it should be conceived to be cut off by a plane parallel to the fracture, so that the momentum of the part retrenched be to its resistance in the same ratio as the momentum of the whole is to its resistance. These four powers act by arms of levers peculiar to themselves, and are proportional in the whole, and in each part, of a solid of equal resistance. From this proportion, Varignon deduces two solids, which shall resist equally in all their parts, or be no more liable to break in one part than in another. Galileo had previously found one of these, which is that in which the sides are parabolical: the other, found by Varignon, is in the form of a trumpet, which is to be fixed into the wall by its greater end; so that its magnitude, or weight, is always diminished in proportion as its length, or the arm of the lever by which it acts, is increased. It is remarkable, that, however different the two systems may be, the solids of equal resistance are the same in both.

The following is a general synopsis of the most important results which have been drawn by different writers on this subject, both practical and theoretical.

1. The resistance of a beam or bar, to a fracture, by a force acting laterally, is as the solid made by a section of the beam in the place where the force is applied, into the distance of its centre of gravity from the point or line where the breach will end.

2. In square beams, the lateral strengths are as the cubes of their breadths or depths.

3. In cylindric beams the resistances or strengths are as the cubes of the diameters.

4. In rectangular beams, the lateral strengths are conjointly as the breadths and squares of the depths.

5. The lateral resistance of any beams, whose sections are similar figures and alike placed, are as the cubes of the like dimensions of those figures.

6. The lateral strength of a beam, with its narrower face upwards, is to its strength with the broader face upwards, as the breadth of the broader face to the breadth of the narrower.

7. The lateral strengths of prismatic beams of the same materials, are as the areas of the sections, and the distance of their centre of gravity, directly, and as their lengths and weights reciprocally.

8. When the beam is fixed at both ends, the same property has place, except that, in this case, we must consider the beam as only half the length of the former.

9. Cylinders and square prisms have their lateral strengths proportional to the cubes of their diameters, or depths, directly, and their lengths and weights inversely.

10. Similar prisms and cylinders have their strength inversely proportional to their linear dimensions.

The following results are wholly drawn from experiments on different substances, by Emerson and other writers, by means of which the propositions stated in the preceding part of this article may be submitted to computations.

The relative Resistances or Strengths of Wood and other Bodies.

	Proportional Resistance.
Box, yew, plum-tree, oak	11
Elm, ash	8½
Walnut, thorn	7½
Red fir, holly, elder, plane crab-tree, apple-tree	7
Beech, cherry-tree, hazel	6⅝
Alder, asp, birch, white fir, willow	6
Iron	107
Brass	50
Bone	22
Lead	6½
Fine free-stone	1

A cylindric rod of good clean fir, of an inch circumference, drawn in length, will bear at its extremity 400lb.; and a spear of fir, of two inches diameter, will bear about seven ton weight. A rod of good iron, of an inch circumference, will bear nearly three ton weight. A good hempen rope of an inch circumference, will bear 1,000lb. at its extremity. Hence Emerson concludes, that if a rod of fir, or a rope, or a rod of iron, of d inches diameter, were to lift a quarter of the extreme weight that they would support, then

The fir would bear . . $8\frac{4}{5} d^2$ hundred weight.
The rope . . . . $22\ d^2$ ditto.
The iron . . . . $6\frac{3}{4} d^2$ tons.

To these results we may add, from the experiments and investigations of Professor Robison, that a prism of white marble, an inch square and a foot long, bears about 500 lb. And that, from the various authors he has collected, the cohesive force of a square inch of gold, when cast, is about 20,000 lb; of silver, 40,000 lb.; cast-iron from 40,000 to 60,000 lb.; wrought iron from 60,000 to 90,000; soft steel, 12,000 lb.; razor steel, 15,000 lb.; oak and beech, in the direction of their fibres, from 8,000 to 17,000 lb.; willow, 12,000; cedar, 5,000 lb.; fir, 8,000 lb.; ivory, 16,000 lb.; bone, 5,000 lb; rope, 20,000 lb. And a cylinder, an inch in diameter, loaded to one-fourth, will carry, if of iron, 135 cwt.; of rope, 22 cwt.; oak, 14 cwt.; and fir, 9 cwt.

The resistance of some metals is doubled, or tripled, by the operation of forging and wire-drawing; and the cohesive, as well as the repulsive force of wood, is often increased by moderate compression. Oak will *suspend* much more than fir; but fir will *support* twice as much as oak; which difference is supposed to arise from the curvature of the fibres of oak; yet oak has been known to support, with safety, more than two tons for every square inch. Stone will support from 250 to 850,000 pounds, on a foot square; brick, 300 lb.; and sometimes they are practically made to support one-sixth as much. Stone is said to be capable of bearing a much greater weight in that position in which it is found in the quarry, than in any other position.

RESOLUTION OF FORCES, the division of a force into two separate forces, acting in different directions, which shall have an equivalent effect to the original force. *See* FORCES.

RESPOND, a half pillar or pier attached to or abutting against a wall.

RESSAULT, (French) the effect of a body, which either projects, or falls back, *i. e.* stands either more out or in than another; so as to be out of the line, or range, with it.

The term is little used in English; though the want of a word of equal import pleads for its naturalization.

RETAINING WALL, a wall erected for the purpose of retaining earth, or other loose or shifting material, and preventing slips and similar accidents; such are the wing-walls of bridges, &c.

RETICULATED, a term applied to any plane surface, formed into squares by chequered lines. The use of reticulation is to make a drawing similar to a given original, in the easiest manner: for this purpose, the original is divided into squares, and the size of the drawing, required to be copied, is divided into the same number of squares; then tracing the lines through all the squares as they appear in the respective squares of the original will give the outline of the design.

RETICULATED WORK, a kind of masonry or brick-work, formed of small square stones or bricks, set lozenge-wise, and presenting the appearance of net-work on the face.

RETRENCHMENT, (from the French, *retranchment*, formed of *re*, and *trancher*, to cut) in architecture, carpentry, &c., is used not only for what is cut off from a piece when too large, in order to better proportioning it, or some other convenience, but also for the projectures taken out of streets, public ways, &c., to render them more even, and in a line.

RETRENCHMENT, in war, denotes any kind of work cast up to strengthen or defend a post against the enemy. Such are ditches, with parapets, gabions, facines, &c. for a covering, &c.

RETRENCHMENT, (in fortification) is more particularly used for a simple ritirade made on a hornwork, or bastion, when it is intended to dispute the ground inch by inch.

RETURN, in building, denotes a side, or part that falls away from the front of any straight work.

RETURN BEAD, a bead which appears on the face and edge of a piece of stuff in the same manner, forming a double quirk.

REVELS (pronounced *reveals*, from the Latin, *revello*, to retract or draw back) the vertical retreating surface of an aperture, or, the two vertical sides of the aperture, between the front of the wall and the windows or door-frame, most commonly posited at right angles to the upright surface.

The revels of windows, in common brick buildings, are generally $4\frac{1}{2}$ inches in breadth, receding from the face of the wall to the sash-frame; but, in massy stone buildings, they ought to be of greater thickness, according to the magnitude or dimensions of the aperture.

REVOLUTION, (from the Latin, *revolvo*) in geometry, the motion of any figure quite round a fixed line as an axis. Thus, a right-angled triangle, revolving round one of its legs as an axis, generates by that revolution, a *cone*. *See* CONE.

RHOMB. *See* RHOMBUS.

RHOMBOIDES, (Greek) a quadrilateral figure, whose opposite sides and angles are equal, but which is neither equilateral nor equiangular; or, it is an oblique-angled parallelogram.

RHOMBUS, or RHOMB, (from the Greek, ῥεμβω, *to encompass*, or *turn round*) an equilateral rhomboid; or a quadrilateral figure, whose sides are equal and parallel, but the angles unequal; two of the opposite ones being obtuse, and the other two acute.

RIB, (Saxon) an arch-formed piece of timber. Also the projecting moulding on the soffit of a vaulted roof, which divides the vault into severies or compartments; and serves to conduct the thrust of the vault to the pier erected for its support.

RIBBING, the whole of the timber-work for sustaining a vaulted or coved ceiling.

RIBET, a term used in Scotland for the recess made in the sides of apertures of stone or brick work, to admit of door or window-frames.

RIBS, arch-formed timbers for sustaining the plaster-work of a vault, or coved ceiling.

RIDGE, (from the Saxon, *hrigg*) the highest part of the roof, or covering of a house. The term is particularly used for a piece of wood in which the rafters meet.

RIDGE-TILE. *See* TILE.

RIGGEN, a provincial term for the ridge of a roof.

RIGHT ANGLE, an angle which subtends a quadrant or quarter of a circle, containing 90 out of the 360 degrees into which the circumference is divided.

ROADS, as regards the history of road-making, the first steps towards the construction of permanent and durable roadways are said to have been taken by the Greeks, and also that this people expended considerable care and labour in their construction. But more noted than the Greeks in this matter, were the Carthaginians, from whom the Romans are by some reported to have derived their success in similar works. The first Roman road was constructed during the censorship of Appius Claudius, about 309, B.C.; it was first carried to Capua, and afterwards extended to Brundusium, a length of 350 miles; its breadth is about 14 feet, and its thickness, 3 feet; the paving being laid upon a foundation of rough stones cemented with mortar, and that again upon a bed of gravel. This road is still entire; it was called the Via Appia in honour of the consul, as was the second, the Via Aurelia, and the third the Via Flaminia. In the time of Julius Cæsar, the number of roads had greatly increased, so that all the principal cities of Italy were connected with Rome by paved roads, and from that period such means of communication began to be extended into the provinces, their principal object being to provide a ready mode of access into distant provinces, for the passage of troops and similar purposes.

Augustus, when emperor, paid more attention to the great roads than he had done during his consulate. He conducted roads into the Alps; his plan was to continue them to the eastern and western extremities of Europe. He gave orders for making an infinite number in Spain; he enlarged and extended the Via Medina to Gades. At the same time, and through the same mountains, there were opened two roads to Lyons, one of them traversed the Tarentaise, and the other was made to the Alphenin.

Agrippa seconded Augustus ably in this part of his government. It was at Lyons he began the extension of roads throughout all Gaul. There are four of them particularly remarkable for their length, and the difficulty of the country through which they passed. One traversed the mountains of Auvergne, and penetrated to the bottom of Aquetaine. Another was extended to the Rhine at the mouth of the Meuse, and followed the course of the river to the German Ocean; the third crossed Burgundy, Champagne, and Picardy, and ended at Boulogne-sur-mer; the fourth extended along the Rhone, entered the bottom of Languedoe, and terminated at Marseilles. From these principal roads, there were an infinite number of branch roads, namely, to Treves, Strasburg, Belgrade, &c. There were also great roads from the eastern provinces of Europe to Constantinople, and into Croatia, Hungary, Macedonia, and to the north of the Danube at Torres.

The seas were able to cut across the roads undertaken by the Romans, but not to stop them. Witness Sicily, Corsica, Sardinia, England, Asia, and Africa, the roads of which countries communicated with the roads of Europe by the nearest ports. What labours! when we embrace in one point of view, the extent and the difficulties which opposed themselves—the forests opened, the mountains cut through, the hills lowered, the valleys filled up, the marshes drained, and the bridges that were built.

"The Roman roads," says Mr. Tredgold, "ran nearly in direct lines; natural obstructions were removed or overcome by the effort of labour or art, whether they consisted of marshes, lakes, rivers, or mountains. In flat districts, the middle part of the road was raised into a terrace.

"In mountainous districts, the roads were alternately cut through mountains, and raised above the valleys, so as to preserve either a level line or a uniform inclination. They founded the road on piles, where the ground was not solid; and raised it by strong side-walls, or by arches and piers, where it was necessary to gain elevation. The paved part of the great military road was sixteen Roman feet wide, with two side-ways, each eight feet wide, separated from the middle way by two raised paths of two feet each."

Even to such a remote province as Britain were such means of communication opened, good evidence of which still exists in the present day. In this country, a grand trunk, as it may be called, passed from the south to the north, and another to the west, with branches in almost every direction that general convenience and expedition could require. What is called the Watling street, led from Richborough, in Kent, the ancient Ruterpiæ, north-east through London to Chester. The Ermine street passed from London to Lincoln, thence to Carlisle and into Scotland.

The fossway is supposed to have led from Bath and the western regions north-east, till it joined the Ermine street. The last celebrated road was Ikeneld or Ikneld, supposed to have extended from near Norwich southward into Dorsetshire.

If we carefully trace the distance from the wall of Antoninus in (Britain) to Rome, and from thence to Jerusalem, it will be found that the great chain of communication from the north-west to the south-east part of the empire, was drawn out to a length of 4,080 Roman miles, or 3,740 English miles; the public roads were accurately divided by milestones and ran in a direct line from one city to another, with very little respect for the obstacles either of nature or private property; mountains were passed, and bold arches thrown over the broadest and most rapid streams. The middle part of the road was raised into a terrace, which commanded the adjacent country, and consisted of several strata of sand, gravel, and cement, and was paved with large stones, which in some places near the capital were of granite. It is estimated that the Romans constructed, in all, not less than 14,000 miles of paved roadway.

Since the Romans, no country seems to have surpassed or even equalled them in the hardness and durability of their roads; in England we may presume that this branch of engineering has been carried on with greater succes of late years than in any other country of modern times; we say of late years, for it was not until the latter half of the eighteenth century, that any considerable improvement was effected; the roads previous to that period having been of a most rude and unsatisfactory description. The greatest share of praise for improvement in the construction of roads, is due to Mr. Telford, the eminent engineer, who reduced the practice into a system conformable to the laws and requirements of science.

Practice of road-making.—The first object to be attended to in the formation of a road, is the preparing of a good solid foundation; for on this, more than on anything else, depends the durability and convenience of the road. This premiss has been denied by some persons, and the contrary assertion put forward by Mr. McAdam, a name which has become intimately associated with road-making, from the circumstance of that gentleman having introduced into England that system which has been named after him, and is known under the title, "Macadamized." This gentleman we believe was the first publicly to maintain the opinion, that an elastic road was equally good as one with a firm unyielding surface, and not only so, but even preferable. In a publication on this subject, he says—

"That a foundation or bottoming of large stones is unnecessary and injurious on any kind of subsoil.

"That the maximum strength, or depth of metal, requisite for any road, is only ten inches.

"That the duration only, and not the condition of a road, depends upon the quality and nature of the material used.

"That freestone will make as good a road as any other kind of stone.

"That it is no matter whether the substratum be soft or hard."

In contradiction to such assertions as these, we have the universal experience of practical men, and the testimony of both practical and scientific men, such as Telford and Lardner.

To comprehend thoroughly the great importance of making a regular and strong foundation, it should be borne in mind that roads are structures that have to sustain great weights, and violent percussion; the same rules, therefore, ought to be followed with them as are followed with regard to other structures. A road will never be of long duration, nor at any time in a satisfactory condition, which has not a firm and substantial foundation. But not only is its durability affected under such circumstances, it has disadvantages in other points equally important and essential to a good roadway. Besides the durability of a structure, we have to consider its economy, and its adaptation to the special purpose for which it is intended. Now, the object to be attained by a good road is the conveyance or transport of goods in the readiest and most economical manner, so that the constantly-occurring expense of transit ought to be taken into even more careful consideration than the original outlay upon the road itself; we want goods to be conveyed at as small an expense as possible. Now, the largest item in the expenditure for the conveyance of goods consists in the expense of the power employed; and as much as we can reduce the amount of this power, by so much do we reduce the expense likewise. According to all experience, as well as science, the power required to draw a carriage, or any body, over a yielding or elastic surface, is much greater than that required to draw the same over a hard unyielding surface; and the reason is plain—there is not so much friction in the latter case as in the former, and the surface in contact with the wheels of the conveyance is not so great as on a yielding roadway. "The resistance," says Professor Leslie, "which friction occasions, partakes of the nature of the resistance of fluids; it consists of the consumption of the moving-force, or of the horse's labour, occasioned by the soft surface of the road, and the continually depressing of the spongy and elastic substrata of the road. In fact, on a yielding roadway, the carriage or waggon has to be drawn over a series of hillocks, for, as the load passes over it depresses that portion of the road immediately beneath it, and has before it, to be passed over in its turn, a portion which has not yet undergone this process: the comparison between the tractive power employed on roads of different elasticities, has been well illustrated—thus:—An ivory ball set in motion with a certain velocity over a turkey carpet, will suffer a visible relaxation of its course; but with the same impelling force it will advance farther, if rolled over a superfine cloth; still farther over smooth oaken planks; and it will scarcely seem to abate its velocity over a sheet of fine ice."

The fact of greater tractive power being required in elastic than in hard roads has been proved beyond a doubt, by the experiments made by Sir John Macneil, by his machine invented for this purpose.

These experiments uniformly show, that the force of traction is in every case in an exact proportion to the strength and hardness of a road. The following are the results on a well-made pavement:—The power required to draw a waggon is 34 lbs.; on a road made with 6 inches of broken stones of great hardness, laid on a foundation of large stones set in the form of a pavement, the power required is 46 lbs.; on a road made with a thick coating of broken stone, laid on earth, the power required is 65 lbs.; and on a road made with a thick coating of gravel, the power required is 147 lbs.: thus it appears that the results of actual experiments fully correspond with those deduced from the laws of science.

Sir John, in his examination before a Commitee of the House of Commons in 1836, says, "The great advantage of the roads appearing by the machine is certainly in proportion to their solidity and their strength, and their want of yielding. If it could be a perfectly solid mass of stone or metal, the least resistance would be presented; that is shown both on stone tramways and on metal tramways, and metal rails."

This foundation should be composed either of a rough paving of large stones, or of a sufficient bed of concrete, the former being the practice of Mr. Telford, and the latter of many engineers of the present day; the selection of either of these materials will depend upon their economy in various places; whichever is most accessible, may be safely used; but whatever material be used, it is necessary that the substratum should be of uniform strength and solidity over the entire surface, otherwise, after the pavement has been laid, the weaker parts will give way, while the stronger maintain their position, and so the surface of the road becomes broken and uneven, rugged, and full of hollows; for this reason we prefer the use of concrete, which offers greater security against this defect than foundations made of large stones or rubble, though in many roads even concrete is not sufficient entirely to prevent it. We are inclined to think that the value of concrete for this purpose has not been fairly tested, for the work, especially in London roads, is usually got through in so hurried a manner as not to allow a sufficient time for setting: we imagine, that with a somewhat thicker bed of concrete, the materials of which have been properly mixed, and allowed a sufficient time to set before the metalling is put on, we should be enabled to construct roads sufficiently firm to bear the extraordinary wear and tear of London traffic, and that, too, at a less cost than is expended on the present roadways. We are aware that there are many disadvantages to contend with in London roads; that they are continually being pulled up, and thereby destroyed, for works connected with water, gas, or sewers, and that this acts as a great discouragement to the construction of good roads. That any necessity of this nature should be allowed to exist is much to be lamented, but we feel confident that such practices might be restricted to a very considerable extent, without doing any injury to the public convenience. The concrete foundation should be slightly curved, falling from the centre towards both sides, which form will assist to drain it, and also to give the proper form to the surface of the roadway. It is necessary that this lower surface should be properly drained, otherwise the water will lie there, and destroy the road. If the concrete were laid 18 inches thick, we should not deem the extra expense ill laid out for a good road. With respect to the other kind of foundations, Mr. Parnell says—"In streets where the traffic is not very great, the foundation should be made in the following manner:—A bed should be formed, with a convexity of 2 inches to 10 feet, so as to admit of 12 inches of broken stone being laid upon it: these should be put on in layers of four inches at a time. After the first layer is put on, the street should be kept open for carriages to pass over it. When the first layer has become firm and consolidated, then another layer of 4 inches should be laid on, and worked in as before, care being taken to rake the ruts and tracks of the wheels of carriages, so that the surface may become smooth and consolidated. The same process should be repeated with the third layer of stones, by which means a solid and firm foundation will be established, of 12 inches in thickness, for the dressed paving-stones to lie upon." Such directions deserve greater attention than we fear they usually receive; in all cases, let your foundation be secure before you lay your roadway.

Various kinds of materials are used for the purpose of forming the upper coat of the road, and amongst those most frequently employed may be mentioned broken Guernsey granite, flints, gravel, and cubes of granite of various sizes. Of these the broken granite and granite cubes are most useful, the one for general purposes, the other for roads which are subject to great wear and tear, such as those in the principal thoroughfares of London, for although both descriptions of material are used for this purpose, yet we are inclined to think that the broken stone is scarcely durable enough for such work: and there is this further objection to it, that it is constantly requiring repairs, which must, to a certain extent, inconvenience public business. Besides this, as usually managed, they occasion a great deal of dust and dirt, while the draught of vehicles upon them is very heavy, and their maintenance expensive. It would be scarcely fair, however, to attribute the faults of management to the quality of the material, and we believe that many of the above objections may be removed by skilful management.

In the first place, as regards durability, the objection would be removed to a considerable extent by employing a good foundation, and laying the metal carefully upon it, providing for the proper drainage of surface and substratum as mentioned above, for the lodgment of water either above or below such roads is very injurious, and tends, perhaps more than anything else, to their destruction. Having obtained a good foundation, the next point is to cover it with a hard compact crust impervious to water, and laid to a proper cross section, so that it may be speedily drained and no water be allowed to remain on the surface, which, besides its inconvenience to passengers, is very destructive to the surface of the road. A practice has come into vogue of late, of covering the road when made, with a binding composed of the grit collected off the road in wet weather, and by the operation of water-sweeping. The binding is laid on regularly and watered until the new material is firmly set, which it does very quickly, and when the binding is of good quality and properly laid on, it assists its formation very considerably, and altogether improves the condition of the road and economizes the material, for it saves the wear and attrition of the new stone. Some road-makers object to this binding on the ground, that it destroys or rots the road, and that when the road is set it has to be carted away again; but this is only the case where improper binding is used, such as is swept from streets which are not properly cleansed, and therefore consists principally of mud, and not of grit, or rather of grit so mixed with dirt as to be for the most part useless for binding. This method of binding a road removes in part the objection which is made against the resistance occasioned by the loose stones of a newly-laid broken road.

We alluded just now to the cleansing of roads, and it is a matter which deserves considerable attention, and is applicable to every variety of road; a dirty road is a constant source, only not of inconvenience, but of expense, for scarcely any thing destroys a road more readily than dirt. And not only is this the case, but the tractive power also required on a dirty road is twice as great as that required on a clean one: when we come to add to this the damage done to property by the mud in wet weather, and the dust in dry, we shall be able to form some notion of the waste occasioned by dirty roads.

The best method of cleansing roads is by water-sweeping: a method of watering and sweeping combined, the roads being first watered and then swept, by which means the road is thoroughly washed from its impurities. The watering is usually carried on by means of a water-cart, but a more effectual means, as far as the cleansing of the road is concerned, is afforded by the hose and jet. The sweeping is mostly effected by hand, and in some places this method is carried on systematically, which is an improvement upon the old practice; but of all methods offered to the public, that of Whitworth's sweeping-machine, is the most effective, and in the end, we believe, the most economical, By this machine an endless chain of brooms is made to revolve by the motion of the wheels, and to sweep the dirt immediately from the roads up an inclined plane into the cart, without fear of splashing, or any other annoyance to the public, which is a vast improvement on the old practice of stacking the mud or dust up in heaps, and letting it remain in that state until the carts come round, during which period a considerable portion of it had probably been spattered about by the traffic, or blown in all directions by the wind, and even then passengers must expect to be bespattered by the negligent manner in which the refuse was carted away. This machine, too, presents other advantages, in the width of the brooms, and the uniform pressure exerted throughout, a pressure which can also be regulated as occasion demands. Water-sweeping by this machine is, we venture to assert, one of the best, if not the best method of cleansing roads, and our assertion is supported by facts. It has been objected that water-sweeping removes the material of the road, but the contrary has been proved to be the case. Mr. Smith, the eminent surveyor of Birmingham, says, "I have found that the use of sweeping-machines, with the proper employment of water, has reduced the amount of material required for the repair of roads in Birmingham one-third, viz., from 20,000 to 13,000 cubic yards; the first named amount is the average of seven years preceding the introduction of the machines, the latter of the three years subsequent." On the 22nd of March, 1848, some experiments were made upon the subject in the Quadrant, Regent-street, the road being then covered with a thick coating of dust, which was causing great annoyance as well as injury to the road, but could not be removed by scraping without removing also much of the new stone to which it adhered. It was determined to sweep half of it dry, and half after proper watering. This was done, and the sweepings removed were washed, to separate the refuse from the stony matter mixed with it; one third part of that which was taken dry consisted of coarse grit which would have been useful on the road; one-twelfth part only of that which was removed in the form of slop was stony matter, and that was so completely pulverized as to be of scarcely any use—it had done its work. After the two portions of the road had been cleansed, the difference between them was very striking. That which was swept dry was still covered with adhesive matter, which, together with the stones to which it adhered, was lifted by the wheels, the whole road being rough and uneven. The portion which had been swept with water was perfectly even and smooth. On the 24th both portions were swept, but only one quarter as much dirt was taken from that which had been water-swept as from the other. On the 26th it rained, and three times as much slop was taken off the part of the road which had not been water-swept on the 22nd. The preservative effect of water-sweeping by machine was most striking, by the decidedly better condition of that portion of the road cleansed in this effective manner.

The granite-cube roads are preferable to macadamized in point of durability, and therefore are more eligible in this respect for places where there is great traffic, but nevertheless there are objections which partly outweigh these advantages, one of which, of considerable importance, arises from the circumstance of the wear and tear of vehicles being very great on such roads on account of the frequency and violence of the concussions to which they are subject; and although the draught upon macadamized roads is, generally speaking, heavier than upon pavement, yet this advantage is probably more than neutralized by the concussions alluded to, which form a great impediment and injury to vehicles travelling quickly.

Another objection is, that a horse has not nearly so secure a footing upon paving as upon a broken-granite road.

A system of tram-roads has been adopted for special traffic on some roads with great advantage, as in the Commercial and East India Dock roads, where two parallel lines or tramways of masonry are laid for the wheels to run upon, the space between being paved with the ordinary paving. These trams were made of large blocks of granite 5 or 6 feet in length, 16 inches wide, and 12 inches deep, and have been found to stand the heavy traffic much better than ordinary pavement would have done.

Roads paved with blocks of wood are of comparatively recent invention, and offer many advantages over common roads, in the evenness of the surface, but more especially by the prevention of noise, which is a great inconvenience on paved roads. It is to be regretted, however, that with such advantages it has defects, which, until removed, will put an effectual bar to its general employment; we allude to its want of durability, and consequent expense, but more especially to its slipperiness in wet and damp weather. The former objection we feel confident may be removed by employing greater care in the construction and drainage of the substructure; and the latter has been remedied, in some degree, by spreading broken granite on the surface.

In concluding this article, we beg to recapitulate the principal points to be attended to in the construction and management of roads:—viz.; a good solid foundation, proper drainage, and efficient cleansing. We subjoin a table of the comparative costs of various kinds of Roads with some cursory observations on their peculiarities.

A Table showing the comparative First Cost, Annual Expense, and Durability, of different descriptions of Carriage-Roads, as for example, in a road 42 feet wide, with ordinary substratum.

Material used.	First Cost for square yard.	Cost for square yrd. per annum for repairs.	Value of materials at end of			Observations on durability and condition the road would be in at the end of 20 years.	Cleanliness.
			10 yrs.	20 yrs.	30 yrs.		
Guernsey Granite, or Macadamized road.[a]	4s. 6d.	1s. 6d.	3d.	3d.	3d.	The price in each case is taken for London wear; as in the principal thoroughfares at the West End, the road being always renewed at the expense stated, the value of materials would be the same at each period.	The mud in wet and the dust in dry weather, are the chief objections to these roads; they are very expensive to keep clean.
Grueby & Whinstone.	about the same	see 2d column					Grueby stone turns to a light mud in bad weather, and roads made with it, cost more to keep clean than granite roads.
Ightam stone, a small quantity of this stone is sometimes sent into the London market.	3s. 6d.	2s.	nil.	nil.	nil.	This material will not bear the traffic granite will; it has been used in streets of secondary traffic, but grinds to powder in dry, and goes off to light mud in wet weather.—The same remarks as above as to value at 20 years.	Same remarks as made upon Grueby stone, apply to this in reference to cleansing the roads.
Flints............	3s.	2s. 3d.	nil.	nil.	nil.	The same observations which have been made in reference to Ightam stone, apply in a still stronger degree to flint roads, as they are much inferior in durability, though well suited to some localities.	Very difficult to keep clean.
Aberdeen Granite, 3-inch cubes, concrete foundations.[b]	17s. 6d.	For the first 3 yrs. nil, afterwards 3d. per annum.	7s.	4s.	2s. 6d.	The price named as value of a certain number of years' wear, is what the materials would sell for if removed. They would be worth more, if removed to other streets.	This is the best and cleanest of pavements, as it offers the greatest facilities for washing.
CUBES. 9 inch deep by 5 wide[c]	14s.	do.	6s. 6d.	4s.	3s.	Do.	Good pavement, but not so clean.
WOOD. Metropolitan Wood-paving Comp.; Concrete foundation included.[d]	12s. 6d.	1s. 6d.	The value of material when relaid at the end of every eight years, 1s. per square yard.			The price named as for annual repairs, is sufficient to lay with new when required, and it is presumed this would be necessary at the end of every eight years.	Wood offers great facilities for cleansing; it is swept easier, and at less cost, and the sweepings are valuable for manure, while the sweepings of broken-stone roads are not. It can be easily washed also, but should not be kept wet, if possible to avoid.
There are other forms of Wood Pavement, but none equal to the above.							

Remarks.

[a] The Guernsey granite is the only material which has been found to stand the extraordinary wear and tear of London traffic, all other stone has failed, or has not been procurable at a reasonable price.

[b] The annual cost of repairs depends not only on the traffic over the road, but on its good or bad formation originally. Some part of the New Road, for instance, is made on so bad a bottom, that in wet weather, the substratum works up, and destroys the new material. An eminent contractor, some time since, sent in an estimate, to take out the substratum to a certain depth, fill in with good hard stuff, and make them a good road over it. This done, he would have undertaken to keep the road in repair at 1s. per yard per annum.

A road made with the centre of granite, and sides of flints, has been found to answer well in the neighbourhood of London; also flints in the centre, and the sides paved with granite stones, (cubes.)

[c] This is not equal to the 3-inch cubes described above.

[d] The first cost of this description of road, has alone prevented its becoming more general; but there seems little reason to doubt, that it will be found almost the only pavement suited to London wear.

The contract price for keeping in repair Regent-street, is 6d. per square yard per annum for 7, 14, or 21 years.

This piece of wood has been strewed with clear Guernsey Granite, broken in small pieces, which has been found in a great degree to prevent the slipperiness so much complained of. The expense of the experiment, borne by the Commissioners, was £125, or about 2d. per yard.

ROD, a linear measure of $16\frac{1}{2}$ feet. Also a superficial measure of $272\frac{1}{4}$ square feet, by which brickwork is usually calculated; the rod contains $272\frac{1}{4}$ square feet of brickwork, a brick and half thick, or 306 cubic feet.

ROE-STONE, or OOLITE, a variety of limestone, composed of small round globules, resembling the roes of fishes, imbedded in a calcareous cement. These globules are composed of concentric lamellæ, and are evidently the result of crystallization. They vary in size from a grain of mustard-seed to that of a pea: when they are as large as the latter, it is called *pea-stone.* Roe-stone is one of the secondary limestones, which may be considered as belonging to the chalk-formation. It lies under chalk in various parts of England, being separated from it by beds of sand and clay. It is found also in many parts of Europe; but, according to Humboldt, is not met with in South America. Some of the strata of this stone are extensively used for purposes of architecture: the most distinguished are the Ketten stone, in Northamptonshire; the Bath firestone, in Somersetshire; and Portland stone, in the island of Portland. Portland stone is of a yellowish-white colour: the more compact varieties, when closely inspected, show a tendency to crystalline arrangement; it is composed of carbonate of lime, with a small admixture of silex and alumina.

ROLL-MOULDING, a moulding in Gothic architecture of a circular section, though frequently interrupted or broken by a fillet.

ROLLS or ROLLERS, among carpenters, masons, &c., plain cylinders of wood, seven or eight inches in diameter, and three or four feet long; used for the removing of beams, huge stones, and similar burdens, which are cumbersome, but not exceedingly heavy. These rollers are placed, successively, under the fore part of the masses to be removed; which, at the same time, are pushed forward by levers, &c., applied behind.

When blocks of marble, or other excessively heavy loads, are to be removed, they use what they call *endless rolls.* These, to give them the greater force, and prevent their bursting, are made of wood joined together by cross-quarters; they are about double the length and thickness of the common roller, and, besides, are girt with several large iron hoops at each end. At a foot distance from the ends are four mortices, or rather only two, but pierced through and through, into which are put the ends of long levers, which the workmen draw by ropes fastened to the ends, still changing the mortise, as the roll has made a quarter of a turn.

ROMAN ARCHITECTURE. The early Romans can scarcely be said to have possessed any style of architecture of their own, but borrowed their ideas of building first from the Etruscans, and, at a later period, from the Greeks. In the time of Romulus, their buildings would seem to have been of the most rude description, their dwelling-houses being composed chiefly of straw, and thence termed culmina; and at a somewhat later period, even their temples were only small square erections scarcely large enough to contain the statue of the deity.

Ancus Martius was the first king who commenced works of a larger class requiring skill in their construction, and his first attempt was the construction of the city and port of Ostia, at the mouth of the Tiber. Tarquin the Elder brought with him the skill and enterprise of the Etruscans, and set about improving the city with energy and perseverance; his first work was to erect the grand circus; he also constructed the walls of the city with large hewn stones, and commenced the great cloaca, or public sewer, as well as the temple of Jupiter Capitolinus, which was continued by Servius Tullius, who also enlarged the city. Tarquinius Superbus yielded to none of his predecessors in the decoration and improvement of the city. During his reign the circus was completed, as was also the cloaca maxima, which was considered one of the wonders of the world, and still remains as a monument of the enterprising spirit of the Tarquins. It was constructed of wrought stone, and was of such dimensions, that a wagon loaded with hay could pass through it; and was carried through rocks and under hills, and many were the engineering difficulties overcome in its construction. The temple of Jupiter Capitolinus was not completed till after the expulsion of the kings, but was considerably advanced by this king.

After this period, some of the principal works were—the completion of the Capitol, commenced by Tarquinius, the formation of the Campus Martius, and the outlet for the relief of the lake Alba. In the year 389, B. C., the city was burned by Brennus, which afforded an opportunity for rebuilding it in a more convenient and sumptuous manner; but unfortunately, the opportunity was not taken advantage of, and the houses were erected after a more irregular plan than they had previously been; for whereas, in the old city, the public sewers ran under the roadway; in its re-edification, the streets were laid out without any reference to this arrangement—a want of consideration, the effects of which were greatly felt at a subsequent period.

During the censorship of Appius Claudius, 309 B.C., the first paved road was laid by the Romans; it extended from Rome to Capua, and afterwards to Brundusium, a length of 350 miles, and is to be seen at the present day. It was 14 feet in width, and about 3 feet deep, being composed of three thicknesses, the lower one consisting of rough stones grouted together, the second of gravel, and the third of stones of various dimensions, but so accurately pointed, as to have the appearance of a single stone. The credit of constructing the first aqueduct also belongs to this censor, by which a supply of water was conveyed from Præneste to Rome, by means of a deep subterraneous channel upwards of 11 miles in length. During the two first Punic wars, many temples were erected, but they do not appear to have been of great magnificence. Cato adorned the city with a basilica, which he named Portia, and Sempronius erected a second, which was called after his own name.

The censors Fulvius Flaccus and A. Postumius Albinus, contributed much to the embellishment of the city; they paved it, adorned it with porticos, enlarged the circus, and made public ways and bridges on the outside. At this period, the more wealthy Romans began to live out of the city, and build country-residences, which were, in many cases, of considerable extent and luxurious decoration. To such an extent was the magnificence of these villas carried at last, that we find Cicero in the habit of employing no less than two architects.

All this time but little taste had been exhibited in the decoration of their buildings, which were mostly of brick, or, at best, of stone obtained in the neighbourhood; but as their conquests extended, and they became intimate with the more costly buildings of their enemies, they began to entertain more expanded ideas of magnificence in art. Metellus Macedonicus, the contemporary of Mummius, the victor of Corinth, was the first to build at Rome a temple of marble; but from this time most of the larger edifices were constructed of this material. At this period also, Grecian art and architects were introduced, and many works of art brought thence to decorate Rome; Sulla carried away the columns, &c., from the temple of Jupiter Olympius at Athens, to embellish that of Jupiter Capitolinus at Rome.

The first permanent theatre was erected by Pompey; previous to his time, such erections were not allowed to remain

Ruins of Ancient Rome

after the shows, and therefore only temporary buildings were erected for the purpose. Of these, however, some were of great size and magnificence; M. Æmilius Scaurus, when ædile, erected one capable of containing 80,000 persons, which is reported to have been sumptuously decorated. Another theatre was erected by Curio, one of Cæsar's partisans, which exhibited great mechanical skill. Two large theatres of timber were constructed back to back, and on one side so connected with hinges and machinery for the purpose, that when the theatrical exhibition had closed, they were wheeled or slung round, so as to form an amphitheatre, wherein, in the afternoon, shows of gladiators were exhibited. Pompey's theatre was built of stone, and was made capable of accommodating 40,000 persons; it was surrounded by a portico for shelter in case of unseasonable weather, and had attached to it a curia provided with a basilica, or hall of justice, as also a temple dedicated to Venus.

Under the auspices of Julius Cæsar, many new and magnificent buildings were erected. On his return from Utica, after his threefold victory, he brought into the treasury no less than 65,000 talents, and 2,822 crowns of gold, which afforded him every facility for carrying out his magnificent projects, amongst which may be mentioned the extension of the circus, and formation of a lake for the exhibition of Egyptian and Tyrian galleys, a new forum, two temples to Venus, one of which was on an exceedingly grand scale, and a third to Clemency. Besides these, he commenced a vast theatre, the drainage of the Pontine marshes, the improvement of the navigation of the Tiber, by forming a new bed from Rome to the sea, a canal through the Isthmus of Corinth, the formation of a port at Ostia, and of a causeway across the Apennines, from the Adriatic to Rome; add to this, the re-building of Corinth and Carthage, and we shall be enabled to form a conception of the vast ideas and ready execution of this great man.

Such an introduction as this was worthy the golden age which followed in the next reign, an age which the peace purchased by the victorious arms of Cæsar had yielded to the cultivation of civil arts, and that excessive refinement which led the way to luxury and consequent ruin. In this reign most of the finest buildings were erected, and architects flocked from all quarters, and especially from Greece to assist in beautifying the city, the latter being highly esteemed and eagerly employed; in short, Greece at this time had become the standard of taste amongst the Romans, not only in the arts, but in customs and manners. Augustus had conceived the project of making Rome the most splendid city in the world; and not only set about embellishing it himself with the greatest ardour, but also incited his friends, and the principal personages of the empire to follow his example, which indeed they were not slow in following; and amongst the buildings erected by them may be mentioned, a temple of Hercules Musagetes, by Marcius Philippus; a temple of Diana, by L. Corfidius; of Saturn, by M. Plaucus; of Concord, and of Castor and Pollux, by Tiberius; the Atrium Libertatis, by Asinius Pollio; a theatre, by Cornelius Balbus; and an amphitheatre, by Statilius Taurus. His friend Agrippa was highly distinguished in this respect; he erected many magnificent buildings, aqueducts, baths, fountains, &c., but he stands pre-eminent above all his countrymen, by the erection of that monument of Roman skill and enterprise, the Pantheon. The principal edifices erected by Augustus himself were—the forum and temple of Mars Ultor; the temple of Apollo Palatine, with portico and library; the temple of Jupiter Tonans, on the Capitol; the porticos of Livia and Octavia; the basilica of Caius and Lucius; the theatre of Marcellus; and a mausoleum for himself and family. After such an enumeration, the boast of Augustus will not appear a vain one, "that he found Rome built of brick, and left it of marble."

During the reigns of the immediate successors of Augustus, architecture fell into decline, and the only building of any importance which we hear of before Nero's time, is the Aqua Claudia, a large aqueduct, which was completed by Claudius. Its length was 46 miles, and for more than 10 it was carried on arches more than 100 feet above the level of the ground. Nero's edifices were gorgeous in the extreme, but more remarkable for expensive decoration than intrinsic merit of design; his Domus Aurea is a remarkable specimen of his prodigality in such matters; it was erected by two architects, Severus and Celar, and was most lavishly embellished, so that it would be difficult to form an idea of its expense.

Under Vespasian, and his successors, architecture again flourished, to which the remains of the Coliseum abundantly testify. This building was commenced by Vespasian, and completed by his son Titus, and its erection is said to have occupied no greater space of time than two years and nine months; it covers nearly six acres of ground, and was reported capable of containing 100,000 spectators. The reign of Titus is also remarkable for the erection of the baths and triumphal arch which bear his name. Trajan is the next name worthy of record, as a liberal patron of architecture, and amongst his works may be mentioned the forum, triumphal arch, and column which has never yet been surpassed. His bridge over the Danube, which was destroyed by Hadrian, was a bold undertaking; it is reported to have consisted of 20 stone piers, 60 feet wide, and 150 in height, the arches between being not less than 170 feet in span; his architect was Apollodorus, who fell a victim to his master's jealousy, for blaming his architectural plans. Few princes erected a great number of edifices than did Hadrian, amongst which were the Maison Carreé at Nismes, his villa and mausoleum, the amphitheatres at Capua and Verona, and the bridge over the Tagus at Alcantara. Besides these, he re-built Jerusalem, which he styled Ælia Capitolina, also part of the temple of Jupiter Olympius at Athens. In this reign also an aqueduct was constructed by Herodes Atticus to supply Troas with water, and, by the same man, a stadium at Athens 600 feet long, a stadium at Delphi, a theatre at Corinth, and baths at Thermopylæ.

Under the Antonines were erected the temple of Antoninus and Faustina, the Antonine column, and that of Marcus Aurelius, besides many other temples and works in the provinces, amongst which may be enumerated the re-building of Smyrna, Laodicea, and other Asiatic cities. After this period architecture gradually declined; a little improvement may be seen in the reigns of Septimius and Alexander Severus, but taste had greatly deteriorated, and art had fallen to too low an ebb to be restored. Antoninus Pius is reported to have erected the vast edifices of Balbec and Palmyra, but the subject admits of a doubt. Dioclesian made a bold effort to restore architecture to its original position, but it was beyond his power, and although his buildings, his baths, and his palace at Spalatro were magnificent in point of extent, and a certain kind of grandeur, yet they bear evident tokens of the state into which architecture had fallen. The palace at Spalatro covered between nine and ten acres, one of the sides being 600, and the other 700 feet in length; attached to it was a portico 500 feet long, embellished with painting and sculpture. Constantine was a great builder, but he transferred the seat of empire to Byzantium, and thus Roman architecture was superseded by the new style which he introduced in his new capital. This change, however, is to be the less regretted, inasmuch as Roman art had already degenrated beyond hope of restoration, and new edifices of barbarous design had begun to be erected at the expense of those of better design already in existence.

In comparing the relative merits of Greek and Roman architecture, there can be no question but that the former by far excels in matter of taste; and this, by many writers, seems to be the only question considered. But this is not fairly the whole point at issue between them; there are other matters to be brought under consideration; and such are—variety, as well in use as in design; the capability of being adapted to different purposes of life; as well as excellency and facility of construction. Now, although the Greeks far exceed their rivals in simple grandeur, chasteness of decoration, and correctness of detail, still it must be remembered that their structures are chargeable with sameness and monotony: their plans scarcely ever varied from the oft-repeated rectangle; the only change consisting in the different arrangement of the columns, and in the applications of the few orders of architecture which they possessed; the only variation in plan which occurs, is to be found in the Erechtheum at Athens, and some smaller monuments, as the Temple of the Winds, the Choragic Monument of Lysicrates, and such like. Grecian architecture was almost entirely devoid of composition; and no attempt was made in them of grouping their several parts, so as to produce a varied, yet effective, outline.

Now, on the other hand, the Romans were not so much a sentimental as a practical people; and this fact, we think, will account in a great measure for their different appreciation of the art under consideration. During the earlier period of their history, it will be found that they constructed only works of public utility and convenience, and whose only claim to beauty consisted in their magnitude, their grand conception, the mechanical skill employed in their construction, and their perfect adaptation to the purposes for which they were intended. The effect produced by them is rather surprise and admiration than pleasure; they awe by their grandeur, rather than satisfy by their display of taste. Such works would not be classed in the present day under the term architecture at all, but under that of engineering—two terms which are perfectly distinct in this application, although both applied to works of construction, to buildings, or artificial erections, the one, however, applies more especially to the science, the other to the art, of building; not that science is absent in either case, but that art—that is, fine art—in the one case stands pre-eminent, as scientific skill does in the other. Under the term engineering we should include the roads, bridges, aqueducts, and sewers, for which the early Romans are so noted, and whose mode of construction was probably learned from the Etruscans, who seem to have been a people of similar character, though of improved civilization, to the Romans. This practical character to which we allude, the Romans never entirely lost, even after they had become acquainted with the voluptuousness of Greece, and during the luxury of the court of Augustus and the succeeding emperors; for although at this period they began to cultivate architecture simply as one of the fine arts, still not even then did they lose sight of utility in their buildings.

With the Greeks, religion was almost the sole purpose for which architecture seemed to exist; with few exceptions, we have no other examples but temples: on the other hand, the temples of the Romans were neither so extensive nor so numerous as their works of public utility or convenience; and this also arises from their national peculiarities; for they were neither so religious, nor so philosophical and contemplative, as the Greeks. Amongst Roman remains, besides the engineering works which we have above alluded to, we have fora, baths, palaces, circi, theatres, amphitheatres, libraries, halls of justice, triumphal arches, commemorative columns, mausolea, and such like. The requirements which were necessary for such buildings as these, led, no doubt, to the practice of composition and grouping, for it is very certain that one uniform plan of building would not have been suitable for such a variety of purposes; but this was not the only cause of variety in their buildings, although, perhaps, the principal one. Another may be observed in the employment of the arch, which allowed much greater latitude of construction than the entablature of the Greeks; with the latter the intercolumniations were fixed to a certain gauge, or at least limited within a determinate range; whereas, with the former, every facility was afforded for increasing or diminishing the space between the piers to almost an unlimited degree. It is not improbable, too, that the semicircular form of the arch, which was in such constant use, assisted in the development and frequent employment of circular plans, or of plans in which circular and curved lines were introduced; for it is not unlikely that the existence of a form or figure in the elevation should suggest its application to the plan likewise. This employment of the circle in the plans of their buildings led inevitably to that which was quite a new feature in architectural design, the dome—a feature, too, which gave a totally distinct character to the buildings in which it was employed, and introduced an important element of variety into architectural design. Of this arrangement the Pantheon is the most remarkable example; and it requires none other, to attest to the importance of the change then introduced. The effect of the interior is strikingly different from anything which had before appeared; a vast area, such as that of the Pantheon, covered over by a single hemispherical dome, must, at the time of its erection, have produced a most wonderful and novel effect. Nor is the exterior devoid of novelty or character—a fact which is especially observable in the rectangular portico—projecting from a larger circular building. Such a combination forms a striking contrast to the uniformity of Grecian edifices. In the instance of the Pantheon, the exterior is destitute of columns, except in the portico. But there are many buildings in which the circular plan was carried out with an external peristyle: such, for instance, is the temples of the Sibyl; or, as it is otherwise named, that of Vesta at Tivoli. Buildings of this class were roofed with hemispherical domes, or with lesser segments of a sphere; but these were not visible on the exterior, being concealed by the projecting colonnade. Even in the Pantheon, where the dome is hemispherical, and of so great diameter, it does not form a conspicuous object on the outside, for its springing line is situated at about the level of the lower cornice; and its external height is still further reduced, by the base of the outer portion of the dome being formed into several courses of steps. Had the entire height of the dome been visible from the exterior, it would have borne by far too great a proportion to its base. In the time of Constantine, the circular plan was employed with an internal colonnade, as in the church of San Stephano Rotundo, and that of Sta Costanga; in both which cases, the circular portion within the colonnade is of greater elevation than that portion embraced between the colonnade and external walls, and is covered with a dome; but in Sta Costanga there is a further peculiarity, for the columns are not only coupled, but are arranged in an unusual manner, in pairs, one behind the other: the columns serve to support in arcade. Both these edifices have been claimed as heathen temples, (the one as dedicated to Faunus, and the other to Bacchus,) but seemingly without any other foundation than conjecture, and the existence of some decorations which a[illegible] applicable to the Christian religion, as well as to the heathen mythology. A more notable example of the circular form is the Church of the Holy Sepulchre at Jerusalem, built by the empress Helena, mother of Constantine.

The circular form was also a favourite one for tombs and mausolea, amongst the more remarkable of which are those of Augustus and Hadrian. The former consisted of four cylindrical stories, the diameter of each being somewhat smaller than that below it, and the uppermost crowned by a colossal statue of the emperor. The latter is now the well-known castle of St. Angelo, and originally consisted of a cylindrical building, placed upon a square base, the height of which was about half that of the superstructure. No remains are now left of the uppermost stage of the building, which was also circular, and was surmounted with a peristyle of 34 Corinthian columns; its diameter being about one-third that of the larger cylinder. Of a similar form is the tomb of Cecilia Metella, but devoid of the upper story. A more curious example is the sepulchral monument at St. Renie, which consists of three stories, the lowest a square base, raised on gradini, and covered on each side with sculptures in relief; the next square, with an attached fluted Corinthian pillar at the angles, and an open arch on each side; and the uppermost a Corinthian rotunda, forming an open or monopteral temple, in which are two statues. The tomb of Virgil consists of a square base, surmounted by a conical structure; and a cenotaph at Constantina, in Africa, has the lower story cylindrical, surrounded by a peristyle; while the upper is a lofty cone, formed in receding courses or steps. Edifices erected on polygonal plans were not uncommon, of which the octagonal were most frequent; the latter form was commonly employed in saloons to public baths; and there is an octagonal temple in Dioclesian's palace at Spalatro. Buildings of six sides were not common; but there is one at Balbec of peculiar form, two of the sides measuring 110 feet each, and the four remaining only 88 feet. There is also a curious circular temple at Balbec, of curious design; it is placed upon an octagonal base, the sides of which are curved inwardly, presenting a concave face; and at the angles of which are placed columns bearing an entablature, which is curved in a similar manner to the base.

We have alluded to the previous examples, for the purpose of showing how infinitely varied Roman edifices were in the arrangement of the main parts, and how readily a different distribution of the same or similar parts were made to exhibit a dissimilar effect. Many examples in proof of the same might be offered, were it within our limits to do so, and these on a more extensive scale, as witness the baths, fora, &c., with their many courts, saloons, galleries, and porticos, each of which might present some different method of distribution. It will thus be seen, how, in point of practical utility, the Romans took precedence of the Greeks, and how they were enabled to erect buildings suitable for any purposes which might be required. In such matters, they undoubtedly have the pre-eminence, but in matters of pure taste, they must be content to yield priority to the Greeks; for although in many cases they have shown proof of excellency of design, of which we need no other illustration than the Corinthian order, which was fairly their own; yet at the same time, the generality of their designs do not exhibit that purity and simplicity which is the mark of true excellence. But besides this, many violations of true taste are constantly occurring even in their best works, indeed they seem to have been inherent in the system; amongst these, we may mention the inconsistent employment of the arch and entablature in the same design; and it is to be lamented, that instead of endeavouring vainly to unite the two systems, they had not struck out in a bolder course by themselves, and worked out a consistent style of building. It is true that they employed the arch very freely, and sometimes probably more so than correct taste would warrant; yet at the same time they did not take that advantage of the possession of such means of construction as they might have done in a scientific point of view; they piled arch over arch, and seemed to be pleased with their acquisition, and content to make use of it, but not to apply it with any idea of improvement. But there are still one or two other points which merit reprehension, for instance, the employment of columns merely for the purpose of decoration, as where they are half inserted in the walls, or where pilasters supply their place. Now, columns are evidently intended for support, and they should always manifest such intention; and where they are used in positions where such support is not required, their employment is certainly objectionable, and would not be admitted in accordance with strict taste: the construction of ornament merely as ornament, and especially when its employment is liable to deceive, is to be condemned. A forcible illustration of the above kind is to be observed in triumphal arches, in which, although the columns be entirely isolated, and standing in front of the wall, they serve no practical purpose, their only use being to support a projecting portion of the entablature; and if it be asked for what purpose this projection is made, the most ready reply will be to give an useless column something to do. The fact is, that they are both added for the sake of effect, probably for variety in outline and for the sake of the deep shadow which such a projection would cast: but as far as construction goes, the whole thing is a sham, and deceptions in buildings indicate a low ebb of taste and science in architecture. Another characteristic of Roman art, and one which entered very largely into the system, is the employment of order above order in the same building, which illustrates at once its virtues and faults; for while on the one hand, such an arrangement is incompatible with the requirements of the highest standards of taste, yet still at the same time it proves their aptness of invention, and versatility of design.

We have now endeavoured to show in as fair a light as possible, the comparative merit of the two styles; and while, as a question of taste, we must without doubt yield the palm to Greece, we are inclined to think with Mr. Freeman, that architecture would have flourished more successfully at Rome, had she remained unacquainted with that of her rival.

Descriptions of some of the principal Roman buildings will be found in the body of this work; we may refer especially to the articles under the following heads:—PANTHEON, AMPHITHEATRE, BALBEC, PALMYRA, &c. The adaptation of the orders will be found noticed under CORINTHIAN, DORIC, IONIC, ROMAN, and TUSCAN ORDERS.

ROMAN ORDER, an ordinance of architecture, invented by the Romans from the Ionic and Corinthian orders; and hence, it has also obtained the name of the COMPOSITE ORDER. *See* ORDER.

Vitruvius, the most ancient writer on architecture, after describing the three Grecian orders, mentions several fanciful compositions, without giving them any particular denomination. The name of *Composite order* is of modern application, and has been applied in consequence of the numerous examples to be found at Rome, and other parts of the ancient Roman territory, of an order compounded of the Ionic and Corinthian, which is of a very uniform character.

The capital of the Roman order is compounded of the Ionic and Corinthian, the upper part being the Ionic, and the lower the Corinthian. The entablature, as found in the ancient remains of Roman architecture, is Corinthian, and not one example is to be found in the Roman antiquities as published by Desgodetz, but what have Corinthian entablatures.

The Composite order, as is to be found in several of the works of the principal Italian architects, has been compounded from the remains of the frontispiece of Nero, which is entirely Corinthian, and from the temple of Concord at Rome : the cornice is imitated from that of the frontispiece of Nero, which is the boldest, and one of the most beautiful remains of Roman grandeur. The upper part of the capital is taken from the temple of Concord, where the sides, or flanks, are the same as on the fronts, and project at every angle, the face of the abacus being concave ; and the two lower rows of leaves are what is usually found in any example of the Corinthian order ; but there is some little difference between the caulicoles, or stalks, that spring up between the leaves, which, though suitable to the composition, are not so elegant as in the Corinthian order.

It does not appear quite satisfactory to us why the examples included under this description, should be especially entitled to the term Roman, for the Corinthian has quite an equal claim ; they both owe their existence to the Romans. Why, indeed, any such marked distinction should be set up between the two, is not quite clear, for they are evidently but different modifications of the same idea ; and we think there can be discovered as much diversity in examples included under the term Corinthian, as between them and the Composite.

We subjoin a list, extracted from one of Mr. Weale's works, showing the proportions of the order in various examples.

	Base.	Column.	Capital.	Architrave.	Frieze.	Cornice.	Entablature.	Diam. of Column.
	Diam. Mod. Ht.	Diam. Mod. Ht.	Diam. Mod. Ht.	Diam. Mod. Ht.	Diam. Mod. Ht.	Diam. Mod. Ht.	Diam. Mod. Ht.	Ft. Inch.

The example of the Roman order which we have given, is from that exquisite remain of antiquity, the arch of Titus, at Rome.

ROMANESQUE ARCHITECTURE, a term applied to different purposes by various writers ; but the most useful and consistent application seems to include all the various kinds of building which originated from the Roman, and which appeared after the decline of art in that country, but with this limitation, that they still retain the semicircular arch. Under this general title, then, will be embraced the debased Roman, the Byzantine, Lombardic, Saxon, Norman, and the several varieties of the same class. For further information, *see* the above articles.

ROOD, a crucifix more especially applied to those which were placed in an elevated situation at the east end of churches between the nave and chancel. They were of large dimensions, and usually of wood, with figures of the Virgin and St. John placed on either side, and at the foot of the upright arm of the cross.

Rood Beam, a beam carried over the entrance to the chancel, for the purpose of supporting the rood.

Rood Loft, an elevated loft or gallery occupying a similar position to the rood-beam, but resting or appearing to rest on a screen below. It was usually spread out from the top of the screen on both sides of it, so as to give a landing at top of sufficient space for the rood-screen, and for the passage of persons to and fro. It was from this place that a part of the Romish service was performed. The soffit of the loft on either side of the screen, was either coved, or in the form of a semi-vault, with groining and ribs. The loft was approached by a staircase in the chancel-pier or main walls of the church, and these are frequently the only evidence of the existence of the loft.

Rood-Screen, the screen of open work which in most churches separated the nave and chancel ; the lower portion being panelled, and the upper perforated with rich tracery-work in the head. In the centre was a door, or pair of gates giving admission to the chancel. Such screens were usually of wood, but sometimes of stone, especially in cathedrals and larger churches ; they are also sometimes double ; as at St. David's Cathedral, and Gilden Morden, Cambridgeshire. Rood-screens, as well as the loft, and rood itself, were often of most elaborate workmanship, highly decorated with gilding and colour.

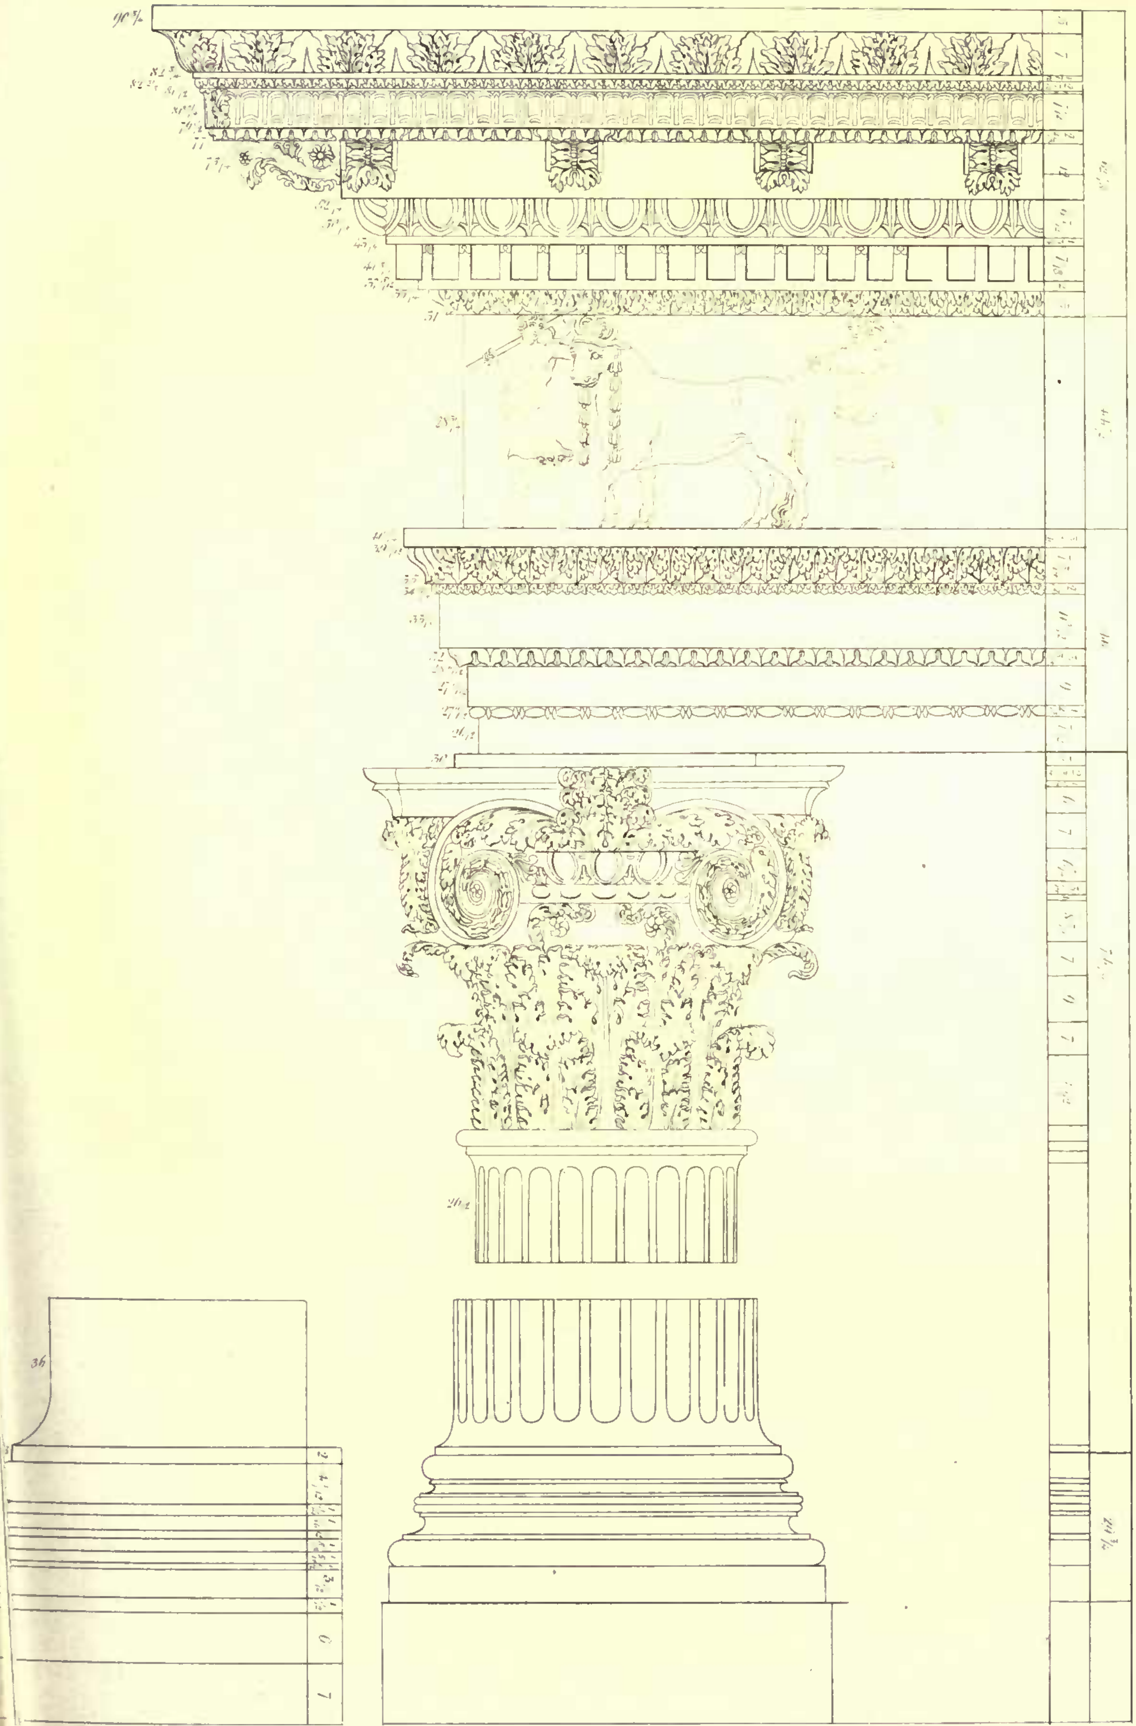
Rood Tower, the tower at the intersection of nave and transepts.

ROOF, (from the Saxon, *hrof,*) the cover, or top of a building, generally consisting of two sloping sides, though occasionally of other figures.

The ancient Egyptians, Babylonians, Persians, as well as other Eastern nations, had their roofs quite flat. The Greeks appear to have been the first who made roofs with a declination each way from the middle to the edges ; this was very gentle, the height from the ridge to the level of the walls not exceeding one-ninth or one-eighth part of the span, as may be seen by many ancient temples now remaining. In northern climates, subject to heavy rains and falls of snow, the ridge must be very considerably elevated. In most old buildings in Britain, the equilateral triangle seems to have been considered as the standard, both in private and public edifices ; and this pitch continued for several centuries, till the disuse of what is called Gothic architecture. The ridge was then made somewhat lower, the rafters being *three-fourths* of the breadth of the building. This was called *true pitch ;* but, subsequently, the *square* seems to have been considered as the true pitch. The heights of roofs were gradually depressed from the square to *one-third* of the width, and from that to *a fourth*, which is now a very general standard ; though they have even been executed much lower. There are some advantages in high-pitched roofs, as they discharge the rain with greater facility ; the snow continues a much shorter time on the surface, and they are less liable to be stripped by heavy winds. Low roofs require large slates, and the utmost care in execution ; but they have the advantage of bein

ROMAN ORDER

PLATE I.



much cheaper, since they require shorter timbers, and of a much less scantling. When executed with judgment, the roof is one of the principal ties to a building; as it binds the exterior walls to the interior, and to the partitions, which act like strong counterforts against them.

Roofs are of various forms, according to the nature of the plan, and the law of the horizontal and vertical sections. The most simple form of a roof is that which has only one row of timbers, arranged in an inclined plane, which throws the roof entirely to one side. This is called *a shed-roof*, or *lean-to.* The most elegant roof for a rectangular building, consists of two rectangular planes, of equal breadth, equally inclined, and terminating in a line parallel to the horizon; consequently, its form is that of a triangular prism, each side being equally inclined to the plane of the wall-head. This is sometimes called a *pent-roof.*

When the plan is a trapezium, and the wall-heads properly levelled, the roof cannot be executed in plane surfaces, so as to terminate in a level ridge. The sides, therefore, instead of being planes, are made to wind, in order to have the summit parallel to the horizon; but the most eligible method is to make the sides of the roof planes, enclosing a level space, or flat, in the form of a triangle, or trapezium, at the summit of the roof. Roofs flat on the top are said to be *truncated:* these are chiefly employed with a view to diminish the height, so as not to predominate over that of the walls.

When all the four sides of the roof are formed by inclined planes, it is said to be *hipped*, and is, therefore, called a *hipped-roof;* and the inclined ridges springing from the angles of the walls are called *hips.* Roofs of this description are frequently truncated; and when the plan of the walls is in the form of a trapezium, the truncation of the roof becomes necessary.

Roofs upon circular bases, with all their horizontal sections circular, the centres of the circles being in a straight line drawn from the centre of the base perpendicular to the horizon, are called *revolved-roofs*, or *roofs of revolution.*

When the plan of the roof is a regular polygon, or a circle, or an ellipsis, the horizontal sections being all similar to the base, and the vertical section a portion of any curve convex on the outside, the roof is called *a dome.*

To save the expense of lead in the roofs of rectangular buildings, instead of the flat, a valley is sometimes used, which makes the vertical section in the form of the letter M, or rather an inverted W; and hence it has obtained the name of *an M roof.*

Definitions.—In order to be understood by the reader, it will be necessary to explain such terms as are used in the subsequent part of the article, by way of definitions.

Wall-plates, pieces of timber laid on the wall, in order to distribute the pressure of the roof equally, and to bind the walls together. They are sometimes called *raising-plates.*

Trusses, strong frames of carpentry, generally of a triangular form, supporting the covering. They are disposed at equal distances, and are used when the expansion of the walls is too great to admit of common rafters alone, which would be in danger of being bent or broken by the weight of the covering, for the want of some intermediate support. They are variously constructed, according to the width of the building, the contour of the roof, and the circumstances of walling below, &c.

Tie, any piece of timber connected at its extremities to two others, acted upon by opposite pressures, which have a tendency from each other; or, to extend the tie, as a rope or chain.

Straining-piece, a piece of timber, connected at its extremities to two others, acted upon by opposite pressures, which have a tendency towards each other.

Hence, a tie acts contrary to a straining-piece. A chain, rope, or small bar of iron, may be used for the former; but the latter must always be inflexible, being in a state of compression.

Principal rafters, two pieces of timber in the sides of a truss, supporting a grated frame of timber-work over them, on which the slating or covering rests.

Purlins, horizontal pieces of timber fixed upon the principal rafters.

Tie-beam, a horizontal piece of timber, connected to two opposite principal rafters. It answers a twofold purpose, viz., that of preventing the walls from being pushed outwards by the weight of the covering, and of supporting the ceiling of the rooms below. When placed above the bottom of the rafters, it is called *a collar-beam.*

Common rafters, pieces of timber of a small section, placed equidistantly upon the purlins, and parallel to the principal rafters: they support the boarding to which the slating is fixed.

Pole-plates, pieces of timber resting on the ends of the tie-beams, and supporting the lower ends of the common rafters.

King-posts, an upright piece of timber in the middle of a truss, framed at the upper end into the principal rafters, and at the lower end into the tie-beam: this prevents the tie-beam from sinking in the middle.

Queen-posts, two upright pieces of timber framed below into the tie-beam, and above into the principal rafters, placed equidistantly from the middle of the trruss, or its extremities.

Struts, oblique straining-pieces, framed below into the king-posts or queen-posts, and above into the principal rafters, which are supported by them; or sometimes they have their upper ends framed into beams, which are too long to support themselves without bending. They are often called *braces.*

Puncheons, short transverse pieces of timber fixed between two others for supporting them equally, so that when any force operates on the one, the other resists it equally; and if one break, the other will also break. These are sometimes called *studs.*

Straining-beam, a piece of timber placed between two queen-posts at the upper ends, in order to withstand the thrust of the principal rafters.

Straining-sill, a piece of timber placed at the bottom of two queen-posts, upon the tie-beam, in order to withstand the force of the braces, which are acted upon by the weight of the covering.

Camber-beams, horizontal pieces of timber, made on the upper edge, sloping from the middle towards each end, in an obtuse angle, for discharging the water. They are placed above the straining-beam in a truncated roof, for fixing the boarding on which the lead is laid; their ends run three or four inches above the sloping plain of the common rafters, in order to form a roll for fixing the lead.

Auxiliary rafters, pieces of timber framed in the same vertical plane with the principal rafters, under and parallel to them, for giving additional support, when the extent of the building requires their introduction. They are sometimes called *principal braces* and sometimes *cushion-rafters.*

Joggles, the joints at the meeting of struts with king-posts, queen-posts, or principal rafters; or, at the meeting of principal rafters with king and queen-posts: the best form is that which is at right angles to the struts.

Cocking, or *cogging*, the particular manner of fixing the tie-beams to the wall-plates: one method is by dove-tailing, the other is by notching the under side of the tie-beam, and cutting the wall-plate in a reverse form to fit it. This method is far preferable to the other, as it is not liable to be drawn, which the other is very subject to when the timber shrinks.

Ridge-tree, a piece of timber fixed in the vertex of a roof, where the common rafters meet on each side of it; the upper edge of it is higher than the rafters, for the purpose of fixing the lead which goes over it to cover the ends of the slates in the upper course.

Straps, thin pieces of iron running across the junction of two or more parts of a truss, or frame of carpentry, branching out from the intersection in the direction of the several pieces, for the purpose of securing them to each other. They ought always to be double, viz., one strap on each side, and their ends strongly bolted to each of the pieces.

The uses of these various parts will be illustrated in what follows; and here, it may be proper to observe, that though every one of the parts above defined *may* be found in the same roof, it is not necessary that a complete roof should have them all; the introduction of many of them depends on the distance of the walls, the contour of the roof, the partitions below, the quantity of head room wanted in the garrets, &c.

Other names of timbers will be fully illustrated in the descriptions of other roofs, in due order of succession.

Before we proceed to the construction of roofing, it will be necessary to show upon what principles a body, or piece of timber, may be supported in various positions.

Proposition I. *Plate* I. (*of Mechanical Carpentry*) *Figure* 1.—*If a heavy body*, A B C D, *be suspended by any two inclined strings*, D E *and* C F, *in a vertical plane, a right line drawn through the intersection, perpendicular to the horizon, will pass through the centre of gravity of the body.*

It is shown by the writers on mechanics, that if any three forces act upon a point, or a body, their directions will tend to the same point, or be parallel to each other. It is well known that every body acts with its full force in one point only, viz., its centre of gravity, and in a direction perpendicular to the horizon: therefore, if a body be sustained at E and F, it will revolve round these points, till the line, G H, passing through the intersection, H, of the two strings, D E and C F, and the centre of gravity, G, becomes perpendicular to the horizon.

Corollary 1.—Hence, if any body be supported by two strings, it may also be supported by two planes perpendicular to those strings, provided the two points of the body supported be in the direction of the strings; for every body acting upon a plane acts in a line perpendicular to that plane.

Corollary 2.—Hence, also, a body may be supported by two props in any two directions that it may be supported by strings, provided the surface of the body, at the points of contact, or the ends of the props, be planes, at right angles to the strings.

Corollary 3.—Hence, all the properties that have been demonstrated of three forces acting upon a body supposed to be void of weight, will equally flow from a heavy body supported by two strings, by substituting the weight of the body for the middle force; and hence, if the direction of any force supporting a heavy body be given, the other may easily be found.

Proposition II.—*Given the position in which a body should be placed, and the position of a plane supporting the body at one end; to find the position of another plane to support it at another given point, and to find the pressure on the planes, the weight of the body being given.*

Through the centre of gravity of the body draw a vertical line, and through any point on which the body rests on the given plane, draw a line perpendicular to that plane, meeting the vertical line: from the intersection draw a line to the other point, which is to be supported; from that point draw a plane at right angles to this line, which will be the direction of the plane required.

To find the intensity of the forces, take any distance on the vertical line, to represent the weight of the beam, from the intersection; on that line, as a diagonal, complete a parallelogram, whose sides are in the directions of the lines perpendicular to the supporting planes; and the side of the parallelogram, perpendicular to either plane, will represent the force on that plane.

Example 1. *Figure* 2.—Let the body, A B C D, lie upon the top of the wall, K C at C, so as to touch the lower edge, B C, of the body, at that point, C; it is required to find the direction of a plane that will support the lower end at B, and to find the pressure of the body on the wall and on the plane.

Through the centre of gravity, G, of the body, draw the vertical line G F; draw C F perpendicular to C B; join F B, and draw B I perpendicular to F B; and B I will be the direction of the plane required. On the vertical line, G F, make F M to represent the weight of the body, and complete the parallelogram L M N F; then F N will represent the force on the wall-head, in the direction F C; and F L the force acting perpendicular to the plane, or in the direction B F. But if the vertical and horizontal thrusts on the wall at C be required, draw N P perpendicular to F G, meeting it in P; then the force, F N, will be resolved into two forces, F P and P N. P N will represent the horizontal part of the force, viz., that which pushes the wall in a direction parallel to the horizon; and F P the other part, which tends to press it downwards in a direction perpendicular to the horizon.

Example 2. *Figure* 3.—Let the sloping body, A B C D, be supported by a wall at its lower end, D, which coincides with the surface of the body, and let G be the centre of gravity; it is required to cut a notch out of the body, at the upper end, C, so that it may rest upon the top of a wall, which is made to fit the notch, and to find the pressure on the walls.

Draw the vertical line, G E; from D draw D E perpendicular to D C; join E C, and make C F at right angles to it; then, the notch H C F being cut, the body, A B C D, will be at rest. To find the pressure on the walls, complete the parallelogram, E I K L, having a given angle, D E C, and its diagonal on the given line, E O; then, if K E represent the weight of the body, I E will represent the pressure in the direction D E, upon the wall at D, and L D the pressure in the direction C E, The horizontal and perpendicular pressures upon each wall may be found, as in the preceding example, by resolving each of the forces I E and L E, into two; one of which is perpendicular to the horizon, and the other parallel to it.

Scholium.—It must be observed in this example, that the notch, which is cut out at C, will remove the centre of gravity nearer to the lower end, D, and consequently alter the slope, C F; but as this can only be in a very small degree, the equilibrium will hardly be affected by it, when the notch is very small.

Example 3. *Figure* 4.—Let one of the corners of a sloping body, A B C D, rest upon the top of a wall at D, which is quite level: it is required to find the position of a notch, cut out of the upper end, C, so that the body may rest upon a wall made to fit the notch.

Let the small part, F C H, be so cut that C H may be parallel to the horizon, then the body will be supported by the two walls at C and D. For, draw D I, O K, and C L perpendicular

to the horizon, these lines being produced, they may be supposed to meet at an infinite distance. To find the pressure on the walls: join D C, and produce the vertical line, K G, to meet it in E; then, if G be supposed to be the weight of the body, the pressure on D will be $\frac{EC \times G}{DC}$, and the pressure on C $= \frac{DE \times G}{DC}$.

Example 4. *Figure* 5.—Let the body, A B C D, lie with its upper end against the vertical face of a wall at C; it is required to find the position of a plane supporting the lower end, D, so that the body may be at rest.

Draw the vertical line G E; also C E perpendicular to the face of the wall, C L; join E D, and draw D F perpendicular to E D; then D F will be the position of the plane required. Complete the parallelogram, E H I K; then the pressure on D and on C, and the weight of the body, will be to each other as E H, E K, E I.

Example 5. *Figure* 6.—To support a body, A B C D, by two props at two given points, E and I, the direction of one of the props, E F, being given:

Draw the vertical line, G K; produce F E to K; draw K I H; and I H will be the prop required. On the vertical line, G K, take K M to represent the weight of the body; and on K M, as a diagonal, describe the parallelogram, K L M N; then K L will be the compression of the prop E F, and K N the compression of the prop I H.

CONSTRUCTION.—*Plate* II. *Figure* 1.—Of common roofs, the simplest construction is that which consists of two rafters, as A B and B C; D and E are wall-plates, on which the feet, A and C, of the rafters rest; the bottoms of the rafters are cut in the form of a right angle (called by the workmen *a bird's mouth*) reversed to the wall-plate, and are fixed to it with nails; but this form can only be applied to buildings that have their walls at no great distance from each other.

Figure 2.—The next form is that of having two rafters, as A B, B C, a collar-beam, D E, with two wall-plates, F and G, below. This form will admit of a greater distance between the walls than the other: the beam is placed in the situation D E, in order to give head-room within; but when the span, F G, of the walls is considerable, the parts A D and C E being considered as levers, and acted upon by the reaction of the walls, the rafters are either liable to be broken at the points D and E, or curved with a concavity on the upper edges.

Figure 3.—The third form of common roofs consists of two rafters, A B, B C; a tie-beam, A C, for preventing the rafters from pushing out the walls; a collar, or straining-beam, D E, and two puncheons, or studs, F G and H I, for keeping the rafters straight; this construction is used for cheapness, and may be executed with safety in houses not exceeding 45 feet wide; but it is necessary to have partitions immediately below, or at no great distance from the studs. Instead of supporting every opposite pair of rafters, as in this example, it happens, in many roofs of this construction, that the rafters take the place of principals, and are fixed at 7, 8, 9 or 10 feet from each other; while purlins run over the heads of the puncheons at K and L; and, at the ends of the collar-beams, at M and N, between every two rafters, smaller rafters are fixed to the purlins, the wall-plates at bottom, and the ridge-tree at the top.

Figure 4.—The most simple construction of a truss consists of the following parts:—A B the tie-beam, cocked upon the wall-plates, C and D; E K the king-post; A G and B H principal rafters, fixed to the king-post at the joggles, G and H; M and N O struts, mortised into the rafters at L and N, and joggled to the king-post at M and O.

PROPOSITION III.—*In any roof constructed with two equal rafters only; as the height of the roof is to half the breadth of the building, so is half the weight of the roof to the horizontal thrust, or lateral pressure.*

Figure 5.—Let A B C be a roof, having the two equal rafters, A B, B C; join the bottom of the rafters, A C; draw B D perpendicular to it; complete the parallelogram B E F G, and draw E G, cutting B D in H. Then, because the triangles, B H E and B D A are similar,

B D : D A : : B H : H E.

Corollary 1.—Hence, in a roof with two rafters and a tie-beam at the bottom, the tension, H E, of the tie-beam is $= \frac{DA \times BH}{BD}$.

Corollary 2.—Hence, also, B D : B A : : B H : B E; that is, as the height of the roof is to the length of the rafter, so is half the weight of the roof, represented by B H, to the compression of the rafters $= \frac{BA \times BH}{BD}$.

Corollary 3.—Half the weight of the roof, the tension of the tie-beam, and the compression of the rafters, are to each other as the height of the roof, half the breadth of the span, and the length of the rafters; for the triangle B H E is similar to the triangle B D A.

PROPOSITION IV.—*If a rafter bear any weight, or have a weight uniformly diffused over it, the force tending to break it is equal to the cosine of elevation multiplied into the weight, divided by radius.*

Figure 6.—Let A B, B C, be two equal rafters; join A C, draw B G perpendicular to it meeting it in G; and let the weight W be suspended by the string D E. Draw D F perpendicular to A B, and E F parallel to it; then, if D E represent the weight, D F will represent the force tending to break the rafter; and E E its tendency to push it from B towards A.

Now because E F is parallel to A B, the alternate angles A D E and D E F are equal, and the angles D F E and A G B are right angles; the triangles E D F and B A G are similar; therefore A B : A G : : D E : D F $= \frac{AG \times DE}{AB}$; but if A G be made the radius, then D E will be the cosine of elevation; therefore R : cos' elevation : : D E : D F $= \frac{\text{cos' elevation} \times DE}{R}$

Corollary 1.—Hence the weight employed, the pressure in a direction of the length of a rafter at A, the tendency to break it, are as radius, the sine, and cosine of elevation.

Corollary 2.—Because D F $= \frac{\text{cos' elevation} \times DE}{R}$, and because the stress is as the length, when the weight is given, the stress is as the cosine of elevation multiplied into the weight, and this product multiplied into the length of the rafter; the radius being a constant quantity.

PROPOSITION V.—*To prevent the rafters of a roof, with a tie-beam, from bending in the middle; and to remove lateral pressure from the walls, when there is no beam.*

A variety of methods may be used for this purpose; but the best are those in which the shortest and least quantity of timber are employed, without producing a transverse strain upon any part. When a roof consists of two rafters only, no part of the rafters can be loaded between their extremities; nor indeed will they bear their own weight without producing a concavity on the upper side, which will be greater as the length of the rafter and weight applied to it are greater. Now, because the shorter the rafters are at the same elevation, the greater weight they will bear, and be more able to support their own weight; the object is to support them by a sufficient number of fixed points, either from the roof itself, or from other immoveable places. There are three points for this purpose; if the rafters have a tie-beam below, that is, at the vertex, and at the two extremities of the rafters, the triangle being immoveable at the angles, every force applied there tends either to compress or extend the sides of the frame, without a transverse strain.

Examples.—Let it be required to divide each of the rafters into three equal lengths, in order to support two purlins on each side; this may be done, as in *Plate* III. *Figure* 1, by pieces, C E, C D, A G, A F, reaching from the two lower angles, C and A, and to the opposite sides of the rafters, A B and B C, intersecting each other at H and I, and halved upon each other at these intersections: this mode prevents the rafters from sagging, but does not afford any support to the tie-beam. The meeting of so many braces at the same point, too, gives little opportunity of making the ends entirely secure, even though assisted by iron straps.

Another mode may be by introducing a king-post. B K, *Figure* 2, to which the struts, D H, E I, F M, G L, may be firmly joggled at H, I, M, L, and mortised to the rafters at D, E, F, G: this method keeps up the middle of the beam; but when the roof is low, and the span great, the struts, D H and F M, require themselves to be supported, and are much too oblique to prevent a change of figure.

Another method may be, as in *Figure* 3, with the king-post in the middle, as before, two queen-posts under the rafters at E and F, two struts, H E and I F, joggled to the bottom of the king-post at H and I, and to the top of the queen-posts at E and F; and in order to secure the points N and P, two other braces, N Q, P R, are joggled to the bottom of the queen-posts at Q and R, and mortised into the rafters at the upper end. This construction supports the tie-beam in three different points, and each of the rafters in two. The timbers are much shorter than those of the preceding; but so many joggles are certainly an objection to this method, as the shrinking of the timber must be very considerable in three breadths, which would allow the roof to descend.

When the span is great, and the points to be supported many, an excellent method may be as in *Figure* 4, where there are two arches of cast-iron, or good English oak, introduced, which abut on the king-post, and at the other extremity at the ends of the beam. The rafters and the beam, by this mode, may be supported by as many equidistant points as we please.

When the tie-beam is removed from the bottom, as in *Figure* 5, and no fixed points are to be found from below, a longitudinal truss may be constructed, the end of which is shown at A B, and the manner of framing it in *Figure* 6, the two ends being supposed to be firmly fixed into the gables; but where the length is great, the form of *Figure* 7, with a parabolic arch, would be much better: by this method, the rafters will be kept nearly in the same plane, and all lateral pressure from the walls will be removed; for it is evident that if the ridge-tree is supported, there can be no motion downwards in the direction of the rafters, the whole roof being hung to this longitudinal frame.

Proposition VI.—*Figure* 8.—If a roof be constructed with two equal rafters, A M, C M, with a tie extending from the bottom of each to an intermediate point in the opposite rafter, and the ties halved together at their intersection, B, so as to form with the rafters a quadrilateral, M D B E, at the vertex, and two triangles, A D B and C E B; then, if M D be equal to M E, and C P represent the direction and quantity of force on the wall at C, the force tending to break the rafters at D and E is $\frac{\text{S. PCK} \times \text{S. DME} \times \text{LK} \times \text{DM}}{\text{S. LCK} \times \text{R}}$.

For completing the parallelogram P C L K; making [...] equal to C L; and N O parallel, and M O perpendicular to A M, [...] triangles C B E and A B D may be looked upon as solid lev[...] (at least with regard to forces applied to the angles) movea[...] round B. Then the force C P will communicate the force [...] to the rafter, and C L is the power acting obliquely at M u[...] the rafter A M: then because N O is parallel, and O M perp[...]dicular to A M, O M is the force tending to break the raf[...] at D, and O N that pushing it towards A: therefore, let M[...] be considered radius, and O M will be the sine of the an[...] D M N, or D M E; for produce A M to Q, and the angle N M[...] will be the supplement of the vertical angle D M E; theref[...] the sine of N M Q, equal to the sine of the angle M N O, is [...] same with the sine of N M A; then by trigonometry,

LK : LC :: S. LCK : S. CKL or S. PCK

NM or LC : MO :: R : S. DME = S. MNO;

therefore, LK : MO :: S. LCK × R : S. PCK × S. DME.

Hence $\text{MO} = \frac{\text{S. PCK} \times \text{S. DME} \times \text{LK}}{\text{S. LCK} \times \text{R}}$ = the force acti[...] perpendicular to A M at M; but the force tending to bre[...] the rafter at D is as the lever D M multiplied into this forc[...] that is $= \frac{\text{S. PCK} \times \text{S. DME} \times \text{LK} \times \text{DM}}{\text{S. LCK} \times \text{R}}$.

Corollary 1.—Hence, if the angle D M E is a rig[...] angle, the force tending to break the rafter at D will [...] $\frac{\text{S. PCK} \times \text{LK} \times \text{DM}}{\text{S. LCK}}$.

Corollary 2.—Hence the rafters of every roof of this co[...]struction must sag in a greater or less degree, by the acti[...] of the rafters against each other at the point M; that is, th[...] will be bent into curves concave on the upper edges; but [...] a diagonal connect the two vertical points M and B, th[...] change of figure will be prevented.

Proposition VII.—*To remove the lateral pressure of [...] roof without any intermediate beam, brace, or strut.*

Plate IV. *Figure* 1. No. 2.—Let A B, B C, be two rafte[...] and let there be constructed a strong wall-plate, D E F G, No. [...] firmly bolted together at the angles; then if the roof [...] to be gable ended, after having fixed the rafters to a comm[...] ridge-tree, let two curves be made of cast-iron or go[...] English oak, of a parabolic form, and let into the rafters, eith[...] on the upper or under surface, and firmly secured to them b[...] bolts or nails, and at their lower extremities to the angles [...] the wall-plates, the vertex of each curve meeting the ridg[...] piece on each side of it or nearly so, as may be convenien[...] One half of the plan, No. 1, exhibits the form for th[...] execution of a gable-ended roof, and the other for a hippe[...] roof. The two sides, laid in plano for each form, are show[...] in No. 3 and No. 4; at H I K L and M N O P, H L and D[...] represent the same wall-plate; D G, N O, and E F anoth[...] wall-plate, I K and M P meeting the ridge on each side of i[...] but it must be observed when the roof is to be hipped, th[...] the ridge-tree must be very strong, as the compressure wi[...] be very great, the hip-rafters acting like powerful braces [...] its extremities. Hence it is evident that the wall-plates ac[...] as the tie-beams of a common roof, and the curves as th[...] rafters; or, more naturally, like an arch of a bridge in equ[...]librio. It has already been shown that equal weights acting in equidistant lines, require an arch of a paraboli[...] form to keep them in equilibrio. In this it is to b[...] considered, that as the arches are placed with their crow[...] upwards, they are in a state of compression, and may be go[...] out very conveniently in several lengths; but if the arche[...] were inverted, they would be in a state of tension; each arc[...] must then be in one piece, as the ridge would be compresse[...]

by the tension of the two curves. This inverted disposition of equilibration is not so secure as when the crown of the arches either meets the ridge or lies towards it.

Though the above construction will prevent lateral pressure, it will not hinder the rafters from sagging; but the addition of a collar-beam will effectually answer this purpose in all moderate spans.

PROPOSITION VIII.—*Given the construction of a roof, of which not more than three timbers meet at the same junction, and a force in the direction of any one of the timbers; to find the forces communicated to the other timbers, so that the roof shall be in equilibrio.*

Begin with the given force, and take a part of the line of its direction from the junction to represent it; then, with the other two directions, complete a parallelogram, and apply them from the next junctions on the same straight line from which they were taken, and complete parallelograms, as before. Proceed in this manner, from one junction to another, until parallelograms have been made at every one. Then the parts of these parallelograms, in the directions of the timbers, are the forces in these directions; and to ascertain the state of tension or compression of any timber, observe that when two of the angles formed by three directions are less than two right angles, the middle force acts always contrary to the two extreme ones, as has already been explained; and that when any two of the angles of direction are greater than two right angles, then the forces will act towards or from the same point.

Example 1.—*Figure* 2.—Let A B C D A be a roof, consisting of two rafters, A B, B C, two beams, C D, D A, and a king-post, D B, supported by the walls A O and C E. Let C E represent half the weight of the roof, or the reaction of the wall, C E; complete the parallelogram C E F G; make D L equal to F C, and complete the parallelogram L M N D; then C F, or D L, is the force in the direction of the beam C D, or A D, and D M is the force in the direction of the post D B; now, because the angles E F C and F C G are less than two right angles, and because the point C is pressed by the reaction of the wall E C, it will also be pressed by the force G C, and drawn by the force C F; therefore the beam C D is in a state of tension, and the rafter B C in a state of compression. Again, because C D B and B D A are greater than the two right angles, and because C D is in a state of tension, B D and D A are also in a state of tension.

If B H be made equal to G C, and the parallelogram B H I K completed, and if B P be made equal to D M, then will P I be equal to twice C E, the pressure on the walls.

Example 2.—*Figure* 3.—Let A B C D E A be a roof, supported by walls in the directions P A and Q C, and let there be two pieces of timber, B D and B E, connecting the angular points, D and E, to the ridge at B.

Take C F to represent half the weight of the roof, or the reaction of the wall Q C: complete the parallelogram C F G H; produce C D to K; make D K equal to G C, and complete the parallelogram D I K L; then G C, or D K, is the force in the direction of the timber C D or A E, and is in a state of tension, because the angles F C G and G C H are less than two right angles, and because C F is in a state of compression; C H, the force in a direction of the rafter B C, is also in a state of compression; and because any two of the three angles, G D B, G D E, E D B, are greater than two right angles, and D C is in a state of tension, the two pieces, D B and D E, are also in a state of tension; that is, E A, E D, E D, D D, D C, are all ties. The force in D B or E B is D L, that in D E is D I.

If D R and B S be made equal to C H, and the parallelogram B R W S completed; and if B T and B U be made equal to L D, and the parallelogram B T V U completed, then will V W be equal to twice C F; that is, by reducing the force in the direction of the pieces B E and B D to an equivalent one.

PROPOSITION IX.—*Given the lengths* A B, B C, C D, D E, *of the rafters of a roof and their angles of position, to find those angles that require ties, and those which require struts.*

Plate V. *Figure* 1.—Let A B be to B C as 3 to 4, that is, as 6 to 8, the proportion of the weight of the rafters; then if 8 be taken for the weight of each of the upper rafters, $\frac{8+8}{2} = 8$ will be the weight on the vertical angle C, and $\frac{6+8}{2} = 7$, will be the stress on each of the vertical angles B and D, so that the weight on the vertical angle is to that on each of the lower angles, as 8 to 7. Draw the vertical line D G F, and draw A G, A F, parallel to the rafters B C, C D; then if F G be to G B as 8 to 7, the rafters will be in equilibrio, and require no ties. But suppose it should be found that F G is to G B as 1 to 2; as that will keep it in equilibrio, it would require a very considerable addition laid on the angle, D, to keep it from springing outward, so that if two braces, F G and K L, No 2, were fixed to the rafters, A B, B C, C D, D E, these would be in a state of compression; and if the brace, H I, were fixed at the top, it would be in a state of tension: F G and K L only require firm butments, but H I to be well bolted. It may here be observed, that if the vertical angle only be braced and secured to the two rafters, the whole frame will then be immoveable.

PROPOSITION X.—*To discover the effect of bracing the angles of a roof flat on the top, supported by puncheons at the bottom of the rafters, to accommodate a semicircular ceiling within.*

Figure 2. No. 1.—Let A B C D E F be the truss, divested of its braces, the bottoms of the puncheons resting firmly on the walls at A and F, and the joints at B, C, D, E, to be quite moveable, like rule-joints. Now, as this disposition of timbers would fall, and in falling, would assume the form of No. 2, the angles at C and D would become more and more obtuse, while those at A and E would, in the same proportion, become acute; the latter would, therefore, require straining-pieces, and the former ties; the straining-pieces must have good abutments, and the ties must be well bolted at their extremities.

Let No. 3 be the truss, with braces disposed in the lower angles; this disposition will bend the rafters B C, D E, and the puncheons, B A, E F, convex towards the outside, which is entirely occasioned by the braces, G H, N O: the camber-beam, C D, is no otherwise affected than by its own weight. Let it now be supposed, that the angles C and D, No. 4, are braced at I K, L M. In this disposition, the puncheons, B A, E F, are not affected in respect of transverse strains; the rafters C B, D E, and the beam C D, would all become concave on the outside; and the points B and E, at the bottom of the rafters and top of the puncheons, would be pushed out beyond the perpendicular of A and F, at the bottom: here it is necessary to observe that the effect produced in this case on the rafters C B and D E is contrary to the effect produced in No. 3, by the braces being disposed in the lower angles. Lastly, suppose that all the angles are braced, as in No. 5, it is evident, since the braces, H G, N O, produce a contrary effect to the braces K I, L M, these bending the rafters downwards, and those upwards, that the rafters C B and D E will become nearly straight, or assume an undulated line: the puncheons B A and E F, receiving the force of the braces H G and N O at the points G and O, must still be bent, so long as the under ends, G and O, of the braces do not coincide with the under ends, A and E, of the puncheons: in this case, there is no other remedy than by giving the puncheons a scantling sufficient to withstand this transverse strain, or horizontal thrust, at the points G and O; however, the shape of the contour may be pretty well secured by introducing two abutments, H I and M N, No. 6; these by being bolted through the two ends, will add greatly to the stiffness of the rafters B C and D E; the bolts that go through the upper ends may also serve for the braces I K and L M: the shape of the horizontal beam, C D, will likewise be very much preserved by the piece K L, bolted in three places, one at each end, into the braces I K and L M, and another in the middle: the contour of a roof, thus supported, would be quite unchangeable, if the rafters were inflexible; but, as this is not the case, and as they are acted upon transversely by the braces, the truss will therefore, in some degree, be expanded at B and E, and consequently occasion lateral pressure on the walls; it will, therefore, be unfit for an oblong building, without other precautions for this purpose. By inserting parabolic curves in the sides B C and D E, as in *Plate* IV. *Figure* 1, it will be effectually prevented.

In roofs of this description, joggle-pieces of wood should never be used, as their shrinking would tend greatly to alter the outline of the rafters.

Having laid down such principles as will enable the workman to judge of the strength and strain of timbers in the framings of carpentry, it will now be necessary to proceed to show the mode of constructing roofs to answer various purposes; to give some practical observations relative to their strength, and to show the various modes of joining timbers, the forms of traps, &c.

As we have above stated, the simplest form of a perfect trussed roof, consists of two principal rafters inclined to each other, and meeting at the apex, the lower ends being tied together by a horizontal tie-beam, to prevent their spreading and thrusting out the walls upon which they are supported. As, however, the gravity of this tie-beam, especially if of any considerable length, is apt to cause it to sag in the centre, between the bearings, it is necessary to provide another bearing for it between the walls, and this is effected by suspending it in the centre by means of what is termed a *king-post*, which, in its turn, is held up between the principal rafters at the apex of the roof. To assist in effecting the same object, the tie-beam is sometimes cambered or arched, but this plan can scarcely be recommended, for if the timbers settle, as in all probability they will do, the cambered beam being extended into a straight one is liable to push out the walls, and cause the mischief which it was intended to prevent. The better plan is, to camber the beam only on the upper side, the lower side being horizontal, so as to have the greater scantling in the centre; this plan, however, is not without objection, for by it you have the greater weight at the centre, where it is most effective to cause the beam to sag. To afford the same assistance to the principals, and to prevent their sagging by their own weight and that of the covering which they have to support, short struts are carried from their centre to the foot of the king-post on either side of it, and on this they have their support. In a truss of this kind we have the tie-beam and king-post in a state of tension, while the principals and struts are subject to compression. Roofs of this class are very common, and are adapted for buildings where the span is not above 30 or 35 feet.

When the span gets beyond this, it is necessary to suspend the tie-beam at more points, and first of all, at two where the extreme bearings are not much more distant. In this case two suspenders, termed *queen-posts*, are employed, holding up the tie-beam at two points equidistant from each other and from the walls of the building; the principals are not extended to meet each other at the apex, but terminate at the queen-posts against which they abut, and the queen-posts are retained at the required distance from each other by means of a *straining beam*, which also abuts against the head of the queen-posts, and by this means they are suspended. This description of truss is something like the first, if we suppose the king-post separated into two halves, with a horizontal strut placed between them, to prevent the principals from being pressed together; struts are also placed at the foot of the queen-posts, to support the principals.

A truss for a still greater span is formed by suspending the tie-beam at three intermediate points, having a king-post between two queen-posts, without a straining-beam, the principals being carried to meet each other at the apex, as in the first description of roof; struts are carried from the foot of the king-post to the head of the queen-posts, and from the foot of the queen-posts to the principals. In many cases a roof with the same number of suspenders is somewhat differently constructed, and this consists, in the first place, of a roof precisely similar to the second above described, having, however, in addition, a king-post in the centre, carried up through and above the straining-beam, which is divided into two lengths, and abuts against the king-post on either side. Above and parallel to the principals is placed another pair of principals, which are continued to meet at the apex, where they abut against the king-post; these alone are termed principals, the other subordinate rafters which abut against the queen-posts, being termed *straining braces*, or *auxiliary rafters*. The principals are further supported at the upper part by struts, which spring from the king-post above the straining-beam, and below by a continuous bearing on the straining-braces, which, in their turn, are supported by the struts from the foot of the queen-posts. The last form of roof is calculated for a span of 60 to 80 feet, and the previous one for a span of 50 or 60 feet. Sometimes, instead of a single king-post, this kind of truss will have the king-post, as it were, split in half and hung on either side of the truss, from the heads of the upper principals, extending down to the tie-beam; in this case the straining or collar beam is in one piece, and passes between the halves of the king-post. Another variation consists in splitting the truss into two half-trusses, and keeping the king-post between them both, so as to form one mass. A roof of this kind was constructed over the basilica of St. Paul at Rome more than four centuries ago.

This expedient may be entirely obviated by the use of iron king-posts, which, in all cases, would seem preferable to those of wood, both for king or queen-posts, or, indeed, for any member of the truss which is subjected to tension, as for ties, where its employment, to a very considerable extent, obviates the difficulty which is experienced by the sagging of tie-beams of timber. The number of suspenders, especially if composed of iron-rods, may be still further extended to seven or eight, or, indeed, any number, the only limit being found in the length of the principals.

For the strength of different materials the reader may consult the article on that subject, but as a general remark it may be observed, that oak when exposed to tension is weaker than fir, and is therefore less adapted for ties. Being, however, less compressible, it is usually preferred for rafters, straining-pieces, and struts; but Tredgold observes, that its greater tendency to warping in summer renders it less fit for rafters and purlins than foreign fir. Cast-iron is not much used, except in fire-proof roofs, and each piece requires to be well tested. Wrought-iron is very useful for straps and also for ties and trussing-posts; but care is always necessary to guard against imperfections, which are more likely to pass unobserved than in wood. Wherever iron is applied, pro-

ision should be made for its expansion and contraction, nd it is desirable to protect it from oxidation by painting. 'hough iron is far stronger for its size than any kind of imber, it is neither so strong nor so cheap as yellow-fir, *veight for weight.*

Plate VI. *Figure* 1, is the roof of the chapel of the royal ospital at Greenwich, constructed by Mr. S. Wyatt.

It is constructed with two queen-posts, and is similar to he second kind of roof above described, but it has in addiion two struts from the foot of the queen-posts to the strainng-beam, which abut against a second straining-piece undereath the first; the tie-beam is also further suspended from he straining-beam by an iron-rod, which answers the purose of a queen-post.

The following are the scantlings of the various timbers :—

		Inches Scantling.
A,	The tie-beam, 57 feet long, the span of the walls being 51 feet	14 × 12
,	Queen-posts	9 × 12
,	Braces	9 × 7
,	Straining-beam	10 × 7
,	Straining-piece	6 × 7
,	Principal rafters	10 × 7
,	Camber-beam, for the platform	9 × 7
,	An iron rod, supporting the tie-beam	2 × 2

The trusses are seven feet clear; the platform is covered vith lead, which is supported by horizontal beams six by our inches.

The timbers of this truss are well disposed, and perhaps ontain less wood than most roofs of the same dimensions.

Figure 2 is the roof of St. Paul's, Covent-Garden, esigned by Mr. Hardwick, and constructed by Mr. Wapshot 1796.

This roof, although of the same general construction as the st, varies from it in several particulars. The lower portion precisely the same as the second class of truss, but in addion there is a second pair of principals, which are supported the lower by studs, and the lower principals thus becoming ly auxiliaries; the queen-posts are continued up to the incipals, and a king-post is carried from the apex to the raining-beam.

The scantlings are :—

		Inches Scantling.
,	The tie-beam, spanning 50 feet 2 inches	16 × 12
	Queen-posts	9 × 8
	Straining-beam	10 × 8
	King-post, 14 inches at the joggle	9 × 8
	Strut	9 × 8
,	Auxiliary rafters, at bottom	10 × $8\frac{1}{2}$
,	Principal rafters, at bottom	10 × $8\frac{1}{2}$
	Studs supporting the principals	8 × 8

This roof is much better constructed than the original one Inigo Jones. A truss of the present design contains only cubic feet of timber, whereas that by Inigo Jones had , and was very insufficient at the joggles, and had some ts timbers very ill disposed: the interior truss is well coned for supporting the exterior, which reaches seven feet ond the walls. The tie-beam has, perhaps, too much cam being six inches; for since it acts as a string, it will gthen in the settling of the roof.

Figure 3 represents the roof of Drury-lane theatre, 80 feet ches span, and the trusses 15 feet apart; constructed by Edward Gray Saunders. This was destroyed by fire 1809.

This is rather a curious form of roof; the principal truss is simply one of the second class with queen-posts and straining-beam, but above this, and partially resting upon it, are three other smaller trusses, which form the outer-roof. These are simple trusses of the first class with king-post and struts, the central one having a continuous bearing on the straining-beam of the main truss, and the side ones resting at one end on the straining-beam, and at the other on the wall.

		Inches Scantling
A,	Beams	10 × 7
U,U,	Rafters	7 × 7
C,	King-posts	12 × 7
D,	Strut	5 × 7
E,	Purlins	9 × 5
G,	Pole-plates	5 × 5
H,	Common-rafters	5 × 4
I,	Tie-beam	15 × 12
K,	Posts to ditto	15 × 12
L,	Principal braces to ditto	14 and 12 × 12
M,	Strut	8 × 12
N,	Straining-beam	12 × 12

The principal beams are trussed in the middle space with oak braces, five inches square. This was requisite on account of its width, which is 32 feet, that the floors might carry the work-shops necessary for the use of the theatre. This truss, which is most admirably constructed, is hardly to be equalled for strength, stiffness, and lightness, and will safely bear a load of nearly 300 tons, which is four times more than ever it is likely to be loaded with.

Plate VII. *Figure* 1, exhibits the roof of Covent Garden theatre. The tie-beam in this case is supported by five suspenders, a king-post in the centre, and two queen-posts on either side; between the two innermost queen-posts is a straining-beam, and on the other sides of them are auxiliary-rafters, which abut against a shoulder near their heads. A strut is carried from the foot of the inner queen-post to the head of the outer. The straining-beam is suspended by two queen-posts, between which is another straining-piece, and a strut from their head to the angle formed by the king-post and straining-beam below. The posts are all made double, and are shown in the Plate above the roof in their respective places.

Figure 2 represents the present roof of Drury-lane theatre. There are here both principal and auxiliary rafters, the tie-beam being suspended at two points from the former, and at two from the latter, the two first queen-posts being the inner ones. These are kept apart by a straining-beam, against which they are pressed from the other side by the auxiliary rafters; struts are placed between the feet of the principal and the head of the secondary queen-posts, and the bearing of the sub-rafters is still further reduced by a strut from the foot, and on the other side of the smaller queen-posts. The straining-beam is supported by a king-post from the apex of the principals, which in their turn are supported by struts from the foot of the king-post, the other portion having a continuous bearing on the auxiliary rafters.

The Figure above on the left-hand, shows how the timbers join at the top of the queen-posts, and that on the right how the timbers join at the end of the tie-beam.

The roof over the church of St. Martin-in-the-fields, designed by Gibbs, is rather curious. The entire breadth of the building is 69 feet, which is divided into 3 parts, the nave measuring 40 feet, and the remaining 29 feet being divided between the two aisles. The central portion is covered by a truss, which is supported at either end by an upright timber-post above the columns, and at two intermediate points by braces from these posts to the tie-beam, which is suspended from the principals at three points by a king-post and two queen-posts; struts are carried from the foot of the king-post to the head of the queen-posts, and from the feet of the latter to the principals. Above the aisles, hammer-beams are supported at one end on upright posts in the wall; and at the other, on the post above the columns, and two intermediate bearings are afforded by struts from the same posts. The main principals have a continuous bearing on the rafters of the truss over the roof, another on a post which rests upon the hammer-beams, and at the extremities are strapped to the hammer-beams. From the last-named post there is a brace to the top of post over column. The scantlings of the timber are rather full, and are as follow :—

Main principal, 13 inches by 10 inches at bottom, and 11 inches by 10 inches at top.

Straining-brace or principal of nave-truss, 14 inches by 10 inches at bottom, and 11 inches by 10 inches at top.

King-post, 9 inches by 9 inches.

Strut on king-post, 7 inches by 7½ inches.

Queen-post, 8 inches by 9½ inches.

Strut on queen-post, 7 inches by 7½ inches.

Tie-beam, 14 inches by 9½ inches.

Post over column, 14 inches by 9½ inches.

Brace below tie-beam, 7 inches by 7 inches.

Hammer-beam, 14 inches by 9½ inches.

Brace from uprights to hammer-beam, 8 inches by 8 inches.

Post on hammer-beam, 8 inches by 9 inches.

Purlin rafters, 4 inches by 6 inches.

The roof the basilica of St. Paolo fuori le murà, executed in the fifteenth century, has double trusses, each consisting of two similar frames nearly 15 inches apart, and placed at intervals of 10½ feet from each other. The tie-beam, which is in two lengths scarfed together and secured by three iron straps, is suspended at three points by a king and two queen-posts, the latter being separated by a straining-beam, and having auxiliary rafters abutting against their heads. The king-post is of curious construction, and consists of three pieces for the double truss; that piece against which the principals abut, is very short, only extending as low as the straining-beam. Between the trusses another piece is placed, and sustained by a strong key of wood passing through it and the two upper short pieces; and this piece, in its turn, sustains the tie-beams by means of another strong key. The scantlings are :—

Tie-beams, 22½ inches by 15 inches.

Principal rafters, 21¾ inches by 15 inches.

Auxiliary rafters, 13¾ inches by 13¼ inches.

Straining-beam, 15 inches by 12¾ inches.

Purlins, 8½ inches by 8½ inches.

Common rafters 5¼ inches by 4¼ inches.

The purlins are 5 feet 7 inches apart, and the rafters 8½ inches.

The span of the roof is 78 feet.

The roof over the Passengers' Shed of the Croydon Railway, at London Bridge, is of simple construction, consisting only of tie-beam, principals, and iron suspending-rods, with timber-struts between each two, the tie being suspended at eleven points.

The tie-beams, principals, and struts being framed together, the suspending-rods are introduced, and screwed up by nuts upon their lower ends, until the whole is firmly united. The tie-beams camber 6 inches in the centre. There are 14 of these trusses, 12 feet 6 inches apart, connected by the ridge-piece and purlins. These extend to within 25 feet of either end, where a half-truss of similar construction is framed into the centre of each extreme truss at right angles to the same, to form the hip, with ridge-pieces as usual. The whole is covered in with 1¼-inch rough boarding, upon which zinc is laid and joined. The under side of the roll that covers the joint is grooved to admit the edges of the zinc, and the angle next it rounded, to allow the zinc to expand or contract. The rolls are painted, and are sometimes covered with zinc or lead.

The entire length of the Passengers' Shed (to which this roof belongs) is 212 feet, and 53 feet wide. There is room for about 24 carriages, which is divided into three lines of rails ; the outer lines being for the arrival and departure of trains, and the centre line for spare carriages. On each side of the shed is a platform raised nearly level with the floor of the carriages, 11 feet wide, and connected at the end; this is covered with asphalte, and coped next the rails with stone. In the centre of the shed is a carriage-truck, that moves transversely to the rails, for the purpose of shifting carriages from one line to another, when any extra are required in a train. Between the rails of each line (170 feet in length) the ground is sunk between walls a sufficient depth to enable workmen to get at the under side of the carriages and engines when required.

The roof of Christ's Hospital is well worthy consideration. It covers an area 51 feet wide by 187 feet in length, and consists of principal trusses running across the building, with smaller longitudinal trusses between every two main trusses, to carry the rafters. In the main truss the tie-beam is suspended from five points by king and queen-posts, which are however of iron, and bolted through the tie. Between the two innermost queen-posts, or suspenders, is a straining-beam, which abuts against their heads and is also bolted to the principals ; its length is 16 feet, and it is supported at two intermediate points by struts from the feet of the queen-posts ; there is also another strut for the other side of the post to the head of the further or outermost one. The extremities of the tie-beams and rafters rest in iron shoes, and partially upon cast-iron standards supported on stone corbels 10 feet below the ceiling line.

The five longitudinal trusses, to support the main rafter between the principal trusses, is extended from each queen-post in one cross truss to the corresponding one in the next; the distance between the main trusses, and therefore the length of the tie-beams, being 17 feet. These are simple king-post trusses without struts, and carry the main rafter on top of the king-post, which, in this case, is of timber, bolted to the tie-beam. Filling-in beams are placed between these trusses to receive the ceiling-joists. The scantlings of this roof are as follow :—

Principal truss :

Tie-beam, 14 inches by 14 inches.

Principal rafters outside the innermost queen-posts, 12 inches by 9 inches at lower end ; 10 inches by 9 inches at upper end.

Principals within and above the innermost queen-posts, 9 inches by 9 inches.

Straining-beam, 12 inches by 9 inches.

Struts, 6 inches by 6 inches, (longitudinal trusses.)

Tie-beams, 12 inches by 7 inches.

King-post, 6 inches by 6 inches.

Struts, 6 inches by 6 inches.

Main rafters between trusses :—

At lower ends, 12 inches by 7 inches.

At upper end, above queen-posts, 9 inches by 7 inches.

Common rafters, (longitudinal) 7 inches by 5 inches.

The roof over Exeter Hall is of simple construction, the span being not less than 76 feet, and the height of the roof from the underside of the tie-beam, 21 feet 6 inches; the trusses are placed at alternate intervals of 2 feet 6 inches, and 9 feet.

Each truss has the tie-beam, which is scarfed, suspended in six points by queen-posts, the innermost pair being provided with a straining-beam; and with auxiliary rafters on the other side of them, each of which is supported by two struts resting on the foot of the queen-posts. The two outermost queen-posts on either side are hollow, and are suspended from the principal rafters, as are also the inner ones, by means of straps. The straining-beam, which is 22 feet long, is suspended from the apex of the principals by a king-post, from which struts are raised to shorten the bearing of the principals. Two sloping timbers but against the feet of the inner queen-posts, from the apex of which an iron suspender is bolted to the tie-beam. The ends of the tie-beams and principals rest in iron shoes. The scantlings are:—

Tie-beams, 14½ inches by 7½ inches.
Principals, 8½ inches by 7½ inches.
Auxiliary rafters, or under principals, 14 inches by 7½ inches.
Inner queen-posts, 8½ inches by 7½ inches.
Outer ditto, 10 inches by 4½ inches.
Intermediate ditto, 12 inches by 4½ inches.
King-post, 6 inches by 7½ inches.
Straining-beam, 14 inches by 7½ inches.
Braces, 7½ inches by 7½ inches.
Upper ditto, 6 inches by 7½ inches.
Purlins, 7½ inches by 4 inches.
Common rafters, 5 inches by 2½ inches.
Ridge-piece, 8 inches by 3½ inches.
Wall-plates, 13½ inches by 6½ inches.
Pole-plates, 12 inches by 4 inches.

The truss over the arched roof of St. George's Hall, Liverpool, which is 65 feet in width, is of very simple construction. The tie-beam is sustained at five points by a king-post and four queen-posts. The principals have auxiliaries under them, but do not meet at an apex, reaching only as far as the inner queen-posts, which are kept apart by a double straining-beam at top, and by another at their feet. Struts are placed between the head of the king-post, and feet of the queen-posts, and thence again to the head of the outer queen-posts.

Having given these descriptions of various kinds of roofs, it will not be out of place to give some rules for finding the proper scantlings of the different members, as determined by Tredgold, and the manner in which each member is affected.

King-Post.—The king-post is intended to support the ceiling, and by means of the braces, to support part of the weight of the roof. The weight suspended by the king-post, will be proportional to the span of the roof; therefore, to find the scantling:

Rule.—Multiply the length of the post in feet, by the span in feet. Then multiply this product by the decimal 0.12 for fir, or by 0.13 for oak, which will give the area of section of the king-post in inches; and this area divided by the breadth, will give the thickness; or by the thickness, will give the breadth.

Queen-Posts.—Queen-posts and suspending-pieces are strained in a similar manner to king-posts, but the load upon them is only proportional to that part of the length of the tie-beam suspended by each suspending piece or queen-post. In queen-posts, the part suspended by each is generally half the span.

Rule.—Multiply the length in feet, of the queen-post or suspending piece, by that part of the length of tie-beam it supports, also in feet. This product multiplied by the decimal 0.27 for fir, or by 0.32 for oak, will give the area of the section of the first in inches; and this area divided by the thickness will give the breadth.

Tie-Beams.—A tie-beam is affected by two strains, the one in the direction of the length from the thrust of the principal rafters, the other is a cross strain from the weight of the ceiling. In estimating the strength, the thrust of the rafters need not be considered, because the beam is always abundantly strong to resist this strain; and when a beam is strained in the direction of the length, it rather increases the strength to resist a cross strain. Therefore the pressure of the weight supported by the tie-beams will be proportional to the length of the longest part of it that is unsupported.

To find the scantling of a tie-beam, which has only to support a ceiling, the length of the longest unsupported part being given:

Rule.—Divide the length of the longest unsupported part by the cube-root of the breadth; and the quotient multiplied by 1.47, will be the depth required for fir, in inches; or multiply by 1.52, which will give the depth for oak in inches.

Principal Rafters.—In estimating the strength of principal rafters, we may suppose them supported by struts, either at or very near all the points where the purlins rest upon. The pressure on a principal rafter, is in the direction of its length, and is in proportion to the magnitude of the roof; but the effect of this pressure does not bear the same proportion to the weight, when there is a king-post, as when there are queen-posts; therefore the same constant number will not answer for both cases.

Case 1.—To find the scantling of the principal rafter, when there is a king-post in the middle.

Rule.—Multiply the square of the length of the rafter in feet, by the span in feet, and divide the product by the cube of the thickness in inches. For fir, multiply the quotient by 0.96, which will give the depth in inches.

Case 2.—To find the scantling of a principal rafter, when there are two queen-posts:

Rule.—Multiply the square of the length of the rafter in feet, by the span in feet, and divide the product by the cube of the thickness in inches. For fir, multiply the quotient by 0.155, which will give the depth in inches.

Straining Beams.—A straining-beam is a horizontal piece between the heads of the queen-posts. In order that this beam may be the strongest possible, its depth should be to its thickness as 10 is to 7.

Rule.—Multiply the square root of the span in feet, by the length of the straining-beam in feet, and extract the square root of the product. Multiply the root by 0.9, for fir, which will give the depth in inches.

To find the thickness, multiply the depth by the decimal 0.7.

Struts and Braces.—That part of a roof that is supported by a strut or brace, is easily ascertained from the design; but the effect of a load must depend on the position of a brace; when it is square from the back of the rafter, the strain upon it will be the least; and when it has the same inclination on the roof, the same strain will be thrown on the lower part of the principal rafter, as is borne by the strut. But as the degree of obliqueness does not vary much, we shall not attempt to include its effect in the rule for the scantling.

Rule.—Multiply the square root of the length supported in feet, by the length of the brace or strut in feet, and the square root of the product multiplied by 0.8 for fir, will give the depth in inches, and the depth multiplied by 0.6, will give the breadth in inches.

Purlins.—The stress upon purlins is proportionable to the distance they are apart, and the weight being uniformly diffused, the stiffness is reciprocally as the cube of the length.

Rule.—Multiply the cube of the length of the purlin in feet, by the distance the purlins are apart in feet; and the fourth root of the product for fir will give the depth in inches; or multiplied by 1.04, will give the depth for oak; and the depth multiplied by the decimal 0.6, will give the breadth.

Common Rafters.—Common rafters are uniformly loaded, and the breadth need not be more than from 2 inches to $2\frac{1}{4}$ inches. The depth for Welsh slate may be found by the following rule:

Rule.—Divide the length of bearing in feet, by the cube root of the breadth in inches; and the quotient multiplied by 0.72 for fir, or 0.74 for oak, will give the depth in inches.

The largest roof ever executed was that of the Riding House, built at Moscow, in 1790, by Paul I. Emperor of Russia. The span was 235 feet, and the slope of the roof about 19 degrees. The principal support of this immense truss consisted in an arch or curved rib of timber, in three thicknesses, indented or notched together, and strapped and bolted with iron. The principal rafters and the tie-beams, were supported by several vertical pieces notched to the curved rib; and the whole stiffened by diagonal braces. The disposition of the parts of this roof is extremely ingenious; but it was too slight for the immense extent of the span, and it appears that it settled so much, that it was proposed to add another curved rib to the original design. This example affords an instance of the impropriety of adding material so near to the neutral line of the framing; a like want of attention to principle is sometimes found in a first design; a roof designed by Bettancourt for a riding-school, as given by Krafft, is an example. The external dimensions of the building were 1,920 feet by 310 feet; it was lighted from the top by a lantern; and there was a gallery round the inside of the building for spectators. The method of notching the timber in the curved rib, is objectionable, on account of the danger of the splitting of the timber under a considerable strain. This system of trussing is termed the *bow suspension truss*, and has been much used of late for bridges for railway-works.

Of a somewhat similar construction are the roofs executed by Philibert de Lorme, in the sixteenth century, which are constructed with a series of arched timber ribs in lieu of trusses, these ribs being formed of planks in short lengths, placed edgewise, and bolted together in thicknesses, the planks in one thickness breaking joint with those in the adjoining thickness.

A fine example of this class of roof was that constructed over the Halle au Blé, at Paris, 120 feet in diameter, which has been destroyed by fire.

A smaller example, but nearer home, is to be found over the central compartment of the Pantheon, Oxford-street; the span measures 38 feet. The roof is circular, and is supported by nine semicircular ribs. Each rib is in three thicknesses; the middle thickness is of teak, the side thicknesses or flitches are of fir; the pieces of timber forming these thicknesses are scribed on the under side to the curve of the roof, (and ceiling,) but the top edge is left straight; therefore at their abutting ends they are considerably broader than at their middle. Each abutment of every piece, throughout every rib, has a shoe of cast-iron interposed. Iron bolts connect the three thicknesses together at each end, with a washer connecting each pair of bolts, as explained on the section. The ribs rest alternately on the pillars, (hereafter described) and on the centre of the longitudinal plate extending the whole length of the roof. In the former case the ribs are framed into strong upright pieces, which become the king-post of a semi-truss. These semi-trusses, besides carrying the timber of the roof and ceiling over the galleries, are calculated to receive the lateral thrust of the semicircular roof, a large cast iron shoe laid upon a stone template, receives the end of the tie-beam of these semi-trusses next the outer wall; the object of this shoe being to prevent the possible decay of this end of the beam from affecting the stability of the roof.

There is also a cast-iron shoe receiving the other end of this beam, which is formed with sockets and flanges, so as to receive and connect together the king-post and tie-beam of the above named semi-truss, and the longitudinal plate alluded to above, and the head of the great iron upright or pillar. The chief use of this iron shoe is to prevent the lateral compression of the timbers, and to prevent the natural shrinkage of the horizontal plate from letting down the roof.

The intermediate ribs (those which do not rest on the iron pillars) rest on another iron shoe, which is fitted on to the head of an upright piece that rests on the centre of the longitudinal plate; but the bearing is thrown on to the iron pillars by stout braces framed into the said upright piece and longitudinal plate.

It will thus be seen, that throughout the skeleton of this roof there is no case of any important timber resting with its *end* upon the *side* of any other piece, but that they all bear with an *end-grain* abutment, so that the cracks and failures arising from the necessary shrinkage, as well as from the lateral compression of the timbers, are avoided. This was a precaution rendered necessary by the very large scantlings of the timbers, and by the discharge of the whole weight of roof and ceiling being thrown on so few points of support. The circular part of the roof is covered with copper laid on diagonal boarding, which is supported on rafters notched on to the great ribs, and running longitudinally. The roofs over the sides or galleries are slated, with a flat plaster ceiling; the ceiling of the circular part is deeply panelled, the main ribs forming the core for the cradling. The enrichments are of papier maché, a material that was well adapted for the large architectural ornaments, from its lightness, and from the safety with which it could be screwed up to the timbers.

The longitudinal plate above alluded to consists of two pieces of fir, each 12 × 6, bolted together: the bearings between the iron pillars are reduced by braces, which discharge the bearing on to the iron pillar, and at the same time receive the wood cradling for the spandrels. Each end of this plate is let into the wall, and is received by a corbel of teak wood, on to which it is bolted and locked down.

A considerable improvement upon the system of Philibert de Lorme was effected by Colonel Emy, a French engineer, in the early part of the present century, by the employment of *laminated* ribs. The principal difference between the two consists in this, that in Colonel Emy's improvement the direction of the fibres of the wood coincides with the curvature of the rib, and in consequence the joints are much less frequent, and the rib possesses greater elasticity, so as slightly to yield, rather than break, under any violent strain. The alternate thicknesses break joint, as in De Lorme's roof, and all are securely bolted together.

The earliest roof constructed after this fashion was at Marac, near Bayonne, in 1825. The span is 65 feet, and the main ribs are formed of planks bent round on templates to the proper curve, and kept together by iron straps, and also by the radiating struts which support the principals; they are in pairs, notched out so as to clip the rib between them. In this roof the entire weight of the roof is thrown on the walls at the feet of the ribs, which are considerably below the principals, so that the weight of the upper part of the walls serves to diminish the effect of any thrust against the lower part of the walls. A great saving of wall-material is hereby effected.

This principle has often been applied in the case of railway bridges, and there is at present one erecting at the London terminus of the Great Northern Railway. In this instance the spandrels are of cast-iron.

Of somewhat similar construction is the roof over the transept of the Great Exhibition building. The principals, or main ribs, of which are placed at intervals of 24 feet from centre to centre, and are made up of three planks, two of 2 inches in thickness, and the middle one 4 inches thick, with a moulded piece on the under side $2\frac{3}{8}$ inches thick, and two 11-inch planks at the top, each one inch thick, and nailed together to form the gutter-board, the whole being firmly connected together by wrought-iron bolts passing through belts of the same material, running at top and bottom of each rib. In order to form the ribs with the proper curvature, each plank, $13\frac{3}{4}$ inches wide, was cut on one edge to its proper segmental form, and the two complements cut off were nailed to the lower or straight edge of the flank; the whole being put together, so as to breach joint throughout, the length of each section so cut being about 9 feet 4 inches. The preparation for the reception of the ends of the purlins was on this wise: the two wide planks were cut across, so as to form a cavity to admit the ends of the purlins, the parts of the planks thus separated being connected together by cast-iron plates. The openings thus made were filled in temporarily with wooden blocks, until the joiners were ready to fit in the ends of the purlins.

The strength of every purlin has been duly calculated, according to its relative position in the arch; thus, the three uppermost purlins, having the greatest strain on them, are each $13\frac{1}{2}$ inches in depth by $4\frac{1}{2}$ in width; while the four lower purlins on each side, having gradually less strain to bear, diminish regularly in depth to 9 inches, all having the same width as those at the crown; whereas, the lowest one on each side of the arch, being nearly horizontal, is increased to a scantling of 8 inches by $6\frac{1}{4}$ inches.

Between each pair of main ribs are two intermediate ribs, or, as called in ordinary roofing, common rafters, 4 inches deep by 3 inches wide. On the top of these are gutter-boards, in two thicknesses, as those described for the main ribs. The gutters, each 5 inches wide, are formed by two splayed fillets, let into and nailed securely to the upper side of the boards. These fillets also serve as abutments for the skylight bars, which are rather larger in section and size, as those for the skylights in other parts of the building. Each bar is nailed at the lower end to the fillet, and at the upper end to the ridge-piece, which is formed of three pieces of fir, one above another, the lower section being 4 inches wide by $1\frac{1}{4}$ thick; the middle piece, 3 inches by $\frac{13}{16}$ths inch; and the upper piece, 2 inches by $1\frac{3}{8}$ths inch, the latter having a groove on each side to receive the glass. The three thicknesses are necessary, in order to suit the curvature of the arch. The lower end of each ridge-piece is carried down to, and rests on, the lead flat. Condensation-gutters are formed in this roof, as in the roofs of the aisles and avenues, but by a different method. A sloping fillet is nailed on to each side of the gutter-board, and continued from the springing of the arch on one side, to the corresponding point on the other. With a view to retain the ridges in their places, wrought-iron rods of $\frac{3}{8}$ inch diameter, extend from the purlins to the under side of the ridges. In order thoroughly to carry off the rain-water from every part of the roof, all the skylight bars are fixed diagonally from the ridge to the gutter, and the water collected in each curved gutter, is carried into a sloping trough at bottom, and thus discharged on to the lead flat, which is sloped towards the water-heads at tops of the hollow columns. Looking at the roof from the lead flats, the whole has a herring-bone appearance.

Temporary ladders, fixed to suit the arched roof, were used for fixing the ridge-pieces, skylight bars, &c.; but, in order to facilitate and expedite the glazing of this roof, travelling scaffolds were used, which could be raised and lowered at pleasure, by means of ropes and pulleys, and by the power of four men working a crab engine, placed on the lead flat contiguous. Each travelling scaffold is formed with sides and ends, and has boxes, in convenient positions, for the glass, putty, and tools; the whole running on small friction rollers, suited to the tops of the ridge-pieces, which serve as rails: without such a contrivance, the glazing of the roof of the transept would have been almost an endless job.

The vertical supports for the roof consist of cast-iron columns placed one above another in three tiers, sixteen in each tier on either side. Above the top pier are fixed the trussed girders, 3 feet in depth, spanning from column to column, which are each 24 feet from centre to centre; and across the intersecting lines of the middle arch, are two double trussed girders, 6 feet in depth, and corresponding in length with three spaces of 24 feet each; except under the columns of the south-east angle of the transept, the whole are placed on broad base plates, which rest on concrete foundations. In the exceptional case, the foundation consists of a solid brick pier, built in cement. At the top of each column which supports the roof, is a cast-iron socket, 4 feet 4 inches in height. The use of these sockets is to receive what may be termed the vertical legs or supports of the ribs, and which form parts of the ribs as framed together on the ground. In order to resist the lateral thrust of the roof, a strong gangway, 24 feet wide, is formed on each side of the transept, which may be considered as an abutment, being constructed of strongly-framed and braced flooring, supported by trussed girders. The main ribs have their bearing immediately above the columns, the intermediate ones on the girders between the columns.

The following is a description of a system of construction in roofs, invented by M. Laver, architect to the king of Hanover. It is also applicable to bridges, and similar works.

This new principle consists in a combination of the two principal forces of materials—that of resistance to compression and resistance to tension. The first of these forces has been used from the remotest periods in the construction of bridges, and arches in general; the second has been more lately employed—at least in Europe—for the construction of suspension bridges by the application of chains. The first requires great masses of materials and strong abutments; the second requires less materials than the first, but secure fastenings, for the chains are frequently obtained with difficulty. Very sensible vibrations and undulations are experienced where this last mode of construction is employed.

The disposition of the principal parts of this truss is, that of two segments of a circle, placed with the concave sides opposite each other, and tied together at the extremities, being further connected together, or rather kept apart, from each other, by vertical and diagonal struts. Imagine two bows so disposed; it will be perceived, the chain a k g, fastened at the extremities of the upper bow, acts with the positive force of tension, which the strongest materials possess, varying from 10 to 20,000 lbs. for every square inch of the transverse section of the several kinds of wood employed in construction, and from 20 to 100,000 lbs. for the several metals.

The bow, a d g, by its resistance to compression, serves to prevent the chain, a k g, from contracting or drawing together the extremities a and g. The lower bow a k g, acting as a chain, prevents the upper bow, a d g, from pushing or pressing out at the points of support. The vertical and diagonal struts unite in a firm manner the two bows, and the two forces thus neutralized form a complete whole, that sustains itself, and can neither thrust out nor draw in.

It must be observed, first, that the strength of the chains, which act in a similar manner to that of suspension bridges, depends upon the depth of the versed sine, and that the more they deflect below the horizontal line, or chord of the arc, the stronger they would be; secondly, that the upper bow, owing to the elasticity of the material, must absolutely have the convex form; so that, when any great sudden weight is thrown on it, causing the lengthening of the chains by tension, and the shortening of the upper bow by compression, the upper bow may not be reduced to a horizontal line, a n g, beneath which it could no longer serve by resistance to the statical equilibrium of the construction; thirdly, that the method of combining the extremities, a and g, of the bows, must depend upon the materials employed: for instance, in a wooden bridge, the notching and scarfing at the joints of the different pieces of wood ought to be calculated and executed to the force which they have the power of resisting. The rules and forms most applicable to these joints have also been proved by the experiments of the inventor.

This system of construction is applicable to roofs and bridges of every denomination, such as draw and swing bridges, but especially for suspension bridges, where the locality on either side, or on both, does not admit of secure fastenings for the chains. For covering large rooms, riding-schools, and other openings of large space, it is particularly useful; also the erection of scaffolding, and ladders of large dimensions, and to the stiffening of beams, masts, and supports in general.

The application of this system to roofs and floors of large span, is extremely economical and useful, and by simple modifications serves for the covering of large spaces, without any intermediate points of support, and also presents this farther advantage, that from its vertical pressure, it requires no other support than walls of moderate thickness. When applied to floors, bridging-joists will remedy the inequality of the surface in the beam itself. In roofs of larger span, the posts may be continued upwards, so as to receive the purlins, and when continued downwards, serve to hold up the ceiling, whether flat, vaulted, or mixed.

The open Gothic roofs of the middle ages, differing as they do in essential matters of construction from those at present in use, ought not to be passed over in silence. In many, if not the majority of such roofs, tie-beams were altogether dispensed with; the only tie between the principals, to prevent their spreading, consisting of a collar-beam placed high up in the roof. So much care, however, to prevent spreading, in these roofs, was not required; for the principals were laid at a high pitch, and therefore had not so much tendency to thrust outwards, as a roof of modern construction; beside which, the walls were built of very great thicknesses, and were often strengthened by massive buttresses. Sometimes, in lieu of a collar-beam, two cross-braces were used springing at about half way up the principals, and intersecting each other in their course upward to the opposite principal, and occasionally these and the collar-beam were employed in the same roof; not unfrequently we find the collar strutted up from the rafters. Sometimes again, the principals rest on arched beams or planks, of which some are carried down the walls, and rest on corbels projecting from them; by this means, the thrust is carried down lower, and you gain the advantage of the weight of the walls above, to resist it.

Sometimes tie-beams are used, which are usually of large scantling, and have the upper surface sloped upwards to the centre, so that the depth there is greater than at any other part. Occasionally, upon the centre of the tie-beam is placed a post, from which spring branches to prop up the collar beam, and sometimes the rafters also. This post must not be confounded with the king-post of modern roofs, for it is not used to hang up the tie-beams, but rests upon the tie-beams to support the upper part of the roof.

Such were the most usual form of roofs in the earlier Gothic examples; but at a later time, when the pitch of the roof was lowered, other methods were adopted. Sometimes, merely a horizontal beam was thrown across the upper side, being formed into two inclined planes similar to the tie-beams mentioned above; at others, inclined rafters were used with their ends resting upon upright posts, placed against the walls and resting on projecting corbels at a distance from the top of the walls, the rafters being connected with it by a curved strut, so as to prevent deflection of the rafters near the centre. The upright posts are termed pendant posts, and the struts are often cut out of thick planking, so forming solid spandrels.

Frequently a horizontal beam is laid across the roof on top of the pendant posts, supported by curved struts as before, and above this, rafters are introduced, strutted up in the centre from the horizontal beam. Where the pitch is somewhat higher than usual, inclined struts are added to the central strut, so as to divide the bearings of the rafters. This kind of roof is very similar in appearance to a king-post truss, but this is not the case; that which has the appearance of the king-post, not being employed to suspend the tie-beam, but to support the rafters.

The hammer-beam roofs so common in halls of the 15th and 16th centuries, are of a different description to any of the above. They are usually of a high pitch, and of considerable span, and often bear evidence of very great skill in construction: a simple roof of the kind, consists of two principals connected by a collar-beam, and resting on the ends of two hammer-beams, which project horizontally from the wall and carry two queen-posts. The queen-posts and the collar-beam are usually connected by a curved brace, as are also sometimes the hammer-beams with pendant posts. Of such roofs, the most remarkable are those of Hampton Court and Westminster Hall.

The roof of the great hall, Hampton Court, consists of principals which fall short of the apex, and are secured to a collar or straining-beam at their upper extremities, which is supported by three vertical posts resting on a lower collar-beam, at about halfway down the principals. Under the lower end of the principals, and resting on the top of the walls, is a hammer-beam projecting out about a quarter of the entire space, and supported at its inner extremity by a curved brace, which rests upon a pendant post, and this again upon a corbel projecting from the wall. The hammer-beam carries two uprights, one of which supports the principal rafters, and the other the lower collar, which is still further supported at its centre by a curved brace, which rests upon the extremity of the hammer-beam. A couple of inclined rafters springing from the top of the principals, meet at an apex over the centre of the roof, where they are supported by a strut resting on the collar-beam.

The roof of Westminster Hall has always been much admired; and to its great height and extensive dimensions, must be attributed much of the grandeur of the building. It is, indeed, impossible to enter this magnificent room, without being struck with admiration. An uninterrupted open space, nearly equal to the size of a large cathedral church, is presented in one view, and the scientific spectator, gazing with delight on its lofty roof, admires the elaborate and artist-like arrangement of its timbers. These serving at once the purposes of utility and decoration, and uniting the apparently opposite qualities of massive solidity and airy lightness.

The angle of the roof is formed on what country workmen still term common pitch, the length of the rafters being about three-fourths of the entire span. The cutting off the girders, or tie-beams, which, crossing from wall to wall in common roofs, restrain all lateral expansion, was the first circumstance peculiar to this construction. To provide against lateral pressure, we find trusses, or principals, as they are technically designated, raised at the distances of about eighteen feet throughout the whole length of the building. These trusses abut against the solid parts of the walls between the windows, which are strengthened in those parts by arch-butresses on the outside. Every truss comprehends one large arch, springing from corbels of stone, which project from the walls at twenty-one feet below the base-line of the roof, and at nearly the same height from the floor. The ribs forming this arch, are framed at its crown into a collar-beam, which connects the rafters in the middle of their length. A smaller arch is turned within this large one, springing from the hammer-beam which is level with the base-line of the roof, and supported by two brackets or half-arches, issuing from the springers of the main arch. By this construction of the trusses, each one acts like an arch, and by placing these springers so far below the top of the walls, a more firm abutment is obtained. The main arched rib is constructed of three thicknesses, somewhat after the principle of Philibert de Lorne. From the extremity of the hammer-beam rises a vertical post which supports the end of the collar-beam already alluded to, and this again, by means of two other cubical posts, supports a second collar-beam, and a central or king-post.

Of late years, many roofs have been constructed of iron, a material which at first began to be introduced for particular members, such as tie and suspension-rods, but afterwards became employed for the entire truss, and sometimes for the covering likewise. Iron roofs are for the most part of similar construction to those already described of timber, those members which are subjected to tension, such as ties and suspending rods, being of wrought-iron rods, and those which suffer compression, such as principals and struts, of cast-iron. Such roofs have been very extensively employed in railway works, for the covering of passenger and engine sheds, and such like.

The roof of the passengers' arrival and departure shed at Euston Grove has a very light and elegant appearance; it is constructed principally of wrought-iron, the bressumers, columns, and gutters, only being of cast-iron. The entire width is 80 feet, formed in two spans of 40 feet each, a row of iron columns and bressumers supporting the rafters in the centre and outside, and on the opposite side by iron corbels built in the wall, and further secured thereto by strong bolts and nuts; the rafters are six feet eight inches apart, and are of wrought iron, in form of the letter T; the slate battons, as they may be called, are of angle-iron, firmly riveted to the back of the rafters, at such a distance as the slates require, and to which they are secured by strips of copper. The roof is firmly tied from side to side by a tension-rod of one inch and a quarter diameter, to each pair of rafters, and is further supported and braced by struts of T iron and suspension-rods, with nuts and screws to adjust their length. The entire length of the roof is 200 feet; the gutters are cast in lengths of 10 feet each, joined together by flanges and bolts, and so fixed as to form an incline towards each column, which, being cast hollow, and having a pipe connected with a drain, they form a convenient and easy conveyance for rain from the roof.

The truss consists of two principals—a tie-beam, which is sustained by three suspending-rods and four struts, two on either side; one from the head of the central suspending-rod to the foot of the outer one, and another thence to the principal.

The roof of the locomotive engine-house at Camden Town is of very similar construction to the one above described: the rafters are of T iron, and the slates are supported by angle-iron riveted to the rafters. There are cast-iron chairs secured down to a stone coping on the walls, and from which the rafters spring; each pair of rafters is tied by means of a tension-rod, and otherwise supported and braced by struts of T iron, and suspension-rods of round iron, which make the whole very firm, and gives it a light and pleasing appearance.

Both these roofs were manufactured and erected by Messrs. Cubit, of Gray's Inn Road, under the direction of C. Fox, Esq., now resident engineer to the Company.

Of the numerous roofs of this material which have been erected over railway works, the following examples will give some of the principal varieties. The first, for a roof 30 feet span, consists of two principals, with tie-rod, which is suspended at two points, by two oblique rods meeting at the apex, by which means the king-rod is dispensed with. At the meeting of the suspension-rods with the tie-rod, a strut branches out at right angles to the principal, which it meets at half way. The rafters and rods are connected at the ridge in a separate casting, or the two ends of the rafters may be cast to half lap over each other, and the rods secured by wrought pins and nuts.

The rafters are of cast-iron of the ⊐ section, the dimensions of the lower table or flange being, in the centre of the length, $3\frac{1}{2}$ inches wide, and at the two extremities, $1\frac{1}{2}$ inch, with a thickness of $\frac{1}{2}$ inch; and those of the upper table $2\frac{1}{2}$ inches throughout the entire length, and $\frac{5}{8}$ inch thick. The depth is the same throughout, being $4\frac{3}{4}$ inches.

The tension-rods are 1 inch round at the outer ends, and $\frac{3}{4}$ inch midway; and the oblique suspension-rods $\frac{3}{4}$ inch round throughout.

The second example for the same span consists of two principals and tie-rod, which is suspended at three points by a king-rod and two queen-rods, dividing the bearings into three equal parts: struts rise from the foot of the king-rod to the heads of the queen-rods.

The rafters are formed of two parallel bars, 3 inches by $\frac{1}{4}$ inch, having a wooden rib $1\frac{1}{2}$ inch thick between them. The struts are of T iron, $2\frac{1}{4}$ inches wide over the top table, and $\frac{3}{8}$ inch thick; rib $2\frac{1}{2}$ inches deep, and $\frac{1}{2}$ inch in thickness.

The tension rod is $1\frac{1}{8}$ inch round, the king-rod $\frac{7}{8}$ inch, and the queen-rods $\frac{5}{8}$ inch round.

The timber between the bars in the rafters serves to fix battens for the covering,

The third example is for a roof 35 feet wide, constructed wholly of malleable iron. It consists of rafters and tie-rod, suspended at three points by king-rod and queen-rods, with struts from the bottom of the king-rod to the top of the queen-rods, and from the foot of the latter to the rafters.

The rafters and struts are of T iron, the rafters being $2\frac{1}{2}$

inches, and the struts 2 inches, deep; the rib in both cases being $\frac{3}{8}$ inch, and the top table $\frac{1}{4}$ inch in thickness.

The tie rods are 1 inch round, the king-rod $\frac{3}{4}$ inch, and the queen-rod $\frac{1}{2}$ inch.

The fourth example is for a span of 60 feet, and consists of rafters and tie-rod, suspended at five points by a king and four queen-rods, two on either side. The four struts spring from the feet of the inner suspension-rod to the head of the outer.

The rafters are formed in the same manner as in the second example, of two parallel plates of bar-iron, with plank between; the scantlings are, however, somewhat heavier, the depth of the bar-iron being 4 inches, and its thickness $\frac{5}{16}$. The struts are of T iron, the top table being 3 inches wide and $\frac{1}{2}$ inch deep, and the rib $3\frac{1}{2}$ inches deep and $\frac{3}{8}$ thick.

The tension-rod is of round iron, and is, from the extremity to the first suspension-rod, $1\frac{1}{2}$ inch thick, thence to the second rod $1\frac{3}{8}$ inch, and thence to the king-rod $1\frac{1}{4}$ inch. The king-rod is $1\frac{1}{8}$ inch round, the intermediate $\frac{3}{4}$ inch, and the outermost $\frac{5}{8}$ inch. The fifth example is for the same span, and consists of rafters and tension-rod, suspended at five points by king-rod and four queen-rods, placed closer together than in the last example. There are six struts placed as above, but the last on either side buts against the rafter where there is no queen-rod.

The entire roof is of malleable iron, the rafters of the T-form measuring 3 inches across the top table, which is $\frac{3}{8}$ inch thick, and $3\frac{3}{4}$ inches in the depth of the rib, which is $\frac{1}{2}$ inch in thickness. The struts are also of T iron, the inner ones being $2\frac{3}{4}$ inches wide over the top table, which is $\frac{3}{8}$ inch thick, and $3\frac{1}{4}$ inches in the depth of the rib, which is $\frac{1}{2}$ inch thick. The outer struts are $2\frac{1}{2}$ inches wide over the top table, and $2\frac{1}{2}$ inches in the depth of the rib, the former being $\frac{3}{8}$ inch thick, and the latter $\frac{1}{2}$ inch.

The tension-rods are $1\frac{3}{8}$ inch round near the springing, $1\frac{1}{4}$ inch in the middle, and $1\frac{1}{8}$ near the king-rod.

In all such roofs, it is necessary to strengthen them with iron tie-rods, passing obliquely from the springing to the ridge across one bay, and secured on the under side of the purlins. The distance between the principals varies from 5 to 7 feet.

The roof over the Museum of Practical Geology, Piccadilly, of which Mr. Pennethorne was architect, is entirely of cast-iron, which is somewhat differently applied to any instance we have alluded to. The total width of the building is 67 feet, but there is an intermediate bearing on either side 6 feet from the external wall, thus making the clear width of the roof 55 feet. Each rib is composed of five separate pieces or girders, securely bolted together at the ends; the first piece, one end of which rests upon the wall, and the other on the intermediate bearing, is of a triangular form, with a perforated spandrel; the lower side is horizontal, resting upon the supports, the upper taking the slope of the roof, and the inner one springing from the inner support, with a curve of 5 feet radius, to range with the curvature of the other part of the roof, the radius of which is 48 feet. This girder is 1 foot 6 inches in depth, with a rib on either side in the centre. The next girder is of the same depth throughout, viz. 1 foot 6 inches, and in the cross section has a rib in the centre, and one of less projection at the lower edge; this portion is covered with slate slabs, $\frac{3}{4}$ inch thick. The central girder differs from the rest, being 2 feet in depth, with a flanche at top and bottom, the girder between being perforated for the sake of diminishing the weight; this portion is covered with glass. Each of the girders have abutment plates at the end, by means of which they are bolted together. The total rise or versed sine of the roof is about 12 feet.

The roof over the palm-house, Kew Gardens, is also worthy of description, on account of its exceedingly light and elegant appearance. The total length of this house is 362 feet 6 inches in the clear, the central portion measuring 137 feet 6 inches long, and 100 feet wide, by 63 feet high in the clear, exclusive of the lantern, which is 6 feet. The wings are each 112 feet 6 inches long, and 50 feet wide, and 27 feet high from the floor to the bottom of the lantern. The roof is in this case entirely of wrought-iron, the main ribs being formed of 9 inch deck-beam iron of circular section, hollow at the core, with four double flanges at right angles to each other. These ribs are obtained in lengths of about 12 feet, and are welded together to the required length, about 42 feet, and then bent upon a template to the requisite curvature.

The roof of the wings is of a single span, the rib being curved of a semicircular form, the extremities of which spring from the ground on either side of the plan, and foot into a solid block of granite, upon a concrete foundation. In the main or central building this semicircle is divided into two quadrants, which cover the aisles of this compartment, the lower ends being bedded upon granite, as above, and the upper ends into the tops of strong cast-iron columns which divide the width of this portion of the building into three aisles. From the top of the same columns springs a circular rib, similar to that in the wings, which is again surmounted by a lantern 6 feet in height. From the top of the columns brackets project, which on one side carry a gallery, running round the bottom of the upper roof, and on the other side serve to assist in the strengthening of the ribs. The column heads are connected by a continuous curb of similar scantling to the ribs, and the whole of the ribs are braced together and strutted by wrought-iron tie-rods, passing through cast-iron tubes, which act as purlins. These purlins are formed of a round bar $1\frac{1}{8}$ inch in thickness, welded in long lengths, and passing through the ribs, so as to form a continuous tension-rod all round the house at each purlin, with means of straining them as tight as possible. This tension-bar is covered or enclosed in a tubular bar of wrought-iron, exactly fitting between the ribs, and acting as distance-pieces in opposition to the strain of the tension-rods: thus is the entire structure compacted together. The distance between the main ribs is 12 feet 6 inches, and between the purlins 9 or 10 feet. This is in every respect a very elegant roof, and astonishingly light for so great a span.

The iron roof erected over the railway station at Lime-street Liverpool, is of great span, and of novel and ingenious construction. The area roofed over in one span extends from the façade in Lime-street to the viaduct over which Hotham-street passes, and from the inner faces of the receiving offices to about the middle of the old parcel offices on the opposite side; thus making the extreme length 374 feet and the breadth 153 feet 6 inches. The roof consists of a series of segmental principals, or girders, fixed at intervals of 21 feet 6 inches from centre to centre: these are supported on one side upon the walls of the offices, as far as they extend, and thence to the viaduct, a distance of 60 feet 4 inches, upon a box-beam of wrought-iron, whilst on the other side they rest on cast iron columns. The principals are trussed vertically by a series of radiating struts, which are made to act upon them by straining the tie-rods and diagonal braces; they are trussed laterally by purlins placed over the radiating struts, and intermediately between them, as well as by diagonal bracing, extending from the bottom of the radiating struts to the top of the corresponding struts in the adjoining principal. These diagonal braces are connected with linking plates, by a bar of the same scantling, and also with the purlins already referred to. The curved ribs are thus firmly drawn together and attached to one another, and a rigid framework is formed, upon which the covering of corrugated iron and glass is laid.

Each principal girder is composed of a wrought-iron deck-beam, 9 inches in depth, with a plate 10 inches wide and $\frac{1}{4}$ inch thick, riveted on the top. The upper flange of the deck-beam is $4\frac{1}{2}$ inches wide and $\frac{1}{2}$ inch thick; the lower flange 3 inches wide and one thick: the web is about $\frac{7}{8}$ inch thick. This curved rib is formed of seven pieces connected with each other at the points where the radiating struts are attached, by means of plates riveted on both sides: these plates are 6 feet long, 7 inches broad, and $\frac{7}{16}$ inch thick. The beam is also strengthened at the haunches, for a distance of 27 feet from the springing, by plates 7 inches broad and $\frac{3}{8}$ inch thick, fastened by rivets.

There are 6 radiating struts in each rib, varying in length from 6 feet to 12 feet, the length increasing from the springing to the centre. They are similar in section to the principals, but are only 7 inches in depth, being attached to them, and to the tie-rods, by means of wrought-iron linking-plates. The top of the strut is made to touch the under side of the principal, in which position it is clasped by linking-plates, and secured by a bolt $1\frac{1}{4}$ inch in diameter.

The tie-rods in each rib are composed of three lines of rods between the two extreme radiating struts, and from these struts to the extremities of the principals they are in two lines, the sectional area in each case being the same, viz. $6\frac{1}{2}$ square inches. The ends of the tie-rods, which are prepared with eyes to receive the bolts, are placed side by side between the linking plates, attached to the struts, and a bolt is then passed through them: it will thus be evident, that if any elongation takes place in the ties, the struts will be acted upon.

The diagonal braces extend from the bottom of each strut to the top of one next towards the springing; they hold the struts tight up against the principal, and at the same time assist the tie-rods in their duty. These braces are formed of round-iron, $1\frac{3}{8}$ inch in diameter, secured at top by bolts passing through the linking-plates, and at bottom by wedges, so as to give an opportunity of tightening them up if required.

Each compartment of principals is thus separately trussed and tied, and the whole made fast at the extremities by passing a strap or stirrup iron round the back of a metal chair, in which each end of the girder rests, and to which it is bolted at the side; the jaws of this stirrup-iron are attached to the extremities of the rods by wedges.

The ends of the principals are fixed in cast-iron chains resting on one side of a metal pillar, and on the other on the wall, or upon the box-beam; those upon the pillars are cast upon the upper cap, and those upon the wall and box-girder rest upon two rollers, which can travel a space of 3 inches upon a metal plate, so as to admit of expansion and contraction.

The purlins are each formed by a combination of three T irons, the centre T iron running straight from principal to principal, and those at the sides branching off at 5 feet from each end, so as to strut the girder in three points. The purlins are secured to the deck-beam by angle plates, fixed on both sides, one limb being fixed to the blade of the purlin, and the other to the deck-beam.

In addition to the lateral trussing which the ribs receive from these purlins, diagonal braces are fixed between each two corresponding struts, connected at the top with the purlins, and at bottom with the linking-plates, by bars of their own scantling; thus the ribs are all braced together, and a firm and rigid mass of framing, formed to carry the covering.

The box-beam, upon which a portion of one side of the roof is supported, is 63 feet 4 inches long; 3 feet 2 inches deep at the ends; and 2 feet 6 inches at the centre, the versed sine being 8 inches. The upper chamber is 20 inches wide, and 8 inches deep, and the body is $13\frac{5}{8}$ inches wide, by 1 foot 10 inches deep. The bottom, $19\frac{5}{8}$ inches wide, is formed of two rows of plates, $\frac{8}{16}$ths inch thick in the middle, and $\frac{6}{16}$ths at the ends. The thickness of all the other plates is $\frac{5}{16}$ths inch. On the opposite side of the roof, 17 cast-iron columns, 21 feet 6 inches apart, serve to support the ribs. The columns are 19 feet high from the base to the cap, and 4 feet 3 inches from the cap to the metal chair. At the bottom they are fastened into stones of 5 tons weight each, at 3 feet below the base. The roof is covered with galvanized corrugated wrought-iron and rough plate-glass. The total cost was £15,000.

A patent was taken out recently by Mr. Nasmyth, for improvements in the construction of fire-proof flooring and roofing.

These improvements consist in constructing floors and roofs of iron plates, which are bent into the form of a segment of a circle, or into a conical, polygonal, or other shape, by the ordinary plate-bending machinery, or by any other suitable means. These bent plates are supported on chord plates, or tension-bars which have their ends bent upwards, whereby the plates are retained in their curved position, when subjected to pressure. The ends of the chords rest upon flanges of cast or wrought-iron girders, above which are cast or riveted knee-pieces, which prevent the bent ends of the chords from springing; or, instead of iron-plates, angle, or T iron, bent into the required shape, and supported upon chords resting upon the flanges of girders, may be employed. Over these curved ribs, iron-plates are bent, with their ends placed underneath the bent-up ends of the chords. The spaces above the iron-plates are filled up, to form the flooring with Portland cement, mixed with broken bricks and other suitable materials. The improved girders are formed by bolting iron plates to the sides and tops of stone arches and chords combined as before. The side plates are made with flanges to support the arches and chords which form the joists, and have also knee-pieces bolted to them to prevent the chords from springing, when the arch is subjected to pressure. The arches and chords may be made of one piece each, or may be made of several pieces, and bolted or riveted together.

Allusion has been made in a previous column, to the various materials used for the covering of roofs, with reference to the different degrees of inclination suitable for them. Thatched roofs have been considered by some to maintain the most equable temperature in the buildings covered by them; keeping out alike the extreme heat of summer, and cold of winter. They are objectionable on account of their harbouring vermin, being easily damaged by wind, and dangerously combustible. The frequent repairs required, make thatch also an expensive material. Besides straw, reeds and heath are sometimes used for thatching, and possess the adavntage of greater durability. Tiles admit heat and moisture more than good slates. Pantiles having no holes for nailing through, are simply hung by ledges, upon laths nailed to the rafters. Plain tiles, laid in mortar, and overlapping so as to be double thickness everywhere, make a very good, though heavy covering. Tiles of a peculiar form, called *hip-tiles*, are used for covering salient angles; and *gutter-tiles*, which are similar to them, but placed with the concave side upwards, in the valleys or receding angles. Slates are laid in various ways. They are sometimes nailed down on across boarding: or if large, on *battens*, or pieces of wood from two and a half to three inches wide, and three-quarters of an inch to an inch thick, which are nailed to the rafters at intervals regulated by the length of the slates. Lozenge-shaped slating is occasionally used, and has an ornamental appearance, but is easily injured, as there is but one nail through each slate. It is always laid on boarding. For what is called patent slating, the best large slates are selected, and fixed without either boarding or battening, the common rafters being placed at such a width as to come under the joints. The slates are screwed down, the courses over-lapping about two inches. The meeting-joints are covered by fillets of slate, about three inches wide, set in putty, and screwed down; and the hips and ridges are sometimes covered in the same manner, though it is best, in all such cases, to use lead. Patent slating, when well executed, is water-tight, with as low a slope as one in six. In some districts, laminæ of stone are used in lieu of slates or tiles. Shingles, which are like slates, but made of wood, were formerly much used in covering pyramidal steeples, and in roofs of steep pitch. They are still used in the United States, and are usually laid on boarding, in a similar manner to common slates.

Sheets of metal are very convenient for covering domes, and curved angular surfaces generally, and also for flat roofs, or such as have too little slope for slating. Lead is the most common material for such purposes, though copper, iron, tinned-iron, and recently zinc, are also used. Lead terraces, or flats, are commonly laid on boarding or plaster. The joints are sometimes soldered, but the most approved method is to roll or wrap the edges into each other, making allowance for expansion and contraction. A fall of a quarter of an inch in a foot, is sufficient for surfaces covered with sheet metal.

The weight of lead is somewhat against its use for roof-covering; it is used in sheets weighing from 4 lbs. to 8 lbs. per foot super. Copper is much lighter, and is used in sheets weighing about 1 lb. per foot super, but its expensiveness precludes its adoption for general purposes. Zinc is much lighter than lead, weighing from 12 to 20 ounces per foot super; and of late has been very widely employed on this account, as well as because of its cheapness; it forms a very useful covering. Iron galvanized, or coated with zinc, has also been very extensively used for this purpose, for which it is also well adapted. Sometimes it is corrugated, by which it is considerably strengthened, and thus some of the strength of the roof itself may be dispensed with, especially in small spans, where curved roofs of corrugated iron may be safely employed. Tiles of this material also, are sometimes used; they are treated much in the same way as common tiles, being simply nailed to battens or boarding. The following table, giving the weight per square of 100 feet for different kinds of roof-covering, may prove serviceable:—

	Cwts.
Plain tiles	18
Pantiles	9½
Slating	7
Lead at 7 lbs. to foot super . . .	6½
Corrugated iron	2
Copper or zinc at 16 ounces to ditto.	1

Having now given a description of the several varieties of roofs covering a square or rectangular plan, it may not be improper to give a few examples of domes, and show how they may be constructed under various circumstances. If the dome to be constructed be on a circular plan, with no lantern above, the ribs may be built in the following manner, with planks of convenient lengths, in three or more thicknesses. Having ascertained the length of the ribs, and the number of pieces in that length, and having properly shaped all the pieces to the curve, the middle piece at the bottom may be one of these lengths; to each side may be joined two other pieces, one reaching to a third of the middle piece, and the other to two-thirds from the bottom, so that by continuing with planks of the whole length to the other extremity of the rib, the middle thickness will always be covered two-thirds from the bottom on one side, and one-third on the other; the deficiency at the top must be filled up with pieces, one of a third, and the other of two-thirds, as at the bottom; the whole being well bolted together, and strapped across the joints, will be nearly as strong as a solid rib.

Plate VIII. *Figure* 1, shows the manner of constructing this kind of dome; No. 1 being the semi-plan; No. 2, the elevation; No. 3, the manner of building the rib. In domes of this kind, it may sometimes be necessary to discontinue the ribs, that the spaces may be more equally divided for the horizontal ribs. It is evident that a dome built in this manner, may be carried to almost any extent, provided it have a sufficient number of horizontal ribs. Of this construction is the Halle du Blé, at Paris, of 200 feet in diameter, the invention of a judicious carpenter, the Sieur Molineau, a man of little scientific education, but of considerable mechanical experience. Being convinced that a very thin shell of timber might not only be so shaped as to be nearly in equilibrio, but that, if well connected with horizontal ribs, it would have all the requisite stiffness, he presented his scheme to the magistracy of Paris. The grandeur of the idea pleased them but they referred it to the Academy of Sciences. The members, who were competent judges, were struck with the justness of M. Molineau's principles, and astonished that a thing so plain, had not become familiar to every house-carpenter. It quickly became a universal topic of conversation, dispute and cabal, in the polite circles of Paris. But the Acadamy having given a favourable report of their opinion, the project was immediately carried into execution, and soon completed, and now stands as one of the greatest exhibitions in Paris. The circular ribs, which compose this dome, consist of planks 9 feet long, 13 inches broad, and 3 inches thick, made in three thicknesses, as in that already described. At various distances, these ribs are connected horizontally by purlins and iron straps, which make so many hoops to the whole. When the work had reached such a height, that the distance of the ribs was two-thirds of the original distance, every second (now consisting of two ribs, very near each other,) was discontinued, and the void glazed. A little above this, the heads of the ribs are framed into a circular ring of timber, which forms a wide opening in the middle, over which is a glazed canopy, or umbrella, with an opening between it and the dome, for allowing the heated air to get out. All who have seen this dome agree in describing it as the most beautiful and magnificent object they ever beheld.

The only difficulty in the construction of wooden domes is when they are loaded in the upper part by a heavy lantern, or cupola. Such a dome as has been described would be in danger of being crushed inwardly; the most effectual method of preventing which, is by making the ribs in the form of trusses, with an inclined timber extending from the base of the dome to the bottom of the lantern, connecting the two extremities of the exterior side, forming as it were the base of a truss in a common roof, and acting contrary to the nature of a tie-beam; they resist the vertical pressure of the lantern, without having any tendency to burst out the sides by acting entirely longitudinally on the wall-plate. In order

wn by P. Nicholson.

Engraved by J.C. Buttre.

to secure the lantern, horizontal braces are fixed from the bottom of the lantern to the middle of the principal braces under the joggles, so that the whole is resolved into triangles, which are all immoveable at the angles. The wall-plates should be framed as the ribs of a dome constructed as in the last example.

When a dome is to support a heavy cupola of stone, such a construction as that of the cathedral of St. Paul's, London, may be employed. *Figure* 3, No. 1, exhibits the truss of this dome, taken from accurate measurement. A *a a* A, a dome of brick, two bricks thick, which, as it rises every five feet, has a course of strong bricks 18 inches long, bonding through the whole thickness. B *b b* B is a cone, built with bricks 1 foot 6 inches in thickness, for supporting the heavy cupola above, of Portland stone, which is 21 feet in diameter and near 61 feet high, and also the timber-work of the dome. The horizontal, or hammer-beams, C C, &c. are curiously tied to the corbels, D, D, D, &c. with iron cramps, bedded into the corbels with lead, and bolted to the hammer-beams. No. 2 shows more particularly the manner of tying the hammer-beams to the corbels.

This dome is boarded from the base upwards, and the ribs are therefore fixed horizontally, having their sides in planes tending to the centre of the dome. The contour of the dome is formed of two circular segments, which meet in the axis like a pointed arch. The scantlings of the curve rib of the truss are 10 inches by 11½ at the bottom, and 6 inches by 6 at top. It has a very strong double iron chain, linked together at the bottom of the cone, and several other less chains between that and the cupola. This dome was turned upon a centre, supported without standards from below. As every story of the scantling was circular, and the ends of the ledges meeting like so many rings, and truly wrought, it supported itself; and as it was both centering and scaffolding it remained for the use of the painter, there being a space of twelve feet between it and the dome. This machine, it is said, was original of its kind.

A description of a dome constructed mainly of cast-iron girders, over the cathedral of St. Isaac, St. Petersburg, will be found under the article DOME, to which we must refer for further information on the general subject, as well as to CURB ROOF, VAULTING, MECHANICAL CARPENTRY, &c.

Before concluding this article, we must state that we are much indebted for the descriptions, &c. to *Tredgold's Carpentry*, the *Transactions of the Institution of Civil Engineers*, the *Builder*, and other similar works.

ROOF, *Hipped*, see HIPPED ROOF.

ROOFING, in rural economy, a word sometimes applied provincially to the the ridge-cap of thatched roofs. It also signifies any sort of material employed in forming the roof of a building, whether in the framework or covering. In the business of roofing farm or other buildings, the chief circumstance necessary to be attended to, is that of tying the two side-parts well together, and in a safe manner, by means of the wall-plates and binding-beams; especially in those erections which are of the longer kind, without any cross-walls to stiffen and support them. It has been remarked, that it is generally for want of attention to these matters that farm-buildings, as well as those of other sorts, are so frequently seen propped up with shores and buttresses; or fallen to the ground half a century sooner, perhaps, than they would have done under a better and more judicious management. And it ought, indeed, to be a general principle, or line of conduct, which every careful and intelligent manager should follow in erecting such buildings;—a principle which is equally applicable to the other parts, as well as the timber and the covering;—which is, that of sparing no requisite expenditure, as a few shillings, or pounds, of additional cost in the first instance, may be the saving of ten times the sum in the end.

In the work of repairing buildings of this nature, the roofing claims equally the regard of the manager, with the foundations and other external parts. But the inside works, in all cases, more commonly and properly demand the notice of the occupiers.

ROOM, see APARTMENT, and BUILDING.

ROSE, an ornament applied to the centre of each side of the abacus of the Corinthian capital.

ROSE WINDOW, a circular window, divided into lights by mullions or tracery branching from the centre, and disposed in a variety of different patterns. Windows of this kind are also termed Catherine-wheel and marigold windows.

ROSTRUM (Latin, signifying *a bird's beak*, or *the prow of a ship*), a part of the Roman forum, where in orations, pleadings, funeral harangues, &c. were delivered.

The rostrum was a kind of chapel taken out of the forum, and furnished with a suggestum, or eminence, called more particularly *the rostrum*, where the orators stood to speak.

It was adorned, or, as Livy says, built, with the beaks of ships taken from the people of Antium, in a naval engagement; whence the name.

There are two kinds of rostra; *rostra vetera* and *rostra nova*. The latter was erected by Augustus, and decorated with the prows of vessels which he took at the battle of Actium. The first were those already described.

ROTONDO, or ROTUNDA (from the Latin *rotundus*, round), a popular term for any building that is round both within and without, whether it be a church, hall, saloon, vestibule, or the like.

The most celebrated rotondo of antiquity is the Pantheon at Rome, dedicated to Cybele and all the gods, by Agrippa, son-in-law of Augustus; but since consecrated, by pope Boniface IV., to the Virgin and all the saints, under the title of Sta. Maria della Rotondo.

The chapel of the Escurial, which is the burying-place of the kings of Spain, is also a rotondo; and, in imitation of that of Rome, is also called Pantheon.

ROUGH-CAST, or ROUGH-CASTING, see PLASTERING.

ROUND CHURCH, this appellation is given to a few churches which exist of a peculiar construction, being erected on a plan either simply circular, or circular with a rectangular projection: the circular portion in both cases being that which forms its peculiarity. There are only four such structures in England—the Temple Church, London, which is the largest and most magnificent; the Church of the Holy Sepulchre at Cambridge; one with the same dedication at Northampton; and a small church at Little Maplestead, in Essex. In all these, the round or circular portion bears evidence of greater antiquity than the other parts of the edifice: and there can be no doubt but that the latter are more recent additions to the original structure, which for the most part are employed as a choir, the circular part being retained as the nave. The round consists generally of two, sometimes of three stories, the upper stories being of less diameter than the lower one, and supported on massive piers and arches of Norman-work, by which an aisle is formed all round the interior, between the arcade and the external wall: above the arcade is a triforium, and above this again a clerestory, the roof above being vaulted.

It was at one time held that such buildings had been originally constructed by the Jews for synagogues; but this mistake is now exploded, and it is universally allowed that they were built by the Knights Templars, or Hospitallers, who were engaged in the Crusade to recover possession of the Holy Sepulchre at Jerusalem out of the hands of the infidels, and that the peculiar form was copied from that building. That the form of the church erected over the Holy Sepulchre by the empress Helena was of a circular form, there seems to be every reason to believe, for we have the evidence of written testimony as well as the form of the existing building; and although, no doubt, this has been rebuilt and much altered, by additions and otherwise, since the time of Constantine, still there is sufficient reason to satisfy us that its general form has not been departed from. It would seem very natural, too, that the Crusaders, when they returned from the East, and began to erect new churches, should adopt that form which they had seen employed in the building, for the defence of which they had undergone such labours; the novelty of the form, too, would be likely to attract their attention, and lead to their emulation of it. When, in addition to this, it is considered that no less than two out of the four churches are dedicated under the name of the Holy Sepulchre, there can be little question as to its origin. Further, a third is named the Temple Church; and there is evidence that it was consecrated by Heraclius, bishop of Jerusalem, when he came to England to ask subsidies for carrying on the Crusade; and there was never any question as to its erection by the Knights Templars, who were especially associated for the defence of the Holy Sepulchre at Jerusalem.

Two of these round churches—the Temple, London, and St. Sepulchre's, Cambridge—have, within these last few years, been very creditably restored; especially the former, on which no expense has been spared to restore it to its pristine splendour; it is one of the most spirited and liberal restorations which have been attempted, and reflects great honour upon those by whom it was carried into effect. The second has been also very well and carefully restored by the Cambridge Camden, now the Ecclesiological Society; but it is to be regretted that the effect of the restoration has been partially destroyed by the bigoted introduction of some ornamental accessories, which are totally misplaced in such a building.

ROUND TOWERS. This term is applied to a particular class of towers built upon a circular plan, which are found in considerable numbers in Ireland, and almost exclusively in that country. They are evidently of great antiquity, and have long been a subject of antiquarian dispute. Mr. Petrie has, within the last few years, published a very elaborate work upon the subject, upon which he brings to bear very considerable knowledge and a clear judgment. His general description of the towers is as follows:—

They are rotund, cylindrical structures, usually tapering upwards, and varying in height from 50 to perhaps 150 feet; and, in external circumference, at the base, from 40 to 60 feet, or somewhat more. They have usually a circular projecting base, consisting of one, two, or three steps or plinths, and are finished at the top with a conical roof of stone, which frequently, as there is every reason to believe, terminated with a cross formed of a single stone. The wall towards the base is never less than 3 feet in thickness, but is usually more, and occasionally 5 feet, being always in accordance with the general proportions of the building. In the interior they are divided into stories varying in number from four to eight, as the height of the tower permitted, and usually about 12 feet in height. These stories are marked either by projecting belts of stone, set-offs or ledges, or by holes in the wall to receive joists, on which rested the floors, which were almost always of wood. In the uppermost of these stories the wall is perforated by two, four, five, six, or eight apertures, but most usually four, which sometimes face the cardinal points, and sometimes not. The lowest story, or rather its place, is sometimes composed of solid masonry, and when not so, it has never any aperture to light it. In the second story, the wall is usually perforated by the entrance-doorway, which is generally from 8 to 30 feet from the ground, and only large enough to admit a single person at a time. The intermediate stories are each lighted by a single aperture, placed variously, and usually of very small size, though, in several instances, that directly over the doorway is of a size little less than that of the doorway, and would appear to be intended as a second entrance.

In their masonic construction, they present a considerable variety; but the generality of them are built in that kind of masonry called spawled rubble, in which small stones, shaped by the hammer, in default of suitable stones at hand, are placed in every interstice of the larger stones, so that very little mortar appears to be intermixed in the body of the wall; and thus the outside of spawled masonry, especially, presents an almost uninterrupted surface of stone, supplementary splinters being carefully inserted in the points of the undried wall.

His conclusion, with respect to the use to which such towers were put, and also as to their date and origin, is:—

I. That the towers are of Christian and ecclesiastical origin, and were erected at various periods between the fifth and thirteenth centuries. 2. That they were designed to answer, at least, a twofold use, namely to serve as belfries, and as keeps or places of strength, in which the sacred utensils, books, relics, and other valuables, were deposited, and into which the ecclesiastics, to whom they belong, could retire for security in cases of sudden predatory attack. 3. That they were probably also used, when occasion required, as beacons and watch-towers.

These conclusions, which have been already advocated, separately, by many distinguished antiquaries, among whom are Molyneux, Ledwitch, Pinkerton, Sir Walter Scott, Montmorenci, Brewer, and Otway, will be proved by the following evidences:—

For the first conclusion, namely, that the towers are of Christian origin:—

1. The towers are never found unconnected with ancient ecclesiastical foundations. 2. Their architectural styles exhibited no features or peculiarities not equally found in the original churches with which they are locally connected when such remain. 3. On several of them Christian emblems are observable, and others display in the details a style of architecture universally acknowledged to be of Christian origin. 4. They possess invariably architectural features not found in any buildings in Ireland, ascertained to be of Pagan times.

For the second conclusion, namely, that they were intended to serve the double purpose of belfries and keeps, or castles, for the uses already specified:

1. Their architectural construction, as will appear, eminently favours this conclusion. 2. A variety of passages, extracted from our annals, and other authentic documents, will prove that they were constantly applied to both these purposes.

For the third conclusion, namely, that they may also have been occasionally used as beacons and watch-towers:

1. There are some historical evidences which render such an hypothesis extremely probable. 2. The necessity which must have existed in early Christian times for such beacons and watch-towers, and the perfect fitness of the round towers to answer such purposes, will strongly support this conclusion.

These conclusions, or at least such of them as presume the towers to have had a Christian origin, and to have served the purpose of a belfry, will be further corroborated by the uniform and concurrent tradition of the country, and by authentic evidences relating to the erection of several of the towers, with the names and eras of their founders.

A description of one or two of these towers will assist in giving an idea of their varieties and general character. That at Monasterboice, near Drogheda, is 110 feet high and 17 in diameter; the thickness of the wall is 3 feet 6 inches. The ancient church, which is close to it, is now in ruins. In the churchyard are two very old and curious crosses; one about 18 feet high, covered with sculpture, is called St. Boyne's cross, and is esteemed the most ancient religious relic in Ireland. The round tower at Drumisken, in Louth, is 130 feet high; and that of Kildare 133 feet high and 18 in diameter. The walls of the latter are $3\frac{1}{2}$ feet thick, and are built of fine white granite, to about 12 feet from the ground.

Of the two round towers in Scotland, that at Brechin consists of sixty regular courses of hewn stone, of a brighter colour than the adjoining church; it is 85 feet high to the cornice, whence rises a low pointed roof of stone, with windows, and a vane at the top. The other tower at Abernethy is 75 feet high, and like that of Brechin, is about 48 feet in external circumference. On the front of the tower at Brechin are two arches, one within the other, in relief. On the point of the outermost is a crucifix, and between both, towards the middle, are figures of the Virgin Mary and St. John, the latter holding a cup with a lamb. The outer arch is adorned with knobs, and within both is a small slit or loop; at the bottom of the outer arch are two beasts, couchant, one of them, by its proboscis, is evidently intended for an elephant.

There are some few round towers in France, which some antiquaries are inclined to think similar in origin and employment. The French, however, are unlike the Irish towers. Those of the former are of various figures, principally octagonal, and of moderate heights. The tower of Quineville, called Cheminée de Quineville, is one of these. It is situated within eight leagues of Cherbourg, is hollow throughout, having neither stairs nor floors. It consists of a base, circular within, and 17 feet high, constructed in that style called by the Romans *opus reticulatum;* above this is placed a cylindrical column $11\frac{1}{2}$ feet in height and 20 feet in circumference. The external face is ornamented with Corinthian and Tuscan pilasters supporting an entablature, above which rises a dome, roofed in the form of a truncated cone. Some think that it has served as a pharos, others as a belfry. But it is neither within view of the sea, nor near to any church. There are, however, in France, isolated towers in the vicinity of churches. They belong to the middle ages. In the cemetery of the Innocents' at Paris, is one of an octagon form, surmounted by a dome; it is 44 feet in height and 12 feet in diameter. At Mouthran, near Martignon, is another octagon, 35 feet high and 16 in diameter. The door is 8 feet from the ground. In the cloister of the Monastery des Dames, at Fontevrault, is an ancient tower 76 feet in height and 20 feet in diameter. For our own part, we are not of opinion that these towers, or at least all of them, are of the same origin as those in Ireland.

RUBBLE-WORK, a rough, irregular kind of masonry.

RUDENTURE, (from the Latin, *rudens*, a rope,) the figure of a rope, or staff, sometimes plain, sometimes carved; with which a third part of the fluting of columns is frequently filled up. It is by some called a cabling; and the columns, whose flutings are thus filled, they call rudented or cable columns. There are also rudentures in relievo, laid on the naked of pilasters, not fluted; an instance of which we have in the church of S. Sapienza at Rome.

RUDERATION, (from the Latin, *ruderatio*,) in building, a term used by Vitruvius for laying a pavement with pebbles or little stones. To perform the ruderation, it is necessary that the ground be first well beaten, to make it firm, and to prevent its cracking. Then a stratum of small stones is laid, to be afterwards bound together by mortar made of lime and sand, called by Vitruvius *statumen.* If the sand be new, its proportion to the lime may be as three to one; but if dug out of old pavements, or walls, as five to two.

Ruderation, Davilier observes, is used by Vitruvius, lib. vii. cap. 1, for the coarsest and most artless kind of masonry; where a wall is, as it were, cobbled up.

RUINS, (from the Latin *ruina*,) a term particularly used for magnificent buildings fallen to decay through lapse of time, and of which there only remains a confused heap of materials. Such are the ruins of the Tower of Babel, or the Tower of Belus, two days' journey from Bagdad, in Syria, on the banks of the Euphrates; which are now no more than a heap of bricks cemented by bitumen; and of which we only perceive the plan to have been square. Such also are the ruins of a famous temple, or palace, near Schiras in Persia, which the antiquaries will have to have been built by Ahasuerus; and which the Persians now call Tchelminar, or Chelminar; *q. d.*, the forty columns; because there are so many columns remaining nearly entire, with traces of others; a great quantity of basso-relievos, and unknown characters, sufficient to show the magnificence of the antique architecture. The ruins of Palmyra may also be reckoned in the class of famous ruins.

RULE, or Ruler, (from the Latin, *regula*,) a very simple instrument, ordinarily of hard wood, thin, narrow, and straight, serving to direct the drawing of right lines. The rule is of principal use in all the mechanical arts. To prove whether or no it be just, draw a line by it on paper; then turn the rule about, the right end to the left, and apply the same edge this way to the line; if the edge now agree exactly with the line, the ruler is true.

The stone-cutter's rule is usually 4 feet long, and divided into feet and inches. The mason's rule is 12 or 15 feet long, and is applied under the level to regulate the courses, to make the piedroits equal, &c.

Rule, *Parallel.* See Parallel and Instruments.

Rule, is also applied to certain instruments which have other considerable uses besides that of drawing lines. Such are carpenter's joint-rule, Everard's and Coggeshall's sliding-rules, &c.

Rule, *Carpenter's Joint,* an instrument, usually of box, 24 inches long, and $1\frac{1}{2}$ broad, each inch being subdivided into eight parts; on the same side with these divisions is usually added Gunter's line of numbers. On the other side are lines of timber and board-measure, the first beginning at $8\frac{1}{2}$, and continued to 36, near the other end; the latter is numbered from 7 to 36, 4 inches from the other end. The division of the timber-line is formed from a consideration that 1,728 inches make a solid foot, in the following manner:—thus, 9 is so placed against one of the divisions of inches, or parts on the other side of the rule, beginning from the right hand, that its square, which is 81 inches multiplied by that number of inches and parts, must make 1,728 inches; which, dividing 1,728 by 81, must be placed against $21\frac{1}{3}$ from the right-hand; and 10 must be placed against $17\frac{28}{100}$ inches; because 1,728, divided by the square of 10 or 100, gives $17\frac{28}{100}$, &c. But, because a square, whose side is 1,2, &c., to 8 inches, requires more than 24 inches in length, as a multiplier, in order to produce 1,728 inches; and since the length of the rule is only 24 inches, there is a table upon the left end of it, which supplies its defect of length. In this table, the upper row of figures, viz., 1, 2, 3, 4, 5, 6, 7, 8, denotes inches, or the lengths of the sides of squares; and the second and third rows are the correspondent feet and inches to make up a solid foot. It is made by dividing 144 inches by the squares of 1, 2, 3, 4, 5, 6, 7, 8.

The line of board-measure is thus divided: suppose the division 7 to be marked; divide 144, the number of inches in a square foot, by 7, and the quotient will be $20\frac{4}{7}$ inches; whence the division 7 must be against $20\frac{4}{7}$ inches on the other side of the rule. To mark the division 8, divide 144 by 8, and the quotient, which is 18 inches, must be placed on the line of board-measure against 18 inches on the other side, &c. But because the side of a long square, that is, 1, 2, 3, 4, 5 inches, requires the other side to be more than 24 inches, the whole length of the rule, there is a table annexed, formed by dividing 144 inches by each of the numbers in the upper row, and then each of the quotients by 12 to reduce into feet.

Rule, *Use of the Carpenter's Joint.* The application of the inches in measuring lengths, breadths, &c., is obvious. That of the Gunter's line, see under *Gunter's Lines*, in the article Instruments. The use of the other side is all we need here illustrate.

1. *The breadth of any surface, as board, glass, &c. being given; to find how much in length will make a square foot.*—Find the number of inches the surface is broad, in the line of board-measure; and right against it, on the inches side, is the number of inches required. Thus, if the surface were 8 inches broad, 18 inches will be found to make a superficial foot.

Or, more readily, thus: Apply to the breadth of the board or glass, that end of the rule marked 36, laying it even with the edge; the other edge of the surface will show the inches and quarters of inches which go to a square foot.

To find the content of a given surface: Find the breadth and how much makes one foot; then turn that over as many times as you can upon the length of the surface, and so many feet does the surface contain.

2. *Use of the table at the end of the board-measure.*—If a surface be one inch broad, how many inches long will make a superficial foot? Look in the upper row of figures for 1 inch, and under it, in the second row, is 12 inches, the answer to the question.

3. *Use of the line of timber-measure.*—This resembles the former; for, having learned how much the piece is square, look for that number on the line of timber-measure; the space thence, to the end of the rule, is the length, which, at that breadth, makes a foot of timber. Thus, if the piece be 9 inches square, the length necessary to make a solid foot of timber is $21\frac{1}{3}$ inches. If the timber be small, and under 9 inches square, seek the square in the upper rank of the table, and immediately under it are the feet and inches that make a solid foot. Thus, if it be 7 inches square, 2 feet 11 inches will be found to make a solid foot.

If the piece be not exactly square, but broader at one end than the other, the method is, to add the two together, and take half the sum for the side of the square. For round timber, the method is, to girt it round with a string, and to allow the fourth part for the side of the square. But this method is erroneous; for hereby above a fifth of the true solidity is lost. *See* Sliding Rule, and Timber.

Rule, *Bow. See* Ship Carpenter's Rule.

RULER, *Parallel. See* Instruments.

RUSTIC, a mode of building in imitation of simple or coarse nature, rather than according to the rules of art.

Rustic Chamfered, that when the face of the stones are smoothed and parallel to the surface of the wall, and where the margins are bevelled, at an angle of 135 degrees with the face of the stone; and as the joints are at right angles to the faces, the margins will also be at an angle of 135 degrees with the joints: so that, when two rustics come together, the bevelling, or chamfering, will form an internal right angle.

Rustic Coins, (by Vitruvius called *lapides minantes*,) the stones which are frequently placed at the external angles of buildings, so as to project beyond the naked of the wall; the edges being either bevelled, or the margins recessed in a plane parallel to the face or plane of the wall. The recesses, which are at the joints, have, therefore, three sides; one in the plane of the wall, or parallel thereto; and the other two generally perpendicular to the said plane. Rustic coins were much in use about eighty years ago, particularly in brick buildings. *See* Quoins.

Rustic Frieze. *See* Frieze.

Rustic Order, an order decorated with rustic quoins, rustic work, &c. Felibien says, it is properly where the several parts of the five orders are not exactly observed; but this confounds rustic with Gothic.

Rustic Work is where the stones in the face, &c. of a building, instead of being smooth, are hatched or picked with the point of an instrument.

The most coarse or common kind of rustic work, is that where the edges are simply cut about one-half or two-thirds of an inch round the margin, so as to be in the plane of the wall, or parallel to the said plane, and the intermediate part is broken with the hammer, so that the protuberant parts may project generally about an inch beyond the margin.

The recesses of rustics either run with the horizontal joints only, and have, therefore, the appearance of boards placed at small intervals; and sometimes the recesses run with both the horizontal and vertical joints; and, therefore when disposed in this manner, they have the appearance of projecting tablets.

Rustic Work, *Frosted*, that where the margins are reduced to a plane, parallel to the plane of the wall, and where the intermediate part has the effect of ice, with an irregular surface in protuberant parts.

Rustic Work. *Vermiculated*, that where the margins are reduced to a plane parallel to the face of the wall, and where the intermediate part of the stone, or general surface, is so formed as to have the effect of being eaten by worms.

S.

SACELLUM, in Roman antiquity, denoted a place sacred to the gods, without a roof.

SACRARIUM, a small family chapel in a Roman house, also the place in temples in which sacred things were deposited.

SACRINGE, or SANCTUS BELL, a bell to be found frequently over the eastern or chancel end of a church, supposed to have been rung at the elevation of the host.

SACRISTY, or VESTRY, a room attached to a church, in which the sacred vessels, vestments, and other valuables, are deposited.

SADDLE-BACKED-COPING. Coping weathered on both sides, having two sloping tables on the top, falling from a central ridge.

SAG, or SAGGING, the bending of a body that would be straight in a vertical position; but, when included, or laid horizontallly upon supporters at each end, becomes curved in the middle, from its own gravity: in which case it is said *to sag*.

SAGITTA, in architecture, a name sometimes used for the key-piece of an arch.

SAGITTA, in geometry, a term used by some writers, for the abscissa of a curve.

SAGITTA, in trigonometry, &c. the same as the versed sine of an arc; and so called by some writers because it is like a dart, or arrow, standing on the chord of the arc.

SAINT PETER'S, a celebrated church, at Rome, better known by the name of *Basilica Vaticana*, from its original form, and the Vatican hill, on which it stands, founded by Constantine the Great, over the reputed grave of St. Peter, to whom it was also dedicated. In the days of Paganism, the circus of Caius, afterwards of Nero, stood upon its site; and when Constantine, urged by Sylvester I., bishop of Rome, determined upon erecting this basilica, he destroyed the circus, and began himself to dig the foundation, carrying away, on his shoulders, twelve troughs of the earth, in honour of the twelve apostles. *See* BASILICA. Some of the walls of the circus were, however, permitted to remain, and were used for the basilica, in order to accelerate its completion: a quantity of marble was also taken from various ancient buildings, for its decoration, and it was adorned with a hundred columns. Being magnificently finished, it was consecrated by Sylvester on the 18th November, A.D. 324, and was richly furnished and endowed by Constantine, as it was afterward by other emperors, kings, and particularly by the popes. In 460, or 461, Pope Hilary presented two gold vases, set with jewels, weighing 15 lbs. each, with ten chalices, and twenty-four silver lamps. His successor, Simplicius, gave twelve more silver lamps, and a golden vase, of 16 lbs. weight: Pope Symmachus, about the beginning of the sixth century, presented twenty additional lamps of silver, besides twenty-two arches of the same metal, weighing 20 lbs. each. His successor, Hormisdas, had a silver beam made, of 1400 lbs. weight, to sustain the lamps given by his predecessors, and which burned night and day before the tomb of the apostles. Pelagius I., about the middle of the same century, adorned the tomb with silver, and Gregory I. added a canopy, supported by silver columns, of 180 lbs. each. Honorius I., who was raised to the pontificate in 625, had silver doors made to the basilica, each weighing 975 lbs., and he covered the roof with sheets of gilt metal, taken from the temple of Jupiter Capitolinus. Adrian I., towards the close of the eighth century, had a lamp made, in form of a cross, with 1,360 branches, that were lighted four times a year; and he adorned the tomb, used as a confessional, with 1,328 lbs. of gold. His successor, Leo III., built a tower, then unequalled. In the year 846, the basilica was stripped of all its treasure by the Saracens; but after they had been repulsed, Leo IV. had new doors made, with some basso-relievos of silver; after which, the building seems to have experienced very little alteration till the time of Nicholas III., who ascended the papal chair in 1277. This pontiff adorned it with mosaic-work, and engaged Giotto to execute many paintings for it. He also erected a magnificent habitation, called the *Canonica*, for a chapter of canons, successors of the monks of four monasteries, who had formerly officiated in this temple, by turns, day and night. This Canonica has since been pulled down, to make room for the modern basilica.

About 1,200 years from its foundation, this costly edifice began to exhibit symptoms of considerable decay; and, in 1506, Pope Julius II. began the new basilica, by enclosing all the old one. The first architect engaged in this undertaking was Bramante (see BRAMANTE), who, dying in 1514, was succeeded by Raphael d'Urbino, with others; he dying in 1520, the building was prosecuted by Baldassare Peruzzi. The troubles during the pontificate of Clement VII. caused a suspension of the work; nor was it resumed till 1546, when Paul III. employed Sangallo to carry it forward; but he dying the same year, the work was committed to the celebrated Michael Angelo Bonarotti (see BONAROTTI), who converted the design into the form of a Greek cross, and executed the design for the cupola. Bonarotti lived to see the building carried to the height of the tambour; and, on his death, which took place in 1564, he was succeeded by Giacomo Barozio da Vignola, till 1573, when Giacomo della Porta, assisted by Domenico Fontana, in the pontificate of Sixtus V., raised up the wonderful cupola from Bonarotti's model; and, to complete the small cupola, he added a ball of metal, as a supporter to the cross; the concavity of which ball contains commodiously thirty-two persons sitting This building had been sixty-seven years in hand, under the superintendence of seven architects, and during the reigns of twelve popes.

In 1606, the plan of this building was changed from a Greek cross to a Latin one, by pope Paul V., who also erected the portico with the grand front, after a design of Carlo Maderno.

This church surpasses all the most celebrated buildings, ancient or modern, not only in its size, which is immense, but in the excellency of its construction, within and without, and in the admirable works in marble, mosaic, metal, and gilt stucco, with which it is adorned.

At the foot of the grand ascent to the church are the statues of St. Peter and St. Paul, executed for the old basilica in the pontificate of Pius II., by Mino da Fiesole. The basso-relievo on the front, under the benediction gallery, representing our Lord committing the keys to St. Peter's care, is by Malvicino. The portico is ornamented with statues of the first popes, who suffered martyrdom, surrounded by festoons, angels, and gilt stucco; the performance of Algardi: the marble columns, of surprising magnitude, are from the original temple. On the right is a marble equestrian statue of the founder, Constantine the Great, in the attitude of observing the celebrated cross in the heavens, with the motto, *In hoc signo vinces :* it is the work of Cav. Bernini. In the four niches of the vestibule of the portico are as many statues, viz., Hope, by Livoni; Faith, by Rossi; Charity, by Ludovisi; and the Church, by Frascari. At the other end, on the left, is the equestrian statue of Charlemagne, as defender of the church, by Agostino Cornachini. In the vestibule, on the near side, are four other statues, viz., Prudence, by Livoni; Fortitude, by Ottone; Justice, by Rossi; and Temperance, by Rafaelli. Over the middle door is a large basso-relievo, in marble, of Christ committing his flock to St. Peter, by Bernini: and opposite to it is the celebrated *Navicelli*, or small ship, painted by Giotto, about the year 1300: this was formerly placed in the yard of the square portico, as a symbol of the Catholic Church, agitated, but not overwhelmed, from the tempest of many persecutions.

The entrance to the basilica is by five doors: that in the middle is metal, and was executed by order of Pope Eugenius IV., at Constantinople, by Filareto; its ornaments represent the martyrdom of St. Peter and St. Paul, and some deeds of the pope who ordered it.

The fifth door called *Porta Santa*, or holy door, is only opened in the jubilee year; and under the portico, near this middle door, the first bull for the jubilee, composed by Boniface VIII., is inscribed upon marble. Near the Porta Santa are two other inscriptions; one consisting of verses made by Charlemagne, in 795, in praise of Pope Adrian I.; the other describing the donations of Pope Gregory II. to this church, of olive grounds and other lands, for supplying the lamps at the sepulchre of the Apostles.

On first entering this vast temple, the imagination is raised with the expectation of beholding exquisite beauty and elegance; but the admiration it excites does not equal its fame, till the spectator begins to observe its several parts. On drawing near to one of the basins of holy water, on the first pilaster, the marble cherubim, that support it, appear at first regular and natural; but afterwards they are found to be gigantic, and almost out of proportion; they are the work of Livoni, Moderati, Rossi, and Cornachini. The doves, of marble, with olive-branches, that seem at first as if they could be touched by the hand, prove, on a nearer approach, to be very high, and appear to be flying still higher: an effect observable in most of the other works.

The middle aisle has a magnificent marble pavement, and the ceiling is grandly ornamented with gilt stucco, worked in grotesque with fruits, by Provenzale, by order of Pope Paul V., whose arms are in the centre, in mosaic; and every part is embellished with beautiful marble columns, and excellent basso-relievos, among which are fifty-six large medallions, with the portraits of as many sainted popes, sculptured by Nicolo Salé, a Frenchman, from designs of Bernini. Fixed against the pilasters are two remarkable stones, on one of which, it is said, Pope Sylvester I. divided the bodies of St. Peter and St. Paul; and, on the other, many martyrs were tortured and put to death. There are also two round black stones, which the Gentiles tied to the feet of the martyrs when on the *eculeo*, an instrument of torture in the form of a horse. The bronze statue of St. Peter, sitting, in the act of giving his benediction, was executed by order of Leo I., from the Jupiter Capitolinus, as an acknowledgment of the liberation of Rome from the persecution of Attila the Hun.

In the centre of the cross aisle, under the grand cupola, is the altar, called the *Confessional of the Apostles;* and under it is the ancient altar, turned toward the east, beneath which are said to be half the body of St. Peter and half that of St. Paul, with those of the early sainted popes. Here was the Vatican cemetery, where Anacletes first buried the body of St. Peter: and a small temple was built over it, which was afterwards pulled down, by order of the emperor Heliogabalus, to enlarge the passage for the triumphal cars. Around this shrine were formerly a vast number of lamps, with wicks of asbestos, continually burning balsam. Pope Calixtus II., in 1119, repaired and adorned it with costly marble, and consecrated it in the presence of the fathers of the general council convoked by him, and consisting of about a thousand bishops. It suffered no change, though the church was rebuilt in the interval, till the time of Clement VIII., who, about the year 1600, without removing any part of it, had it erected over the present altar. Paul V., a few years afterwards, having enlarged the basilica, as already noticed, adorned this confessional with precious marble, jasper, four alabaster columns, the statues of the two apostles, in bronze gilt, with other ornaments of the same material; and erected two noble descents, for the convenience of devotees approaching nearer the sanctuary to pray, around which one hundred and twenty-two silver lamps are continually burning. Urban VIII., at an expense of 100 000 crowns for workmanship alone, employed Bernini to erect a canopy of bronze over this shrine, supported by four twisted columns of the same metal, ornamented with very fine cherubim, modelled by Famingo, and partly gilt; with other remarkable works cast by Rossi.

The height of this canopy, including the cross on its top, is 124 palms; 186,392 lbs. of metal were consumed in making it, and, for the gilding, 46,000 crowns of gold.

The grand cupola is said by some to equal that of the ancient Pantheon; but others insist that it exceeds it by 37 palms in breadth, and 30 palms in height; being in magnitude 200 palms. The ball is 12 palms in diameter, and the cross is 25 feet in height, cast in bronze. The inside of the cupola is covered with mosaic work, from the cartoons of Cav. d'Arpino. The cherubim and flowers are by Roncalli and Provenzale; the evangelists, St. Matthew and St. Mark, by Nebbia; and St. Luke and St. John, by Vecchi. In the pilasters, Bernini opened four galleries, for exhibiting the sacred relics kept within the tabernacles. In that over the statue of Sta. Veronica is said to be part of the holy cross; the spear that pierced the side of our Lord, (presented by Sultan Bajazet II. to Pope Innocent III.); and the veil of Veronica, on which the face of Christ is impressed, and brought by her to Rome; but to these precious remnants no one is permitted to ascend, except the canons, without special leave of the pope. Over the statue of Sta. Helena, are many other relics, which are publicly exhibited at various times of the year. The eight columns in these galleries are said to have stood originally in Solomon's temple. The four marble statues in the niches are each twenty-two palms in height; that of Sta. Veronica is by Mochi; that of Sta. Helena by Bolgi; that of St. Andrew, by Quesnoy Fiamingo; and that of St. Longinus by Bernini; which last also executed the angels and other ornaments in the galleries. Against the pedestal of each statue is an altar-piece in mosaic, taken from the paintings of Andrea Sacchi.

Near these statues is the descent to the Grotto Vaticani, or the old church, into which women are only permitted to enter on Whit Sunday, when men are prohibited to approach. Here is the sepulchre of the apostles, erected by Anacletes, and among the ornaments of the high altar, are a statue of St. James, a Poliandro col pro Christo, containing many bones found in various piles of marble; and a chapel, with an image of God the Father, in marble.

On leaving this chapel is observed the old tribune, of mosaic, repaired by Giotto; the verses were cut on the frieze of the cornice, and the large cross was on the top of the ancient front. In the chapel of the blessed Virgin are the statues of St. Matthew and St. John; two sepulchral urns; various basso-relievos; part of a bull of Gregory III. inscribed on marble; besides other curiosities, too numerous to be particularized.

In the front of St. Peter's church towards the east, in the ancient camp, or valley, where the gentiles performed the Vaticini, and prepared for the triumphal processions, is the piazza of the Vatican basilica, in the form of an amphitheatre, which, for extent, magnificence, the distribution and elegance of the porticos, columns, statues, and fountains, astonishes the beholder, and appears to be the *ne plus ultra* of human art and genius. This was the work of Pope Alexander VII. from designs by Bernini, about the middle of the 17th century. The colonnades are of the Doric order, consisting of three hundred and twenty large stone columns, distributed into tetrads, and forming a street in the centre for processions, with walks at the sides for spectators. They are covered, and surrounded with cornices, on which, for greater ornament, are erected a stone balustrade, and one hundred and thirty statues of saints of both sexes, whose relics are preserved in the church, with those of the various founders of the religious orders.

In the centre of this piazza is the celebrated Egyptian obelisk, the only one of its kind that has wholly escaped the ravages of barbarous hands, and the injuries of time. It is of plain red granite, 113½ palms in height, all of a single piece; or, from the base, including the pedestal and cross, 180 palms, the cross alone being 10 palms. This monument, of ancient but uncertain date, is said to have been one of two obelisks dedicated to the sun in Heliopolis, the On of holy writ, by Nuncorius, called also Pheron, son of Sesostris, king of Egypt, on occasion of his recovering his sight, after a blindness of ten years; where it remained till the reign of the emperor Caligula, who, according to Pliny, had it removed to Rome, in the third year of his reign, and set up in the Vatican circus. When Constantine the Great destroyed the circus, the obelisk was left standing, and it remained neglected upwards of one thousand two hundred and fifty years, till the pontificate of Sixtus V., who was made pope in 1585, by which time it was buried to the top of the base in the accumulated ruins and rubbish. Sixtus ordered it to be cleared to its foundation, and employed the architect Dominico Fontana, who, on the 10th of September, 1586, with the labour of eight hundred men, and one hundred horses, removed it to its present situation, and set it up on two large blocks of granite, brought from Egypt at the same time with itself, and which serve for the pedestal, supported by a base of white marble. On the angles are four lions of metal, appearing to sustain the obelisk, cast from a model of Bresciano. The same pope dedicated it in honour of the true God, and, instead of the large metal ball, that was originally on the top, he placed his own arms, consisting of three mounts and a star, and above them a metal cross; which last, being injured by lapse of time and the weather, was taken down in 1740, and being repaired, a particle of the wood of the holy cross was inserted into it, and various indulgences have since been granted to those who, in passing by, have saluted it with a *Paternoster* or an *Avemaria.* The removal of this obelisk to its present situation, was first contemplated by Pope Nicholas V., who intended to have it sustained upon four colossal statues of the evangelists; but his death, in 1445, prevented the execution of his design.

On the right of the obelisk is a fountain, made by Paul V. early in the seventeenth century; and on the left is another, by Clement X., about the year 1671. They are both admirable works, as well for the copious supplies of water they throw up, as for their basins of the finest Egyptian granite, each cut out of one solid block.

For a view of the dimensions of this church, compared with those of St. Paul's, London, the reader is referred to page 674 of this volume.

SALIANT, (from the French, *saillant*, of *sailler*, to project or advance outwards; derived from the Latin, *salire*, to leap) in fortification, a projecting part.

There are two kinds of angles; the one *saliant*, or such as present their points outwards; the other *re-entering*, which have their points inwards. Instances of both kinds occur in tenailles and star-works.

SALLY, (from the French, *saille*, a jutting out) more commonly termed *projecture*, an expression used respecting the end of a piece of timber, when cut with an interior angle, formed by two planes, across the fibres; in which case the interior angle is called *a sally*, or *bird's mouth.* In this manner the feet of common rafters, and the inclined pieces which support the flying steps of a wooden stair, are frequently cut; as are likewise the lower ends of all inclined timbers, which rest upon plates or beams.

Sally-Ports, or Postern Gates, in fortification, underground passages, leading from the inner to the outer works, such as from the higher flank to the lower, or to the tenailles, or the communication from the middle of the curtain to the ravelin. In every place of arms, there are two sally-ports, each ten or twelve feet wide, for the troops to sally out. In time of a siege, they are shut up with barriers, or gates.

SALOON, (from the French, *salon*, a hall) a grand, lofty, spacious apartment, vaulted at top, and usually comprehending two stories, with two ranges of windows.

The saloon is a grand room in the middle of a building, or at the head of a gallery, &c. Its faces, or sides, are all to have a symmetry with each other; and as it usually takes up the height of two stories, its ceiling, Davilier observes, should be made with a moderate sweep.

The saloon is a state-room, much used in the palaces of Italy, and from thence the mode came to us. Ambassadors and other great visitors are usually received in the saloon. It is sometimes built square, sometimes round, or oval; sometimes octagonal, as at Marly, and sometimes in other forms.

To ascertain the superficies of a saloon, find its breadth, by applying a string close to it across the surface; find also its length by measuring along the middle of it, quite round the room; and multiply these results together for the surface. To find its solid contents, multiply the area of a transverse section by the compass taken round the middle part; subtract this product from the whole vacuity of the room, supposing the walls to go upright all the height to the flat ceiling.

SANCTUARY, the presbytery, or eastern extremity of the chancel eastward of the choir, which was set apart for the officiating priests, and in which the altar was stituated. *See* Chancel.

SAND (Dutch), in mineralogy, a name given to all mineral matter that exists in minute detached grains, and more particularly denominated from the prevailing substance as *silicious sand*, *iron sand*, &c.

Sand is generally formed from the disintegration of hard stones, or rocks, by the agency of water, and the particles of silicious stones, possessing a greater degree of hardness than most other kinds. The use of sand in building is an ingredient in mortar. For this purpose, pit-sand is, of all others, the best; and of pit-sand, the whitest is always the worst. Of river-sand, that found in the falls of water is best, because most purged; and sea-sand is worst of all.

Pit-sand, as being fat and tough, is most used in walls and vaults. River sand serves best for rough-casting.

All sand is good in its kind, if, when squeezed and handled, it crackles; and if, being put on a white cloth, it neither stains nor makes it foul. That sand is bad, which, mixed with water, makes it dirty and muddy, and which has been long in the air: for such will retain much earth and rotten humour. Hence some masons wash their sand before they use it.

The sand of Puzzuolo, De Lorme observes, is the best in the world; especially for maritime buildings. *See* Puzzolana.

SAND-STONE, in mineralogy, a stone essentially composed of grains or particles of sand, either united with other mineral substances, or adhering without any visible cement. The grains or particles of sand-stone are generally quartz, sometimes intermixed with felspar, or particles of slate. When the cementing matter is lime, such sand-stones are called calcareous: frequently the cementing matter is oxide of iron intermixed with alumine. The particles of sand in these stones vary greatly in size, some being so minute as scarcely to be visible.

Sand-stone is generally distinctly stratified; and some kinds, which contain a considerable quantity of mica, split into thin laminæ, which are used for slates in some parts of England, particularly in the West Riding of Yorkshire.

The lowest of the principal beds of sand-stone has been called by Werner, and the German geologists, the old red sand-stone. It generally rests on rocks of slate or grey-wacke, and is covered by thick beds of limestone. It is frequently coarse-grained, consisting of particles of quartz, and sometimes of felspar, cemented by iron-shot clay, that gives it the red colour from which its name is derived. According to many geologists, the red sand-stone, which extends on the western side of England, from Penrith in Cumberland to Shropshire, belongs to this formation.

The number and variety of sand-stones in the secondary strata are very great, and the diversity of quality fits them for the various purposes of building-stones, grind-stones, filtering-stones, &c. *See* Stone.

SANGALLO, ANTONIO DE, a celebrated architect, born in the 15th century, in the territory of Florence. His father, Antonio Picconi, was a cooper by trade, and Antonio was brought up to the business of a joiner. Having, however, two uncles, Guiliano and Antonio Sangallo, architects, of considerable reputation at Rome, he placed himself under their tuition, and assumed their name. He soon exhibited considerable talents, and his progress in the art made him known to Bramante, who, in 1512, entrusted to him the execution of several works. He soon obtained employment from some Cardinals; and in the pontificate of Leo X, when his uncle Giuliano quitted Rome, he was appointed his successor as architect of St. Peter's, in conjunction with Raphael. He also manifested great skill as an engineer; and Leo adopted a plan which he gave for the fortification of Civita Vecchia. Under Clement VII. he was employed in enlarging and embellishing the Vatican Palace, and in repairing the fortifications of Parma and Placentia. He is also celebrated for the construction of a remarkable well at Orvietto which had two staircases for the descent and ascent of beasts of burden. He enjoyed the favour of Paul III., who employed him in many important works as architect and engineer; and when Charles V. visited Rome after his Tunisian expedition, Sangallo had the planning of the triumphal decorations with which he was received. The Pauline chapel, and the magnificent staircases by which the chapels of the Vatican communicate with St. Peter's, were of his construction. The grandest effort of his genius was a wooden model of St. Peter's, which, however, was not closely followed. As he was noted for the solidity of his building, he was employed in strengthening the foundations of the Vatican and of the great columns which support the cupola of St. Peter's. Being engaged by the pope to survey the inundations of the lake of Marmora, the heat and the exhalations from the foul water caused a disease, of which he died in the year 1546.

SAP (from the Italian *zappare*, to undermine), in building, a term used when a trench is opened in the ground at the foot of a wall, &c., so as to bring it down all at once for want of support.

To demolish the thick firm walls of old castles, &c, sapping is much the readiest way.

Sap, in the military art, denotes a work carried on under cover of gabions and fascines on the flank, and mantelets, or stuffed gabions, on the front, to gain the descent of a ditch, counterscarp, or the like.

It is performed by digging a deep trench, descending by steps from top to bottom, under a corridor, carrying it as far as the bottom of the ditch, when that is dry; or as far as the surface of the water, when wet.

SAPHETA, more commonly called Soffit, in architecture, the board over the top of a window, placed parallel and opposite to the window-stool at the bottom.

SARACENIC ARCHITECTURE. *See* Moorish Architecture.

SARCOPHAGUS (from σαρκοφαγος), a sort of stone coffin or grave, in which the ancients laid those they had not a mind to burn.

The word, as derived from the Greek, literally signifies *flesh-eater*; because, at first, they used a sort of stone for the making of these tombs, which quickly consumed the bodies. The quarries from whence they dug it were near a city of Troas, named Assum. They had the faculty to waste away a body, except the teeth, in forty days. This stone resembled a reddish pumice-stone, and had a saltish taste. The ancients also made vessels of it to cure the gout, into which they put their feet, not suffering them to continue there too long.

SASH (from the french *chassis*, a frame), a chequered frame for holding the squares of glass in windows, and so formed as to let up and down by means of pulleys. Sashes are either single or double hung.

Sash-frame, the wooden frame in which the sashes are fitted for the convenience of sliding up or down, or sideways, as the nature of the apartment to be lighted may require.

When one or both sashes are to be moved vertically, they are commonly equipoised by weights; and the weights are made to run in vertical trunks, or cases, formed in the sides of the frames, which are therefore said to be *cased;* but when the sides are not made hollow for weights, the frame is said to be *solid.* In a sash-frame, the under side of the head is most commonly disposed in the same surface as the soffit, or intrados, of the stone or brick head of the window on the outside; consequently, it partakes of the shape of the head of the window, whether straight or circular. In a cased sash-frame, each case consists of four pieces; the inside piece, on each side, or that next the aperture, is most commonly disposed in the same plain with the jamb of the stone, or side of the aperture, on the outside, the two sides forming parallel planes: these two pieces are called *pulley-pieces*, from their containing the pulleys, over which the ropes pass, by which the sashes and weights are suspended. The other three parts of each trunk are called *linings;* that parallel to the pulley-piece, and next to the jamb, on either side, is called

Fig.1.N

the back lining; the one next the outside, and parallel to the face of the wall, is *the outside lining;* and the remaining one next to the inside of the room, is denominated *the inside lining.* The best-made sash-frames have the pulley-pieces tongued into the outside and inside linings; the back lining is generally tongued into the outside, and nailed to the edge of the inside lining; on each pulley-piece two channels, of equal breadth, for the edges of the sashes to run in, are formed by nailing a slip of wood round the inner margin of the pulley-piece, and suffering the outside lining to project within it; between which a narrow slip is inserted in a groove, left in the middle of the intervening space. As the edge of this slip is generally rounded, it is called the *parting bead;* and the inner slip, for the same reason, is termed *the inside bead;* while the edge of the outer lining is called *the outside bead.* Within the case, there is also a vertical slip, suspended from the head, and passing longitudinally through the middle of the hollow space, for separating the two weights, which is therefore called *the parting slip.* The head, sill, and inside linings, have generally each a groove next to the inside of the room; the groove in the head and sill is commonly three-eighths of an inch from the edge next to the opening; that in the head is for inserting the edge of the soffit, and that in the sill for receiving the edge of the capping bead, upon the upper edge of the back. The grooves, in the inside lining, are for the edges of the back lining of the boxing; the distance of these grooves from the niner edge of the inside depends on the depth of the boxing, and the distance of each line of hinges from the inner edge of the inside lining, or of that next to the opening. The line of hinges is generally about three-eighths of an inch from the inner edge of the inside lining; so that the shutters, soffit, and capping bead, may have their terminating edges with the sash-frame of the same margin all round; that is, at the same distance as the inner edge of the sash-frame; this, however, is not positively necessary, but may be varied at the discretion of the architect or workman. The line of hinges being determined, the depth of the boxing is found by adding to the thickness of the wall that of the inside finishing, whether of plaster alone, or of lath and plaster (the former requiring about an inch and the latter $2\frac{1}{4}$ inches); and subtracting from the sum, the thickness of the sash-frame, and its distance from the outside of the wall; then, if the remainder be equal to, or exceed half the distance of the hinge-lines, such half distance is the breadth of both the boxing and the shutter; it must, however, be observed, that the outer edge of the shutter must not be rebated, as that would prevent the edges of both coming close to the architrave, or margin style which forms the side of the boxing, opposite to the inner lining of the sash-frame, when each shutter consists of one piece only; to remedy this, each shutter must either consist of two folds, *viz.*, a front part, and a back flap; and the breadth of the boxing must be contracted, either by introducing a margin style at the edge of each boxing; or, if one was necessary before, by making it broader; then the thickness of the two folds will be the neat distance of the groove from the line of hinges. If, on the other hand, the remainder, before mentioned, be less than the half distance between the hinge lines, it is the breadth of the boxing; divide the half distance between the hinge lines, by the breadth of the boxing, and the quotient will give the number of folds; and if there be a remainder, there must be one fold more than is shown by the quotient. The aggregate, or sum of all the folds, is the neat depth of the boxing: but, in order to make the folds clear each other and the back of the boxing, add the eighth or tenth part of an inch for each fold. Thus, suppose the wall to be of eighteen-inch brickwork, and the finishing within to be lath and plaster; suppose, also, the breadth of the window to be 4 feet, the sash-frame 6 inches thick, and its distance from the wall 4 inches: then, $20\frac{1}{4}$ inches is the thickness of the wall and finishing; the thickness of the sash-frame and its distance from the face of the wall are, together, 10 inches; this, taken from $20\frac{1}{4}$ inches, gives $10\frac{1}{4}$ inches for a remainder, which is the breadth both of the boxing and of the shutter, because $10\frac{1}{4}$ inches are less than 24 inches, the half distance between the lines of hinges: $10\frac{1}{4}$ is contained twice in 24 inches with a remainder; there are, therefore, three folds, *viz.*, a front fold and two back flaps; suppose the front fold to be $1\frac{1}{2}$ inch thick, each back $1\frac{1}{4}$ inch thick; then $1\frac{1}{2}+1\frac{1}{4}+1\frac{1}{4}=4$ inches; and because there are three folds, add $\frac{3}{8}$ of an inch more, and the depth of the boxing will be $4\frac{3}{8}$ inches. Sash-frames are made in Dublin with half-sills.

Figure. No. 1. Represents part of the frame of a common sash, showing a section through one of the sides, and a part of the plan of the sill.

No. 2 The side of the sash frame, with the pulley style, and the sections through the sill and head.

No. 3. Part of the elevation of the sash-frame, the inside lining being removed to show the weight.

Figure 2. No. 1. A complete plan of a sash-frame, where the lines are concealed; this, however, does not affect the plan, so as to make it differ from that of common sashes, as shown at *Figure* 1, No. 1.

No. 2. The pulley style, exhibiting the pulleys in the middle, instead of being much nearer the top than the middle.

No. 3. Part of the elevation, showing how the line is fixed to the lower sash, and hooked to a piece fixed to the trunk for the purpose.

No. 4. Part of the elevation on the other side, showing the manner of fixing the line to the upper sash, and to the dividing piece.

No. 5. The inside of the sash-frame, with both weights exposed.

SAW, (from the Saxon *saga*, or Danish *sawe*) a thin plate of steel, indented on the edge, for cutting, or dividing wood or soft metals, by a reciprocal change of motion in the hands of the workman, by pushing it from, and drawing it towards him. The cut which it makes, or the part taken away, in a board, is a thin slice, contained between parallel planes, or a deep narrow groove of equal thickness. Saws are of several kinds, as the *pit-saw*, the *bow-saw*, the *ripping-saw*, the *half-ripper*, the *hand-saw*, the *panel-saw*, the *tenon-saw*, the *sash-saw*, the *dove-tailed saw*, the *compass-saw*, and the *key-hole* or *turning saw.* The teeth of these saws are all formed so as to contain an angle of 60 degrees, both externally and internally, and incline more or less forward as the saw is made to cut transverse to, or in the direction of the fibres; they are also of different lengths and breadths, according to their use. The teeth of a saw are bent alternately to each side, that the plate may clear the wood; and, for this purpose, also, the edge on which the teeth are cut is thicker than the other edge.

The best saws are made of steel, ground bright and smooth. If, in bending the plate of a saw, the resistance be great, and the curvature uniform, it is a proof that it has been evenly ground, and well hammered. Saws intended to cut hard wood, must be so sharpened as to lean more from the perpendicular drawn from the internal angle, to the line passing along the bottom of the teeth, than those which are intended for cutting soft wood.

The *pit-saw* is used by two sawyers, for dividing the trunks of trees into boards of any thickness, or for dividing larger pieces of timber into smaller scantlings.

Wilfrid; he erected a great altar or shrine over the place where Edwin had been baptized. This shrine was adorned with gold, silver, and precious stones, and above it was suspended by a chain from the roof, a large chandelier or *corona lucis*, with nine rows of lights, three in each row, to light it up by night. A large cross was raised at the back of this altar, of equally precious workmanship.

In Alfred's reign, Grimbald erected the ancient church of St. Peter at Oxford, and also the cathedral church at Winchester, at both which places, remains of his work are still supposed to exist. It is not improbable that some portions of Oxford cathedral are his work. It has been supposed that Grimbald was the first architect in this country who raised an arched roof, such as is to be seen at St. Peter's, Oxford, and at Winchester, in the crypts of those churches. But it is plain from Alcuin's account of the church built by him and Eanbald at York, one hundred years earlier, that that church had an arched roof.

The cathedral at Durham was erected by Aldham, A.D. 998, and here also, as at York and other places, a temporary church of timber was first erected, in which service was performed during the erection of the larger stone edifice. St. Dunstan was a great builder and restorer of churches and monasteries, and it is related, that during his episcopate, no less than forty monasteries were built or restored, amongst which may be mentioned the restoration of Ely, Peterborough, Tewkesbury, Malmesbury, Glastonbury, Evesham, Bath, and Abingdon; as also the foundation of the new abbeys of Ramsey, Hunts; Tavistock and Milton Abbas, Devon; and Cerne Abbas, Dorset.

Some idea of the number of churches erected during the Saxon period, will be formed, when we learn that, at the time of the Conquest, there were in Northamptonshire, where the forests were very extensive, and consequently but a small proportion of inhabitants, upwards of sixty village-churches, while the county-town contained eight or nine. In Derbyshire, there were not less than fifty, and five at least in the county-town, and these are exclusive of monasteries and the churches belonging to them; of which there were three or four in Northamptonshire, without reckoning Peterborough. In the town of Newark and the manor round it, including twelve or fourteen villages, were ten churches. In Lincolnshire, which was one of the most populous counties at this period, there were more than two hundred village-churches, without reckoning those of Lincoln and Stamford, or the monastic establishments.

Having established this fact, we have next to ascertain as to the character and appearance of such buildings, and also as to the material and method of construction. An opinion has been entertained by many, and still obtains amongst some persons, that the Saxon churches were very mean buildings, of a temporary character, and mostly constructed only of timber. To a certain extent this is true; many of their churches were certainly erected of timber, and were also mean in character when compared with those of a much later date; yet at the same time there can be no doubt, but that many, if not the majority, especially in the later part of the Saxon era, were constructed in a durable manner of stone, and were by no means so insignificant as some would have us to suppose. Many of the accounts left us by Saxon historians, and some of those above quoted, would lead us to form a much higher opinion of such structures; and although we must receive the panegyrics of these men not without some modification, considering that they spoke of things as beautiful only in a comparative sense, and that the standard of their comparison was fixed only by their own churches; still, we must not cast them aside as utterly groundless, or wilfully exaggerated. If we may believe, as there is good evidence for believing, that some remains of these old Saxon foundations still exist in the crypts of some of our larger churches, we shall be induced to give more credit to the Saxon accounts, than many persons are inclined to yield them. That churches were at this period constructed of masonry, we suppose few would question, after reading the above accounts; for in many instances the fact is especially mentioned, and in one or two instances such buildings are spoken of, and contrasted with those of timber, as at the cathedral at York, built by king Edwin, and that at Durham, erected at a considerably later period by Aldham, in both which cases, the stone structure is especially mentioned as being a substitute for the original or temporary building of timber. It may strike the reader as perhaps somewhat strange, that timber churches should still be constructed at so late a period, when the method of building in masonry had been known and practised for three centuries. A sufficient explanation of this apparent difficulty, is readily afforded in this particular instance, in the fact of the timber building being erected only for a temporary purpose, until the permanent edifice was ready for use. This inconsistency does, however, really exist in other cases, the one method of building did not cease, when the improved system had become established, but both were adopted in churches erected about the same period; both being equally intended for permanent use: the explanation is thus given:—

It is not indeed altogether to be wondered at, that in every age when society was thinly scattered over the face of the country, and the resources upon which ecclesiastical architecture depended, proceeded chiefly from the bounty of individuals, many churches not designed for a temporary purpose, would be constructed of materials so ordinary and so cheap; but we have other and more satisfactory reasons given by Saxon historians for this fact. These writers distinguish the two methods of building under the two terms *opus Scoticum*, and *opus Romanum*, the former referring to the more fragile structures, which were composed of split oak, and the latter to the more durable erections of stone.

Of this Scotch method, Bede says, "that Adrian, the first bishop of Lindisfarn, having departed this life, Finan, sent and ordained by the Scots, succeeded him in the bishopric, where he built a church in the isle of Lindisfarn, or Holy Island, since called the bishopric of Durham, after the manner of the Scots. This he made not of stone, but of hewed oak, and covered it with reeds; and the same was afterwards dedicated in honour of St. Peter, the apostle, by the venerable Bishop Meadows. Eadburh, the seventh bishop of that place, afterwards taking off the thatch, covered it with plates of lead, that is, both the roof and the walls."

It is probable, then, that the Saxons learned this method from their northern neighbours, against whom they had been brought over by the Britons, but with whom they had afterwards allied themselves, and by whose assistance they had been enabled to drive out the British, and establish themselves in their country. Whether the method had originally been brought from Ireland by the Scots, or whether it was a method common to both them and the Picts, is not certain; but it would seem, from an incident which we shall afterwards allude to, that a similar mode of building was employed by both people; or, at any rate, that the Picts were not acquainted with the method of building in stone.

These timber buildings were constructed of split or reft timbers, stood on their ends, and placed in close contact to each other. The ends were laid on an oak sill, and the heads framed together in a sort of lintel: of such simple construction were the walls; and the roof consisted, in all probability, of nothing more than reeds or thatch. A description of a church of this kind, which there is good evidence to believe is of Saxon date, is given under the article CHURCH: it is situated at Greenstead, near Ongar (the Saxon Aungre), in Essex. In this village, they have a tradition that the dead body of some king once rested here for a short time, and that the first edifice was a wooden chapel, erected for its reception. This is supposed to have been the body of St. Edmund, the king who was slain A. D. 946. In a manuscript, entitled *The Life and Passion of St. Edmund*, preserved in the library of Lambeth Palace, it is recorded, that, in the year 1010, and the thirteenth year of the reign of Ethelred, the body of St. Edmund was removed from Ailwin to London, on account of an invasion of the Danes, but that, at the end of three years, it was returned to Bedriceworth. And in another manuscript, cited by Dugdale in the Monasticon, and entitled "The Register of St. Edmund's Abbey," it is further added, "he was also sheltered near Aungre, where a wooden chapel remains as a memorial to this day." Now, the parish of Aungre, or Ongar, adjoins to that of Greenstead, where this church is situated, and the ancient road from London to Suffolk lay through it. It seems therefore not improbable, that this rough and unpolished fabric was first erected as a sort of shrine for the reception of the corpse of St. Edmund, which, in its return from London to Bedriceworth, or Bury St. Edmund's, as Lydgate, the monk of that abbey, says, was carried in a chest. Indeed, that the old oaken structure now called Greenstead church is this wooden chapel near Aungre, no doubt has ever been entertained; and the very style and character of the building would claim for it a Saxon antiquity.

The missionaries who had been accustomed to the buildings of Rome, introduced the manner of building churches among the Saxons more substantially, with stone, and in the Roman manner. Thus we find the king of the Picts—a people inhabiting the northern parts of Britain—soliciting Ceolfrid, a monastic abbot, to send him architects to build a church in his nation, after the Roman manner, promising to dedicate the same in honour of St. Peter, the prince of the apostles: and that he and all his people would always follow the custom of the holy Roman and Apostolic Church, as far forth as, being so remote from the Roman language and nation, they could learn the same. Here we also see the deficiency of the Picts, as well as that of the Anglo-Saxons, in the knowledge of sacred architecture, one building with wood, and the other with rough unhewn stones: and these, as well as the Irish churches, are covered with reeds and rushes, and the walls with skins. The windows, in some instances, were formed with lattice-of-wicker; in others, of horn and shells, oil-paper, &c.; and the rafts were of oak.

Buildings of this class, however, would seem to have been of very rude construction, the walls being composed either of coarse rubble-work, or of flints, piled up irregularly, and bound together by cement of some sort: such walls were, of course, obliged to be of great thickness. Sometimes we find Roman bricks worked up in the walls with other materials, but they are not laid in regular courses, as in the structures which had been erected by the Romans during their residence in Britain; they are found built up with the other materials, without regard to order or regularity. By this means, the buildings erected by the Romans in this island may be distinguished from the works of the Saxons; and it is curious that this test is similar to that applied to the buildings of Babylon; for it is there noted, that in the earlier buildings, the bricks indented with arrow-headed characters are always placed in a particular position with respect to the inscriptions.

Whether, indeed, the method of building such stone erections was learned from the Roman missionaries, or originated in an imitation of the edifices which the Romans had left in the island, is by no means certain; we are inclined to think, however, that the latter is the more probable, for it would appear very unnatural that the Saxons should not have attempted to imitate the buildings which they found in the country even before Augustine made his appearance; although it is not unlikely that he and his companions might have given them further instructions, and imparted to them some knowledge of the method of building at Rome. This seems the more reasonable when we call to mind the letter which Gregory, bishop of Rome, sent by Melitus to Augustine, respecting the employment of existing buildings for places of Christian worship.

"When, therefore," says he, "Almighty God shall bring you to the most reverend man, our brother, Bishop Augustine, tell him what I have, upon mature deliberation on the affair of the English, thought of, viz., that the temples of the idols in that nation ought not to be destroyed; let holy water be made and sprinkled in the said temples: let altars be erected and relics placed; for if those temples are well built, it is requisite that they be converted from the worship of devils to the service of the true God, that the nation, not seeing those temples destroyed, may remove error from their hearts, and, knowing and adoring the true God, may the more familiarly resort to the same places they were wont."

From this it would appear, that the Saxons had erected temples for their worship before Augustine's appearance amongst them: and we hear, also, at a subsequent period, of Coifi, the heathen arch-priest in Northumbria, desecrating and destroying the idol's temple, upon his conversion to Christianity. That they had temples, therefore, there can be no doubt; the only question is, whether they built them themselves, or made use of such buildings as they found ready to their hands: the latter supposition is by no means improbable: whichever be the case, however, it is almost impossible, that, after a century's residence in the island, the Saxons should still remain totally unacquainted with the method of construction of those buildings which they had found there on their arrival.

"At the time the Saxons were converted," Mr. Bentham observes, "the art of constructing arches and vaultings, and of supporting stone edifices by columns, was well known among them; they had many instances of such kind of buildings before them in the churches and other public edifices erected in the time of the Romans. For notwithstanding the havoc that had been made of the Christian churches by the Picts and Scots, and by the Saxons themselves, some of them were then in being. Bede mentions two in the city of Canterbury; that dedicated to St. Martin, on the east side of the city, wherein queen Bertha performed her devotions, and which Augustine and his companions made use of at their first coming; and the other, that which the king, after his conversion, gave to Augustine, and which he repaired and dedicated to our blessed Saviour, and made it his archi-episcopal see. Besides these two ancient Roman churches, it is likely there were others of the same age in different parts of the kingdom, which were then repaired, and restored to their former use."

We do not suppose, however, that their acquaintance with the Roman method of building was very intimate, or that they had acquired much skill in the construction of vaults and arches, for their time was too much occupied with wars with the Britons, and quarrels amongst themselves, to admit of much opportunity for the cultivation of the arts of peace. All that we wish to assert is, that we were not entirely ignorant of Roman building, although practically, in all probability, not very expert in it, so that they would be ready to adopt some more easy method of construction, such as that afforded them by the Scots.

When at a later period the Anglo-Saxon Christians made a journey to Rome to visit the tombs of the Apostles, where churches were erected over them, and had seen those buildings, they blushed at the inferiority of their own low, dark, and gloomy fanes, and henceforth resolved to imitate what they had learnt to admire. Walls of wrought-stone, therefore, succeeded the rough material. After this we find that architects and work-people were frequently procured from abroad, to plan and raise ecclesiastical structures. The Anglo-Saxon churches, nevertheless, were of comparatively rude construction, until the time of Alfred the Great, when many, according to Asser, were rebuilt with stone, and, as far as can be ascertained, up to this time they were, with some few exceptions, of no great magnitude or dimensions, and almost entirely devoid of ornamental mouldings, though, in some instances, decorative sculpture and mouldings are to be met with. This improved method might be more properly termed the Roman manner, as being imported from Rome, and carried into execution by Roman and French workmen.

The general form of Saxon churches seems to have been that of a simple oblong or parallelogram, as we learn from Bede and other writers; some, however, were cruciform in plan, as that of St. Mary at Hexham, erected by St. Wilfrid, and which is described by Richard, prior of the same place, as being furnished with a "tower of a round form, from which four porticos or aisles proceeded." The church at Ramsay in Huntingdonshire, erected A. D. 969, was also of this form. This church also is said to have had two towers, one at the west end, and another in the centre of the transept, supported by four arches. Wolstan informs us that the old church at Winchester had a tower at the west end, but the new one at the east end of the church. Representations of buildings of this kind in some of the old Saxon illuminated books, tend to confirm this testimony. Dr. Milner observes that "The use of small bells (*nolæ*) in this country, if we may credit William of Malmsbury, may be traced as high as the fifth century. And it is clear from Bede, that even those of the larger kind (*campanæ*), such as sounded in the air, and called a numerous congregation to divine service, were employed in England as early as the year 680, being that in which the abbot Hilda died." Towers were also useful for other purposes, such as strongholds or places of refuge, to which the people might resort in cases of sudden incursion, to which they were especially liable from the Danes; also as beacons for travellers during the night, for we learn from Wolstan that the new tower at Winchester consisted of five stories, in each of which were four windows looking towards the cardinal points, which were illuminated every night. Such lights were most useful in those days, when the roads were few and bad, and the forests thick and numerous.

The few buildings which now remain, that can by written documents be proved to be of an age prior to the Conquest, have caused many writers to assert, that there is at present scarcely a true specimen of Anglo-Saxon architecture extant. This opinion has been very prevalent of late years; but we are strongly inclined to believe, that many more examples remain than is generally admitted. The causes by which the great scarcity of examples is accounted for by such writers, are principally these:—the necessary antiquity of the buildings; the furor of the middle-age architects for rebuilding churches in the latest styles; and the ravages of the Danes. Now we know from written testimony, as above shown, that a large number of churches were erected by the Saxons, and many of these built of stone in a durable manner. Will, therefore, the above causes be deemed sufficient to account for their total demolition? We think not. In the first place, then, as regards their antiquity, it may at the first blush appear unreasonable to expect to find many churches standing, after a lapse of twelve centuries; nor is it quite fair to cite such examples as those of Egypt, Greece, or Babylon, to refute this statement; for we are well aware, that they were constructed with much greater skill and strength than the Saxon churches. But there is no occasion to refer to such examples; we all admit that specimens of Norman architecture are still to be found without much difficulty, and in tolerable abundance; does it not, however, appear somewhat extraordinary, that we should have no lack of examples of structures built immediately after the Conquest, and yet scarcely any of the period just preceding that event; surely, it is not natural that the differences of numbers should be so very great; certainly, the difference of age will not account for it. This difficulty, which nullifies the first cause assigned for the paucity of examples, will equally affect the second. The third is somewhat more plausible, yet at the same time we cannot think that it accounts for such an extraordinary difference of numbers between Saxon and Norman remains as the advocates of this opinion would have us to believe; if so, the ravages of the Danes must have been of a more formidable description than we think history warrants us in believing.

But there are some positive reasons, which would lead us to conclude that a greater number of Saxon remains are now in existence, than is generally supposed. For instance, there are some churches in which Norman work is inserted into structures of a decidedly earlier, nay, much earlier date, which must in consequence belong to the period before the Conquest. The fact of work being anterior to the Conquest, is not, we are well aware, sufficient to prove it purely Saxon, for it is generally allowed as probable, that the Norman style was partially introduced into England before the invasion by William. In many of these instances, however, the older work is of a totally different character to the Norman, of a much more rude and barbarous description, and bears undoubted evidence of being of a date considerably antecedent to the Norman addition. In some cases, such remains are found in churches which are principally Norman, and this affords further proof of its antiquity; for it is reasonable to suppose, that a church partly re-edified in the Norman era must have been at that time a very old one.

An instance of the kind we allude to has recently come to light at Iver, Bucks, where it was discovered during restoration, that the north wall of the nave, which was apparently Norman, was in reality of earlier date, containing under the plaster the jambs of a door and window, as well as a string-course, both in the north and south walls, of an undoubtedly earlier epoch; a matter which was still further confirmed by the discovery of Roman bricks in the quoins of the east end of the nave-walls, thus proving that the shell of the building was of greater antiquity than its general appearance denoted.

On this subject, Mr. Freeman has introduced some very reasonable remarks, which we take the liberty of inserting:—

"I certainly think this," says he, "one of the strongest cases in favour of the existence, not only of buildings older than the Norman conquest, but of the existence of a distinct Anglo-Saxon style—two questions which ought never to be confused together in the way that they too often have been. To this subject I shall presently recur. In this Iver case, we have Norman work, and something older. There is no possibility of mistake; we have the marked familiar Norman work of the twelfth century, introduced into an older building; no piece of architectural history can be more certain than that these arches are more recent than the wall in which they are inserted, and the window whose mutilation they have caused. There is no room for any question as to chronological sequence. The only possibility is, that they might be *late* Norman arches, cut through an early Norman wall. Mr. Scott, however, thinks that the 'northern piers and arches were probably erected about the year 1100.' With every deference to so eminent an authority, I should have placed them rather later, as the bases of the responds certainly seem to me too advanced for that date. But even putting the Norman work later in the century, we still have the fact, that the earlier work is not at all like early Norman, or Norman at all. There is this *a priori* objection to its being since 1066; while against its being of Anglo-Saxon date, there is nothing but the disinclination that exists in some minds to admit anything to be Anglo-Saxon. And though it would prove nothing against documentary evidence or strong architectural presumption, still, without such evidence or presumption, we should be shy of supposing such frequent reconstructions of such magnitude in an obscure village-church, as would be involved in the supposition that we have here two pure Norman dates; for though I should place the arches later than Mr. Scott does, they are certainly pure Norman, and not transitional, the case is briefly this: we have unmistakeable Norman work; we have also something else, at once earlier in date and different in character. The inference seems unavoidable.

"I observed above, that the questions of Saxon *date* and Saxon *style* are quite distinct. The real question is, whether the English, before the Conquest, possessed a national style distinct from Norman, in the same sense as other forms of Romanesque are distinct from it. In this sense, it does not prove a building to be Norman, to show that it was built after 1066; or to be Saxon, that it was built before Edward the Confessor. Certainly Harold himself not improbably built in the Norman style before that period; and, in obscure places, one cannot doubt but that Saxon churches were built for some time after. Even St. Alban's abbey is in many respects distinctly Saxon in character; and I am well pleased to find these facts taken up under this aspect in Mr. Parker's newly published 'Introduction to Gothic Architecture.' He there says, that 'the ordinary parish churches which required rebuilding (soon after the Conquest) must have been left to the Saxons themselves, and were probably built in the same manner as before, with such slight improvements as they might have learned in the Norman works.' He then goes on to mention—I presume from historical evidence—the Saxon churches of Lincoln as having been built after the Conquest, by the English inhabitants, dispossessed of their dwellings in the upper city by William and Bishop Remigius. No fact could be more acceptable to the believers in a distinct Saxon style, if the Englishmen of Lincoln continued—even when the Norman cathedral was rising immediately over their heads—to build in a manner, not differing merely as ruder work from more finished, but having essentially distinct characters of its own: the inference is irresistible, that this was but the continuation of a distinct style, which, in those larger edifices, which have been almost wholly lost to us, would probably present distinctive features still more indisputable. The mere chronological proof of any existing building being older than the Conquest, would never have half the same value as such a testimony as this, which represents Saxon and Norman architecture co-existing in antagonistic juxtaposition. The fact is, however, only the same as we find occurring, to a greater or less extent, at every change of style. At all such transitional periods, we find not only every intermediate style, but the simultaneous use of the two styles, each in a state of tolerable purity. And the circumstances which attended the change from Saxon to Norman architecture, would naturally tend to make this phenomenon more conspicuous than in subsequent transitions. This change was no native development; it was the innovation not only of foreigners, but of conquerors and oppressors; and, whilst national honour might require, the circumstances of the time would compel, the rude and obscure structures which still continued to be raised by Englishmen, to adhere in all respects to the native precedents of better times. Wealth, art, ecclesiastical influence, and munificence were all enlisted on the side of their tyrants."

The tower of Earls-Barton church in Northamptonshire, as well as that of Barton-upon-Humber in Lincolnshire, bear marks of great antiquity, and are ascribed by Mr. Britton to the Anglo-Saxons. Both are evidently much older than the church to which they belong, which are good specimens of the Norman style. Nothing, Mr. Britton observes, can be found more resembling the towers now under notice, than the architectural drawings in certain manuscripts of acknowledged Saxon origin. In the British Museum, and in the Gregorian Gospels preserved in the library of Salisbury Cathedral, are drawings by Anglo-Saxon scribes, in which the triangular arch and columns, resembling balusters with two or three bands, are represented, and seem to be rude delineations of architectural members, very similar to those in the towers of the two Bartons and Barneck, in Northamptonshire, in which they are employed.

In some churches where work—supposed to be Saxon—exists, are to be seen Saxon and Latin dedicatory inscriptions, in which the founders, and others connected with the church, are alluded to, and by this means we are enabled to form some certain judgment as to their date.

"In the church of Kirkdale, in Rydale, in the North Riding of Yorkshire, over the south door, is a curious inscription in Saxon characters, of which a plate is given in the fifth volume of 'Archæologia.' The inscription is accompanied by an ancient dial, and is placed over a doorway with a plain semicircular arch. It is engraved on one entire freestone, 7 feet 5 inches long, and 1 foot 10 inches high, and is in perfect preservation, except a small part in the centre, where the inscription is disfigured, but not obliterated, by the weather. This seems in some measure to be owing to its being defended by the porch, which entirely covers it, except by two angles, and consequently must have been of later erection; which is further improved by its having been formerly plastered over with lime, or some other cement, as appears by the remains of it in the interstices of the letters, and in the vacancy where the hand of the dial has been broken off. The inscription may be read thus: Orm. Gamal. Suna. Bohte. Sanctus. Gregorius. Minster. Thonne, Hit. West. æl. To. Brocan. And. To. Falan. Chehitle. And. Man. Newan. From. Grunde. Christe. And. Sanctus. Gregorius. In. Eadward. Dagum. Cng. In. Tosti. Dagum. Earl. "Orm, Gamal's son bought St. Gregory's church then it was all fallen down. and gone to ruin. Chehitle and others renewed it from the ground to Christ and St. Gregory, in Eadward's days, the king, and in Tosti's days, the Earl;" and under the dial. And. Hawarth Me. Wroht. And. Brand. Prs. "and Hawarth me made and Brand the priest."

"Tosti, who was fourth son of Godwin, earl of Kent, and brother to king Harold, was made earl of Northumberland, by Edward the Confessor, in 1056, on the death of earl Leward. This earl was driven from his earldom by his oppression, and was killed at Stamford bridge, near York, in 1066.

The inscription must therefore be dated between those years. From Doomsday book it appears that Orm was the owner of Kirkdale and the districts adjacent, in Edward the Confessor's time; and from Simeon of Durham we learn, that a certain thane in Yorkshire, by name Orm, the son of Gamal, married Ethelrith, one of the five daughters of Aldred, earl of Northumberland," &c.

"On one of the walls of the church of Aldborough in Yorkshire, is the following Saxon inscription:—'Ulf hit araeran cyrice for Hanum and for Gunthard saula;' *i. e.*, Ulf commanded this church to be erected for the souls of Hanum and Gunthard." From many circumstances, this church is evidently the original Anglo-Saxon structure, with a few modern additions, as pointed windows, &c. The walls in general are made of round pebble-stones, supposed to have been gathered from the sea-shore in the neighbourhood, which kind of stones, by a strong cement, made very durable buildings; but the lower part of the south wall of the chancel is built with hewn stone, such as was generally used in our most ancient cathedral churches, upon which there are some grotesque figures; and in the north wall is a narrow window, about 5 feet high; the chancel door also, which is a south entrance, is low and narrow, and has over it an elliptic arch, ornamented with zig-zag work. Ulf, who is mentioned in the inscription as its founder, was lord of the whole of this part of the Saxon province of Deira, or the country bounded by the Humber and the Tees, about the time of Canute."

Another inscription-stone was dug up at Deerhurst, and is now amongst the Arundelian marbles at Oxford: it commemorates the construction of a church there by earl Odda, who died A.D. 1056. The most ancient inscription, however, is probably that at Jarrow, which is apparently of the same date as the erection of the church, A. D. 684.

Our object in bringing these examples forward, is not so much to prove each example of Saxon origin, but rather to establish the date of a particular class of work; for if in one or two cases this be indubitably proved to be Saxon, we have every right to conclude that the same kind of work is of the same origin wherever it may be found. It somewhat corroborates our position, that many churches in which such work has been discovered have been alluded to by the Saxon historians. Thus a probable inference may be deduced from the ancient chronicles of the monastery of Dover, that the old church near the castle was founded by Eadbald, king of Kent. The churches of Jarrow and Monk-Wearmouth, in which supposed Saxon work exists, are both mentioned as having been founded by Benedict Biscopius, A. D. 681: so also of the churches of Ripon and Hexham.

That the church at Brixworth, in Northamptonshire—which is one of the most perfect specimens of this kind of building—is of an age anterior to the Conquest, we have many proofs. Mr. Britton judges it to be a building of the time when the Romans were in possession of the island, after the Britons were converted. It is evident, from Doomsday book, that it was in existence at that time; and in Leland's Collectanea we may trace it to the time of Cuthbald, the second abbot of Medeshamsted, afterwards called Peterborough, who was contemporary with Wulphere, king of Mercia, who died in 670. The building is almost entirely formed of Roman bricks; it has, at its western end, in addition to the square tower, a round one, containing a newell staircase. In its original form, it appears to have consisted of a spacious nave and narrow aisles, a large chancel, and a western tower, with a clerestory to the nave, and the chancel divided from it by a large arch. The construction of this church is particularly curious, the walls being mostly built with rough red-stone rag, in pieces not much larger than common bricks; and all the arches turned, and most of them covered with courses of bricks, or tiles, as they may be called. The original doors and windows have all round arches; but many additions have been made in more recent ages.

Further proof in favour of such work belonging to the Saxon age, is to be observed in the similarity which exists between the details of such buildings and those found in the illuminated Saxon manuscripts, where representations of buildings are introduced. In the illuminations in the paraphrase of Cædmon, of which the date is supposed to be about A. D. 1000, are various representations of architectural details; and amongst these are specimens of *long and short* work, semicircular and triangular arches, graduated imposts or capitals, low pyramidal roofs to towers, and the well-known baluster-shafts.

Putting all this evidence together, we think there can remain little doubt but that the particular style in which many of our existing churches, or portions of churches, have been erected, is nothing else than decided Saxon.

It is now time that we give some description of the architectural peculiarities of this style; such description will be necessarily short and imperfect, on account of the comparative paucity of the remains, and the uncertainty respecting them. The general character is extreme rudeness of construction, and almost total absence of ornament; the workmanship, at the same time, being rough and unfinished.

The masonry consists of rubble or rag-stone, rudely piled together, and often rendered on the exterior with a coating of plaster. The angles are bonded together with quoins of ashlar-work, arranged in a peculiar manner, and termed *long and short* work. They are composed of stones of two different lengths, placed alternately one above another—first a short one, then a long one, and so on; or, in other words, of stones laid alternately flat and upright on the edge, the flat ones exceeding in horizontal dimensions, the upright in vertical; the latter, however, are usually of greater dimensions in the height than the former in width. We frequently find, also, projecting a little from the general face of the masonry, narrow square-edged strips of ashlar, carried up vertically from bottom to top of the walls, and consisting generally of long and short pieces of stone placed alternately. Not unfrequently strips of stone of a precisely similar character were carried horizontally along the walls, after the manner of a string-course, especially in towers, where they are employed to divide the height into different stories; they also serve for the upright strips to terminate against both at top and bottom. The vertical strips bear some resemblance to pilasters. By some persons this arrangement is said to be in imitation of timber-construction; but, for our own part, we think it bears a much closer likeness to the pilaster strip-work so common in the Lombardic structures of the continent. So remarkable, indeed, is this resemblance, that we consider it almost sufficient evidence of itself, to prove that such buildings have been erected in imitation of the continental ones. *See* LOMBARDIC ARCHITECTURE. In many cases, the walls are so covered with this strip-work as to be divided by them into a number of panels. Sometimes, as in the tower of Earls-Barton church, we have them arranged after a kind of ornamental design, in diamonds, semicircles, &c. Occasionally, in all probability, work of this kind is hidden from view by the rendering of plaster on the walls.

Roman bricks are frequently found worked up in walls of Saxon masonry, but, as we have said before, without any regularity or arrangement. Herring-bone masonry, which consists of stones or bricks laid at opposite inclinations in alternate courses, is also to be found in Saxon-work; but it is not peculiar to it, being also found in both Roman and Norman walls.

The arches in this style were either semicircular or triangular, if the latter can be properly styled arches, which consist merely of two long stones resting on imposts, and inclined towards each other till they meet, and abut against each other at the apex. The semicircular form is, however, by far the more common of the two; it is usually quite plain, having only a single soffit, without any recess or sub-arch: not unfrequently arches of this kind receive somewhat of a finish by the addition of a hood-mould, composed of square-edged strip-work, projecting a few inches from the surface of the wall: it follows the shape of the arch, and is either terminated by the impost, or continued down to the ground. Occasionally we find arches recessed, or having a sub-arch, as at Bishophill, York; but this is probably of late date, although truly Saxon, as is evident from the square-edged strip forming a hood-mould, as just described: rarely, also, the arch is enriched with bold roll-mouldings on the face or soffit, or on both, as at Wittering church, Northamptonshire; and these are sometimes continued down the impost to the ground.

The imposts on which the arches rest are usually nothing more than square-edged projecting blocks of stone, having sometimes the lower arris chamfered; occasionally they are moulded, the mouldings consisting chiefly of fillets or platbands varied with bold semi-cylindrical or roll-mouldings; and sometimes they are enriched with rude attempts at sculpture. The piers are mostly square, plain, and with no more capital than is formed by the impost.

The doorways are constructed with both kinds of arches; the semicircular being most prevalent, and in some of the more ancient examples, the archivolt is composed of Roman bricks; they are mostly, however, of stone, of the description given above, being frequently provided with the projecting hood-mould, which is sometimes stopped on the impost, or a horizontal string-course of strip-work, and at others continued to the ground. The imposts or abaci are of the same description as above, and the jambs are either composed of the usual long and short work, with the horizontal stone bonding into the wall, or of two long blocks placed upright on their ends with a shorter one between them, which is, however, no wider than the long ones. Triangular-headed doorways are of similar general description to the semicircular; there is an example in Brigstock church.

The windows are generally of a very rude description; those in the body of the church, consisting principally of single lights of small size, and having semicircular heads; they present a marked difference from the Norman windows to the same kind, in being splayed from the middle of the thickness of the wall both ways, that is to say equally both towards the interior and exterior of the building; whereas the Norman windows splay from the exterior only in one direction, the glazing being inserted near the external surface of the wall. Small windows are sometimes seen with square heads, of a rude oblong form.

The windows, which deserve the greatest attention, and which form a characteristic of the style, are those found in the upper stages of Saxon towers. They generally consist of two semicircular-headed lights, divided by a rude shaft of peculiar description, and termed *baluster-shafts*, from their appearance, which is that of a baluster with a bold capital and base, both of which are usually composed of cylindrical or roll-mouldings, and the former surmounted with a heavy abacus. This abacus runs nearly through the thickness of the wall, and from it the arch springs, being supported on the other side by an impost of similar description worked up in the wall. The baluster-shaft frequently swells out in the middle of its height, and is sometimes divided in the middle by a band of roll-mouldings, swelling out above and below midway between the band and capital and the band and base; it is often plainly cylindrical, without bands or other interruption. At Monk-Wearmouth, the shaft swells in the centre, but has neither capital nor base. Sometimes, such windows of two lights are coupled together by a semicircular hood of strip-work extending over both, and carried down vertically to the bottom of the lights. In the topmost story of the tower of Earls-Barton church, there is a window of the above description, divided by baluster-shafts into six lights. Triangular-headed lights are found in this and other situations.

Respecting Saxon vaulting, the following account of that in the crypt of Repton church, is given by Mr. Bloxam, in his valuable manual:—"The crypt beneath the chancel of Repton church, Derbyshire, is, perhaps, the most perfect specimen existing of a crypt in the Anglo-Saxon style; and of a stone-vaulted roof sustained by four piers of singular character, slender and cylindrical, with a spiral band or moulding round each, and the entasis exhibiting that peculiar swell we find on the baluster-shafts of Anglo-Saxon belfry windows; the vaulting, which is without diagonal groins, bears a greater similarity to Roman than to Norman vaulting; and the crypt was entered through the church, by means of two winding passages."

Amongst the more noted churches in which Saxon remains are supposed to exist, we may mention the following:—Barton-upon-Humber, Lincolnshire; St. Benedict's, Cambridge; Brigstock, Northamptonshire; Brixworth, in the same county; Bosham, Sussex; Clee, Lincolnshire; church near Dover-Castle; Earls-Barton, Northamptonshire; Deerhurst, Gloucestershire; Hexham, Durham; Jarrow, in the same county; Kingsbury, Middlesex; Lavendon, Bedfordshire; St. Michael's, St. Alban's, Herts; Monk-Wearmouth, Durham; Repton, Derbyshire; Sompting, Essex; Tintagel, Cornwall; Wing, Bucks; Worth, Sussex; St. Mary, jun., Bishophill, York.

For further information on this subject, we refer the reader to CATHEDRAL, CHURCH, and other articles of a similar character.

SCABELLUM, (Latin,) in ancient architecture, a kind of pedestal, usually square, sometimes polygonal, and very slender and high, commonly ending in a sort of sheath, or scabbard, or profile, in the manner of a baluster. It was used to support bustos, or relievos.

SCAFFOLD, (from the French, *eschafaut*, or Dutch, *schavot*,) an assemblage of planks, or boards, sustained by tressels, or pieces of wood fixed in the wall, upon which masons, bricklayers, &c., stand, whilst carrying up a wall; or used by plasterers, &c., when plastering the ceiling.

The different members of a scaffold are termed standards, ledgers, and putlogs. The standards are upright poles of fir of considerable length, and about 6 inches in diameter, fixed firmly in the ground; the ledgers are horizontal poles lashed to the standards, and running parallel to the work to be erected, and the putlogs are transverse pieces about 6 feet in length, laid horizontally from the ledgers to the walls, on which the scaffold-boards are placed.

Of late years, a much improved method of building scaffolds has been employed, especially on large works; they are more regular in their construction than the old method, being composed of a series of trussed frames, consisting of a number of vertical and horizontal timbers braced together diagonally; they have the advantage of being erected independent of the building itself. At the top of such scaffolds is frequently a carriage running on a rail in a longitudinal direction; and this carries a windlass, which moves across it in a transverse direction, and therefore can be brought to act at any point which may be desirable.

SCAGLIOLA, an imitation of the most beautiful marbles, such as sienna, jasper, brocatello, and porphyry: it is hard, and, when finished, bears a very fine polish. For the method of preparing it, *See* PLASTERING.

SCALE, (from the Saxon,) a line divided into a certain number of equal parts, each of which is subdivided into others, in order to express the parts of an object of a different size, either in a drawing or in a model, but in the same proportion as the original.

SCALE, a mathematical instrument, consisting of one or more lines drawn on wood, metal, or other matter, divided into equal or unequal parts, of great use in laying down distances in proportion, or in measuring distances already laid down. There are scales of several kinds, accommodated to the several uses; the principal are, the *plane scale*, the *diagonal scale*, *Gunter's scale*, and the *plotting scale*. *See* INSTRUMENTS, and PLOTTING SCALE.

SCALENE TRIANGLE, (from the Greek, σκαληνος, *oblique*, or *unequal*,) a triangle that has no two equal sides, nor any of its angles a right angle. A cylinder, or cone, whose axis is inclined to its base, is likewise said to be *scaleneous*.

SCAMILLI IMPARES, a term of uncertain meaning, used by Vitruvius, and much contended about among the critics, though, in effect, it signifies no more than certain zoccoes, or blocks, serving to raise the rest of the members of an order, column, statue, or the like, and to prevent their being lost to the eye, which may chance to be placed below the level, or below the projecture of some of the ornaments. The scamilli are well enough represented by the pedestals of statues. *See* PEDESTAL.

SCAMOZZI, VINCENZO, a celebrated architect, born at Vicenza in 1552. He was educated under his father, Gian-Domenico, an able artist in the same branch; and, at the age of seventeen, he made designs for buildings that were very highly esteemed. He went to Venice for improvement, where Palladio and others were then employed about works of magnitude and consideration, and he made very rapid advances in his profession. At the age of twenty-two, he composed a treatise, in six books, *De Teatri e delle Scene*, which has never been published. In a visit to Rome, he was engaged in the diligent study of the remains of antiquity to be found in that city, and in the study of mathematics under the celebrated Clavio. After extending his tour to Naples, he returned, in 1583, to his native city, and settled at Venice, where, Palladio being dead, he became the first architect, and was employed in various public and private works, of which one of the most remarkable was the additions to the library of St. Mark. He was sent for to Vicenza to finish the famous Olympic theatre, by which he gained credit. In 1588, Duke Vespasian Gonzaga engaged him in the construction of a new theatre at his town of Sabioneta. After this, he visited many of the chief places on the continent; and decorated several other cities in Italy, besides Venice and Vicenza, and few artists seem to have enjoyed a more extensive reputation. In 1615, he published a work, entitled *L'Idea dell'Architettura Universale*, in six books, which contains many useful observations and instructions. The sixth book, which contains the five orders of architecture, is most esteemed, and has been translated into the French language. Scamozzi died in 1616. Besides the writings above-mentioned, he published a work of descriptions, of which three chapters contained the buildings and topography of Rome.

SCANDULÆ, in ancient house-building, shingles, or flat pieces of wood, used by the Romans instead of tiles, to cover houses. This, according to Cornelius Nepos, was the only covering used in Rome till the war with Pyrrhus, 470th year of the city.

SCANDULARII, among the Romans, mechanics who prepared the scandulæ used in covering houses, who were exempted from all public services.

SCANTLING, (from the French, *eschantillon*,) the transverse dimensions of a piece of timber in breadth and thickness.

SCANTLING is also the name of a piece of timber; as of quartering for a partition, or the rafter, purlin, or pole-plate of a roof.

All quartering, under five inches square, is termed *scantling*.

In all scantlings for shoaring, the master-carpenter charges one-third for use and waste; though, when used in very considerable quantities, and in large scantlings, one-fourth is deemed sufficient.

SCANTLING, in masonry, the size of the stones in length, breadth, and thickness.

SCAPE, (from the Latin, *scapus*, a stalk, or stem) the fust or shaft of a column. It is also used for the little hollow, above or below, which connects the shaft of a column with its base, or the part where it appears to rise out of the base.

SCAPPLE, to reduce a stone to a plane surface, without working it smooth.

SCARFING, a term used to denote the junction of two pieces of timber, by being bolted or nailed transversely together, so that the two appear but as one. The joint is denominated a *scarf*, and the timbers are said to be *scarfed*.

In scarfing a beam, the joint or seam must have its dividing surface or surfaces perpendicular to one side of the beam, so as to resist a strain in the direction of the fibres. *See* CARPENTRY.

SCENOGRAPHY, (from σκηνη, *a scene*, and γραφω, *to describe*,) the method of representing solids in perspective; the ichnography is the ground-plan; the elevation, a representation of the vertical planes upon a vertical plane given in position; and when the whole is represented at one view, the representation is called *the scenography*.

SCENOGRAPHY OF A PYRAMID, the same as its perspective representation.

SCHEME, (from the Greek, σχῆμα,) the representation of any design, or geometrical figure, by lines, so as to render it clear to the understanding.

SCHEME ARCH, or SKENE ARCH, a circular arch, whose dimensions are not greater than a semicircle. *See* ARCH.

SCHOFEET. *See* SOFFIT.

SCHOLIUM, (from σχολιον) a note, annotation, or remark, occasionally made on some passage, proposition, or the like. The term is much used in geometry, and other parts of mathematics; where, after demonstrating a proposition, it is frequent to point out how it might be done some other way; or to give some advice or precaution, in order to prevent mistakes; or add some particular use or application thereof. Wolfius has given abundance of curious and useful arts and methods, and a good part of the modern philosophy, the description of mathematical instruments, &c., all by way of scholia to the respective propositions, in his *Elementa Matheseos*.

SCIAGRAPHY, or SCIOGRAPHY, (from σκια, *a shadow*, and γραφω, *to describe*,) the draught of a building, cut in its length and breadth, to display the interior: in other words, the profile, or section of it.

SCIMA. *See* SIMA.

SCOLLOPED MOULDING, a moulding commonly found in Norman buildings, of which the title is sufficiently descriptive.

SCOPAS, an eminent Grecian artist, of the isle of Paros, who flourished in the year before Christ 430. He was equally distinguished as a statuary and sculptor, and was the author of many works which placed his name on a level with those of Phidias and Praxiteles. One of the columns in the temple of Ephesus was his performance; as was one of the four sides of the famous tomb of Mausoleus. Rome possessed several fine works, the productions of Scopas; among which, the most admired were the great group of Neptune and other marine deities, in the Flaminian circus; which, of themselves, might, according to Pliny, have been the labour of a whole life. The same writer speaks of a Venus, the work of Scopas, surpassing that of Praxiteles.

SCOTIA, (from σκοτος, *obscurity* or *darkness*,) a recessed moulding, of an elliptical or circular section, placed between the tori, in the bases of columns. The scotia is most frequently formed by the junction of circular areas of two differant radii; but this is upon an erroneous principle, as it ought rather to be a regular portion of an ellipsis. *See* MOULDINGS.

The scotia has an effect just opposite to that of the quarter-round. The workmen frequently call it *the casement;* and, from its form, it is sometimes termed *the trochilus.* According to Felibien, the cavetto is a fourth part of the scotia.

In the Ionic and Corinthian bases, there are two scotias, the upper of which is the smallest.

SCRATCH WORK, (from the Italian, *sgraffiata*,) a mode of painting in fresco, by preparing a black ground, on which is laid a white plaster; which white being taken off with an iron bodkin, the black appears through the holes, and serves for shadows. This kind of work is lasting; but being very rough, it is unpleasant to the sight. It is chiefly used to embellish the fronts of palaces, and other magnificent buildings.

SCREEN, a partition, or means of separating one part of an edifice from another. Screens are very frequent in churches, especially in those of a more important character, where they are used to partition off chantry-chapels, and such like, from the main building; to enclose the choir, and to separate the chancel from the nave, &c. Such screens are of various materials, but usually of wood or stone, and many of them are of excellent designs and workmanship. *See* ROOD-SCREEN.

The term is also applied to any means of shelter or protection against heat, cold, light, &c.

SCREEN, (from the French, *escran*,) an implement used in making mortar, consisting of three wooden ledges joined to a rectangular frame at the bottom; the upper part of which frame is filled with reticulated wirework, for sifting sand or lime.

SCREW, (from the Dutch, *scroeve*,) one of the six mechanical powers; chiefly used in pressing or squeezing bodies close, though sometimes also in raising weights.

The screw is a spiral thread, or grove, cut round a cylinder, and everywhere making the same angel with the length of it. So that, if the surface of the cylinder, with this spiral thread upon it, were unfolded and stretched into a plane, the spiral thread would form the section of an inclined plane, whose length would be to its height, as the circumference of the cylinder is to the distance between two threads of the screw; as is evident by considering, that in making one round, the spiral rises along the cylinder the distance between the two threads.

Hence the threads of a screw may be traced upon the smooth surface of a cylinder thus: cut a sheet of paper into the form of a right-angled triangle, having its base to its height in the above proportion, viz., as the circumference of the cylinder of the screw is to the intended distance between two threads; then wrap this paper triangle about the cylinder, and the hypothenuse of it will trace out the line of the spiral thread.

When the spiral thread is upon the outside of a cylinder, the screw is said to be a *male* one; but if the thread be cut along the inner surface of a hollow cylinder, or a round perforation, it is said to be *female;* and this latter is also sometimes called the *box* or *nut*.

When motion is to be given, the male and female screw are necessarily conjoined; that is, whenever the screw is to be used as a simple engine, or mechanical power. But when joined with an axis in peritrochio, there is no occasion for a female; but in that case it becomes part of a compound engine.

The screw cannot properly be called a simple machine, because it is never used without the application of a lever, or winch, to assist in turning it. The force of a power applied to turn a screw round, is to the force with which it presses upwards or downwards, setting aside the friction, as the distance between two threads is to the circumference where the power is applied.

For the screw being only an inclined plane, or half wedge, whose height is the distance between two threads, and its base the said circumference; and the force, in horizontal direction, being to that in the vertical one as the lines perpendicular to them, viz., as the height of the plane or distance of the two threads, is to the base of the plane, or circumference, at the place where the power is applied; therefore the power is to the pressure, as the distance of two threads is to that circumference.

Hence, when the screw is put in motion; then the power is to the weight which would keep it in equilibrio, as the velocity of the latter is to that of the former. And hence their two momenta are equal, which are produced by multiplying each weight, or power, by its own velocity.

SCRIBING, a term applied to the edge of a board, when fitted upon any surface.

Thus the skirting of a room is scribed to the floor, in the most ordinary cases; and the method of doing it is as follows: —Lay the edge of the intended skirting upon the floor; then take a pair of compasses, and extend the points so as to be equal to the greatest breadth of the hollow between the floor and the skirting-board, taken in a vertical direction; begin at one end of the board, and, with one point upon the floor, and the other upon the wood, and both points in a line perpendicular to the horizon, draw the compass towards the other end, keeping both points always in a straight line, parallel to the floor, and in the surface of the board, or in the surface of the board extended; and the upper point will trade a line on the board, exactly similar to the surface of the floor; so that, if the superfluous part below the line be cut away, the board will fit close to the floor.

SCRIBING, in joinery, the act of fitting one piece of wood upon another, so that the fibres of both may be perpendicular to each other, and the end cut away across the fibres, so as to fit upon the side of the other.

This method is useful in doors and sashes, when it can be done; but in quirked mouldings, recourse must be had to mitering.

SCROLL, see VOLUTE.

SCULPTURE, (from the Latin *sculptura*,) the art of carving in wood, stone, &c. The term is also used for the carved work itself.

SCUTCHEON, an heraldic shield.

SCYRIUM MARMOR, a name given by the ancients, sometimes to a white, and sometimes to a yellowish marble; both used in the public buildings of the Romans, but seldom in statuary, not being capable of a high polish.

SEALING, the fixing of a piece of wood or iron on a wall with plaster, mortar, cement, lead, or other binding, for staples, hinges, or joints.

SEASONING TIMBER, the act of preparing it for building, by expelling the natural sap.

Added to the other defects of modern English building, particularly that of the metropolis and its immediate neighbourhood, is the improper state in which timber is used.

The major part of our best timber is imported from the north of Europe, *and is immersed in docks*, and lies there floating till it is sold for immediate use; the consequence of this is, that the timber (though even it may be previously seasoned) becomes swelled to much beyond its former and its ultimate bulk; is hastily framed together while the very water is running from it; and very soon after it is so converted, it shrinks to such a degree, that every tenon becomes loose, every joint strains falsely from the shrinkage, and every ceiling and quartered partition cracks by the opening, diminishing, and distortion of the wood.

Some persons fancy, that to immerse timber in water seasons it; however this may be, (and it may well be doubted,) it does not render it fit for use, but the very reverse of it. Timber for ordinary purposes should be shrunken to its smallest limits before it is worked up; the least possible change should occur in the timber after the work is framed and adapted; for all the oblique joints of it, by shrinkage, become perfect, each bearing-timber then hangs straining upon a single point, instead of upon a flat direct abutment; thence many of the struts and other bearing-timbers rend by the weight, hanging merely upon their angles.

In very many cases, dry-rot is engendered in our hastily-constructed buildings, by the quantity of dock-water pent up in the timber, by its mortises and other joints, by the plastering, by the brickwork, and by many other causes. While our timber is at the saw-pit, the water not unfrequently streams from it, and though it may appear choice and close when first selected and wrought, the sun and air in a very few days suffice to render it coarse, open, full of cracks, and wholly unfit for good work.

Our specifications are very strict in the requirement of the perfection and proper seasoning of timber, but these precautions are almost useless. The builder can hardly procure, at any price, timber which is not in a dropsical condition; and twelve months, in general, are sufficient to diminish in bulk, and to split our carpentry, alike whether it be framed for the palace or the cottage—for the public or the individual.

After timber is felled, it should be piled up perpendicularly in an airy dry place, with proper interstices to admit a free circulation of air; and thus both rain and the excessive heat of the sun being excluded, the timber will dry without shakes or fissures.

Some persons, however, prefer to keep the timber as moist as they can, by immersing it in water, to prevent its cleaving. In this case, when the boards have laid a fortnight under water, they have them set upright in an airy place during the heat of summer, and turned every day; by this practice, new-sawn boards, it is said by those who are the advocates for the soaking-system, will floor much better than those which have had many years dry-seasoning.

We are, as we have said, opposed to this practice; but to prevent all possible accidents, when floors are laid, let the edges be shot and brought to a joint, or nearly so; lay them down the first year, and finally fasten them the next, they will then remain without shrinking, provided they be kept dry.

The following particulars should be attended to in seasoning wood. The sudden decay of the timber is generally owing to the sappy nature of the exterior surface, which is by no means capable of being remedied by any application of paint previous to its being seasoned; on the contrary, it has been proved, that such application is actually injurious, since it hinders the free admission of air and heat, which would have the property of extracting that sappy quality which so much contributes to decay and rottenness. When this practice is adopted, the sap strikes inwardly, and, making its way to the heart of the wood, the substance is presently contaminated and destroyed.

As a means of preventing this evil, the timber is sometimes scorched over a flame, turning it about till every side acquires a sort of crusty surface; in doing this, it necessarily follows that the external moisture is dissipated. After this process a mixture of pitch and tar, sprinkled with sand and powdered shells, may be advantageously applied to the parts intended to be under water, while those more in sight, after being well scorched, and while the wood is hot, should be rubbed over with linseed-oil mixed with a little tar. This will strike deeply into the grain of the wood, and will soon harden so as to receive as many coats of paint as may appear necessary.

It has been found, that fir-timber, thus prepared is nearly equal to oak for durability.

The following valuable observations on the seasoning of timber are extracted from an able article on "Timber—Its Treatment and Uses," by Mr. James Wylson, published in the Second Volume of the "Builder:"—

"There are natural and artificial means of seasoning, both of which have their recommendations; but the former has certainly the right of preference, as it gives greater toughness, elasticity, and durability, and therefore should always be employed in preparing timber for carpentry.

"When there is time for drying it gradually, all that is necessary to be done, on removing it from the damp ground of the forest, is to place it in a dry yard, sheltered from the sun and wind, and where there is no vegetation; and set it on bearers of iron or brick in such a manner as to admit a circulation of air all round and under it. In this situation it should continue two years, if intended for carpentry, and double that time if for joinery, the loss of weight, which should take place to render it fit for the purposes of the former, being about one-fifth, and for the latter about one-third. If it is to be used round, it is good to bore out the core, as by so doing, the drying is advanced, and splitting prevented, with almost no sacrifice of strength. If it is to be squared into logs, it should be done soon after some slow drying, and whole-squared if large enough; as that removes much of the sap-wood, and facilitates the drying, and prevents the splitting, which is apt to take place when it is in the round form, in consequence of the sap-wood drying before the heart, from being less dense; also, if it may be quartered, it is well to treat it so after some time, as the seasoning is by that means rendered more equal. It is well also to turn it now and then, as the evaporation is greatest from the upper side.

"To prevent timber warping, it should be well seasoned before it is cut into scantlings, and the scantlings should be cut some time before they are to be used, in order that the seasoning may be as perfect as possible; and if they can be set upright, so much the better, as then they will dry more rapidly, and, as the upper dries sooner than the lower side, they ought therefore to be reversed at intervals.

"When there is not time for actual drying, the best method that can be adopted, especially for sappy timber, and if strength is not principally required, is immediately, on felling, to immerse it in running water, and, after allowing it to remain there about a fortnight, to set it in the wind to dry. This renders timber less apt to crack and warp in drying, and less subject to be worm-eaten, especially the more tender woods; but it must be altogether under water, as partial immersion is very destructive.

"Of steeping generally, whether in cold or warm weather, it must be observed, that it dissolves the substance of the wood, and necessarily renders it lighter; therefore the less that is necessary of it the better; indeed, it is known, that, notwithstanding wood that is completely submersed remains good for a very great period after the water has dissolved a certain soluble part, it is, when taken out and dried, brittle, and in every respect unfit for use.

"For the purposes of joinery, steaming and boiling are very good methods, as the loss of elasticity and strength which they produce, and which is so essential in carpentry, is compensated by the tendency to shrinkage being reduced; the durability also is rather improved than otherwise, at least from steaming. It has been ascertained, that of woods seasoned by these methods, those dry soonest which have been steamed; but the drying in either case should be somewhat gradual, and four hours are sufficient for the boiling or steaming process."

Langton's method of seasoning by extraction of the sap, is another that is considered well worthy of notice; it consists in letting the timber into vertical iron cylinders at top; and the water being heated, and steam used to produce a partial vacuum, the sap relieved from the atmospherical pressure oozes from the wood, and, being converted into vapour, passes off through a pipe provided for the purpose. The time required is about ten weeks, and the cost is about ten shillings per load; but the sap is wholly extracted, and the timber fit and ready for any purpose; the diminution of weight is, with a little more shrinking, similar to that in seasoning by the common natural process.

Smoke-drying in an open chimney, or the burning of furze, fern, shavings, or straw under the wood, gives it hardness and durability; and by rendering it better, destroys and prevents worms; it also destroys the germ of any fungus which may have commenced. Scorching and charring are good for preventing and destroying infection, but have to be done slowly, and only to timber that is already thoroughly seasoned; otherwise, by encrusting the surface, the evaporation of any internal moisture is intercepted, and decay in the heart soon ensues; if done hastily, cracks are also caused on the surface, and which receiving from the wood a moisture for which there is not a sufficient means of evaporation, renders it soon liable to decay.

Various methods have been from time to time proposed for seasoning timber, and preventing its rapid decay; but those which have most engrossed the public attention of late years, are those respectively distinguished as Kyan's, Payne's, Burnett's patents, &c. In the year 1833 to 1836, at the Arsenal, Woolwich, experiments were instituted, having for their object the establishing or otherwise the claims of that first mentioned, and the results of which were of a very satisfactory nature; the Kyanised specimens generally, which were submitted to the fungus-pit when taken out at the end of three years, being sound, while duplicate pieces unprepared were found in various stages of decay. Certain questions, however, presented themselves:—1st. Whether the impregnation to which the timber had been subjected, might not be removable by some cause, and perhaps generate an atmosphere noxious and injurious to health. 2nd. Whether the strength of the timber were impaired or otherwise. The first was satisfactorily determined by Dr. Faraday, who proved by experiment, that the combination was not simply mechanical, but chemical; and that a permanently compound material was formed; the second was formed by experiments made by Captain Alderson, C.E., upon ash and Christiana deal, and which showed that the rigidity of the timber was enhanced, but its strength in some measure impaired, its specific gravity also being somewhat diminished. Another question yet remains open—how far, since the impregnation has not been traced to a depth greater than half an inch, does this process meet our requirements, and after the satisfactory conclusion arrived at as above related, and the evidence of the facts upon which it was so reasonably founded, how are we to meet the assertion of Mr. Pritchard, C.E. of Shoreham, made in 1842. The sleepers Kyanised five years ago, and in use at the W. I. Dock warehouses, have been discovered to decay rapidly, and the wooden tanks at the Anti-Dry-Rot Company's principal yard are decayed.

Mr. Kyan's infusion is corrosive sublimate, and the process consists in submersing the timber in tanks for about a week, then taking it out and drying. Sir Humphrey Davy had previously recommended a weak solution of the same thing, to be used as a wash where rot had made its appearance. Dr. Birkbeck made a favourable exposition of the process as pursued by Mr. Kyan. Sir John Barrow and the Duke of Portland impugn it, and Lord Manners and Dr. Moore follow on the same side. The Payanising process, besides professing to preserve timber from dry-rot and the ravages of insects, is said to render it uninflammable, or at least to deprive it in a great measure of combustibility.

Sir William Burnett's patent process seems to have met with great, and, as we think, deserved success. The various testimonials that we have seen in favour of it, and the time that it has maintained itself in the opinion of the public, induce us to think well of its efficacy in performing what it professes to do. Even if not quite realizing all its inventors claim for it, it certainly will effectually preserve timber for a great number of years. The effects ascribed to it are, that it hardens and improves its texture. It enters into permanent chemical combination with the ligneous fibre, and does not come to the surface of the wood by efflorescence, like other crystallizable salts, and no amount of washing or boiling in water, will remove the chemical compound so formed. It preserves wood and other articles from the adherence of animal and vegetable parasites, and also from the attacks of insects, and from *wet* and *dry* rot. Further, it renders wood uninflammable, when used of a certain strength. The basis of his process is chloride of zinc, or, as it is more commonly called, the muriate of zinc, which seems to have a peculiar affinity to woody fibre, entering into intimate union with its component particles, and forming as it were a new mineralized substance. There is a chemical combination of the metallic base; not merely by a mechanical alteration of the position of matter, which might again be disunited. There is no decomposition produced, but the fibre of the wood appears to be permanently pervaded by the zinc, and the atoms of which they are formed enter into a new and fixed arrangement.

SECANT, (from the Latin *seco*, to cut,) a line that cuts another, or divides it into two parts.

In trigonometry, the secant is a line drawn to the centre from some point in the tangent, which consequently cuts the circle.

SECRETARIUM, the vestry of a church, the same as SACRISTY.

SECTION OF A BUILDING, a representation of the building as divided or separated into two parts, by a vertical plane, in order to explain the construction of the interior. The section of a building not only includes the parts that are separated, but also the elevation of the receding parts, which ought, therefore, to be shadowed with a darker tint. It is obvious that the section of a building ought to be taken so as not only to show the greatest number of parts, but also those that present the most difficulty in their construction. Every building ought to have at least two sections, at right angles to each other, and parallel to the sides of the building: a section of the flues will also be necessary, in order to conduct the interior walls, and to avoid the improper placing of timbers, or mistakes that might otherwise unavoidably take place.

SECTION OF A SOLID, the place of separation that divides one part from another; it is always understood to be a plane surface. *See* STEREOTOMY.

SECTIONS, *Conic*, see CONIC SECTIONS.

SECTIONS OF CYLINDERS, see CYLINDERS.

SECTOR (from the French *secteur*), an instrument for measuring or laying off angles, and for dividing straight lines and circles into equal parts. *See* INSTRUMENTS.

SECTOR OF A CIRCLE, the space comprehended between two radii and the arc terminated by them.

The area of a sector is found by multiplying the radius of the circle into half the arc of the sector.

SEDILIA, seats for the officiating clergy, frequently to be found in the south wall of the chancel of our old churches. They are usually arched recesses in the wall, and are often surmounted by canopies and richly decorated with carving, and sometimes quite plain. They consist of a series of from one to five arches, for so many priests, the usual number being three. The seats are sometimes level, but frequently graduated, following the level of the chancel steps; they are occasionally formed in the sill of a window.

SEGMENT (from the Latin *segmentum*, a shred or paring), any part of a whole.

SEGMENT OF A CIRCLE, the area comprehended by an arc and a chord.

All angles in the same segment are equal.

A very useful practical rule for finding the area of the segment of a circle is the following:—multiply the chord into the versed sine; then, to two-thirds of the product, add the quotient arising by dividing the cube of the versed sine by twice the chord. *See* MENSURATION.

SELL, the lowest piece of timber in a building. *See* SILL.

SEMICIRCLE, the half of a circle contained by the diameter and the circumference.

The angle in a semicircle is a right angle.

The arc of a semicircle is, of course, half of the circle. *See* CIRCLE.

SEMICIRCULAR ARCHES, arches constructed with semicircular arcs. They were much used by Roman architects, particularly in the decline of the Roman empire; and also by the Saxons and Normans in England, and their successors, until they were superseded by the pointed arch: they were again brought into use by the introduction of Roman architecture, in the time of Inigo Jones.

SEPTIZON, or SEPTIZONIUM, in ancient architecture, a term almost exclusively appropriated to a celebrated mausoleum of the Antonines, which, Aurelius Victor says, was built in the tenth region of the city of Rome, being a large insulated building, with seven stages, or stories, of columns.

The plan was square, and the upper stories, consisting of columns, falling back much, rendered the pile of a pyramidal form, terminated at the top with the statue of the emperor Septimius Severus, who built it.

It had its name Septizon, or Septizonium, from *septem* and *zona*, *q. d.*, seven zones, or girdles, by reason of its being girt with seven rows of columns. Historians mention another Septizon, more ancient than that of Severus, built near the Thermæ of Antoninus.

SEPULCHRAL (from the Latin *sepulchrum*, a tomb, or place for burial), something relating to sepulchres or tombs.

SEPULCHRAL CHAPEL, or chapel containing a tomb or sepulchral monument, or in which masses were chanted for the repose of the departed, and in this sense the same as CHANTRY CHAPEL. Such buildings were usually appended to churches, and formed a small kind of aisle.

SEPULCHRAL COLUMN, see *Funeral Column*, under COLUMN.

SEPULCHRAL MONUMENT, a monument erected to preserve the memory of some deceased person. They are of various designs at different dates and places; but probably those of the middle ages in this country will never be surpassed in beauty of conception or delicacy of workmanship. Many fine examples are to be found in our cathedrals. Amongst the most beautiful are those of Wykeham and Waynflete, Winchester.

SEPULCHRE (from the Latin *sepulchrum*, a tomb), or place destined for the interment of the dead. The word is chiefly used in speaking of the burial-places of the ancients: those of the moderns are usually called *tombs*.

Besides the usual sepulchres for the interment, either of the whole body, or of the ashes of such as were burnt, the ancients had a peculiar kind, called *cenotaphia*, which were empty sepulchres, in honour of some persons who, perhaps, had no burial at all, from a superstitious opinion, that the souls of those without burial wandered a hundred years before they were admitted into the Elysian fields. The pyramids are generally supposed to have been built as sepulchres for the kings of Egypt, and the obelisks were erected as mementos of eminent persons deceased.

In our old churches is frequently found, at the east end, usually on the north wall of the chancel, a sepulchral monument, enclosed in an arched recess. This is called the altar-tomb, as also the holy sepulchre, or Easter sepulchre, from the circumstance, that, previous to the Reformation, certain ceremonies were performed here between Good Friday and Easter-day. It is not unfrequently the tomb of the founder of the church.

Such tombs are frequently of very elaborate design, and enriched with sculpture and colour. Two magnificent specimens exist in the presbytery of Westminster Abbey.

SERAGLIO, among Oriental builders, the palace of a prince or lord. By way of excellence, the term is used for the palace of the grand signor at Constantinople.

SERLIO, SEBASTIANO, an eminent architect, a native of Bologna. He flourished, at Venice, in the early part of the sixteenth century. He afterwards travelled through Italy, and resided a considerable time at Rome, where he studied the fine arts, and made many excellent drawings of edifices, ancient and modern. He is said to have been the first who examined, with a scientific eye, the remains of ancient architecture. The knowledge he acquired was given to the public in *A Complete Treatise of Architecture*, of which he planned seven books; and the first that appeared was the fourth in order, comprehending the general rules of architecture, which he printed at Venice in 1537, dedicated to Hercules II., duke of Ferrara. The other six books appeared successively at different intervals; and the various editions made of them prove their popularity. In 1541, Serlio was invited to France by Francis I., and employed in the erections at Fontainebleau. Here he continued till he died, at an advanced age, in 1578. Though, as an author, he was much attached to the principles of Vitruvius, yet, in his designs as an artist, he very much neglected them. His school at St. Roche, and palace of Grimani at Venice, are built in a grand and magnificent style.

SESSPOOL, or Cesspool, a well, or deep hole, sunk under the mouth of a drain, for the reception of sediment, and other gross matter, which, if not there detained, would choke the passage. Sesspools ought to be so contrived, that they may be cleaned without difficulty; otherwise they will fill up, and the evil be communicated to the drains.

SET-OFF, that part of a wall where the face is broken by a projection beyond the general surface, such as where the lower portion of a wall is of greater thickness than the upper, and therefore leaves a ledge at the height where the lesser thickness commences, equal in width to the difference in thickness of the two portions of the wall. This practice is very usual in buttresses, and almost universal in those of mediæval date. Such ledges are usually covered with a sloping table of masonry to carry off the wet, and are termed *set-offs*.

SETTING, a term used in masonry, for fixing stones in walls or vaults. In this the utmost care should be taken that the stones rest firmly upon their beds, and that their faces be ranged on the proper surface of the work. This caution is necessary, as bad workmen, in order to make close joints, only make the beds come in contact adjacent to the face of the work; and, in order to bring the joints flush, they frequently do no more than round the work next to the joint: this convexity has a very disagreeable appearance in the sunshine, when the rays of light fall obliquely upon the work.

SETTING-OUT ROD, the rod used by joiners for setting out windows, doors, or other framing.

SEVERY, a bay or compartment; especially applied to the compartments of vaulted roofs.

SEWER, a large main drain, conduit, or conveyance for carrying off refuse, or soil, from a house, or number of houses.

SEWERAGE, the method of removing superfluous water, rain, filth, night-soil, and other refuse matters from a town or other locality.

The subject connected with this article, is of very considerable importance, as it affects the health, morals, and social well-being of the community; as it is now universally allowed, that the accumulation of refuse matter is dangerous to health, and especially in crowded and densely-populated districts, where it is certain to encourage, if it does not generate, various kinds of epidemic disease; besides which, it discourages habits of cleanliness, and so affects the morals of the lower orders. It is a matter which formerly was not sufficiently attended to; but has of late years forced itself upon public notice, and is at the present day receiving that amount of consideration which it so well deserves.

Although, however, the matter has been widely canvassed, and much elaborate investigation entered into, we regret to say, that hitherto, mere matters of detail have received comparatively more attention than they deserved, and general principles have been too much overlooked; not that we would for a moment undervalue the investigation which is being carried on with reference to minutiæ, which are indeed of the utmost importance; but we think that general principles should have had the first place in the order of investigation. Be this as it may, we must confess, that much useful and practical, as well as theoretical knowledge, has been eliminated by the process, and many improvements introduced which are of considerable public benefit. This branch of professional practice is as yet in its infancy, and we may hope that a few years will add considerably to our practical and theoretical acquaintance with it, when theories, which are now only upon trial, shall have been fully and fairly tested, and some further inquiry entered into with respect to the objects which are sought after, in laying out the drainage of a town.

In considering this subject, a question naturally arises at the very outset, as to the objects to be effected by proper drainage of any locality. Now, formerly the object, for there was but one, was very well defined, and very simple; it was this, to remove the refuse from the neighbourhood of inhabited districts, so that it might not become prejudicial to the health of the inhabitants. Within the last few years, however, some new data have been introduced, and in consequence the question has become more complicated. The inquiry has been mooted as to whether it be advisable to throw away as useless the collected refuse, or whether it may not be employed to some useful purpose; and if so, whether it may not be turned to account as a profitable article of commerce. Many subjects have been named, in the manipulation of which, such matters might be advantageously employed; but of all these, the most important, and that which has the highest claim to consideration, seems to be their application to agricultural purposes, in the shape of manure. Whether indeed the refuse of towns is of value for this purpose, has been, and still is a matter of dispute amongst persons well qualified to judge; but we think the evidence in favour of such application decidedly preponderates.

The value of manures as promoters of vegetation, is said to result from their possession of the essential element, nitrogen, in the form of ammonia, with the subordinate properties of alkalies, phosphates, and sulphates, and we learn from the experiments of Liebig, that the quantity of nitrogen contained in the excrements of a man during one year, is 16.41 lbs., and also that this quantity is sufficient for the supply of 800 lbs. of wheat, rye, or oats, or of 900 lbs. of barley. "This is much more," says the same authority, "than it is necessary to add to an acre of land, in order to obtain, with the assistance of the nitrogen absorbed from the atmosphere, the richest crops every year. By adopting a system of rotation of crops, every town and farm might thus supply itself with the manure, which, besides containing the most nitrogen, contains also the most phosphates. By using at the same time bones and the lixiviated ashes of wood, animal excrements might be completely dispensed with on many kinds of soil. When human excrements are treated in a proper manner, so as to remove the moisture without permitting the escape of ammonia, they may be put into such a form as will allow them to be transported even to great distances." Of the success of sewage matters applied as manure, we have favourable evidence in the practice adopted at Edinburgh, where the pasture-land has been made to produce crops very considerably above the average by this means. Experiments of an equally favourable description have also been tried in various parts of this country, as well as on the Continent; at Milan, and various parts of France and Germany. These, however, only speak as to the success of such manure in a liquid form, against which one or two practical objections may be urged. The first is the expense of distribution; for, in the first place, the sewage waters must be raised to a considerable elevation by artificial means, for the purpose of conveying them on to the surface of the surrounding districts, and this elevation will be greater or less according to the level of the neighbourhood. The second objection consists in the limited area to which such a manure could be advantageously applied; for if the distance were great, the necessary outlay for conveyance would form an effectual obstacle to its employment. Of a similar nature to the last, is the objection which arises from the uncertainty of the demand; for in wet seasons, the manure in this condition cannot be applied; and if at any time the soil be supersaturated, the vegetation is supposed to be injured thereby. Besides, if the sewage be allowed to remain on the surface, it will emit very offensive and injurious odours, and become not only detrimental to the land, but highly dangerous to the public health.

To meet these evils, several methods have been suggested for precipitating the valuable portions of the sewage, and preparing them in a dry state for the purposes of commerce, during which process the matters are also de-odorized and disinfected. It is a matter of dispute, indeed, whether the portions of sewage which are specially serviceable for agricultural purposes can be preserved in a dry form; but besides the evidence resulting from experiments with this form of manure, we have the favourable testimony of Liebig, who thus writes:—"Gypsum, chloride of calcium, sulphuric or muriatic acid, and super-phosphates of lime, are substances of a very low price; and if they were added to urine until the latter lost its alkalinity, the ammonia would be converted into salts, which would have no further tendency to volatilize. When a basin, filled with concentrated muriatic acid, is placed in a common necessary, so that its surface is in free communication with the vapours arising from below, it becomes filled, after a few days, with crystals of muriate of ammonia. The ammonia, the presence of which the organs of smell amply testify, combines with the muriatic acid, and loses entirely its volatility, and thick clouds or fumes of salt hang over the basin." And in the quotation which we have previously quoted, the same chemist states his opinion, that the moisture may be removed without permitting the escape of ammonia, and the sewage put into such a form as to allow it to be transported to great distances. In opposition to this, some persons have asserted, that where the smell does not exist, the fertilizing property has been lost; and others, that although the offensive odour is got rid of, the deleterious properties still remain. These opinions are indeed destructive of each other, and we are inclined to yield the greater amount of credit to Liebig's testimony. Mr. Richard Dover, who propounded a scheme for disinfecting the London sewage, and preparing it for transport in a dry state, made some experiments upon sewage-water taken from the Northumberland-street outlet, in the presence of several persons competent to form a judgment on the subject, and who testify to having been satisfied as to the success of the experiment. Manure prepared by this process has been experimentally applied to agricultural purposes, and, it is said, with very satisfactory results. Mr. Dover further proposes to apply the water, which is left, for the purpose of bleaching and other commercial undertakings.

Such are the statements with regard to the employment of sewage-matters for agricultural purposes: that they are useful fertilizing agents, there seems to remain no reason to doubt; but there still does remain a question as to whether it can be profitably employed for this purpose, considering the subject in the light of a commercial undertaking. Can it compete with other manures already in the market, or will the expense of its manipulation destroy its value as a marketable commodity. These questions still remain to be considered; for although the evidence which does exist seems to favour the speculation, yet this is not sufficiently decisive to justify an undertaking of the kind on a large scale.

Now the very first principles of drainage depend upon the resolution of such doubts; for if the sewage-matter is to be thus employed, we should adopt a very different system to that which would be adopted, had we solely to get rid of the noxious refuse. There would be also a difference of treatment, according to the condition in which the manure was to be applied, whether in a wet or dry state; for in the one case we should be tied down to the most economical method of distributing it over the surrounding country by means of pipes, and should have to regulate our levels and outlets accordingly; whereas, under the latter conditions, we should be left at much greater liberty in arranging such preliminaries.

In the first place, if we treat sewage matters as only deleterious to public health, and incapable of being turned to any useful account, we have to deal with a very plain and simple question; our sole object is to get rid of it. Simple, however, as may be the object to be attained, it is by no means easy of attainment; and of the two cases, this is probably the most difficult. We are well aware that we cannot annihilate the elements of which the matters are composed, however much we may be able to alter their combinations, and perhaps destroy their characteristic qualities. Granting, then, that the noxious properties of the soil can be removed, we find two courses open to us, either to disinfect it, and then dispose of it in any manner most suitable to the locality, or else to remove it, in its primary state, to a distance from human habitation. If we adopt the former course, we may disinfect it either during its passage to its outlet, or may collect the various streams into one or more reservoirs, as the nature of the locality may render advisable, and there disinfect it; after which there will probably be no difficulty of disposing of it, either by conducting it into a river or running-stream, or by some other means which the nature of the place may suggest. If the latter expedient be resorted to, we shall have much greater difficulties to encounter, for we can scarcely consider it inoperative for evil, until it is safely and fairly launched into the wide ocean; until it has arrived at this point, we are not secure against its fatal influence. This, however, is no easy matter to accomplish: to effect the object in view, we instinctively look for some natural channel, by means of which it may be conveyed to its proposed destination, and this is presented to us in the shape of a stream or river; to conduct it to the sea by artificial means, would, in the majority of cases, be entirely out of the question, on account of its enormous expense; we must therefore adopt the river as a last resource. We are well aware that this is objectionable on many accounts; but if we are compelled to get rid of the offensive matter, we would ask, what other method of effecting this object remains open to us. We know the question will arise, as to whether under such circumstances the sewage ever reaches its destination; and it would be very difficult to answer positively that it does, and therefore probably we must rest content with a palliative measure, and remove it from the more densely populated districts only. Where there is a good river, not a tidal river, this may be effected readily, for the sewage discharged into the river will be conveyed with its waters in an onward course without interruption, depositing probably some of its heavier particles, but not in such large quantities as to become dangerous. In a tidal river, however, the state of the case is altered, for although we have the advantage of the ebb-tide in conveying the refuse towards the sea, we have the corresponding disadvantage of the flow bringing it back again.

It has been suggested with reference to the drainage of London by the Thames, that as the flow is of only 5 hours' duration, and the ebb of 7, and that during that time the range of flux is 7 miles, and reflux 10, therefore a progressive movement of 3 miles is made towards the outlet every ebb and flow. This conclusion has been arrived at without sufficient data, for it has since been established by actual experiment, that not only is there a progressive and retrograde motion going on every tide, but that the same process takes place with a series of tides, and that after a float has made a certain progress down the river by the excess of the flux over the reflux, it turns, and makes an actual retrogression up the river, by the excess of the reflux over the flux, until it arrives once more nearly up to the point whence it started.

From this it will appear that, in a tidal river, there will be a great difficulty in carrying refuse matters to sea, or even from the vicinity of towns, if it be allowed to discharge at or near the town; it will constantly be carried about backwards and forwards, and depositing its solid matters in the bed, or on the banks, of the river. The sole remedy for this seems to be, to extend the sewer to such a distance from the town for discharge, that the tide may not at any time be able to carry it back near the town. Another object will be, to make the discharge at high-water, or as near high-water as possible, so that it may have all the advantage of the first ebb. This, however, is not always practicable in low-lying districts, unless, indeed, we employ artificial means for raising it ere it reaches the outlet.

Let us now consider the question under another aspect; supposing the refuse to be turned to account for agricultural purposes: this, although somewhat more complicated, we shall probably find more easily dealt with than the previous case. The question again resolves itself into two distinct parts,—the first where the sewage is used in a liquid state, the other where it undergoes a preparation previous to use, and is applied in a dry state,—and these two will require somewhat different treatment. The first arrangement, where the manure is expended entirely upon the surrounding neighbourhood, must depend, in a great measure, upon the character of the neighbourhood, and the comparative levels between it and the town to be drained. In this case it will be advisable to divide the town into different drainage levels, corresponding with the general or average altitudes of each distinct level of the adjacent country, and provide each drainage level with a separate outlet, situated as near the corresponding level of the adjacent land as may be in other respects convenient. By so doing we shall dispense to some extent with the use of pumps, and other expensive contrivances for raising the manure; we shall also save a considerable amount of excavation, and avoid very large main sewers. It must not be supposed, that here, or in any other places in this article, we lay down fixed rules of universal application, but rather throw out hints which may be found generally useful; the peculiarities of each particular locality must decide the method of drainage; there may be some localities where the above directions may not only be unadvisable, but simply impracticable, and we only bring them forward that they may not be left out of consideration in any instance, and may be adopted when found to be eligible. It is useless to think of laying down positive rules in such cases, where the nature of the subject to be treated of must necessarily vary in individual instances.

The last case which we have to consider is, when the sewage is to be applied for agricultural purposes in a dry state, and this will, we think, prove to be the most simple of the three. We have here only to collect the sewage, and conduct it into one or more tanks, in such situations as may be most convenient, where it will undergo a process of disinfection, and will be precipitated, or solidified for the purpose of conveyance to such lands as may require it, either in the neighbourhood, or at a distance. It will be advisable that the tanks be at some distance from the town, to obviate any danger or inconvenience which may arise during the preparation; and it is further to be desired, that they should be near a canal, river, or railway, so as to present facilities for carriage to distant localities; it would be well if they could be placed in proximity to both rail and river, for while the former will be very convenient for the purpose of conveyance, the latter will be further useful for the discharge of the sewage-water which remains after the extraction of the solid matter, if, indeed, it be not applied to some more useful purpose. This water may be discharged into the river without inconvenience or danger, for if not already sufficiently purified, it would be no difficult matter still further to purify it by filtration. If a ready means of discharge for the supernatant water be provided, the size of the tanks may be greatly diminished, and in the same, or rather greater, proportion, the expense and difficulty of their construction.

We have now considered the subject as regards the three different methods of disposal of the refuse most likely to occur in practice. We must again express our regret that greater labour has not been bestowed on the question of the practicability of the two last methods, yet at the same time we must take occasion to remind the reader, that even had this question been generally disposed of, it would not follow that any particular practice would be advisable in every individual case. The proper determination of the method to be adopted, must be the result of a careful investigation of the nature of the several districts to be drained; one method may be convenient in one place—another, a different one, in a second. We have here considered the subject solely as regards the disposal, and principally with reference to outlets, as these are the most affected by the various methods of disposal; let us now turn to the principles of town-drainage generally.

The first thing to be done in laying out a system of drainage, is to prepare a carefully surveyed map of the district to be drained, showing at least the main levels: at the outset, perhaps a block plan will be sufficient; but before the question is finally determined upon, and details entered into, it will be necessary to have the blocks filled in. To do this, it will be requisite that the map be on a sufficiently large scale; that adopted by the Ordnance Survey, five feet to a mile, or one somewhat larger, will be found convenient, and on this, additional levels must be laid down before entering into detail. It will be advisable ere commencing the consideration of the subject, to prepare from this a map on a reduced scale, containing in addition some considerable portion of the surrounding country, so that the consideration may not be confined to a limited space, without reference to the circumstances of the more immediate neighborhood; by so doing, much future trouble and expense may be avoided; by all means let the consideration of the subject be comprehensive. It will greatly assist, if the contour-lines be laid down on this map, so as to afford at a glance a tolerably accurate idea of the nature of the ground. It will be further necessary to obtain information respecting the geology of the district, as well for matters of construction as for other purposes, and also some general notion of the nature of the soil with reference to agricultural matters, in order to determine the extent to which the town-refuse may be employed as manure in the immediate vicinity. These, however, and other matters necessary to be known, will naturally suggest themselves to those engaged in such works.

The surveyor having made himself thoroughly acquainted with the character of the district to be drained, will be in a proper position to determine the system upon which to commence operations. The practice of our predecessors has been, to collect the sewage matter, and convey it by the shortest route to the nearest river, into which it was to discharge; this done, their object was attained; the matter was left to remove itself, or deposit on the banks or bed of the river, as best it might. This method is now generally allowed to have been based upon false principles; but it must at the same time be confessed, that to a certain degree it did follow out the course suggested by nature. That the drainage should be carried towards the river, is not to be objected to; for it amounts to nothing more than conveying it to the lowest level of the district; it is the very course which nature adopts, for rivers and streams are indeed the drains laid out by nature; the only mistake consists in polluting these waters with matters which are prejudicial to health; had we only to deal with surface-drains, the system would be rational enough. Some persons, because this method has been abused, have thought it right to discard it altogether; we cannot follow them thus far; if the area to be drained presents throughout one general slope towards the river, we are inclined to think that this would be the most suitable method of drainage, having the outlet or outlets at the lowest level. If the sewage is to be supplied in its liquid state to the surrounding country, it may be advisable to intercept a portion ere it reaches this point, but this the circumstances of each case must decide; by such means we should of course be better able to irrigate the higher lands, and should also effect a saving in the size of our sewers, for the lower branches will not have so large a quantity to discharge.

If again the levels of the main be greatly diversified, or especially if it consist of basins surrounded by higher ground, it would appear advisable, under any of the above conditions, to provide a separate drainage for each level, so as to avoid the great depth of excavation which would be necessitated, were the drainage of the higher levels to be connected with a main which had already received that of a lower level. The better plan would be to convey this line through the lower levels to its outlet, and to form a separate system for the higher grounds. Whether it would be advisable to drain all the low levels together by one trunk-line, and all the high levels by another, or to drain each level separately, must be determined by the circumstances of each special case; as we said before, no fixed rules can be laid down, we can only propose useful hints to be applied as the nature of each case suggests.

Having disposed of these general matters, we now come to consider the subject more in detail; but before doing so, let us clearly understand, and determine what we have to do, and what class of subjects we have to deal with. Our general object is to convey to a distance the refuse, or a certain portion of the refuse, of the town, or other area to be drained, and what does this consist of; it is mainly of two descriptions, viz., that which may be particularized as house-drainage, consisting of the excrements of the inhabitants, and all refuse matters connected with household economy; and that which is distinguished as surface-drainage, which has especial reference to rainfall and storm-waters. Formerly it was the custom to make no distinction between these two descriptions; but of late, we have begun to consider them as separate items, and a grand question has been raised as to whether it is correct to provide for them both by the same system of drains. In the one case, the supply is, or might be, made tolerably uniform; in the other, it is periodical and uncertain, nor can it be made otherwise; it therefore becomes a question, whether the two can be advantageously combined, but as the inquiry is so mixed up with the determination of the size and shape of sewers, it will be better to consider it under that head. We have made no allusion to subsoil drainage, for it is indeed very rarely required; if the surface be properly drained, there will be no necessity for subsoil drainage, except in cases where springs exist, or where the strata contain water, and, even in such cases, it is questionable whether the water might not be usefully employed, rather than carried away at a considerable expense. We shall leave this part of the subject therefore out of the question, and turn at once to the consideration of the sizes and forms of sewers.

Until the last few years, it was the custom to construct sewers of a very large size, varying in sectional area from 5 to 100 feet, the former being allotted to collateral sewers in courts, alleys, and side-streets, and the latter to the main outlets into the Thames, the average area for main lines being about 12 feet. Now, the fact is, that these sewers were seldom, if ever, fully charged, the sectional area of the stream usually flowing through them, averaging not more than $\frac{1}{10}$ part of the area of the sewer, and the flow being often scarcely perceptible. In continuous wet weather, the area of sewage was greatly increased; and also on such days as fresh water was supplied to the houses; in neither case, however, was the sectional area equal to $\frac{1}{4}$ that of the sewer, and the only occasion on which the sewers were anything like full, was the occurrence of some very heavy storm, such perhaps as does not appear once in the course of a twelvemonth. Now, it appeared to those who have recently brought forward this subject for investigation, that a much smaller size would answer the purpose much better, and be decidedly much more economical in construction. Under this impression, several experiments were made under the Metropolitan Sewage Commission, to test the fact, and the result appears to have been decidedly favourable to the new theory.

In a main line of sewer in Upper George-street, Edgeware-road, which communicates directly with the King's Scholars' pond sewer, and which is 5 feet 6 inches in height, by 3 feet 6 inches wide, an earthenware pipe 12 inches in diameter was inserted, laid immediately upon the invert of the larger sewer, and a head-wall built up above it in the sewer, for the purpose of preventing any sewage-matter passing out by a different channel. The total length of this pipe measured 560 feet, and the whole area drained through it amounted to about 44 acres. The results are stated to have been as follows:—"The velocity of the stream in the pipe has been observed to be $4\frac{1}{2}$ times greater than the velocity of the same amount of water on the bed of the old sewer. The pipe has not been found to contain any deposit, but during heavy rains the stones have been heard distinctly rattling through the pipe. When the pipe is nearly filled, the velocity and concentration of the water are sufficient to clear away any matter which may have been drawn into the pipe from the large sewers, much of which matter, it may be presumed, would never enter a well-regulated system of pipe sewers; also the force of the water issuing from the end of the pipe, is sufficiently great to keep the bottom of the old sewer perfectly clean for 12 feet in length; beyond this distance, a few bricks and stones are deposited, which increase in quantity as the distance from the pipe increases. Beyond a certain distance, mud, sand, and other deposits, occur to the depth of several inches, so that the stream there is wide and comparatively sluggish, and being dammed by the deposit, exerts an unfavourable influence on the flow of water through the pipe. On the invert of the original sewer, which now forms the bed of the pipe, deposit was constantly accumulating, and was only partially kept under by repeated flushes. The superficial velocity of the water in the pipe is generally three, four, and five times greater than the superficial velocity which obtained, under the same circumstances, in the original sewer, and the velocity of the whole mass of water in the pipe approximates much more to its surface velocity, as ascertained by a float, than does the velocity of the whole mass of water in the sewer approximate to its own surface-velocity."

Several experiments in this pipe were also made, to determine the propulsive force exerted by the water in removing obstacles, and it was found that quantities of sand, mud, and pieces of brick and stones, were carried from the inlet through the entire length of the pipe, where they were discharged with considerable force, and carried some distance along the invert of the original sewer. All these experiments were effected when the pipe was only or less than half-full of water. The period of year at which the experiments were made, was principally during the month of October, and the following is the detailed daily account of the depth of water in the pipe:—

September 28 and 29. Very wet both days and nights; there was at this period 96 hours' continuance of rain, and the pipe was never observed to be more than half-filled.

October 19. Morning, depth of water in pipe 3 inches; afternoon, depth 2 inches.

October 21. Heavy rain all day; depth of water in pipe 4 and 5 inches.

October 23. Morning, 3 inches; afternoon, very heavy rain, when the pipe filled.

October 24. Morning, depth varied from 2 to 2½ inches; afternoon, from 2½ to 3 inches.

October 25. During the day, depth of water varied from 2 to 2½ inches; afternoon, from 2½ to 3 inches.

October 26. Morning, depth varied from 4 to 3 inches; afternoon, from 2½ inches to 3 inches. During the above three days, the weather was mostly fine. The considerable variations are due to the times of the water being on at the houses; the sewage at such times is much clearer, as well as increased in quantity.

October 27. On this day a storm occurred, which, for a short period, was very violent; the waters filled the pipe, and rose above it 18 inches, but did not reach the top of the head-wall; when the waters had reached this maximum height, they receded to nearly the level of the pipe in twenty minutes.

October 28. Depth during day varied from 3 inches to 1½ inches.

October 30. Depth during day varied from 2 inches to 2½ inches.

October 31. Depth during day varied from 1½ inches to 2 inches.

November 1. Variation of depth from 1½ inches to 2½ inches.

November 2. Variation of depth from 2 inches to 2½ inches.

Another series of experiments was very carefully superintended by Mr. Lovick, Surveyor to the Commission, in Earl-street, Marylebone: the original sewer presenting a sectional area of 15 feet, and having a flat segmental invert 3 feet in width, in which deposit accumulated at the rate of 6,000 cubic feet in 31 days. The area draining into this sewer was 43.656 acres; and the number of houses drained 1135. Upon the invert of this sewer, a 15-inch glazed stone-ware pipe was laid for a length of 115 feet, and having an inclination of 1 in 153.

From these experiments, it appeared that the average consumption of water was about 5.7 gallons per individual per day, or 51½ gallons per house per day; the average quantity discharged when there was no rain, and no fresh supply of water, was 44½ gallons per house per diem; and on the days when the water was supplied to the houses, 209 gallons per house per day. Thus the mean flow on the days when water was supplied to the houses by the water companies, was nearly 4¾ times greater than the mean flow on ordinary days, or days when there was no supply.

The annexed table, deduced from those experiments, will give a correct idea of the several conditions of discharge on ordinary and water days:—

Days.	Quality of Flow.	Cubic feet per minute.	Sectional area of flow in pipe.	Diameter of circles, equal in area to the sectional area of flow.
			Inches.	Inches.
On ordinary days.	Least	1.78	3.05	2.00
	Mean Least	2.10	—	—
	Mean	5.64	8.57	3.4
	Mean Greatest ..	16.90	18.14	4.9
	Greatest	46.50	—	—
On water days.	Least	1.07	1.66	1.5
	Mean	26.46	27.94	6.00
	Mean Greatest ..	106.00	—	—
	Greatest	150.00	109.79	11.8

The maximum being greater than the minimum, on the water days 140 times, and on ordinary days 26 times. The experiment was continued for 30 days, 16 of which were water days, and the remaining 14 ordinary days, and the period of the year at which it took place was during the months of February and March. The *least flow* in the above table refers to the least flow which occurred at any one time during the range of observations; the *mean least*, to the average of the lowest discharges of every day; the *mean*, to the average of the mean of all the observations; so also of the *greatest* and *mean greatest*.

As an evidence of the false principles on which the old system was based, the same surveyor states that the sectional area of the drains in this block of houses was 596 feet, whereas the sectional area of the outlet sewer was only 15 feet, or about one-fortieth the aggregate sectional area of the house-drains. He also states, as the result of his experience generally, that blocks of houses drained with 3, 4, 6, and 9-inch pipes, have been more efficiently drained than under the old system.

The same opinion, with reference to the size of sewers, was given by Mr. Phillips, also Surveyor to the Metropolitan Commission and the late Westminster Commission, in his examination before the Sanitary Commissioners; but he considers a constant supply of water indispensable, if smaller sizes be adopted. In answer to the question—

"Have you at all considered the capacities of sewers necessary for draining the different areas of ground?" he replies, "Yes; I have given the subject much attention. If the consideration of the sizes of sewers was confined solely to the carrying off the water supplied by the several water-companies, then I apprehend that pipes somewhat larger in size than the supply-pipes themselves, would suffice; but provision has to be made for receiving and carrying away the waters of heavy rains. In London, continuous heavy falls of rain are not of long duration, lasting seldom more than from one to four hours. About one-fifth of the quantity that falls, is absorbed partly by the dryness of the surface of the roofs, the paving, and the ground, and partly by the porosity of the ground itself. A farther proportion is also prevented from flowing to the drains and sewers at all by hollows in the surface, and again reascends into the atmosphere as vapour. There is also a small quantity that enters into the composition of animal and vegetable bodies. Then there is the resistance the flow experiences from the friction of the entire surface, being accelerated or detained in proportion as the surface is more or less inclined. To provide for the discharge of a fall of rain of two inches in depth, has been considered by Mr. Hawksby, C. E., the extreme datum upon which to proportion the capacities of town-sewers generally. Now I believe that, practically, the sizes in his table, although they may appear theoretically correct, are (excepting for the smallest sizes) too large for sewers in London. It is extremely violent rains alone that produce a depth of two inches per hour, and such rains occur only once in four or five years, if so much. I am of opinion that it is unnecessary to proportion the size of the sewers to meet an extraordinary occurrence that may probably happen only once in so many years. My reason for not fearing any serious damage from an excess of rain at remote intervals, being provided for in surface-channels, excepting perhaps in situations peculiarly liable to inundation, (for instance, at the foot of a long or steep declivity, or where the waters may from any cause be suddenly congregated at one focus,) is that I have observed, that in towns entirely destitute of underground drains, no such inconvenience is felt as would justify the formation of enormously large sewers, or the expenditure of large sums of money to provide against it."

The evidence of Mr. Roe, late chief Surveyor to the Metropolitan Commission, and previously to the Holborn and Finsbury Sewers, will be deemed most valuable, if not conclusive on this subject, both on account of his long experience, his straightforwardness, and unbiassed judgment; he was also the first to pay attention to the subject, and introduced many improvements, before it had become the topic of general consideration. In his evidence before the Sanitary Commission, he states as the result of his experience, that a cylindrical sewer, 48 inches in diameter, with a fall of 1 in 240, is sufficient to drain 100 acres of town-area, allowing for a fall of rain unusually large. Also that in a street 924 feet in length, containing 93 houses on an area of 6 acres, 1 rood, 8 poles, a fall of rain 2 inches in depth, producing 346 cubic feet of water per minute, would require a sewer of 2.44 feet capacity, with an inclination of 1 in 480. Allowing further for a supply of water of 75 gallons per day to each house, he would add to the capacity of the sewer .16 of a foot, making a total of 2.6 feet. With respect to uncovered land, he gives as the result of five months' observation, that the greatest amount that was found to reach the invert from a fall of rain of $\frac{1}{2}$-inch in the hour, averaged 3 cubic feet per acre per minute at the period of the greatest flow, and that that period was generally from the greatest to one hour after the heaviest portion of the rain had fallen.

Mr. Roe's observations on the flow of water in the Fleet Sewer are of great practical value. This sewer, at its outlet into the city, is 12 feet high by 12 feet wide, with a superficial area of 120 feet; it receives the discharge of 60 sewers, the total sectional area of which amounts to about 550 feet, and its inclination varies from 1 inch in 100 feet to 1 inch in 2 feet, while some parts are on a level. The area drained by it consists of 1,181 acres of town-area, and 2,656 acres of rural district. During the unusually heavy thunder-storm which occurred on August 1, 1846, the area of flow at this part of the sewer measured 106 feet; in a heavy thunder-storm in July, 1844, the sectional area of flow was 79 feet, and on an extraordinary thaw, after fall of snow in 1841, the area occupied was 54 feet, while the ordinary flow does not cover an area of 10 feet.

The following table, made under the directions of the same gentleman, are from gaugings of several sewers under his charge, and will give a fair notion of the true state of the case:

Table of Gauging of Sewers.

Area drained.	No. of Houses.	Capacity.	Run of Water.			Area occupied.	During greatest rain in 1846, area occupied.	Distance from the Thames.	Height above Thames high-water mark.	Inclination.
			Average common run.	Area occupied.	When water let on from pipes.					
Acres.		Feet.	Inches.	Feet.	Inches.	Feet.	Feet.	Chains.	Feet.	
110	..	13	3	..	..	..	13.00	120	36	$\frac{1}{2}$ Inch in 10 feet, a main line.
5	100	9.0	$1\frac{1}{2}$	0.08	2	0.13	2.50	150	47.0	3 Inches in 50 feet, collateral Sewer
2.70	69	7.65	$\frac{3}{4}$	0.024	$1\frac{1}{4}$	0.06	2.10	166	52.0

0.84	40	1.22	..	0.17	.. Engine waste water.	..	1.22	92	48.0	$5\frac{1}{2}$ Inches in 100 feet.

In opposition to this evidence, we have the authority of such names as Walker, Cubitt, and Brunel, names which may not be passed by unnoticed, although with the previous statements before us, it seems somewhat difficult to coincide with their views. While, however, we pay due deference to gentlemen of such high standing in their profession, we must not forget that such men as Mr. Roe have probably had the greater experience in this particular class of works. Let us attempt to simplify the question as much as possible.

The objections raised against the old system are, 1st, that they are unnecessarily expensive—2ndly, that they are inefficient Their great expense arises from their size, therefore we have to show that their size is unnecessarily large. That they are larger than required for the ordinary drainage cannot, we imagine, be a matter of question, after the result of the above observations and experiments have been made known; nor can we attempt to disprove the unvarying evidence on this point, given by persons practically acquainted with the subject; the table of gaugings by Mr. Roe seems to decide this question, for during the extraordinary storm, in 1846, we find that by far the majority of the examples were not full on that occasion, nor, indeed, nearly so. Out of 16 examples only two were filled on this occasion, one of which was a main line of 13-feet capacity, draining an area of 110 acres, and the other a 15-inch drain, relieving an area of 0.84 acres. During the experiment in the Earl-street sewer, which happened in a wet season of the year, a 15″ pipe was found more than sufficient for the drainage of 44 acres of covered ground, with only one exception, which occurred during a heavy storm, when the discharge amounted to above 300 cubic feet per minute. In the experiments in Upper George-street, during a continuance of 96 hours' rain, the 12-inch pipe was never observed to be more than half full; but on one occasion, during a violent storm, the water rose 18 inches above the pipe; this state of things, however, lasted but a short time. The area drained by the Upper George-street sewer was also 44 acres.

Now, putting aside for the present the question as to whether the pipes used in the above experiments were of sufficient capacity, Mr. Roe's experiments, which give, we think we may say, the very greatest amount of discharge which can ever take place, are decisive thus far—that by far the majority of existing sewers are very much larger than can at any time be necessary; and with respect to the exceptional two, it remains a question, whether under an improved system of drainage they would ever have been put to such a test, but under the old system, when, occasionally, a sewer got smaller towards its outlet, the levels were ill-arranged and defective, &c., it is not to be wondered at, that sometimes one sewer had to perform more than its fair share of work, whilst others were almost inactive; if the sewage had been more equally distributed, no one sewer would have been so much overcharged.

Taking then the maximum quantity ever discharged, as the rule to guide us in fixing the proper dimensions of sewers, we find that the old system is too capacious; but beyond this it is questionable whether it is necessary or advisable to provide for such extraordinary flow, and this question becomes of more importance, if it can be proved that extra capacity is detrimental to the efficient discharge of sewage matters. In this state of the case, the real matter at issue is, whether it be preferable to be subject to a constant inconvenience, or a temporary and problematical one. Some say we must provide for all emergencies; others would rather run the risk. We are inclined towards the latter opinion. But there remains another argument in favour of large sewers, and that is, that they admit the passage of a man, for the purpose of inspection and periodical cleansing, which the advocates of the old system deem to be necessary; if, however, it can be proved that smaller sewers will keep themselves free from deposit by the extra velocity and scour of the water, this objection will be removed. Again, this objection will not hold good against the substitution of very small pipes for those sewers which, although much larger than requisite for the ordinary flow, cannot conveniently be entered for this purpose; for if the work causes great discomfort to the labourer, it is certain that it will not be performed efficiently, if, indeed, it be performed at all; we should imagine that sewers less than 4 feet in height, are not inspected much more frequently than a 15-inch pipe would be.

We have now to consider whether drainage may be more efficiently discharged by a small than a large sewer. The small quantity of water ordinarily passing through the large existing sewers, is allowed, on all hands, to be very sluggish in its movement; and that a deposit of solid matter is always going on, and that to a considerable extent, is evident from the fact, that large quantities of solid matter are obliged to be periodically removed by flushing or hand-labour, and in several cases when old drains have been opened, they have been found to be almost choked up by such accumulations. It is certain, therefore, that large sewers do not of themselves efficiently remove the refuse matters. This defect was observed some years since by Mr. Roe, and the cause being determined upon, it was attempted to remedy it by reducing the width of the invert of the sewer, and thus narrow and deepen the channel for the water, thereby producing less frictional area, a greater depth of water, and consequently a greater velocity and improved scour. This practice was found to succeed, and was afterwards adopted in other localities. It may be noted in passing, that where much deposit has taken place, it is observed that the stream forms for itself a sort of gut or narrow channel, thus giving visible evidence of the requirements of nature in this particular.

As the question relating to the velocity and scour of a body of water in various-sized channels was of considerable importance in determining upon a system of drainage, a series of experiments upon the flow of water through various-sized pipes was made, under the direction of the Metropolitan Commission; and amongst the results given, we find that a 3-inch glazed stone-ware pipe, 50 feet in length, with an inclination of 1 in 120, and being fully charged at the head, will discharge 100 gallons of sewage water in 3 minutes; and that a 4-inch pipe under precisely similar circumstances, will discharge 200 gallons in the same time; and further, that such a flow is sufficient to remove any, and even more than ordinary and usual semi-fluid deposit, such as is usually found in house-drains. A mixture of sand with water, in proportion of from $\frac{1}{16}$ to $\frac{1}{40}$ the volume of water, was also removed. Also that the hydraulic mean pipe of a 3, 4, 6, and 9 inch pipe, when half full, is respectively .749, 1.00, 1.5 and 2.18 inches, and that the fractional line, under the same circumstances, would be 4.71, 6.28, 9.42, and 14.13 inches respectively. Further, that 1 gallon of water through a 3-inch pipe, moved 1 lb.; through a 4-inch pipe, 3 lb.; and through a 6-inch pipe, $\frac{1}{2}$ lb.; and that 3 gallons of water will carry off 1 lb. of solid fæces through a 6-inch pipe with a fall of 1 in 10; but to make these results of use, we ought to be acquainted both with the fall and velocity. Another statement is this: if 81 seconds suffice for the discharge of 50 cubic feet of clean water, 84 will suffice when $\frac{1}{40}$ of solid matter is added, and 91 seconds when the solid matter amounts to $\frac{1}{16}$.

Such results are generally in favour of the small pipes, but it is to be regretted that the experiments were not carried on on a more extensive scale, for they afford little information respecting the larger kinds of pipes. It will be generally allowed, however, that a concentrated body of water will move with greater velocity than the same amount where spread over a large surface, the resistance offered by friction will be less effective in retarding its progress, and the greater depth afforded by narrowing the channel will tend to improve the scour. The scour will depend both upon the depth and velocity of the stream, and will therefore in both ways be more efficient in a contracted channel. On these two properties, depend the efficiency of the drain; for if the velocity be greater, the discharge will also be greater, and the power to keep the sewer free from deposit will increase in like manner; for, in the first place, there will be less tendency to deposit; and in the second, when a deposit takes place, it will be more readily removed. This is both reasonable in theory, and has been proved in practice, for the evidence of Mr. Lovick and others, who have had opportunity of examining the state of small pipes after they have been in use some time, goes to prove that they keep themselves almost perfectly free from deposit. It will be perceived by the following table, prepared from the experiments made in the Earl-street sewer, that the quantity of solid matter in suspension in sewage-water, bears but a small proportion to the liquid, and it is therefore probable, that with a fair velocity of flow there would be but little tendency to deposit.

Tables of Solid Matter in Suspension in the Flow.

No. 1.—On the Extra Water-Days.

The principal objections against the use of small-pipe sewers are: 1st. That if any obstruction occur in the pipe, so as to cause accumulation of deposit, the pipe rapidly becomes completely stopped up, whereas, in the larger sewers, even though obstructions may occur, they will not entirely stop the flow, or at least the accumulation must proceed for a considerable period ere the entire area be filled up. 2nd. That if such stoppage take place, there is no means of ready access to the sewer to examine it, and that the road will probably have to be broken up in several places ere the drainage be repaired; and even then it is almost impracticable to reinstate the pipes in the same conditions as when first laid down. 3rd. That owing to the nicety required in laying the pipes, an uniform inclination is not easily preserved, nor is there any satisfactory means of knowing when the invert is perfectly smooth; that if the pipes be defective in form, or imperfectly laid, or if the cement with which the joints are made be allowed to project within the pipe above the general surface, an obstacle is at once offered to the flow, which is not unlikely to cause deposit, and thereby a stoppage in the pipe.

Now, in the case of the first objection, it does appear feasible, that a small pipe would be more rapidly filled up than a large sewer, but yet there are some grounds for supposing the contrary to be the case; for as the water-way becomes contracted, so also does the scour of the stream increase; and moreover, the stream being ponded back, we shall have a full head of water to increase the power of the flow, so that it would appear, that unless the matter causing the obstruction be extremely difficult of removal, the water-way is not likely to be entirely closed up.

The second objection must be allowed to possess considerable weight; in case of stoppage, it would, in truth, be a matter of great difficulty and inconvenience to remedy the accident; yet, at the same time, we must not forget, that even in brick sewers, if they be of the smaller class, there is no very ready means of access; and moreover, they are more likely to encourage deposit; we are inclined to think, that if pipe-sewers be carefully laid, and fairly used, they would not be likely to silt up. The objection to breaking up the roads, for the purpose of discovering the stoppage, can scarcely be overrated; and it is also true, that it is very difficult to relay the pipes in their former position, unless indeed they be made with half-socket joints, or be made of two semi-cylindrical pipes one laid over the other.

The nicety required in laying the pipes, and the difficulty and uncertainty attending the practice, is certainly objectionable; there is no means of seeing the interior of the pipe, to observe how the work is performed, and it is not unreasonable to suppose, that the cement at the joints, by the carelessness of the workmen, is sometimes left to form a projecting ridge above the surface of the invert. To prevent any obstructions at the joints, it has been proposed to make the pipes of a slightly conical form, inserting the smaller end of the first into the large end of the succeeding pipe; this, however, seems rather an awkward method of meeting the difficulty; and we are inclined to think, that a better method would be, to make the pipes in two pieces, as suggested above, first laying the inverts and securing their accuracy, and then covering them over with the upper half; but neither is this plan without objections.

As regards the separation of house from surface drainage, so long as the latter bears so small a proportion to the former, we do not think it advisable to form a separate system for each; but in cases where the proportion of surface-water is increased, and the house-drainage tolerably uniform, it may possibly be advisable to separate them, if the sewage be intended for dry manure; otherwise, we should scarcely deem it expedient: with reference to the size of sewers, we do not think it necessary to provide for extraordinary storms; we would rather have the advantage of a good general drainage, and the occasional and temporary inconvenience caused by a heavy storm, than be safe from the latter, with the constant inconvenience of imperfect drainage. Generally speaking, we should advise a system of pipe-sewage, somewhat larger in proportion to the area drained, than that observed in those laid down for experiment in Earl-street; for besides, that on such occasions the pipes are likely to be more carefully laid than in ordinary cases, we find that on one occasion during that month, the water reached a height of 9 inches above the head of the pipe. We would allow for such storms as are likely to occur once a month, but not such as occur only once in three or four years. On this one occasion, at Earl-street, the discharge was above 300 cubic feet per minute, and as a similar overflow is recorded in Upper George-street, we may reckon that such discharges are not unfrequent during the rainy season: we must not forget, however, that the pipes in these instances were connected with an imperfect system of collateral drains; and that under a perfect system, the surface-water would have been carried off more rapidly, and there would not have been so great an accumulation at this point. A little experience of the working of a perfect scheme of this description, would readily determine the requisite sizes.

In main lines of sewer, and where they pass under main roads, we should recommend the construction of brick sewers of such size as would be sufficient for the passage of a man, and for room to work in when requisite. In these we would lay not only a pipe-sewer of sufficient capacity for the usual run of water, but also the gas and water-mains, where practicable, in order to obviate any necessity for breaking up the roadway on occasion of repairing, &c. We are convinced that this arrangement is of considerable importance, where the roads have to sustain much traffic, for it is impossible to maintain good roads while they are constantly being broken up by gas and water companies. The expense of this system, as far as regards the sewers, would not be much greater than the present, and there can be no doubt but that the management of the roadways would be much more economical. Under such circumstances, it would be worth while to construct a good solid roadway, which, though a little more expensive in the first outlay, would in the end prove much more economical, not only as regards the repair, but also as requiring a less amount of tractive power, and doing less damage to the vehicles passing over it. It is very advisable, that all subterranean works should be treated of together as separate portions of one system. The pipe-sewers should be laid in the invert, and might be so arranged as to allow of an overflow into the large sewer, when requisite; or the water might be poured back, for the purpose of flushing when deemed advisable. Access would be obtained into the sewer, for the purpose of inspecting and repairing the various pipes by side-entrances, as at present; and the sewer ventilated by shafts in the roadways, without detriment to public health, the pipes which convey the sewage being impermeable. The only difficulty which limits the application of this system to main roads and sewers, is its expense; were it not for this, it might be adopted in every street with much advantage.

Many forms of large sewers have been adopted, but that which appears to be best adapted for the purpose, is the egg-shaped, which was introduced by Mr. Roe; the older forms having mostly a semicircular crown, with upright side-walls, and a semicircular or flat segmental invert. The main improvement effected by the egg-shaped sewers, consisted in narrowing the invert, thereby contracting the lower part of the channel, and increasing the depth of flow, by which means the velocity and scour was much improved; the same quantity of water which moved but sluggishly when spread over the wide surface of a flat invert, being now concentrated in a narrow channel, was made to move with accelerated flow; in short, this alteration had a similar effect to that produced by the employment of small pipe-sewers. Another advantage obtained by this form, was the attainment of greater height with a given area, which enabled men to pass through them with greater facility; it must be confessed though, that the narrow invert is rather inconvenient to walk upon. The shape, moreover, is economical, and based on sound principles as regards construction.

Many proportions, and many methods of describing the egg-shape, have been observed at different places, some being constructed with a semicircular top, flat segmental sides, and a sharp segmental invert; the curves of the sides and invert varying according to varying proportions of height and width, and other circumstances. Others are constructed with six centres, the upper part being described with two radii, instead of being semicircular. Of all these varieties, however, the most eligible is thus described:—Let the height of the sewer be to the width as 3 to 2; then having described a semicircular crown with radius 1, with radius 3, equal to the height, and with the centre on the springing-line, describe a segment touching the semicircle already described; for the invert, with a radius $\frac{1}{2}$ or $\frac{1}{6}$ of the entire height, describe a circle which will be found to touch the segments just described. This form is generally applicable, and has the advantage of being drawn to certain proportions.

The above are the most usual forms for sewers, but occasionally the levels will not allow sufficient height for them beneath the roadway; and, in such cases, it is necessary for the purpose of obtaining sufficient capacity, to construct them of a cylindrical or elliptical form; but even then, the same end may frequently be obtained by placing two or more egg-shaped sewers side by side. Where there is a large and constant flow of water, cylindrical sewers are not objectionable.

The above sewers, if not more than 4 feet in height, and if in good building strata, may be constructed of half-brick work, but in other cases require to be a whole brick thick, unless the sewer be very small. They are constructed mainly of stock-bricks in mortar, the invert or lower portion only being laid in cement; the inverts are usually formed in blocks in cement before they are finally laid in the sewer; the invert consisting of three or more blocks, according to its dimensions. Sometimes blue vitrified bricks are used for the invert; they are very hard and durable, but do not adhere well to the cement. It has been proposed to construct sewers with radiated bricks, and they probably might be used with advantage where the curve is sharp: the joints of common bricks are very open in such cases. Radiated hollow bricks have also been suggested, and, if moderately cheap, they might doubtless be employed successfully.

The pipe-sewers, as at present made, are of a cylindrical form; they are constructed in lengths of 2 or 3 feet, and have a socket at one end for the adjoining pipe to fit into; sometimes, however, they are made with half a socket on either pipe, and this is of advantage in facilitating their removal, if at any time they be required to be taken up. With the whole sockets, it is difficult to take them up without breaking them, and it is almost impracticable to replace them correctly after removal.

If whole-socket pipes be generally used, we should advise the occasional adoption of half-sockets, so that in case of stoppage, or other accident, they may admit of easy removal and replacement, without either destroying the pipes or disturbing the adjoining ones. Cylindrical pipes are made from 3 to 2 feet in diameter. It has been suggested, that such pipes should be made of the egg-shape, rather than cylindrical; but it must be borne in mind, that the contraction of the invert is not of so much consequence in a small pipe, where there is likely, at all times, to be a large current compared with the capacity of the pipe; and if the pipe be generally full, we know that the circumference of a circle contains a larger area than the same extension of boundary-line arranged in any other form; therefore, if a cylindrical pipe be full, there is less frictional surface than in any other kind of pipe of the same capacity. As, however, in present practice, the flow of water varies to a great extent at different times, it might not be unadvisable to adopt the egg-shape, supposing that they can be manufactured with the same accuracy, and at no higher cost. If they be adopted, we should advise their being made in two pieces, the lower one forming the invert, and the upper the semicircular crown; a flange, or socket, might be formed at the edge of the bottom-piece to receive the top, and make a correct joint; the same practice might be adopted in cylindrical pipes of a large size. The advantages attaching to this method are, that the inverts can be laid with great nicety, a matter of considerable importance, and are open to inspection after they are laid, so as to admit of opportunity of testing their accuracy; the objections against the whole pipes, on this head, are of considerable weight. Another advantage is, that the top-half can be taken off at any time for examination or inspection of the pipes, without disturbing the invert, or interfering with the flow.

These pipes are manufactured of stoneware, and various kinds of clay, glazed and unglazed, some being glazed on the interior, and others on both surfaces; the stoneware, glazed on both sides, are most frequently adopted, and are found to answer best; but there is a process of manufacture which produces unglazed pipes equally efficient as the glazed stoneware. The peculiarity of this process consists in submitting the pipe, when half-dry, to an extreme pressure between two polished iron surfaces, whereby a density of substance, and truth of form, is attained, which is equivalent in practice to the best glaze, so far, at least, as the flow of water is concerned. Pipes of the above materials and manufacture have a great advantage over brick-sewers, on account of the comparative smoothness and evenness of surface, which offers very little or no resistance to the current; the amount of frictional resistance being naturally greater over the rough surface of the brick work. In the following table will be found the result of some experiments, for the purpose of determining the advantage gained, in this respect, by glazed pipes:—

Table of Comparative Time of Run of Water through Brick Drains and Glazed Pipes.

Inclination.	Depth of water.	Time through Glazed Pipes.	Time through Brick Drain.
	Inches.		
Level	5	38	50
2 Inches in 50 feet	4½	16½	25
3¾ ditto	5½	19	27
1¼ ditto	3	18	26
½ ditto	3½	25	36
3¼ ditto	4	15	22
1¾ ditto	6	13½	21½

The rate of inclination is a matter which requires some consideration in laying out a system of drainage; the greater the fall, of course the greater the velocity, and, in consequence, the more rapid the discharge; the scour is also proportionately greater. It will thus be seen, that the efficiency of sewers depends a great deal upon their rate of fall towards the outlet; this, however, will depend mainly upon the nature of the locality to be drained. Supposing there exists a certain fall from the highest point to be drained to the outlet, it will be well to see how it can be laid out or expended to the greatest advantage:—the rule is this, give the greatest rate to the house-drains; the next greatest, to the pipes with which they are immediately connected; and so on, diminishing the rate gradually as you get towards the outlet. The reason for this is obvious; for, in the first place, your main object is to remove the sewers from immediate proximity to the houses, so that perfect drainage is of less consequence at a distance than it is in the houses themselves. But beyond this, there is another more important object in this arrangement, for as the body of water is less in the sewers or drains more remote from the outlet, it is more likely to be sluggish in its movements than where there is a large volume of water, and this tendency to sluggishness is overcome by an increased rate of inclination, so that the want of velocity caused by the small body of water in the smaller sewers is compensated by the extra fall, and thus the flow in all cases is rendered equal, or nearly so. In the larger sewers, where the water is collected from the tributaries, the mass of water is sufficient to preserve a good velocity with even a small inclination. The rate will depend, as we said before, upon the nature of the ground; but, as a general rule, it is advisable that the fall in main-pipes should not be less than 1 in 240, and in main-sewers not below 1 in 1,000. It has been deduced from experiments, that no proportionate advantage is gained by a fall of more than 1 in 60. The requisite size of the pipes is dependent, in a great measure, upon their fall, for as the velocity is increased in proportion thereto, so is also the rate of discharge, and therefore the greater the fall, the less will be the sectional area required for the sewers.

Where one sewer discharges its contents into another, the junction should be effected by a curve, drawn tangent to the directions of both sewers, so that the direction of the stream may be changed in as easy a manner as possible, and may not experience any shock either in leaving the smaller or entering the larger sewer. It was formerly the practice to make the junctions rectangular, but by this method the stream from the tributaries, crossing that of the main at right angles, had a tendency to change its direction, the amount of change depending on the comparative force of the two streams; in any case, however, the flow in the main stream was impeded, eddies caused, and deposit thereby accumulated. If, on the contrary, the two streams be tangential at the point of junction, little or no impediment will take place, as they have both a tendency to move in the same direction. It is advisable, that the curve be struck with as large a radius as practicable. In the pipe-sewers, junction-pipes are made for the purpose, in which the junction-curve is commenced on the main-pipe, so that we have a straight pipe, and a portion of a curved one, in the same length; the pipes are made to suit different circumstances, some with one, others with two junctions, and these of various sizes as required. With respect to the time occupied by the passage of water through different junctions, the following results have been arrived at by Mr. Roe, after various experiments:—

Time occupied by the passage of equal quantities of water through similar lengths, and with the same inclination.

Along a straight line—90 seconds.
With true curve—100 seconds.
With turn at right angles—140 seconds.

It is to be observed with reference to junctions, that it is not necessary to increase the capacity of the main line at every junction with a tributary, or that the area of the main should be equal to the area of all the junctions. The reason of this apparent inconsistency is, that although a pipe be full at its head, it will be found to be not nearly full at its outlet, and this is caused by the increased velocity of the particles of water acquired by running down an inclined plane. At a little distance from the head, therefore, some portion of the sectional area of the pipe will be vacant, sufficient to afford room for the discharge of a tributary, which will in its turn add to the velocity of the main stream, and leave space for a second tributary at a joint lower down. There is, of course, a limit to the addition of tributaries, for in time the areas of the main will be comparatively full, and will dam up the water in the junctions; the extent to which the principle can be carried, is to be determined by practice; it will depend to some extent on the fall of the main line.

Where sewers are constructed with the intention of being entered for inspection, it is necessary that they should be properly ventilated; otherwise, the noxious gases generated by the sewage, would forbid entrance, except at considerable risk of life: fatal accidents have occurred, for want of such precaution. The usual plan for effecting this, is to construct a long, narrow, and tapering shaft from the crown of the sewer to the roadway; but this practice is objectionable, on account of the gases vitiating the atmosphere, and thus encouraging disease; and it does appear somewhat inconsistent, that while gullies are trapped to prevent the ascent of the effluvia, other shafts are constructed for the purpose of effecting it. It is true, there is some advantage gained in ventilating by the vertical shaft, but not sufficient, it may be imagined, to counterbalance the inconsistency. Several methods have been attempted, to obviate this difficulty: amongst which may be mentioned, the connection of the ventilator with the rain-water pipes of the houses, and extending them a considerable height above the houses; the passage of the air through a furnace; the ventilation by steam-jet, &c.; each of which plans have been more or less successful. If we adopt the pipe-sewers, all difficulty on this score is at once obviated, for the pipes themselves are impermeable, and if the gullies and house-drains be properly trapped with syphons or flaps, there will be little danger of the escape of noxious vapours; and it must be remembered, that in this case, the sewers themselves are not required to be ventilated, seeing that they do not admit of passage by a man. That they are ventilated, however, to a certain extent, is very probable; for it is well known, that the rapid motion of a stream of water will produce a sensible current of air, and in proportion as the velocity of flow is greater in small than in large sewers, so will their ventilation be more completely effected: besides this, as the deposit is likely to be less, there will be less need of ventilation.

In large sewers, it is necessary that there should be ready means of access to them, and this is best provided for by side-entrances, which consist of vertical shafts descended by iron ladders or step-irons, and covered with cast-iron flaps. These shafts are placed at any convenient spot, at the side of the sewer, generally in the footpath, where the sewer is in the middle of the road, and from the bottom of the shaft an arched passage is carried with a slight inclination under the roadway into the sewer, the lowest level of the bottom being from 6 to 18 inches above the invert.

Gullies require to be constructed at certain intervals, to carry off the surface-water from the roads. The water is carried by gratings in the channel of the road into a cesspool or well, and thence by an overflow-pipe with syphon trap into the sewer. The grating should be made to open, or other access afforded to the cesspool, in order to remove the deposit when requisite.

Having treated upon the subject of drainage generally, we now come to the consideration of house-drainage, which requires a few remarks. The old system of carrying the house-drainage into the main-lines, consisted simply in laying down a drain from each house, connected at the one end with the sinks, water-closets, &c.; and at the other with the main sewer, which ran in the centre of the road. Amongst the recent improvements, a new plan has been adopted, by which the drainage of the house is conducted into a pipe at the back of the premises, and by it into a main sewer; this is termed *back-drainage;* and the old system, *front-drainage;* or whereas in the former case, the sewage is collected at the back, in the latter it is collected at the front of the houses. The system of back-drainage is certainly in many respects an improvement upon the old, but it is not so universally applicable as some persons would lead us to believe; it provides a convenient variation, but not an extensive substitute. One great improvement is effected by carrying the drainage at once away from the premises, instead of its running under them, as before. The objections to the old system in this respect, are, the passage of the drains under the houses, whereby, if not perfectly constructed, the effluvia is likely to be spread all over the interior; and the inconvenience which is thereby occasioned in case of stoppage, or other necessary examination or repair which involves the removal of floors, &c., and the opening of drains in the house; matters not only inconvenient, but sometimes dangerous, on account of the escape of effluvia. In some cases, where the old brick drains have been employed, and, as is not unfrequently the case, improperly constructed, the drainage has been allowed to escape through crevices in the brick-work, and saturate the foundations of the premises; this is frequently the cause of damp basements, and of unpleasant and noxious odours in the lower part of the house. A further objection exists in the frequent apertures required to be made into the main sewer for the insertion of the house-drains, and the many interruptions which are occasioned in the flow of the sewage in the main sewer, by the discharge of so great a number of house-drains.

These objections are obviated almost entirely by the new system; the drains, instead of being carried through the house, are at once removed from it, and the dangers and inconvenience attending the old practice entirely done away with. Such at least is the case in by far the majority of instances: occasionally, where the position of water-closets in front of the house requires the drains to be brought through the house to the back, the employment of the new system would not be so advantageous; the carrying of drains from sinks through the house, is not so objectionable. The large sewers will not be interfered with, except at distant intervals, for the insertion of the main back-drain, discharging the sewage of a block of several houses. There are several other advantages attending the new system, amongst which may be mentioned the following:—The flow of sewage is very considerably improved by its concentration into one drain, instead of being spread over many; the frictional surface is also much reduced. In the old system, the occasional flow of water from each house was so inconsiderable as to produce a mere dribble, which flowed sluggishly, and deposited its solid matters in abundance, under the very dwellings; it was but a small portion that eventually reached, and was discharged into the sewer; whereas, where the back-drainage is adopted, the water is discharged almost immediately into the main back-drain, and the collection of the sewage of all the houses therein produces a considerable volume, sufficient at all times to keep up a moderate flow into the main sewer, and thus prevent deposit; if, however, deposit should occur, it is less objectionable than where it takes place under the house. There is a fair objection to this system when stoppage does occur, for the stoppage in one place will occasion the same in every house which happens to be situate between the stoppage and the first inlet; under the old system, this would not take place. In the separate system, each occupier is subject to the inconvenience occasioned only by his own negligence or carelessness, whereas in the combined system he is, to a certain extent, at the mercy of his neighbours; when, however, we take into consideration the improved flow in the main back-drain, and the less probability of stoppage, this objection will not have so great weight.

It will also be frequently found, that a considerable length of drain is saved by adopting the combined system, and where this is the case, back-drainage is decidedly preferable; for not only is the expense lessened, but the fall is likewise improved, and the contents are more rapidly and more efficiently discharged. Where length of drain can be effected by back-drainage, there can be no question as to its adoption; yet there are some instances in which this is not the case, but the contrary rather; and under such circumstances, considerable discretion will be required in selecting that system which shall be most efficacious.

The drains employed in carrying the sewage from the houses, need not be more than four inches in diameter, of the same material and descriptions as those above recommended for sewers; 6 or 9-inch pipes will generally be found of sufficient capacity for the main back-drains, but of course this will depend upon the number of houses drained into them. These should be trapped at their entrance into the sewers, to prevent the effluvia rising through them from the sewer into the houses. Sinks, water-closets, &c., should also be trapped at the inlets.

We are now arrived at the close of this article; and we are sure that the increasing importance of the subject will excuse the length to which it has been carried.

SEXAGESIMAL, (from the Latin,) the division of a line, first into 60, then each of the parts into 60, and each of these again into 60, and so on, as long as division can be made.

This division is principally employed in dividing the circumference of a circle, and was much used in ancient astronomy. The French have adopted the centesimal division, which is far more convenient for calculation.

SEXAGON, or Hexagon, a six-sided figure.

SHADOWING, in drawing, the art of representing the various degrees of light and shade by means of a dark fluid, or liquid.

The paper intended to be drawn upon, having its rough edges cut off, ought to be wetted, or uniformly moistened, and pasted round its four edges upon a board, observing, in doing this, that no part of the paper ought to be suffered to dry before the edges that are pasted, as the paper will begin to shrink; and, consequently, by its motion towards the centre, will loosen the edges: as soon, therefore, as the middle part appears dry before the edges, it ought to be moistened again with a sponge, and the sponging should be repeated as often as may be found necessary; and, when the paper becomes dry, it will be perfectly flat, and fit for use.

In order to lessen this trouble, some have drawing-boards framed so as to include a panel, which is let into a rebate, on the inner edge of the frame, and fastened, by means of bars, upon the back of the board.

The paper being wetted on the side intended to be drawn upon, the dry side is laid upon the face of the panel, now out of the frame, so that the edges of the paper project alike on all sides, over the edges of the panel; then laying hold of the paper by the edges out of the panel, place it over the aperture in the frame, with the underside reversed, and press it in; after which, bolt the panel to the frame by means of the bars, and the edges of the paper being inserted in the seam, or joint, between the edges of the panel and the adjacent edges of the frame, will prevent the paper, as it contracts in drying, from returning towards the centre, and, when dry, it will be flat and extended; but this method can only be practised in small drawings. The former must, therefore, be considered as the general plan of fixing the paper.

The fluid commonly used in architectural drawings is Indian ink dissolved or mixed in water. The method of doing it is this: fill a small cup with as much water as may be necessary for the quantity of ink intended to be made; then rub the ink upon the tip of the fore-finger, wetted in water, and wash it off in the cup: when the water becomes sufficiently dark, it will be fit for use. This method is, however, too tedious for general use, the more frequent practice is to rub it up as other colours. The stick of ink should be rubbed quite dry, otherwise it will be apt to fall into pieces, and become unfit for use. The liquid thus made is called *ink* or *colour*.

The next thing to be done is to outline the drawing.

Straight lines are drawn with a steel pen, circles by the compass, and curve lines by hand, with camel or sable hair pencils, or with a fine-pointed pen, or with curved ruler and drawing pen.

In drawing very fine lines, the inking-points of the steel pen and compasses ought to be kept very sharp, but not so much as to cut the paper. The outlines being finished, the paper ought to be rubbed clean, and then sponged, or rubbed with a soft brush and water, in order to soften the lines, and to make the paper receive the shadowing more freely. If the paper be even sponged, or brushed, so as to raise the nap in a small degree, it will be the more favourable for producing clear and soft shadows.

In laying the shadowing colour upon the paper, it ought to be spread over the surface uniformly with a camel or sable hair pencil, flowing freely; but not in such quantities as to stand in hollows upon the paper, as, when dry, it becomes cloudy. In making a uniform tint, the first thing to be considered is, the degree of darkness to which the surface is intended to be made. If required to be very light, one tint, or the shade once gone over, will be sufficient; but, if dark, several tints will be necessary. In producing the several degrees of darkness, every tint ought to be nearly dry before the next is laid; the number of repetitions will depend upon the depth of the colour and extension of the surface to be shadowed. It may be observed, that the lightest tint, often repeated, will darken the surface to any degree required. But that too much time may not be dedicated to laying a fine tint, it must also be observed, that the greater the facility with which the tints are laid, the fewer will be required to darken the surface. This facility is to be obtained by sufficient practice.

SHADOWS, *The Doctrine of*, in perspective, is the theory and practice of representing shadows, as projected from a given point at a finite distance, such as a candle; or as projected from the sun, where the distance, though not infinite, is, for the sake of simplicity, considered as such, in order that the rays may be all parallel; or otherwise, for this purpose, the rays may be supposed as proceeding from all points of space in parallel lines.

Definition 1.—A line of shade is the line deprived of light by an opaque point opposed to the luminary.

Definition 2.—A plane of shade is an opaque or dark plane, occasioned by the privation of light from the interposition of a straight line opposed to the luminary; and hence it is evident, that every plane of shade will pass through the luminary.

To find the shadows, upon the surfaces of bodies, occasioned by the privation of the sun's rays.

Proposition I.—*Given the vanishing line of a plane, the vanishing point of the sun's rays, the vanishing point of the seat of a ray on the plane, the representation of a point in space, and the representation of a seat of the point in the plane whose vanishing line is given; to find the representation of the shadow upon the plane of the picture.*

Join the vanishing point of the line to the vanishing point of lines perpendicular to the plane whose vanishing line is given, and the vanishing line of another plane will be obtained, in which is the original of the seat of the point, and the original of the line in projection; and, therefore, the intersection of the vanishing line given of the plane on which the seat of the line required to be drawn, and the vanishing line found, is the vanishing point of the seat of the line. Therefore, draw a straight line through the seat of the point given in projection, to the vanishing point found, and the line thus drawn will be the whole representation of the seat.

This proposition is evident, since the vanishing line of every plane perpendicular to the plane whose vanishing line is given, will pass through the vanishing point of lines perpendicular to that plane; and since the seat of the original line, on the original of the plane given, is formed by a plane passing through the original line perpendicular to the given plane intersecting therewith; therefore the vanishing line of this perpendicular plane will pass through the vanishing point of lines perpendicular to the original of the plane given; but when two points in a vanishing line are given, the whole of the vanishing line is given, being the straight line passing through these points.

A general knowledge of the shadows of lines upon planes in any position ought first to be acquired; but as the relation of lines and planes to the horizon is generally given, it will be necessary to find the relation of these lines and planes to each other; and here it will be proper to observe, that whatever may be the number of planes, the vanishing point of the sun's rays will remain unchangeable, or in the same position in respect of the first vanishing line, and will be common to all the different planes; but every different plane will have its own vanishing point for the seat of the sun's rays in that plane, and that vanishing point will be in the vanishing-line of that plane. As vertical and horizontal planes occur most frequently in practice, these will require particular attention.

Proposition II.—*Given the inclination of a plane to the plane of the picture, both being perpendicular to the original plane, and the seat and inclination of a straight line in the plane of the horizon; to determine the vanishing point of the seat of the line on the vertical plane, and the vanishing point of the line.*

Plate I. *Figure* 1.—Let No. 1, represent the vanishing plane, and No. 2, the plane of the picture. In the vanishing plane, No. 1, let v l be the vanishing line, e the point of sight, or place of the eye, A B the intersection of the original vertical plane, inclined to the plane of the picture in the angle A g l; and let A D be the seat of the line, as given in position, to the horizon: make the angle D A F equal to the inclination of the line to the plane of the horizon; draw D F perpendicular to A D, and D B perpendicular to A B; produce D B to K; make B K equal to D F, and join A K, which is the seat of the line on the vertical plane. Draw e *l* parallel to A B, and draw *l h* perpendicular to v *l*; in v *l* make *l m* equal to *l* e, and make the angle *l m h* equal to B A K; and *h* will be the vanishing point of the seat of the line. Draw e v parallel to D A, and v *i* perpendicular to v *l*; make v *n*, in the vanishing line, equal to v e; make the angle v *n i*, equal to the angle, D A F, which the original line makes with the plane of the horizon; and draw e ⊙ perpendicular to v l, meeting v l in ⊙. In the plane of the picture, No. 2, let V L be the vanishing line answering to v *l*, No. 1: in V L make choice of any convenient point, ⊙, for the centre of the picture: make ⊙ L equal to ⊙ *l*, No. 1, and ⊙ V equal to ⊙ v, No. 1; draw L H and V I perpendicular to V L; then H is the vanishing point of the seat of the line, and I the vanishing-point of the line itself.

The points H and I will be both on the same side of the vanishing line of the horizontal planes.

This problem is the same when the seat and altitude of a ray of the sun are given, with the inclination of a vertical plane to the plane of the picture; to find the vanishing point of a ray of light, and the vanishing point of the seat of the sun's rays.

When the sun is on the same side of the picture with the spectator, the vanishing point of the seat of the rays, and the vanishing point of the rays, will be below the vanishing line, V L; but when on the other side of the picture, the vanishing point of the rays, and the vanishing point of their seat, will be above V L.

Proposition III.—*To find the shadow of a rectangular prism upon the horizon on which it stands, and also upon another rectangular prism; the base of the prism which throws the shadow being in the same horizontal plane with a side of the prism on which the shadow is thrown.*

Figure 2.—Let O be the vanishing-point of the sun's rays, V S the vanishing-line of the horizontal plane on which the two prisms are placed, *a b c d* the base, and *a' b' c' d'* the top of the prism that throws the shadow. Then, because the edges of the prism stand parallel to the picture, they will have no vanishing point but at an infinite distance; thus the line O S, drawn from O, will be parallel to the edges *a a'*, *b b'*, *c c'*, *d d'*, of the erect prism, and will give the vanishing-point, S, of the shadows of *a a'*, *b b'*, *c c'*, *d d'*; therefore, draw *a* S, *d* S, *c* S; and *a'* O, *d'* O, *c'* O, cutting *a* S, *d* S, *c* S, at the points *e*, *f*, *g*; then will *d e f g c* be the shadow on the ground. Let *c* S and *d* S cut the edge of the prism, *o p q r s t u*, at *h* and *i*; draw *i l* and *h k* parallel to O S, cutting the upper edge, *r t*, at *k* and *l*; from the points *k* and *l* draw lines to S, cutting the farther edge, *q s*, at *m* and *n*; then *h k m n l i* will be the shadow upon the recumbent prism, *o p q s t u*.

Proposition IV.—*To find the shadow of a cylinder lying with its convex surface upon a horizontal plane.*

Figure 3.—Let X be one end of the cylinder, Y the other. To find the shadow of the end X upon the horizon, it must be observed, that no line which terminates two surfaces can throw a shadow upon a third, unless one of such two surfaces be in shade. We have, therefore, only to find the shadow of that part of the circumference of the end X, contained between the point of contact on the horizontal plane, and a tangent plane to the surface of the cylinder; and a sufficient number of points will be found by letting fall perpendiculars from as many points in the arc that throws the shadow, to meet the horizontal plane; then find the shadows of the upper extremities of these lines, which will be points in the curve. Or, find the whole ellipsis representing the shadow of the circumference of each end of the cylinder, and draw the line *c g*, to touch these two ellipses; then *d e c g* will be the shadow. To find the shadow of any point, c, in the edge of the end X; draw c d perpendicular to the horizon, meeting the horizon in d; also, draw d O and c S, cutting each other in *c*, then *c* is the shadow of c; in like manner, *e* will be found to be the shadow of e, and so on for as many points as may be necessary.

Proposition V.—*To find the shadow of one cylinder upon another. The cylinder which throws the shadow, and that on which the shadow is thrown, being placed, the former with its end, the latter with its convex surface, upon the same horizontal plane.*

The shadow of the cylinder, which stands upon its end on the horizon, is obtained by finding the shadows of the tops of as many straight lines on the convex surface as may be thought sufficient for the purpose, which will give the points f, g, e. The shadow of the cylinder, which is placed with its convex surface upon the horizon, is found in *Figure* 3. Let A E and G F be the lines of contact with a tangent plane to the point S, then the lines A E and G F will throw the shadow partly upon the horizon and partly upon the convex surface, Z, of the cylinder, which lies on the ground. It is, therefore, only necessary to find the sections of the cylindric surface Z, with the two planes of contact, S A E and S G F; for this purpose, produce the plane A G F E, and the end, T, of the recumbent cylinder, till they meet in P Q. This will be readily done as follows: produce G P, and from the vanishing-point, L, of the end T, of the recumbent cylinder, draw the line L A P, through the point a, and also draw P Q perpendicular to the vanishing-line V L; then P Q is the intersection of the plane passing through G F and A E, with the plane T. Let a *d'* be a vertical diameter from the point of contact, d', of the end T; draw L *d'* Q; then, in P Q take any number of intermediate points, R, S; draw R L, S L; also draw lines from S, R, Q, to the vanishing-point of A G and E F, cutting A E at B, C, D; let the lines from R, S, drawn to L, cut the end T at c, b: draw b V and c V; also draw B L and C L, cutting b V, c V at *b* and c; then *b* and c are points in the shadow. In the same manner, points in the other edge will be found, and the shadow completed.

PROPOSITION VI.—*To find the shadow of a building with a break.*

Figure 5.—Let V L be the vanishing-line of the horizon. V the vanishing-point of the horizontal lines represented by *a c* and *b d*, that form the end of the building, also of *e f*, *g h*, which represent the horizontal lines forming the sides of the break. Let the sun be supposed to be in the plane of the picture, or its rays parallel thereto, and let the planes *a b d c* and *e g h f* be in shade; and the plane *e g h f* will throw a shadow upon the plane *a b l k*, as the plane *a b d c* will also upon the horizon. As the sun's rays are parallel to the picture, they will have no vanishing-point, but still the rule will hold in this case also. Through the vanishing-point L, draw L M perpendicular to V L; then L M is the vanishing-line of the plane *a b l k*, on which the shadow is to be thrown; through V draw V M, parallel to the sun's rays, or make the angle L V M equal to the angle which the sun's rays make with the plane of the horizon. Thus M is the vanishing-point of the shadow of all lines vanishing in V, upon the plane *a b l k:* therefore, to find the shadow of the line *h g*, join M *h*, and produce it to *m;* and draw *g m* parallel to M V; then *m* will be the shadow of the point *g*, and *h m* of *h g*. Draw *m n* parallel to *g e*, and *m n* will be the shadow of *g e:* therefore *h m n f* will be the whole shadow of the plane *h g e f*, upon the plane *a b l k*. To find the shadow of the end *a b c d* upon the plane of the horizon: draw *a o* parallel to L V, and *b o* parallel to M V; then *a o* is the shadow of the vertical line A B: join *o* V, and draw *d p* parallel to M V, and *o p* is the shadow of *b d*: join *p* L, and draw *r q* parallel to M V, and *p q* will be the shadow of the line *d r*, not seen: join *s q*, or draw it parallel to L V; then *a o p q s* will be the shadow of the building upon the plane of the horizon.

Many more examples of shadows might be given; but if the principles here shown are understood, the artist will not be at a loss to find the shadow of any right-lined object whatever: for, to find the shadow of an object constituted by planes, and consequently terminated by straight lines, is no more than to find the shadow of those lines. If a circle be given, the circumference may be divided by parallel lines into parts, and the shadows of the points of division may be obtained by finding the shadows of the intercepted lines, and drawing a curve round their extremities. If it were required to find the shadows upon several planes, first find the shadow in the plane on which the object stands, and observe where the shadow meets the next plane; then, having the vanishing-line of this second plane, observe where the vanishing-line of the plane of shade cuts the vanishing-line of this second plane, and the point of intersection will be the vanishing-point of the shadow on the second plane.

The principles exhibited in the article PROJECTION, will apply equally to the representation of objects in perspective, particularly where the planes which throw the shadow intersect the plane on which the shadow is to be thrown; for by continuing the line that throws the shadow, and the intersection of the planes, to meet each other, the point where the shadow terminates is found; and therefore, if a point be given in the shadow, the direction of the shadow will be known. Thus, in the last example, suppose the line *a o* obtained: since the point *o* is the beginning of the shadow of the line *b d*, produce *a c* and *b d*, to meet in V; join *o* V and draw the ray of the sun, *d p;* then *o p* is the shadow of *b d:* produce *d r* and *c s* to meet in L, and join *p l;* draw the ray *r q* from *r*, and *p q* will be the shadow of *d r*, not seen.

PROPOSITION VII.—*To find the vanishing-line of a pole upon several planes.*

Plate II. *Figure* 1.—Let A B C D E F G H I K be the outline of a building, with a lean-to, or penthouse, D E N P O: V is the vanishing-point of all horizontal lines, in the gable, A B L I K, of the main house, and also of the gable, D M O C, of the penthouse; L^1 is the vanishing-point of all the horizontal lines in the parallel fronts, B F G L and D E N M; and as all vertical planes have vertical vanishing-lines, V R is the vanishing-line of the parallel gables, A B L I K and C D M O; L U the vanishing-line of the fronts, B F G L and D E N M; I L G H is the representation of the roof of the main building, and O M N P that of the penthouse.

Produce L I to meet V R, its vanishing-point, in S: draw S L^1, which will be the vanishing-line of the inclined plane L G H I, for S and L^1 are the vanishing-points of two lines in that plane: produce M O to meet V R in T, and draw T L^1; then T L^1 is the vanishing-line of the inclined plane M N P O of the roof of the penthouse, because T and L^1 are the vanishing-points of two lines in that plane.

Let W X be a pole resting upon the end of the house, in the same plane with the gable, A B L I K; and let Q be the vanishing-point of the sun's rays: produce the pole, X W, to meet V R in R; then R is the vanishing-point of the pole, or of the line that throws the shadow: therefore by drawing Q R, Q R will be the vanishing-line of the plane of shade, and let it cut V L^1, the vanishing-line of the horizon, in Y; and L^1 U, the vanishing-line of the vertical planes, B F G L and D E M N, of the walls, in U; V R, the vanishing-line of the gables, in R; S L^1, the vanishing-line of the main roof, in Z; and T L^1, the vanishing-line of the penthouse, in Z^1: all which does but prepare for drawing the shadow of the pole, W X, upon the horizontal plane and upon the building. Now produce A B to meet W X in X, then X will be the point where the pole rests upon the ground, or horizontal plane: draw X Y, cutting D E in *a;* draw U *a*, cutting D M in *b;* draw *b* R, cutting M O in *c;* draw *c* Z^1, cutting P O in *d;* draw U *d*, cutting G L at L; and draw L Z, cutting the ridge, I H, at *f;* then X *a b c d* L *f* will be the whole shadow of the pole.

For, since the shadow first begins at the foot of the pole, or line, in the plane of the horizon, and since the intersection of the vanishing-line of a plane on which the shadow is to be thrown, with the intersection of the vanishing-line of the plane of shade, gives the vanishing-line of the shadow upon that plane; Y becomes the intersection of the vanishing-line of the plane of shade with the vanishing-line of the horizon; therefore Y is the vanishing-point of the shadow of the line W X upon the plane of the horizon. The next plane on which the shadow is thrown is D E N M; now L U is the vanishing-line of the plane D E N M, and U is the point where the vanishing-line of the plane of shade cuts L^1 U; therefore U is the vanishing point of the shadow upon the plane D E M N. The next plane on which the shadow is projected is the plane C D M O: now V R is the vanishing-line of the plane C D M O, and it intersects the vanishing-line of the plane of shade in R; therefore R is the vanishing-point of the shadow upon the plane C D M O. The next surface on which the shadow is projected is the plane, M N P O, of the roof of the penthouse: now Z^1 is the intersection of the vanishing-line of the plane of shade with the vanishing-line T L^1 of the plane M N P O; therefore Z^1 is the vanishing-point of the shadow on the plane M N P O. The next surface on which the shadow is projected is the plane, B F G L, of the wall; but U has already been shown to be the vanishing-point of the shadow. The plane of the roof is the last surface on which the shadow is projected: now S L^1 is its vanishing-line, and it meets the vanishing-line of the plane of shade in Z, therefore Z is the vanishing-point of the shadow upon the roof.

In carrying the shadow of a line across several planes, it will not be surprising if some little inaccuracy takes place from the obliquity of intersections; it might be a great chance, whether, when the part of the shadow, *d* L, which falls upon the plane B F G L, is drawn from the vanishing-point, U, through the point *d*, it will meet the pole at L, as it ought to do. To remedy this, begin with the shadow, L *d*, and proceed in the reverse order, until it meets the line W X at X, which it must in principle, and will not be liable to vary much in practice.

The points which direct the shadows upon the several planes, might also be found by the methods shown in the article PROJECTION.

The following observations will be useful in the practice of shadows.

When a straight line, that throws a shadow, is parallel to the picture, it is then represented parallel to the original. In this case it has no vanishing-point; or, in other words, the vanishing-point of the line may be said to be at an infinite distance: and, therefore, instead of the vanishing-point of the line being joined to the vanishing-point of the sun's rays, draw a straight line from the vanishing-point of those rays parallel to the projection of the line which throws the shadow, and it will be the vanishing-line of the plane of shade; therefore the intersection of the vanishing-line of the plane of shade with the vanishing-line of the plane on which the shadow is to be thrown, will give the vanishing-point of the shadow on that plane, after the same analogy as lines which are inclined to the picture. This case is similar to that of the sun's rays being parallel to the picture: for here, also, the vanishing-point of the rays is at an infinite distance; but as the plane of shade will still have a vanishing-line, this line will be found by drawing a straight line through the vanishing-point of the line that throws the shadow parallel to the sun's rays, as shown in a former example.

Of shadows projected from a given point; as by the light of a candle or lamp.

It is evident, if the representation of the luminous point be given, with its seat upon any plane, together with the representation of any point in space, and its representation upon that plane, the shadow of the point will be found by drawing a straight line from the luminous point through the point in space, and by drawing another straight line from the seat of the luminous point through the seat of the point in space; and the intersection of the two lines thus drawn will represent the shadow of the point upon the plane. But when the relation of several planes represented in a picture, the representation of the light with its seat, and the representation of a point in space with its seat, are given, to project the shadow of the point on the other planes, other considerations become necessary.

Figure 2.—For this purpose, let A B C D be the inside of a room, consisting internally of the vertical planes A H, E I, F K, G C, and of the horizontal planes A E F G B and D H I K C: also, let L be the luminous point, and M its seat in the plane A E F G B. In order to form an idea of the point L, in respect of the other planes, it is necessary to have the intersection of a line drawn through L, in a given position with one of the planes. Thus, if it is known that the straight line L *a*, parallel to the picture, cuts the plane of the wall, B K, in the point *a*; the position of the point L to any of the other planes may be easily determined, as follows:

Through *a* draw *a b* parallel to the vanishing-line, N O, of the plane B K, cutting B G, the intersection of the planes B K and A G, in *b*; through *b* draw *b* M parallel to P Q, the vanishing-line of the floor, cutting A E, the intersection of the planes A G and A H, in *c*; also F E, the intersection of the planes A G and E I, in *d*. Draw *c* Q parallel to N O, the vanishing-line of the plane A H; and *d f* parallel to R S, the vanishing-line of the plane E I. Then, because the intersecting and vanishing-lines of any plane are parallel to each other, and because a line drawn parallel to the intersecting line is parallel to the picture; therefore the representations of all the lines, *a b*, *b c*, or *b d*, *c* Q, and *d f*, are all parallel to the picture, and in a plane passing through the luminous point L.

Figure 3.—Given the vanishing-lines, A B, C D, E F, of three planes, G H I K, L M N O, and M N I Q R, the common intersection, N O, of the planes G H I K and L M N O; also the intersections, N I, and M N, of the planes G H I K and L M N O with the plane M N I Q R; the representation, *a b*, of a line in the plane L M N O; the point of light, *c*; *c d*, a line parallel to the picture; and *d*, the point where it intersects the plane M N I Q R: to find the shadow of the line on the plane G H I K.

First, find the representation of a ray of light parallel to the picture, thus: draw *d e* parallel to A B, cutting M N at *e*; draw *e f* parallel to E F: then if *a b* be not parallel to *e f*, produce *b a* to *f*, and join *f c*, which is the ray required. Secondly, find the vanishing-line of a plane of shade passing through the line *a b*, and the ray *f c*, thus: produce *a b* to meet C D in D, which is the vanishing-point of *a b*; through D draw D F parallel to *f c*; and D F will be the vanishing-line of the plane required. And, lastly, find the shadow of *a b* upon the plane G H I K, thus: produce O N and *a b* to meet in *g*; from F, through *g*, draw the line F *h i*; and from the point of light, *c*, draw *c b h* and *c a i*; then *h i* will be the shadow of the line, as required.

For *d e* being parallel to A B, the vanishing-line of the plane M N I Q R, *d e* will be parallel to the picture; and since *e f* is drawn parallel to E F, the vanishing-line of the plane L M N O, *e f* will be parallel to the picture; and because *b a* meets *e f* in *f*, *f c* is a ray of light parallel to the picture, meeting the line *a b*; and because C D is the vanishing-line of the plane L M N O, and *a b* is in the plane L M N O, therefore the vanishing-point of *a b* is in C D, and consequently at D, where *a b* produced meets C D: and because D is the vanishing-point of *a b*, the vanishing-line of the plane of shade will pass through D parallel to *f c*; but F is the intersection of the vanishing-line of the plane of shade, with the vanishing-line E F of the plane G H I K, on which the shadow is projected, therefore F is the vanishing-point of the shadow on the plane G H I K; and because g is the intersection of $a\ b$ with the plane G H I K, the shadow will commence at g, and consequently drawing F $g\ h\ i$ gives the direction of the shadow; and, lastly, because c is the luminous point, the rays $c\ a\ i$ and $c\ b\ h$ will terminate the shadow.

As D would be the vanishing-point of all lines parallel to the original of $a\ b$ in the plane represented by L M N O; and as different representations could not meet the line $e\ f$ in the same point, the ray $c\ f$ will have different positions, as will consequently D F, which is drawn parallel thereto; and as the point D is stationary, the point F will be variable.

PROPOSITION VIII.—*Given the representation of three rectangular planes, forming a solid angle, the representation of a point of light, or candle, and the seat of the light on one of the planes; to find the seat of the light on the other two planes.*

Figure 4.—Let the three planes be A B C D, A B G F, A F E D. It is evident that every two adjoining planes have three edges parallel to each other, one common to both, which is their line of concourse; these edges will therefore vanish in a point, or be parallel to each other, according as the original planes are oblique or parallel to the picture; let the original planes be obliquely situated; therefore produce the sides C D, B A, G F, of the two adjoining planes A B C D, A B G F, and they will all meet in V, their vanishing-point; also produce the sides D E, A F, B G, of the two adjoining planes D A F E, F A B G, and they will meet in W, their vanishing-point; likewise produce the sides C B, D A, E F, and they will meet in X, their vanishing-point.

Let I be a luminous point, and S its seat in the plane A B C D: draw S X, cutting A B in a; draw a W, and draw I X, cutting a W, in S^1, then S^1 is the seat of the luminous point in the plane A B G F; draw S V, cutting A D in b; draw b W and I V, cutting each other in S^2, then S^2 is the seat of the luminous point in the plane A D E F.

Because the plane A B C D represents a rectangle, and V is the vanishing-point of the one side, and X that of the other; all the lines drawn to X will represent right angles with the lines which vanish in V; therefore S a and A B represent a right angle in the plane A B C D. For the same reason, $a\ S^1$ represents a right angle in the plane A B G F; and since the planes A B G F and A B C D are at right angles, the angle S a S^1 will represent a right angle; and because a S represents a perpendicular to A B, $a\ S^1$ and S I will represent parallel lines; and since I S^1 and S a have the same vanishing-point, X, the original of I S^1 is parallel to the original of S a; but S a represents a perpendicular to the plane A B G F, therefore I S^1 also represents a perpendicular to the plane A B G F; and because the point S^1 is in the plane A B G F, S^1 is the seat of the luminous point L, in the plane A B G F. In the same manner it may be shown that S^2 is the seat of the luminous point in the plane A D E F.

PROPOSITION IX.—*Given the representation, c d, of a line perpendicular to the original of the plane* A B C D, *and the vanishing-point,* W, *of the line, and the point, d, where the line meets the plane* A B C D, *a luminous point* I, *with its seat* S, *also upon the plane* A B C D; *to find the shadow of the line* C D *upon the said plane.*

Draw S d and I c to meet each other in e, then $d\ e$ will be the shadow of the line $c\ d$, as required. In the same manner, if $f\ g$ represent a line perpendicular to the plane A B G F, and g the point where it meets the plane A B G F, $g\ h$ will be the shadow of the line, by drawing I f and $S^1\ g$ to meet in h.

This method is general for any position of the original planes with respect to the picture; and this position of the planes in respect of each other, is that which most frequently occurs in practice.

Figure 5—Let A B C D be the inside of a room, showing five sides, one, E F G H, being parallel to the picture, and the other four perpendicular to it; C^1 being the centre of the picture.

Let L be the light of a candle, S its seat upon the floor; then to find the seat of the light on all the other four sides: through S draw $a\ b$ parallel to V L^1, the vanishing line of the horizon, cutting B F at a, and C G at b; draw $a\ S^1$ and $b\ S^2$ parallel to Y Z, the vanishing line of the two vertical planes; through L, the point of light, draw $S^1\ S^2$, then S^1 is the seat of the light in the plane A B F E, and S^2 the seat of the light in the plane C D H G. Produce C S to meet B C in c; draw $c\ d$ parallel to Z Y, and join d C^1; draw S S^3 parallel to Y Z; then S^3 is the seat of the light in the plane A E H D; let C S cut the line F G in e; draw $e\ S^4$ parallel to Z Y, cutting L C^1 in S^4, then S^4 will be the seat of the light on the plane E F G H. Then, to project a prism standing perpendicular to any of these planes, suppose that which stands on the floor: from the seat, S, draw S i, meeting C G in o; draw $o\ r$ parallel to Z Y, and draw the ray L $m\ r$; then r will be the shadow of the point m; draw S h, cutting C G in p; draw $p\ s$ parallel to Y Z, and draw L n, cutting $p\ s$ at s; then s is the shadow of the point n; also draw S g, meeting C G in q; draw $q\ t$ parallel to Z Y, and L k, meeting $q\ t$ at t; then t is the shadow of the point k; join $r\ s$ and $s\ t$, which will complete the whole shadow of the prism upon the floor, and on the wall.

The principle of finding the shadows of the prisms on the other sides, is the same, and will be obvious to inspection. The truth of the method has already been shown.

SHAFT, (from the Saxon *sceaft*,) that part of a column which, in the classic examples, may be denominated *the frustrum of a conoid*, situate between the base and capital; it is also called *the fust*, *trunk*, or *body of the column*.

By some architects, columns are diminished from one-third upwards; this occasions a very gouty appearance. Some architects and builders, however, have fallen into the contrary error, by making the sides of columns in a straight line from the base to the capital. Mr. Revely, in his Preface to the third volume of Stewart's *Athens*, expressly says, that all the columns he had seen in Greece were diminished with a gentle curve. The curve is so gentle, that the straight line, which is a tangent at the bottom of the shaft, is not parallel to the axis, but falls nearer to it at the top of the column than at the bottom. For the method of diminishing the shaft of a column, *see* COLUMN.

The method of drawing the shafts of columns upon paper in the most expeditious manner, will be a very useful addition to this article.

Figure 1.—*To represent a fluted column, the height of the column, its diameter at the bottom, and the ratio of the two diameters, being given.*

Let A B represent the height and axis of the column, produce A B to C, make A B + B C to B C in the ratio of the diameter at the base, to its diameter at the capital; draw a line through A, and another through B, at right angles to A B; set half the diameter of the column from A on each side of it, and divide the whole length of this line into parts representing the ratio of the flutes orthographically projected; from the points of division draw lines to C, to meet the line passing through B, and the lines thus drawn will represent the shaft of a column as fluted.

In this example A B + B C is to B C as 4 to 3, therefore the point C will be found by repeating A B four times from A to C.

Figures 1, 2, 3, 4, represent a range of columns, three of which are here supposed to be drawn by this or the fol-

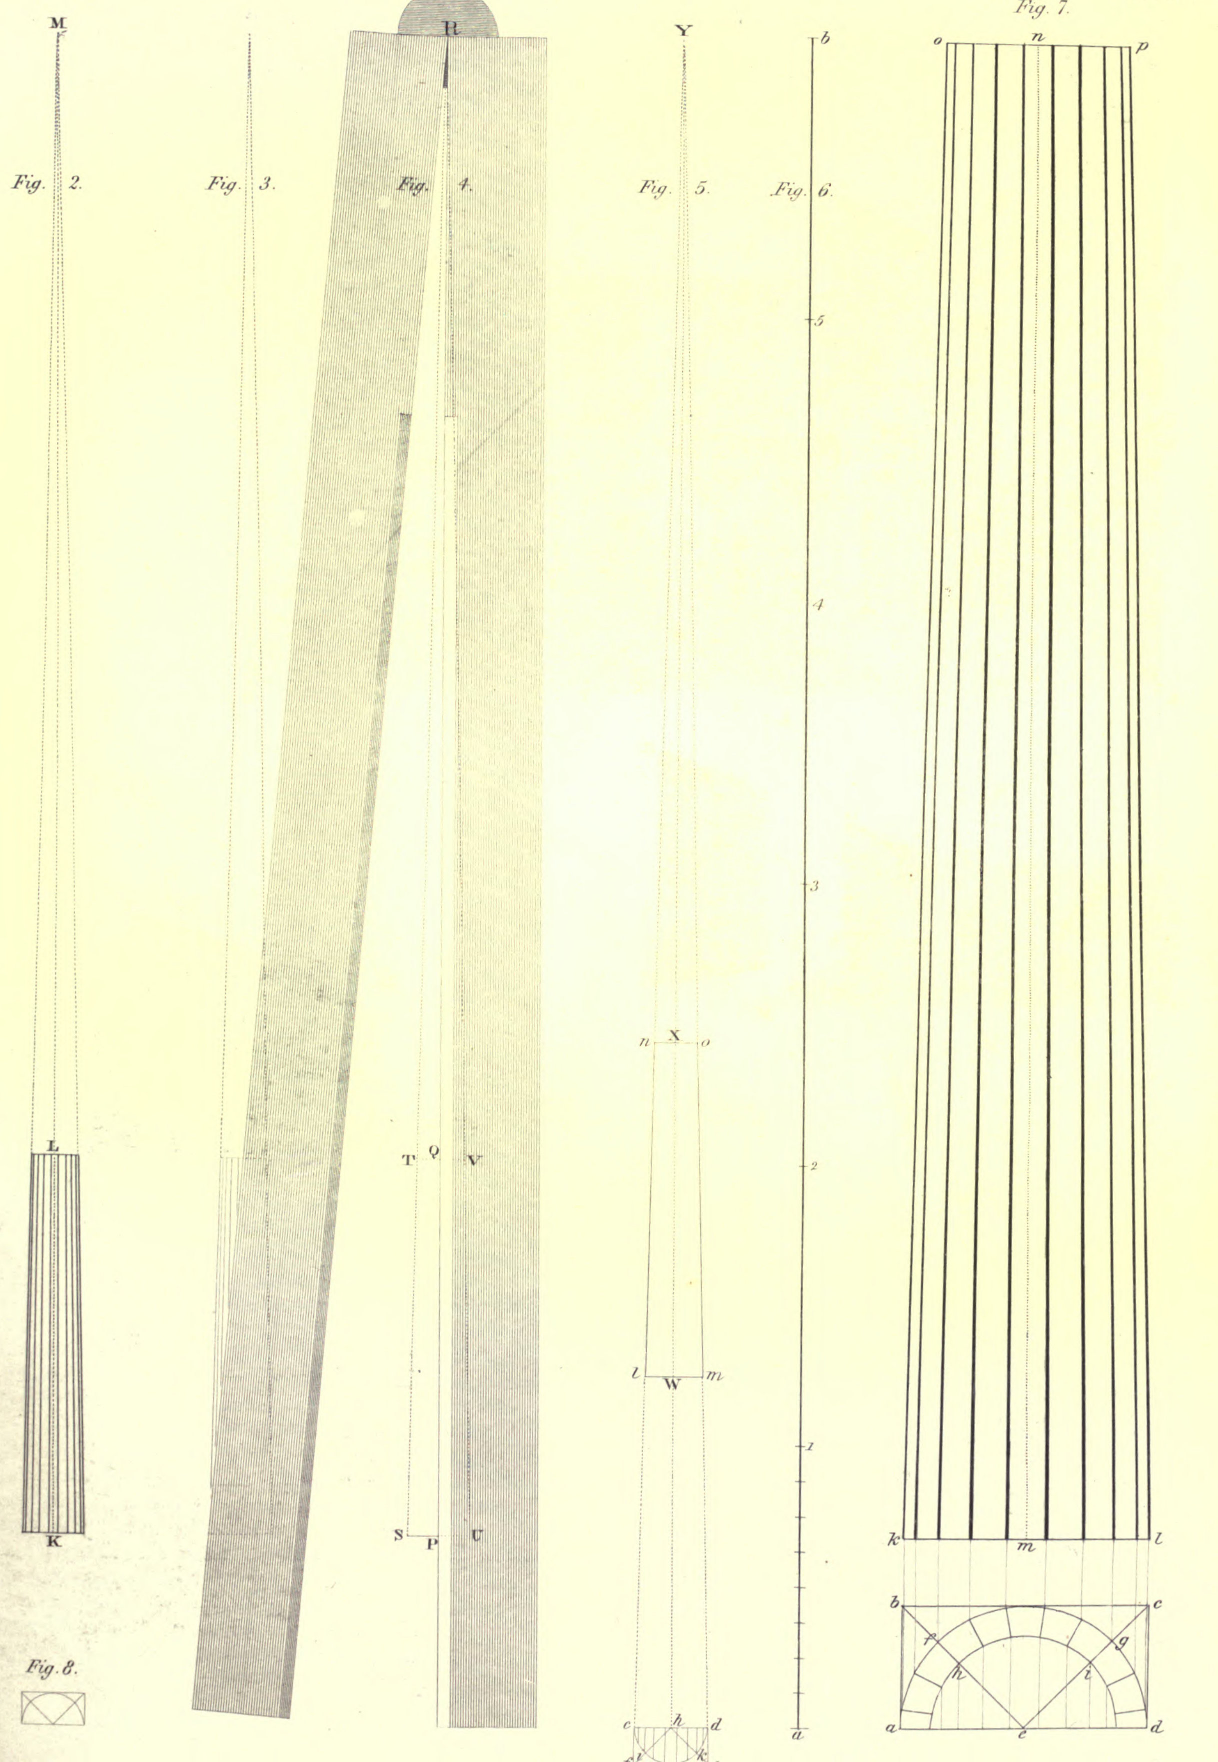
Fig. 2.

SHAFT.

PLATE I.



lowing means, which will be made sufficiently plain by reference to the plate:—

Suppose a compass joint-rule, as in *Figure* 4, bevelled on the upper sides of the inner edges; from R, the centre of the joint, set on the inner edge R P as many times the height of the shaft, P Q, as the diameter at the bottom contains the difference of the two diameters; lay the edge of the rule upon the axis, with the point P on the middle of the bottom diameter, S U; draw the other leg of the rule out to any convenient distance, while the marked leg is kept fast upon the axis; then pressing down the leg which is not over the work, move the marked leg to any point in S U, and draw a line by it, which will represent a flute; and all the other flutes may be drawn by repeating the operation. If the two lines which terminate the breadth of the column be continued downwards to D and G (*Figure* 1) at the waste edge of the paper, and also the axal line A B, the fluting may be projected by means of the semicircle D H I G; the line D G being supposed at right angles to A B. On D G describe a semicircle, and draw the tangent line E F parallel to D G, cutting C D and C G at E and F; then from E and F draw lines to the centre, cutting the circumference at H and I; divide the arc H I into five equal parts, set two on the arc H D, and two on the arc I G, which will be the points for the angles on the semi-circumference; and from these points draw lines to C between the diameters at A and B.

Figures 1, 2, 3, 4, are four equal shafts of columns, placed at equal distances, and supposed to constitute a part of the drawing of a Doric portico. The method of drawing the flutes to a point is most expeditiously performed by means of a joint-rule in the following manner:—Whatever be the intended height of the drawing of the shafts, set as many times that height from the centre of the joint on the inner edge of the rule, as the diameter of the column at the bottom contains the excess of that diameter above the upper diameters. Let us suppose that the upper diameter is to the lower as 3 to 4, as in the plate, then P Q being the representation of the height of the shaft, make R P on the edge of the rule equal to four times P Q; and lay the edge R P on the line representing the axis of the column; while R P is in this position, move the other leg out to any distance, and press upon it so as to make it stationary; then revolve the leg that was first stationary, and the point R will still keep its situation in the axis of the column, so that the moveable leg of the rule, moving round the centre of the joint, will answer the same purpose as a straight-edge moving round a pin; but it is much handier, for if the point falls on the paper, we shall have no occasion to prick it; and if the point extends beyond the surface of the board, we can still use the joint-rule with as much correctness as if the point were in the drawing board. *Figures* 5 and 6 exhibit a very correct modification of the principle just explained. Find the point V as above, extend the axal line V W to the bottom of the board at *h*, where the paper is intended to be cut off when the drawing is finished; then if the upper diameter is to be one-sixth less than the lower diameter, divide *a b*, *Figure* 6, of the same length into six equal parts, and if the column be eight diameters in height, divide the lower sixth part into eight equal parts; then on the point *h* describe the semicircle *c, i, k, d;* with a radius equal to one of these parts, circumscribe the rectangle *c, f, e, d*, and divide the flutes as before.

Figure 7 is the method of drawing the flutes by dividing both diameters in the same ratio as shown by the plan at the bottom.

SHAFT OF A CHIMNEY, the stone or brick turret above the roof. *See* CHIMNEY.

SHAFT OF A KING-POST, the prismatic part between the joggles.

SHAFTED IMPOST, an impost which has horizontal mouldings separating the archivolt from the pier, and where the section of the archivolt is different from that of the pier. Imposts are termed *shafted*, to distinguish them from *banded* imposts, in which the sections above and below the impost-moulding are alike, the shaft or pier seeming to pass through its capital.

SHAKE, or SHAKEN, a term applied to timber that is rent by drying too suddenly; in which the fissure, occasioned by too great a heat, is called *a shake*.

SHAKY, or SHAKEN, a natural defect in timber when full of splits, or clefts.

SHAM DOOR, in joinery, a panel of frame-work, that appears like a door, but does not open. Sham doors are necessary where corresponding symmetry is wanted; they are only wrought and moulded on the side next to the room. *See* DOOR.

SHANK, (from the Saxon *sceanca*,) a name given to the interstitial spaces between the channels of the triglyph, in the Doric frieze; they are sometimes called *the legs of the triglyph*, and by Vitruvius, *femur*.

SHEERS, a machine employed for lifting heavy and cumbrous materials, consisting of two lofty beams or legs of wood, placed vertically, united at the top, and set apart at the feet; a capstan rope passes over a pulley at the top, by means of which the weight is raised.

SHEET LEAD. *See* PLUMBERY.

SHELVES, (from the Saxon *cylf*,) boards fixed against a wall by their edges, and with their sides horizontally disposed, for the purpose of setting articles upon them. Shelves are supported below by brackets, which are either solid pieces, or small trusses; they are also supported at the ends with vertical pieces, called *standards*, or *cut standards*, where they are let in, and moulded on the edge.

SHIDES, or SHINGLES. *See* SHINGLES.

SHINGLES, (from the German *schindel*,) small boards, similar to slates, prepared for covering a building. They are of oak, either sawn or cleft, about an inch thick at one end, thinned off towards the nail or pin; about 4 inches broad, and from 8 to 12 inches in length. This kind of covering is very dear, and seldom used but for the roofs of churches and pyramidal steeples. Nevertheless, when a light covering is required, shingles may be employed with propriety. Before they are used, they should be well seasoned, by steeping them in water, and drying them in the sun. When made of good cleft oak, this covering is preferable to thatch.

SHINGLING, the act of covering a roof with shingles. In this operation, the building must be first covered all over with boards, after which the rest of the process is similar to that of slating. *See* SLATING.

SHOAR, or SHORE (from the Saxon *score*,) among builders, a prop, or oblique timber, acting as a brace upon the sides of a building, the wall itself performing the office of a post, and the ground that of a beam; so that the wall and ground are ties, while the post is a straining-piece. The upper ends of shores should always rest against that part of the wall into which a floor is inserted, in order to make a counter-resistance to its action. Both ends of shoars should rest upon plates, or beams, which, if firmly fixed, will form a much stronger resistance than could be obtained without them. They should be tightly trimmed between the plates, by driving wedges under their lower ends.

SHOAR, *Dead*, an upright piece of wood, built up in a wall, which has been cut or broken through in order to make some alteration in the building. The piece of wood thus enclosed, being necessary for the support of the superincumbent part during the making good of the wall, and left for the security of the work, which would otherwise be in danger of shrinking, and thereby occasion a fracture in the building.

SHOARING, *See* Shoar.

SHOE (from the Saxon *sceo* or *scoe*,) the part at the bottom of a water-trunk, or leaden pipe, for turning the course of the water.

SHOOT, a term expressive of the act of planing the edge of a board straight, and out of winding.

SHOOTING-BOARD, two boards fixed together, with their sides lapped upon each other, so as to form a rebate, for the purpose of making short joints, either oblique to the fibres, or in their direction. By this instrument, the joints of the panels of framing are made, as also those of the mitres of architraves, or the like.

SHOULDER OF A TENON, the transverse plane to the length of a piece of timber, from which the tenon projects. The shoulder should always be at right angles to the length; though it does not always lie in the same plane as here defined, but sometimes in different planes; as, in the binding-joists of a floor, the shoulder consists of two parallel planes, and one oblique plane. As this compound shoulder seldom or never takes place in anything else, it is simply defined, as above, by its form, in order that the meaning may be more easily comprehended; however, it may be generally defined thus: a shoulder is that which can only be resisted when the piece is pushed forwards in the same direction, supposing the piece, and that which resists it, to be polished.

SHOULDERING PIECES, *See* Brackets.

SHREAD HEAD, or Jerkin Head, *See* Jerkin Head.

SHREDINGS, (from the Saxon *screadan*.) In the roofs of many old buildings, the rafters were formed with a knee, or an obtuse exterior angle from the outside, at the bottom, the upper part, above the knee, being straight to the ridge; and the lower part, which rested upon the wall, either plumb, or nearly so: in order to support the slating between the knee and the face of the building, short slight pieces, as bearers, were fixed below, forming a straight line with the upper part of the rafters; these were called *shredings*, or *furring*, of which, the latter term is most commonly used. *See* Furrings.

SHRINE, a tomb in which the remains or relics of some saintly or noble persons were deposited. They are usually of a highly decorative character; fine examples exist in many of our cathedrals; there is one of Edward the Confessor in Westminster Abbey; it is of stone, and measures 15 feet in height; there is another of St. Frideswide at Oxford, but this is of wood, date about 1480.

The term is also applied to small caskets to contain relics, usually in the shape of rectangular boxes with coped coverings; they are mostly of metal, or overlaid with metal, and enriched with precious stones and other valuables.

SHRINKING, the contracting of a piece of timber in its breadth, by seasoning, hot weather, &c. The shrinking of a piece of timber is proportioned to its breadth. The length of timber is unalterable by seasoning, or any kind of weather; and hence it is, that, in unseasoned timber, mitred together, such as the architraves of doors and windows, the mitres are always close on the outside, and open towards the door, forming a wedge-like hollow on each side of the frame. It is to avoid the shrinking of timber, that narrow boards, called *battens*, are used in floors; and when the panels of a piece of framing are very broad, they will shrink so much as to fall out of the grooves.

SHUTTERS, the boards, or framed joinery, by which the aperture of a window is closed. *See* Joinery.

When shutters are made like boards, they are generally clamped, to keep them from warping; in this case they are seldom less than three-fourths of an inch thick. Framed shutters are either square, or moulded on one or both sides: in the latter case, the mouldings on the outside are made to correspond with the doors in the same room. Framed shutters are seldom less than $1\frac{1}{4}$ inch thick. The thickness of shutters generally depends upon the mouldings, which will occasion the panels to be more or less sunk, according as they are placed on one or both sides. Shutters are sometimes cut, that they may fold more readily together; in this case, they have usually a bead attached to one of them, most commonly to the upper one, by which means the ends of the styles are completely covered. Shutters should not be cut for wide windows, such as those of the Venetian kind; for, in consequence of the cutting, the hinges have less power to support them, and they become liable to go wrong. In shutters, the parts that are hinged together are called *folds*; and those folds that appear when the others are depressed within the boxings, are called *front shutters*; while those that are only seen when the aperture is shut, are called *back flaps*, or simply *flaps*: these, in ordinary works, are generally made thinner than the front shutters, and are mostly clamped, or square-framed. *See* Boxings of a Window, and Sash-Frame.

SIDE POSTS, a kind of truss-posts, placed in pairs, each particular post being disposed at the same distance as the rest from the middle of the truss. Their use is not only for the support of the principal-rafters, braces, crown or camber-beams, but also to hang the tie beam below. In extended roofs, two or three pairs of side-posts are employed, with frequently a middle-post, king-post, or crown-post besides, as the whole stress of the roof must be thrown either to the middle-post, or, in case there is no middle-post, to the two side-posts next the centre; these posts must then act upon each other by the intervention of struts. Posts of a roof are most commonly cut into joggles, which are butments, against which the shoulders of the tenons of the struts rest, and then the butments are at right-angles to the length of the struts. The side-posts of a truss, where the principal-rafters meet, sustain as many points, both in the principal-rafter and in the tie-beam, as they are themselves in number.

Side Timbers, a term used in Somersetshire for purlins. *See* Purlins.

Side Wavers, a term used in Lincolnshire for purlins. *See* Purlins.

SILL, or Cill, (from the Saxon *syl*,) in carpentry, a beam disposed in the lower part of walls, or upon the tops of joists, or under apertures. *Ground-sills* are those upon which the posts and superstructure of a timber building are raised. *Door* and *window sills*, sufficiently indicate their place by their names. The bottom pieces, on which quarter and truss partitions are raised, are called *sills*. Sills are either supported throughout their whole length, as in ground and window sills; or in many points, as those of partitions by joists.

SIMA. *See* Mouldings.

Sima-Inversa, *See* Mouldings.

Sima-Recta, *See* Mouldings.

Sima-Reversa, *See* Mouldings.

SIMILAR FIGURES, those of which the several angles are respectively equal, with the sides about the equal angles proportionate.

SINGLE FLOOR, *See* Naked Flooring.

Single Frame and Naked Floor, a floor with only one tier of joists.

Single-Hung, an expression applied to window-sashes, when only one of them is moveable in the same vertical plane.

Single-joist Floor, a floor without binding-joists.

Single Joists, those which are employed singly in a floor.

Single Measure, a term applied to a door that is square on both sides. It stands opposed to *double measure*, or moulded on both sides. When doors are moulded on one side, and square on the other, they are accounted measure and half.

SITE, the situation or locality of a building, &c.; the plot of ground on which it stands.

SKEW ARCH, an arch, the face of which stands obliquely with reference to the inner faces of the piers. *See* a description of a Skew Bridge in the article Stone Bridge.

SKEW-TABLE, a stone built at the bottom of a gable, to carry the raking coping above. The term is of rather doubtful application; and is employed also to signify the coping itself, consisting of either slabs or solid blocks, toothed into the masonry of the walls. It may be, perhaps, further applied to the sloping projecting rib of masonry frequently seen over gable-ends of roofs, where they abut against vertical walls of greater height than the apex of the roof; as when the roof of the nave of a church abuts against the side of a tower.

SKIRTINGS, or Skirting Boards, the narrow boards round the margin of a floor, forming a plinth for the base of the dado, or simply a plinth for the room itself, should there be no dado. The skirting is either scribed close to the floor, or let into it by a groove; in the former case, a fillet is put at the back of the skirting, to keep it firm.

SKIRTS, (from the Swedish *skiorte*,) one or more superficies, laid in plano, but which would cover a body without leaving any interstice, or without any one part lapping upon another. The four sides of a room, when laid out in this manner, are called *skirts;* as are also the sides of a roof laid out upon a plane.

SKREEN, (from the French *escran*) the instrument used by labourers in sifting earth, lime, &c., for making mortar.

SKYLIGHTS, glass frames placed in a roof with one or more inclined planes of glass. Skylights are either in one plane, as when placed in the inclined side of a roof, or pyramidal, conical, conoidal, spherical, or ellipsoidal, when they are placed above the roof; in which last cases the axis is perpendicular, with the vertex, of course, above. Plane skylights, the most common of all, are sometimes made to slide: the pyramidal have a more grand appearance; but the most dignified is the conical and conoidal, particularly when the ceiling below forms a dome. The spherical and ellipsoidal are less graceful than the conical or conoidal, and much more troublesome to execute. In all skylights, it is necessary that the joint between the bottom and the curb on which they rest, should be so secured as to prevent water running through. Plane skylights, not intended to open, are fixed in the following manner: the upper side of the skylight is bevelled all round the edge of the frame; a row of slates is fixed at the bottom of the aperture; the skylight is then fixed, and the other three sides covered in the process of slating.

SLAB, an outside plank, or board, sawn from the sides of a timber tree, and frequently of very unequal thickness.

The word is also employed to express a thin piece of marble, consisting of right angles and plane surfaces.

SLATE, a bluish fossil stone, very soft when dug out of the quarry, and thereby easily cut or sawed into long thin squares, to serve instead of tiles for the covering of houses, making tables, &c.

SLATING, is employed, in architecture, in sundry ways, the principal of which refers to the covering of the roofs of buildings, but such has been lately the perfection of working in slate, that it is now wrought and fitted into many useful utensils, as well as made up into balconies, chimney-pieces, casings to walls, skirtings, staircases, &c.

The slate principally used in London is brought from Wales, taken from quarries on Lord Penrhyn's estate at Bangor, Caernarvonshire, whence it is forwarded to all parts of the United Kingdom. There are also some other kinds of slate in use, the best sort of which is brought from Kendal, in Westmoreland, and is called *Westmoreland slate.* These are of a fine pale bluish-green colour, and are most esteemed by architects. They are not of a large size, but of good substance, and well calculated to give a neat appearance to a roof. The Scottish slate is nearly similar in size and quality to a slate from Wales called *ladies*, but they are very little sought after.

French slates, which were very much in use many years since, are small in size, most commonly not larger than the Welsh doubles, extremely thin, and, consequently, light; but their composition has been found to be not well adapted to this climate, where the atmosphere contains an excess of moisture. By analysis, this slate is ascertained to contain $\frac{1}{30}$ of manganese, besides other matters, such as iron, &c., the excessive affinity of which for oxygen soon shivers the stony portion of the slate, when employed as a covering, in this country.

Slaters class the Welsh slates after the following order and designations, *viz.*

	Ft.	Inch.		Ft.	Inch.
Doubles, average size,	1	1	by	0	6
Ladies,	1	3	by	0	8
Countesses,	1	8	by	0	10
Duchesses,	2	0	by	0	12
Welsh rags,	3	0	by	2	0
Queens,	3	0	by	2	0
Imperials,	2	6	by	2	0
Patent slate,	2	6	by	2	0

The *doubles*, so called from the smallness of their size, are made from fragments of the larger qualities as they are sorted.

The *ladies* are similarly obtained, but in pieces that will square up to the size of such description of slate.

Countesses are a gradation above *ladies;* and *duchesses* still larger.

The slate is extracted from the quarries, as other stony substances usually are, that is, by making perforations between its beds, into which gunpowder is placed and fused. This opens and divides the beds of the slate, which the quarrymen remove in blocks of very considerable size. These blocks are aftewards split by driving iron wedges between their layers, which separates them into scantlings of from four to nine inches in thickness, and as long and wide as may be required. Such of the scantling as is intended for exportation is sawn to the sizes ordered.

For the purpose of sawing the slate, the works in Wales are provided with abundance of ingenious machinery, some of which are put in motion by steam, and others by water, which keep in action a vast number of saws, all cutting the scantlings into pieces adapted to their several purposes.

The *imperial slating* for roofs is uncommonly neat; and is known by having its lower edge sawn, whereas all the other slates, used for covering, are chipped square on their edges only.

The *patent slate* is so called, among the slaters, from the mode adopted to lay it on roofs, as no patent was ever obtained for such a mode of slating. It was first brought into use by Mr. Wyatt, the architect. It allows of being laid on a rafter of much less elevation than any other kind of slate, and is considerably lighter by reason of the laps being less than is necessary for the common sort of slating. This slating was originally made from that description of slates known as *Welsh rags.* The slaters now frequently make it of imperials, which renders it still lighter, and somewhat neater in its appearance. Experiments have been instituted on the Westmoreland slate by the Bishop of Llandaff, from which there appears very little difference in its natural composition from that obtained from Wales.

Thirteen loads of the finest sort of Westmoreland slate will cover 42 square yards of roofing, and 18 loads of the coarsest will cover the same quantity; so that there is half a ton less weight put upon 42 square yards of roof when the finest sort of slate is used, than if it were covered with the coarsest kind, and the difference of expense is very trifling. It must be remarked, that it owes its lightness, not so much to any diversity in the component parts of the stone from which it is split, as to the thinness to which the workmen reduce it; it is therefore not so well calculated to resist violent winds as that which is heavier.

All the kinds before named partake of a similar mode of laying, in as far as refers to the *bonding* or *lap* of one portion of the slate over another. The lap of each joint is generally equal to *one-third* of the length of the slate, and the slater selects all the largest of the description about to be used, to be put on nearest the eaves. When the slates are brought from the quarry, they are not so square as to be immediately fit for use, but are prepared by cutting and sorting. The slater, to effect this, picks and examines the slate, observing which is its strongest and squarest end. He then, by holding the slate a little slanting upon, and projecting about an inch over the edge of a small block of wood, seating himself at the same time on something which is equal to it in height, cuts away straight one of its edges: next, with a slip of wood, he gauges the other edge parallel to the same, and cuts off that also; after which he turns it round and squares the end. The slate is so far prepared, excepting it be the turning of his tool round and pecking through it, on its opposite end, two small holes, which are made for the nails to enter when he lays it on the roof. All the quarry slates require this preparation from the slater. All slates are put on with nails or screws, and two, at least, are assigned to each slate. The copper and zinc nails, or iron nails tinned, are esteemed the best, as being less susceptible of oxidation than those of bare iron.

The preparation necessary for laying slates on roofs, consists in forming a base or floor for the slates to lie compactly and safely upon. For the *doubles* and *ladies*, boarding is essential, if it be expected to have a good water-proof covering. All that is required in the boarding for such slates is, that it be laid very even, with the joints close, the boards being properly secured by nailing them on the rafters.

When the boarding is ready, the slater examines it, and provides himself with several slips of wood, called *tilting fillets.* A tilting fillet is made about two inches and a half wide, three-quarters of an inch thick on one edge, and chamfered away to an arris on the other. These fillets he carefully lays and nails down all round the extreme edges of the roof, beginning with the hips, if any, and, if not, with the sides, eaves, and ridge. When these are all done, he prepares for laying the slates, and begins at the eaves first. For these he picks out all the largest slates, and places them regularly throughout, setting their lower edges to a line; after which, he secures them by nailing them down to the boarding. He then selects such slates as will form the bond to the under sides of the eaves. This part of the work consists in placing another row of slates under those which he has previously laid, so as to cross and cover all their joints; such slates are pushed up lightly under those which are above them, and are seldom nailed, but left dependent for their support on the weight of those above them, and their own weight on the boarding. The *countesses*, and all other descriptions of slates, when intended to be laid in the best manner, are also laid on boards. When the slater has finished the eaves, he strains a line on the face of its upper slates parallel to its outer edge, and as far from it as he deems sufficient for the lap of those slates which he intends shall form the next course, which is laid and nailed even with the line, and crossing the joints of the upper slates of the eaves. This lining and laying of the slates is continued till the slater gets up close to the ridge of the roof, observing throughout to cross the different joints by the slates he lays on, one above another. This method is uniformly followed in laying all the different kinds of slates, excepting what are called *the patent* slates, as will be hereafter explained. All the larger kinds of slate are found to lie firmly on what are called *battens*, in consequence of which they are frequently made use of for the sake of economy, being cheaper than the smaller slates laid on boarding. A batten consists of a narrow portion of deal wood, about two inches and a half, or three inches wide; three of which are commonly taken out of a deal. When *countesses* are to be laid on, battens of three-quarters of an inch in thickness will be an adequate substance for them; but for the larger and heavier kind of slates, inch battens will be necessary. When a roof is to be battened for slates, the slater himself is the best person to fix them, as they are not placed at a uniform distance from each other, but so as to suit the lengths of the slates; and as these vary as they approach the apex or ridge of the roof, it follows that the slater himself becomes the best judge where to fix the batten so as best to support the slates.

The patent slating, as it is called, consists in selecting the largest slates, and those also of uniform thickness. A roof to be covered with this kind of slate, requires that its *common* rafters be left loose upon their purlins, as they must be placed so as to suit the widths of the slates, it being necessary to have a rafter under every one of their meeting joints. Neither battening nor boarding is required for these slates, and the number of rafters will depend on the width of the slates; hence if they are of a large size, very few will be required, and of course a great saving in the timber takes place, besides giving much less weight upon the roof. The work of covering by this kind of slating is commenced, as before, at the eaves, but no crossing or bonding is wanted, the slates being uniformly laid, with each end reaching to the centre of a rafter, and they are all butted up to each other throughout the length of the roof; the rafters being so placed as to come regularly under the ends of two of the slates. When the eaves course is laid, the slates composing it are all screwed down by two or three strong inch-and-a-half screws at each of their ends into the rafters. A line is then strained about two inches below their upper edge, this being allowed as a lap for the next course of slates, which is laid on above, with its edges straight with the line; and this lining, laying with a lap, and screwing down, is continued till the roof is finally covered. The joints are then to be secured by filleting, which consists in covering all the meeting joints with fillets of slate, bedded in glazier's putty, and screwed down through the whole into the rafters. The fillets are usually about three inches wide, and as long as the slate they are intended to cover. They are solidly bedded in the putty and their intersecting joints are lapped as those of the slates; one screw is put in each lap, and one in the middle of the fillet. The fillets, being so laid, are neatly pointed up all round their edges with more putty; and are lastly painted over the colour of the slate. The hips and ridges of such slating are frequently covered by fillets in a similar way, and have a very neat effect. But lead is the best covering for *all* hips and ridges of roofs, and it is not much dearer than covering them by this mode.

The patent slating may be laid so as to be perfectly water-tight, with an elevation of the rafters considerably less than for any other slate or tile covering; a rise of two inches in each foot of the length of the rafter being deemed sufficient; and this, for a rafter of fifteen feet, would be only two feet six inches, a rise in the pitch of a roof, which, on any height from the ground, would be hardly perceived.

Slating is done also in several other ways, but the principles before explained embrace the most of them. Some workmen shape and lay their slates in a lozenge-form. This kind of work consists in getting all the slates to a uniform size, and the shape of a geometrical square; when laid on the roof, (which is always boarded for this work,) they are bonded and lapped as in common slating; observing only to let the elbow, or half of the square, appear above each slate that is under it, and to be regular in the courses all over the roof. One nail or screw only can be used for such slating, hence it soon becomes dilapidated. It is commonly employed in places near to the eye, or where particular neatness is required.

Slaters' tools consist of a few only, which are sometimes found by the master, and sometimes by the men. The tool, called the *saixe*, is composed of tempered iron, about sixteen inches in length, and two inches in width, somewhat bent at one end, with a beech handle at the other.—This instrument is not unlike a large knife, except that it has on its back a projecting piece of iron, about three inches in length, and drawn to a sharp point. With this tool, ground sharp, the slater chips or cuts all his slates to the required sizes.

The *ripper* is of iron, about the same length as the saixe, and very thin in its blade, which is one inch and three-quarters wide, tapered somewhat towards its top, where it has a round head projecting over the blade about half an inch on each side, and having also two little round notches in the two internal angles, at their intersection. At the handle-end of this tool there is a shoulder, which raises it up above the blade, and enables the workman to hold it firmly in his hand. The use of this tool is in repairs of old slating, as by forcing up its blade under the slates, the projecting head catches the nail in the little notch at its intersection, and enables the workman to pull it out, at the same time that it loosens the slate, and allows him to remove it, and insert another in its place.

The *slater's hammer* is somewhat different in shape from the common tool of that description; it is on the hammer, or driving part, about five inches in height, bent on the top a little back, and ground to a tolerably sharp point; its lower or flat end being about three-quarters of an inch in diameter, and quite round. On the side of the driving part is a small projection, with a notch in its centre, which is used as a claw to extract such nails as do not drive satisfactorily.

The *shaving-tool* is used for getting the slates to a smooth face for skirtings, floors of balconies, &c. It consists of an iron blade, sharpened at one of its ends like a chisel, and mortised through the centre of two round wooden handles, one of which is fixed at one end, and the other about the middle of the blade. The blade is about eleven inches long, and two inches wide; the handles are about ten inches long, so that they project four inches on each side of the blade. In using this tool the workman takes it in both his hands, placing one hand to each side of the handle in the middle of the blade, and allowing the other to press against both his wrists; in this manner he works away all the uneven parts from off the surface of the slate, and gets it to a smooth face.

The slater's other working tools consist of numerous *chisels* and *gouges*, together with *files* of all sizes, with which he finishes his slates for the better parts of his work into mouldings, and other forms.

The strength of slate is very great in comparison of any kind of freestone, as it is ascertained that a slate of one inch in thickness will support, in an horizontal position, as much in weight as five inches of Portland stone, similarly suspended. Hence, slates are now wrought and used for galleries and other purposes, where strength and lightness combined are essential.

Slates are also fashioned into chimney-pieces, partaking of the different varieties of labour applied to marble; but it is incapable of receiving a polish like it, except by japanning. It makes excellent skirtings of all descriptions, as well as casings to walls where dilapidations, or great wear and tear, are to be anticipated. It is capable of being fixed, for these purposes, with joints equally neat with wood, and may be painted over if required, to appear like it. Staircases may be executed in slate, and will have an effect not unlike to black marble.

Slaters' work is measured by the surveyors, as most artificers' work now usually is, and is afterwards reduced into squares, each square containing 100 feet superficial.

Slaters are allowed, in addition to the nett dimensions of their work, (when taking the measure of roofs,) six inches for all the eaves, and four inches for the hips; this allowance is made in consequence of the slates being used double in the former case, and for the waste in cutting away the sides of the slates to fit into the latter. Some of these eaves, for instance, when *rags* or *imperial slates* are used, require an additional allowance of nine inches for the eaves, such kind of slates being so much larger than the size of most of the other kinds now in use. All faced work in slate skirtings, staircases, galleries, &c. is charged by the foot superficial, without any addition. Chimney-pieces are made up and sold at per piece, by the masons.

The following Table of Comparisons will be found useful:

	Average gauge when laid	1200 will cover squares.	Weight per thousand of 1200 in tons.	Nails required to a square.	
				Iron, cast or wrought at per huudred.	Copper at per lb.
	Inches.				
Doubles	$5\frac{1}{2}$	$2\frac{1}{4}$	$\frac{3}{4}$	480	5
Ladies	7	$4\frac{1}{2}$	$1\frac{1}{4}$	280	3
Countesses........	10	$7\frac{1}{2}$	2	320	$3\frac{3}{4}$
Duchesses	11	10	3	254	$2\frac{3}{4}$

SLEEPERS, a row of horizontal timbers, disposed in a building, next to the ground, transversely, under walls, ground joists, or the boarding of a floor.

In bad foundations, sleepers are laid upon piles, and planked over, in order to support the incumbent walls. Sleepers under ground-joists, either lie upon the solid earth, or are supported in several places of their length by prop-stones: when in the former position, having no rows of timbers below, these ground-joists are themselves called *sleepers.* Old writers of practical architecture call those rafters which lie in the valley of a roof by the name of *sleepers;* but the word, applied in this sense, is quite antiquated: such rafters take the name of the place under which they are disposed, that is, they are called *valley rafters*, or, more simply, *valleys*.

SLIDING-RULE, a rule constructed with logarithmic lines, formed upon a slip of wood, brass, or ivory, inserted in a groove, in a rule, made to slide longitudinally therein, so that by means of another scale upon the rule itself, the contents of a surface, or solid, may be known. This rule has already been described under the article CARPENTER'S RULE: but as no examples of its use are given under that head, we shall here supply them. To make the matter more intelligible, we shall here state that all squares are to be found upon C, the side, and all roots upon D, the scale adjoining the slide next to the folding-joint; then, whatever value is put on the 10 on D, the value on C will be the square of that on D. A mean proportional, or root, or given side, is to be found on D. The line C contains squares, lengths, and contents of solids. In finding a mean proportional, set the least number on C to the same on D, then against the greater, on the side, stands the mean on D.

EXAMPLE 1. *To multiply numbers together, as* 12 *and* 16.—Set 1 on B, to the Multiplier (12) on A; then against the multiplicand (16) on B, stands the product (192) on A.

EXAMPLE 2. *To find the product of* 35 *and* 19.—Set 1 on B, to the multiplicand (35) on A; then, because 19 on B runs beyond the rule, I look for 1.9 on B, and against it, on A, I find 66.5; but the real multiplier was divided by 10, therefore the product 66.5 must be multiplied by 10, which is done by taking away the decimal point, so the product is 665.

EXAMPLE 3. *To divide one number by another, as* 360 *by* 12.—Set the divisor (12) on A, to 1 on B; then against the dividend (360) on A, stands the quotient (30) on B.

EXAMPLE 4. *To divide* 7680 *by* 24.—Set the divisor (24) on A, to 1 on B; then because 7680 is not contained on A I look for 768 on A, and against it I find 32 on B, the quotient; but because one-tenth of the dividend was taken to make it fall within the compass of the scale A, the quotient must be multiplied by 10, which gives 320.

EXAMPLE 5. *To square any number, as* 25.—Set 1 upon C to 10 upon D. Then observe, that if you call the 10 upon D 1, the 1 on C will be 1; if the 10 on D be called 10, then the 1 on C will be 100; if the 10 on D be called 100, then the 1 on C will be 10,000, &c. This being well understood, it cannot escape notice, that against every number on D stands its square on C.

Thus, against 25 stands 625
against 30 stands 900
against 35 stands 1225
against 40 stands 1600

Reckoning the 10 on D to be 10.

EXAMPLE 6. *To extract the square root of a number.*—Fix the slider exactly as in the preceding example, and estimate the value of the lines D and C in the same manner; then against every number found on C, stands its square root on D.

EXAMPLE 7. *To find a mean proportional between two given numbers, as* 9 *and* 25.—Set the one number (9) on C, to the same (9) on D; then against 25 on C, stands 15 on D, the mean proportional sought.

For, 1 : 15 : : 15 : 25.

EXAMPLE 7. *To find the mean proportional between* 29 *and* 430.—Set 29 on C to 29 on D; and then 430 on C will either fall beyond the scale D, or it will not be contained on C. Therefore take the 100th part of it, and look for 4.3 on C, and against it on D stands 11.2, which being multiplied by 10, will be 112, the mean proportional required.

SLIT DEAL, a name for inch-and-quarter-inch deal cut into two leaves, or made into two boards.

SMOOTHING PLANE. *See* PLANE.

SNACKET, a local term for a kind of hasp for a casement.

SNIPE'S-BILL, a plane with a sharp arris for getting out the quirks of mouldings.

SOCKET-CHISEL, a strong chisel, used by carpenters, for mortising; used by the percussive blows of a mallet.

SOCLE, or ZOCLE, (from the Latin, *soccus*) a square piece, of less height than its horizontal dimension, serving to raise pedestals, or to support vases, and other ornaments. The socle is sometimes continued round a building, or an entire part of a building. It has neither base nor cornice.

SOFFITA, SOFFIT, or SOFIT, in architecture, any timber ceiling formed of cross-beams, or flying cornices, the square compartments, or panels of which, are enriched with sculpture, painting, or gilding.

The word is Italian, and signifies the same with the Latin *lacunar* and *laquear;* with this difference, that *lacunar* is used for any ceiling with square hollow panels, called *lacus;* and *laquear* for compartments interlaced with platbands, after the manner of *knots*, or *laquei.* Such are those in the basilicas and palaces of Italy, and in the apartments of the Luxemburg at Paris.

SOFFITA, or SOFFIT, is also used for the underside of the corona, or larmier, which the ancients called *lacunar*, the French denominate *plafond*, and we, usually, *the drip*.

SOFFITS, the under sides of the heads of apertures, or the parts of mouldings which may be projected upon a horizontal plane, by lines perpendicular from all points of the mouldings upon that plane. Several methods have already been described, under the article ENVELOPE. What is proposed under the present head, is to show the methods adopted by early writers, not with a view of exposing their errors, but in order to guard the student against erroneous principles.

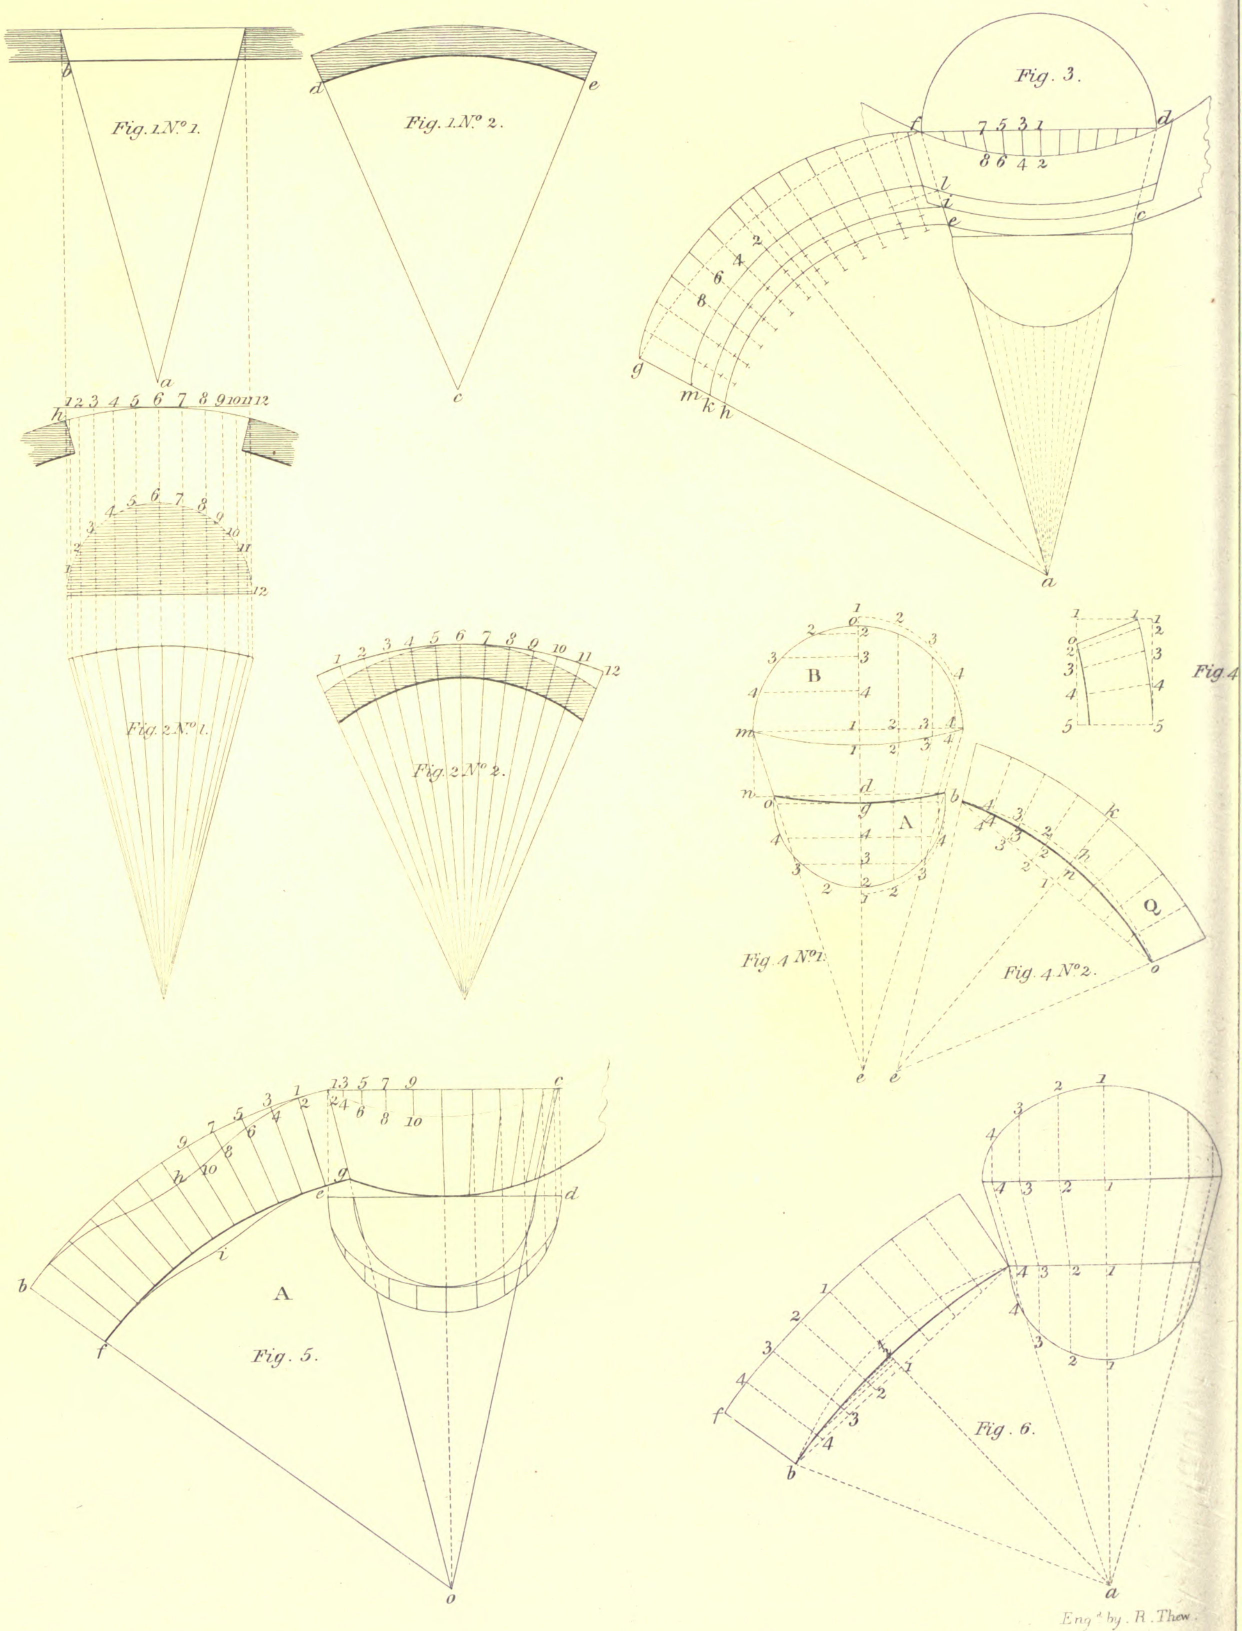
Figure 1, No. 1 and 2, as also *Figure* 2, No. 1 and 2, are from Swan's *British Architect, Plate* I.—"*Figure* 1 shows the opening of a window in a straight wall: draw the lines, ranging with the splay of the jambs; where these meet, s at *a*, is the length of the radius for drawing the curvature of the soffit; then take the distance *a b*, transfer it from *c* to *d*, in *Figure* 2; then set your compasses in *c*, and draw the circular line *e d;* then set on the width of your soffit, and draw the external line; this, when bent to a semicircle, will range along with each part of the straight wall.

"*Figure* 2 represents the opening of a window, of the same width as the former, in a circular wall. The shadowed semicircle above (*Figure* 2, No. 1) shows the opening of the arch. The arch-line may be divided into any number of parts, as here, into twelve. Draw lines perpendicular from the base-line, through all these divisions of the line *h;* then, in *Figure* 2, No. 2, draw a circular line, as for a straight wall; and divide it into the same number of parts as the arch-line above *Figure* 2; then take the distances from the line *h* to the circular wall, and set them from the outside line in *Figure* 2, No. 2, as at 1, 2, 3, &c. to 12; then you will have the true curvature of your soffit, which, when bent to a semicircle, will, in every part, agree with a circular wall."

The following are from the *Carpenters' and Joiners' Repository*, by William Pain:

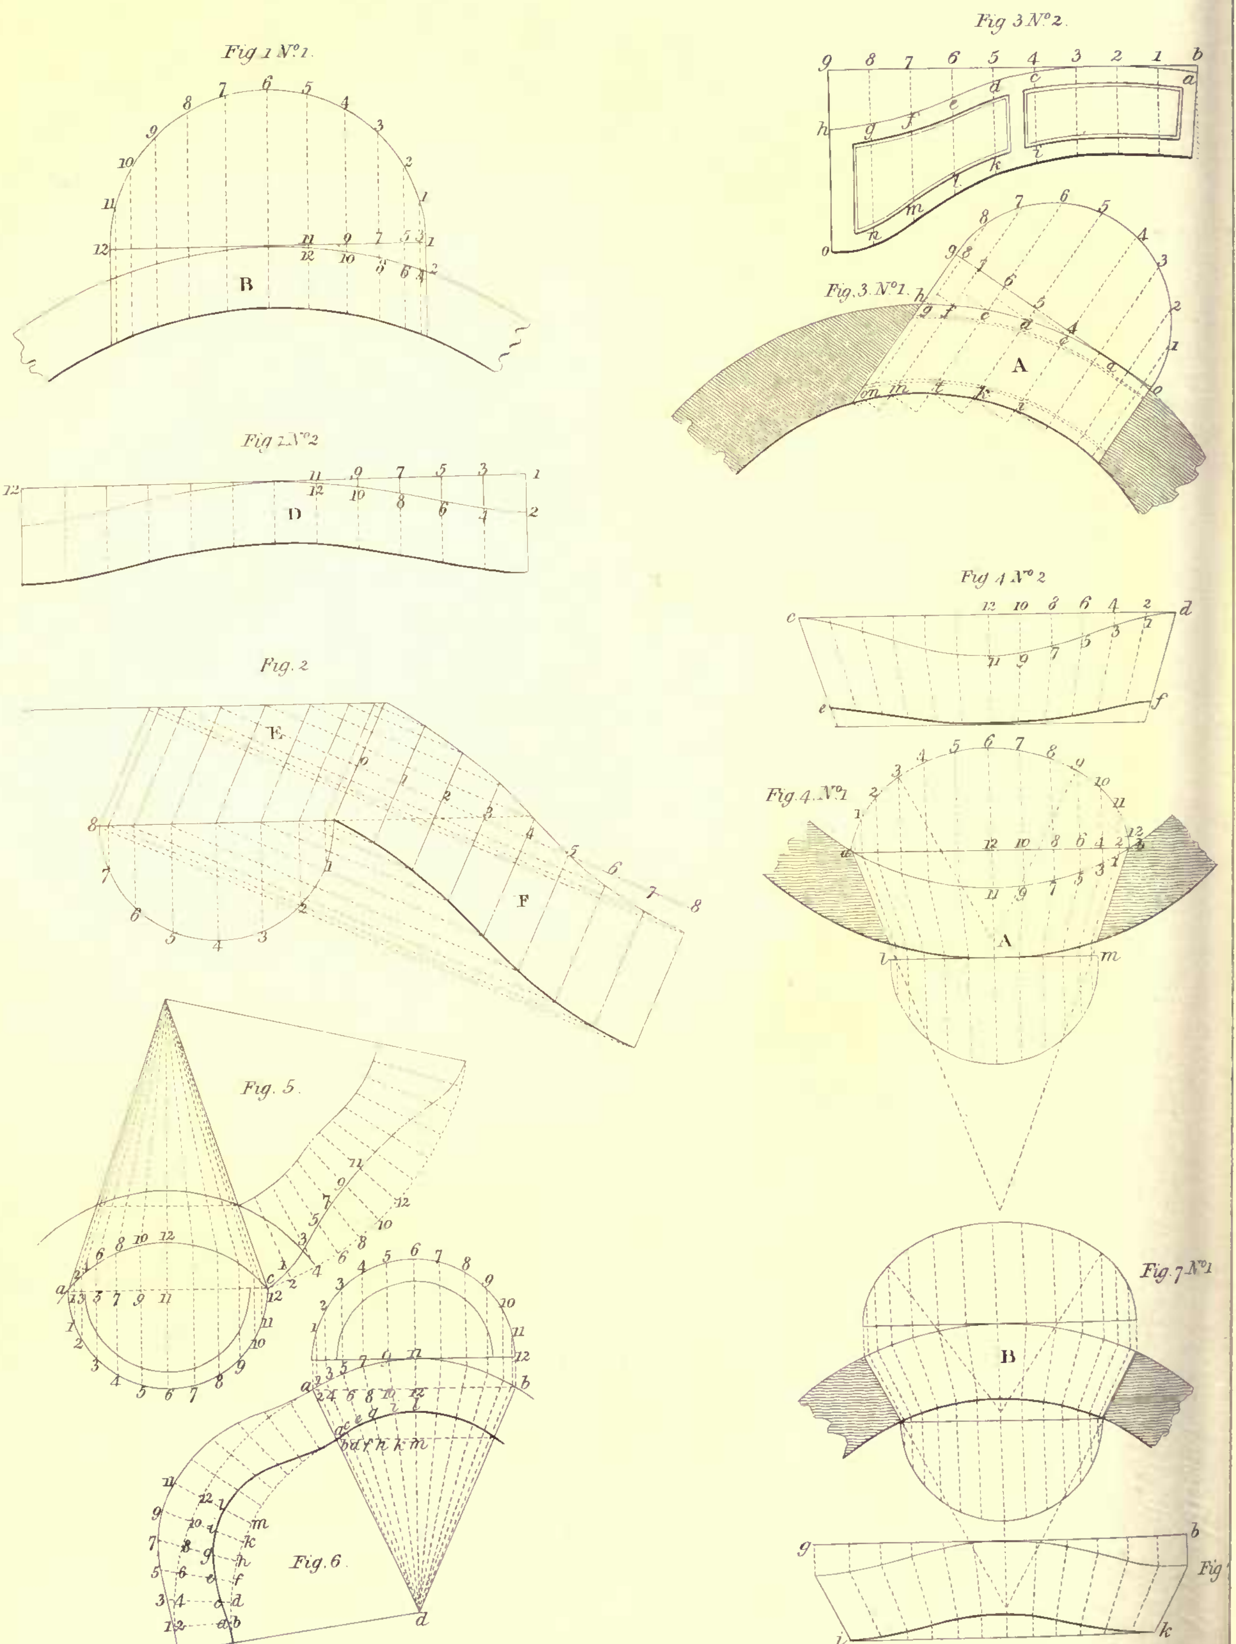
"*Figure* 3 is a circular soffit in flewing jambs. Draw the flewing of the jambs, *c d* and *e f*, to meet at the point *a;* then draw the arch *d f*, and divide the said arch into any

SOFFITS.



Eng^d by . R . Thew .

SOFFITS



Eng^d by. R. Thew.

number of equal parts, the more the truer the work, and run these parts on the dotted arch-line figure; then draw a line from *a* to *g*, which is the soffit stretched out; then draw a dotted line from the centre, *a*, the parts of the arch-line, stretched out far enough to receive the parts taken from the chord-line to the inside of the wall, and set them on the soffit, stretched out, as 1, 2, 3, 4, 5, 6, 7, 8, and so on; which will give the edge of the soffit.

"*Figure* 5.—A is a circular soffit in a circular wall, which is flewing on the jambs, and square at top; which makes the soffit winding as well as flewing. Draw the flewing of the jambs till they meet at *o*. The outside-arch is a semicircle, the inside-arch a semi-ellipsis. On the transverse diameter draw the plan of the wall, and the chord-line *e d*, equal to the opening on the inside 1 *c;* then, on the chord-line, *e d*, draw the semicircle, whose diameter is equal to *e d;* then, on the same chord-line, draw the lesser semicircle to the outside opening; then draw the ellipsis, *e d*, whose height is exactly equal to the height of the lesser semicircle; then divide the greater semicircle into a number of equal parts, and draw dotted lines from these parts to the inside curve of the wall; then apply a rule from the point *o*, to where those lines meet the inside of the wall, and draw the black lines across the plan of the wall, which will give the width of the soffit at those places; then draw, with the centre *o*, the two arch-lines 1 *b*, *f g*, and on the arch 1 *b*, run the parts on the great circle; and, from the centre, *o*, to these parts, draw the black lines across the soffit, stretched out, as 1, 3, 5, 7, 9; then take off the parts between the great semicircle and the ellipsis, and set them on the lines drawn across the soffit, stretched out, as 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, and trace through these points, which will give the inside of the soffit; then take the width of the plan on those black lines, and set it on the soffit, stretched out, will give the line *g i f*, which is the width of the soffit."

The following are taken from the *British Palladio:*—

"*Figure* 4 is a circular flewing soffit, in a circular wall: continue the flewing of the jambs, till they meet at *e;* then take the radius, *e o*, and draw the arch-line *b o;* then divide the greater and lesser arch into the same number of parts, as here into 8; this will do for a straight wall: as this plan flews circular, take half the distance of the chord-line of the lesser arch in the compasses, and strike the dotted arch which divide into four parts; then set them on the chord-line of *b o*, as 1, 2, 3, 4, and draw lines from them to the arch-line stretched out parallel to *e* 1; then take *d g*, the distance of the chord-line of the plan and the curve, and set it from *h* to *n*, on the line *k e;* then set the distances, 2, 3, 4, of the chord-line and curve-line, and set from the arch-line stretched out on the parallel lines, 2, 3, 4; trace through those points from *b* to *n*, and you have half the edge of the soffit. To get the breadth, make a section of the arch, as on the right of *Figure* 4, No. 1; draw the perpendicular lines, 1 5, 1 5, the distances of *m o* on the plan; then take the distances *o*, 2, 3, 4, set them on the perpendicular line to the right, as marked from 1 to 2, 3, 4, 5, at right angles, the distances from the chord-line of the great arch, 1 1, 2 2, 3 3, 4 4, trace through them, and you have one side of this section; for the smaller arch, proceed as before, and on the other perpendicular line, 5 1, of the distances, as figured, 5, 4, 3, 2, 0; from 0 to 1 draw the flewing line of the arch, at the crown; take that distance, and set it from *n* to *k* on the soffit; also, to the perpendicular line on the side of the plan, *m*, *n*, set the compasses in *m*, and strike out the side of the flew to *n;* divide the difference of the line 0 1, from the section to *n*, into as many parts as the great arch; then set off those parts with a small curve, respectively, from 2, 3, 4, 6, on the soffit; then with the parts 1, 2, 3, 4, on the greater dotted arch, cross them from *k;* trace through them, and you have half the soffit; mark them to the other side, and the soffit is complete.

"*Figure* 6 is a circular flewing and winding soffit, in a straight wall. Continue the flewing of the jambs till they meet at *a;* then draw the arch-line *b c*, and make the chords equal to the circumference of the lesser arch, on which set the parts it is divided into, 1, 2, 3, 4; divide the distance of the chord from the arch into five parts; draw a line from 3 to *b*, and mark where it cuts the perpendicular 4 at *d;* draw a line from *d* to 1, parallel to the chord-line; divide 1 2 into four parts; from two of them draw a line parallel to 1 *d;* mark where it cuts the perpendicular of 3, on the chord-line at *e;* draw another parallel line from the third mark, and mark its crossing the perpendicular of 2, on the chord-line at *h;* trace through the points *b*, *d*, *e*, *h*, 2, this gives one side of the soffit, then take the ordinates across the plan, 1 1, 2 2, 3 3, 4 4, and the side of the flew *a f*, and set them from 2, *h*, *e*, *d*, *b;* then take the parts 1, 2, 3, 4, of the greater arch, and set them from 1 to 2, 3, 4, *f;* trace through them, and get the other side; set off these; measure to the other half, and complete the soffit."

Plate II. *Figure* 1.—A soffit, from the *Practical House Carpenter*. No. 1, is the plan and section of the centre. No. 2, is the covering extended in plano. The author describes it thus: "*Figure* B the plan of a circular wall, wherein a circular door, or window, is to be fixed; to make a soffit to fit or stand on the plan, as *Figure* D; draw the base-line of the arch, or soffit, to touch the bow of the wall; divide the arch-line into twelve parts, and drop them down to the plan across it; then stretch out the arch, as 1 to 12, and draw the divisions at right angles from it; then take them from the base-line to the wall, as 1, 2, 3, 4, &c., and transfer them on the parts of the line stretched out, will give the edge of the soffit D."

Figure 2.—A cylindrical soffit, cutting obliquely through a straight wall, from the *Practical House Carpenter*. The author describes it thus: "*Figure* E is a soffit in a straight wall on flewing jambs: F the soffit stretched out; stretch out the arch, as *o* to 8, and draw lines from those divisions parallel with the jambs; then draw the lines from the divisions on each side of the plan; the angle of meeting will give the edge of the soffit." This description is imperfect: for the true method, see the article ENVELOPE.

Figure 3.—A cylindrical soffit in a circular wall, from Pain's *Practical Builder*. The author describes it thus: "*Figure* A is a circular wall, which has a door or window, that stands flewing. Because the jambs do not stand at right angles with the diameter of the circle, find the curve-line of the soffit in this case; draw the chord-line or base-line, of the arch, *o* 9, at right angles with the jambs *o*, *h*, to touch the arch of the wall at *a*, and divide the arch into equal parts, and drop them to the wall; then take off the distances *h g*, 8, 9, 7, *f*, 6, *e*, &c., and put them on the arch stretched out, gives the edge of the soffit." It is singular, that this method should be true, while the former, which is more simple, is false.

Figure 4.—A cono-euneoidal soffit in a circular wall. No. 1 is the plan and sections of the centre: No. 2, the soffit stretched out.

Figure 5.—A conical soffit in a cylindrical wall, where the aperture expands towards the concave surface of the wall.

Figure 6.—A conical soffit in a circular wall, where the aperture expands towards the convex surface of the wall.

Figure 7.—A cono-euneoidal soffit in a circular wall, where the aperture expands towards the convex surface of the wall.

These *Figures*, viz., 4, 5, 6, 7, are from Pain's *Golden Rule*. The principles upon which they are founded are erroneous: see the article ENVELOPE; where are given correct methods for *Figures* 5 and 6, and very near approximations for *Figures* 4 and 7.

SOILS, an obsolete pronunciation for the sills of a window. *See* SILL.

SOILS, in roofing, in Westmoreland, are what are generally denominated in London, PRINCIPAL RAFTERS, which see.

SOLDERING, the method of uniting two or more metals by partial fusion. The union is effected by an alloy or solder, of greater fusibility than the metals to be united.

SOLID, (from the Latin, *solidus*, compact,) in geometry, a magnitude of three dimensions, extended in length, breadth, and thickness.

A solid is terminated, or contained, under one or more plain surfaces, as a surface is under one or more lines. From the circumstances of the terminating lines, solids are divided into *regular* and *irregular*.

Regular solids are terminated by equal and similar planes, so that the apex of their solid angles may be inscribed in a sphere. Under this class come the DODECAHEDRON, the ICOSAHEDRON, the OCTAHEDRON, and the TETRAHEDRON, or CUBE. See those articles.

SOLID ANGLE, an angle formed by three or more plane angles meeting in a point.

The sum of all the plane angles constituting a solid angle, is always less than 360°; otherwise they would constitute the plane of a circle, and not a solid.

If the apex of a solid angle be supposed in the centre of a sphere, the measure of the solid angle is the space intercepted upon the surface of the sphere by the planes of such angle.

Hence the comparison of solid angles is easily effected: for since the areas of spherical triangles are measured by the excess of the sums of their angles, each above two right angles, and the areas of spherical polygons of n sides by the excess of the sum of their angles above $(2\,n—4)$ right angles; it follows, that the magnitude of a trilateral solid angle will be measured by the excess of the sum of three angles above $(2.3—4=2)$ above two right angles; and the magnitude of solid angles, formed by n bounding planes, will be measured by the excess of the sum of the angles of inclination of the several planes above $(2\,n—4)$ right angles.

In all cases, the maximum limit of solid angles will be the plane, towards which various planes determining such angles approach, as they diverge farther from each other about the same summit; the same as a right line is the maximum limit of plane angles, being formed by the two boundary lines, when they make an angle of 180°. The maximum limit of solid angles is measured by the surface of the hemisphere, in like manner as the maximum limit of plane angles is measured by the arc of a semicircle.

The solid right angle is $\frac{1}{4}=(\frac{1}{2})^3$ of the maximum solid angle; while the plane right angle is half the maximum plane angle.

SOLID SHOOT. *See* WATER SHOOT.

SOLIVE, (French,) among carpenters, a joist, rafter, or piece of wood, either slit or sawed, with which the builders lay their ceilings. This word, though generally found in builders' dictionaries, is not used by English carpenters.

SORTANT ANGLE, the same as SALIENT ANGLE, which see.

SOSTRATUS, in biography, the most eminent architect of his time, was a native of Cnidos, in Lesser Asia, the son of Dexiphanes, also an architect, who flourished in the third century before the Christian æra. The high patronage he met with, caused him to be denominated *the friend of kings*. He was particularly in favour with Ptolemy Philadelphus, sovereign of Egypt, and is celebrated in history for the terraces, supported on arcades, with which he adorned his native city. He also built the celebrated lighthouse on the island of Pharos, opposite to Alexandria, which was reckoned among the wonders of the world; and, by a crafty device, he transmitted his name to posterity, in lieu of that of his patron. Being ordered to engrave upon the tower an inscription to the following effect: "King Ptolemy to the gods, the saviours, for the benefit of sailors;" instead of the king's name, he substituted his own, and then filling up the letters with mortar, he painted upon it as he had been directed; but in process of time, the mortar wearing out, the original engraving appeared, and the inscription ran, "Sostratus, of Cnidos, the son of Dexiphanes, to the gods, the saviours, for the benefit of sailors;" which remained as long as the tower stood.

SOUFFLOT, JAMES GERMAIN, an eminent architect, born, in 1714, at Irancy, near Auxerre. His father, an *avocat* of the parliament, destined him for his own profession, and sent him, while very young, to Paris for education; but preferring the science of architecture, he was for some time employed in that art at Lyons, whence he repaired to Italy, for improvement, and, on his return to France, was admitted one of the king's pensioners. It being resolved that several public buildings should be erected at Lyons, he was recommended to undertake part of the work, by the director of the French academy at Rome; and the construction of the Exchange and the Hospital was committed to him. The noble simplicity of the Hospital, together with its excellent adaptation to the object for which it was intended, were universally admired, and raised his reputation as an artist. After this, he was employed to build the Concert-Room and Theatre of the same city. He next travelled again into Italy, and on his return, settled at Paris, where he was successively made comptroller of the buildings at Marly and the Tuilleries, member of the academies of architecture and painting, knight of St. Michael, and intendant of the royal buildings. In 1757, he laid the foundation of the church of St. Geneviève, of which he only finished the portal, the nave, and the towers. In this business, he subjected himself to some severe criticism, especially with respect to the possibility of erecting the intended dome upon the basis designed for it; though some exact calculations justified his plan. The criticisms and unfriendly remarks of his rivals were more than his temper, naturally irritable, could bear; and he died partly of chagrin, in the year 1780, at the age of 67. Besides the public works already mentioned, he executed many others, which display the powers of a great genius; and after his death, M. Dumont, professor of architecture, published a book of designs, which he had left behind him, under the title of *Elévations et Coupes de quelques Edifices de France et d'Italie, désignées par feu M. Soufflot, Architect du Roi, et gravées.*

Though Soufflot was rough and hasty in his manners, he was kind and friendly, whence he obtained the name of *Le Bourru Bienfaisant.*

SOUND-BOARD, the same as a canopy or type over a pulpit, used for the purpose of increasing the sound by reflection.

SOUND-BOARDING, in floors, short boards placed transversely between the joists, and supported by fillets, fixed to the sides of the latter, for holding the pugging, which is any substance that will prevent the transmission of sound from one story to another. The narrower the sound-boards, the better. The fillets, on which the sound-boards rest, may be about three-quarters of an inch thick, and

SPANDREL BRACKETING

ANGLE BRACKETS

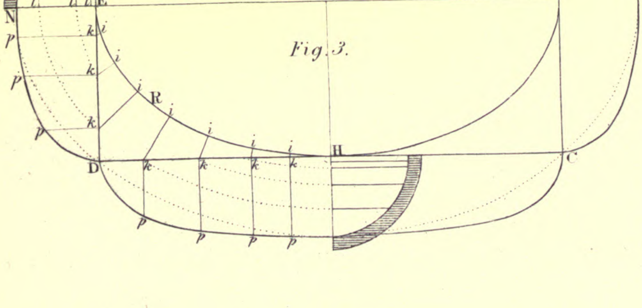

Fig. 3.

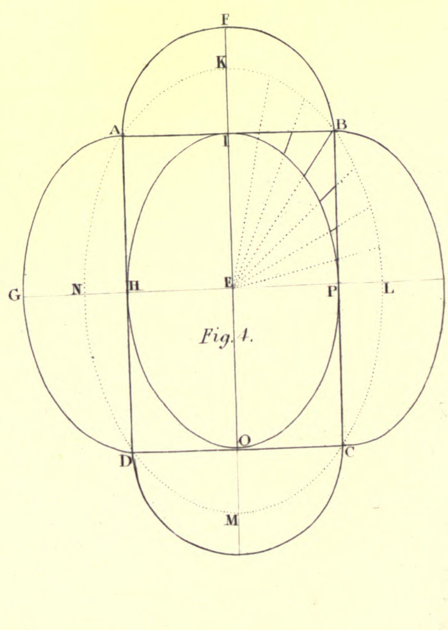

Fig. 4.

Drawn by P. Nicholson

Engraved by J.C. Bu

about an inch broad, nailed to the joists at intervals of one foot each.

SPAN, the width of an arch; the distance between the piers, or the length of an imaginary line extending between its springing on either side; the same as *chord.*

SPANDREL, an irregular triangular space, bounded on one side by the outer or convex curve of an arch, and on the other two by two straight lines touching the curve, and meeting each other at right angles. It is commonly formed in Gothic architecture by an arch with a rectangular hood-mould, the spandrel so formed being frequently enriched with carving or sculpture, sometimes with foliage, at others with quatrefoils, shields of arms, and various devices.

The term is further applied to any surface of a similar form, or formed under similar circumstances.

SPANDREL BRACKETING, a cradling of brackets fixed between one or more curves, each in a vertical plane, and in the circumference of a circle, whose plane is horizontal.

PROPOSITION I.—*Given the plan of a square room to be covered or vaulted with spandrel bracketing, and the vertical section of the cove, whose plane passes through the axis of the room, and through the intersection of two adjoining walls; to find the figure of the springing on the walls, so that the faces of the brackets may be in the surface of a solid, formed by revolving the given section from its place in the angle, round the axis of the room, until it makes a revolution.*

In the given square inscribe a circle, which will represent the ceiling-line, from any angle of the square draw a line to the centre: apply the given section upon this line as a base, to its place at the angle. Take any number of points in the curve, and draw lines perpendicular to the base to cut it. Upon the centre of the square, and with the distance of the several points of section, describe arcs cutting any side of the square. From these points draw perpendiculars to that side, from which make the several lengths of the perpendiculars equal to those of the section; through the extremities draw a curve, which will be the figure of the springing.

Example 1. *Figure* 1.—Let the given square be A B C D, and let E be its centre; join E B; apply the given section, B F, to E B, as a base, so that when turned perpendicular round E B upon the square, it will then be in its place. In the curve, F B, take any number of points, *h*, and draw the lines *h i*, perpendicular to E B, meeting it at the point *i*. On the centre, E, with the radii E *i*, describe arcs, *i k*, meeting A B in the points *k*. From the points *k*, draw the lines, *k l*, perpendicular to A B; and also from M, the points of contact, draw M N. Make the perpendiculars M N, *k l*, *k l*, &c. equal to the lines *i h*: through the points B, *l*, *l*, *l*, &c., to N, draw a curve, which will be half the springing line required. But if the points *p* are taken in the arc, M O, equidistantly, and the points *p* be the upper ends of the brackets, it will be much more convenient to draw the lines E *p k*. On the centre, E, with the radii E *k*, describe the arcs *k i*; draw the perpendiculars *i h* and *k l*, and proceed as before, to complete the curve, as the points *l* will give the spring of the foot of the brackets. In this example, the section here given is a quadrant; but it may be any geometrical curve, or any other line, that fancy may suggest, the same method extending to all.

Example 2. *Figure* 2.—In this example, the section given is a part of a circle, the radius of which is half the diagonal of the square, therefore, the quadrant, one of whose radii is the axis, and the other the half of the diagonal, will generate a hemisphere. It is evident, that if a square be inscribed in its base, and cut by planes through the sides of the square at right angles to the base, the sections will be semicircles; therefore, upon any side, as a diameter, describe a semicircle, and it will give the springing required. The places or springing-points of the brackets, may be found as before.

PROPOSITION II.—*Given the plan of an oblong room, to be coved or vaulted with spandrel bracketing, the ceiling-line an ellipsis inscribed in the plan, and a section of the cove, through the diagonal perpendicular to the ceiling-line; to find the spandrels of the bracketing, such that they may be the intersections made by the planes of the four walls, with the curved surface of a solid, generated by the given section, moving always perpendicular to the ceiling-line, which passes through the upper extremity of the curve of the generating section, and the lower extremity, always in a horizontal plane.*

Figure 3.—Let the oblong, A B C D, be the plan of the walls, and E F G H, the inscribed ellipsis; E G being the greater axis, and F H the lesser, parallel to the sides of the rectangle; consequently, E, F, G, H, the points of contact. In any quadrant, E H, take any number of equidistant points, *i*, or rather in a ratio, in which every succeeding two towards E, the extremity of the longer axis, will be nearer and nearer together, by the property of the ellipsis. Draw the lines, *i k*, perpendicular to the curve, cutting the two sides, D A, D C, in the points *k*. Let N E O be the given section, N E its base, which is a prolongation of G E, the line drawn from D, perpendicular to the curve, meeting it at R; from the point E, on E N, make the distances E *l* respectfully equal to the lines *i k*. Draw the lines *l m* perpendicular to N E, cutting the curve N O in the points *m*, and the lines *k p* perpendicular to A D and D C: make all the lines *k p* equal to the lines *l m*, and through the points *p* draw curves, which will be half the springing line on the two adjacent sides, and the points *p* will be the places for the springing of the brackets. The reader must here observe, that though the points *l* would describe parallel curves on the horizontal plane, yet none of these curves would be ellipses.

PROPOSITION III.—*Given the plan of a rectangular room to be coved with spandrel bracketing, supposing the surface of the solid with which the faces of the brackets are to coincide, to be an ellipsoid, the base of the spandrel solid, a section passing through its axis, given the springing-line of one of the ends, which is a section perpendicular to the fixed axis; to find the springing-line upon the sides, so that they may be of the same height with that upon the ends, and also the curves of the ribs.*

Figure 4.—Let A B C D be the rectangular plan, and let A F B be the section given, which is necessarily semicircular; upon A D, as a transverse axis, and with one-half of A B, as a semi-conjugate, describe the semi-ellipsis A G D, and it will be the springing required for the other two sides. Produce I O and H P, the two axes of the inscribed ellipsis, in all the four directions. Through any point, A, in one of the angular points of the plane, describe an ellipsis, N K L M, whose two axes shall be on the lines H P and O I, and also in the same ratio as those lines, the transverse axis being M K, and the conjugate N L; this ellipsis would be the base of the ellipsoid. Now, as every section passing through the shorter axis of this ellipsoid, viz., all the vertical ellipses passing through E, have the same conjugate axis, it will be very easy to describe the ribs over any given seat, as this seat is the transverse axis, and the radius of the greatest circle is the semi-conjugate.

Two diagrams illustrative of the method of obtaining the projection of angle-brackets are added.

Figure 1, a cove bracket; B A E the plan of the angle-rib; the ordinates *h i*, are taken from the ordinates *g f*.

Figure 2.—Another cove-bracket, of which one side has less projection than the other. B G D, the plan of the angle, as before; the bracket A G B, the angle B G D, and the position of the line, G E, are given; H G E, being an obtuse angle, viz., the angle of the room. The ordinates, *m n*, of one side of the room, are taken from the ordinates, *k i*, of the given bracket, A B G.

SPAN-PIECE, a provincial term in Lincolnshire, and perhaps in other counties, for COLLAR-BEAM, which see.

SPAN-ROOF, a roof consisting of two inclined sides. The term is used in contradistinction to *shed-roofing*. Span-roofing may have simple rafters, with or without a collar-beam; or the roof may be trussed; in which latter case, the term applies only to the external construction.

SPECIES OF TEMPLES: these are determined by the number of columns in the front of the portico; which, with their distance from each other, is regulated by the diameter of the columns at the bottom. *See* TEMPLE.

SPECIFICATION, a detailed and formal description of an edifice to be erected, the materials to be used therein, and the particular uses to which they are to be applied. Specifications are provided for the guidance of the builder in making his tender for work, and are appended to the contract. They are usually divided into several heads, according to the different trades employed in the work, and ought to be made out with great accuracy and precision; the more simple they are, the better.

SPECIFIC GRAVITY, a comparison of every solid, or fluid, with the weight of the same magnitude of rain-water. Rain-water is chosen as the standard of comparison, on account of its being less subject to variation in different circumstances of time, place, &c., than any other body, whether solid or fluid. And by a very fortunate coincidence, at least to English philosophers, it happens, that a cubic foot of rain-water weighs 1,000 ounces avoirdupoise; and consequently, assuming this as the specific gravity of rain-water, and comparing all other bodies with this, the same numbers that express the specific gravity of bodies, will at the same time denote the weight of a cubic foot of each in avoirdupoise ounces, which is a great convenience in numerical computations.

From the preceding definition, we readily draw the following laws of the specific gravity of bodies, viz.,

1. In bodies of equal magnitudes, the specific gravities are directly as the weights, or as their densities.

2. In bodies of the same specific gravities, the weights will be as the magnitudes.

3. In bodies of equal weights, the specific gravities are inversely as the magnitudes.

4. The weights of different bodies are to each other in the compound ratio of their magnitudes and specific gravities.

Hence it is obvious, that if in the magnitude, weight, and specific gravity of a body, any two be given, the third may be found; and we may thus find the magnitude of bodies, which are too irregular to admit of the application of the common rules of mensuration; or we may, by knowing the specific gravity and magnitude, find the weight of bodies which are too ponderous to be submitted to the action of the balance or steel-yard; or, lastly, the magnitude and weight being given, we may ascertain their specific gravities.

Example 1.—*The weight of a marble statue being* 748*lb. avoirdupoise, required the number of cubic feet, &c., which it contains; the specific gravity of marble being* 2742.

Since a cubic foot weighs 2742 ounces, we have
as $2742 : 748 \times 16 :: 1 : 4.36$ feet.

Example 2.—*Required the weight of a block of granite whose length is* 63 *feet, and breadth and thickness each* 12 *feet; the specific gravity of granite being* 3500.

Here $63 \times 12 \times 12 = 9072$ feet: then again
as $1 : 9072 :: 3500 : 31752000$ ounces:
or 885 tons, 18¾ cwt. The above are said to be the dimensions of one of the stones in the walls of Balbec.

Other properties relating to the specific gravity of bodies are as follows, *viz.*

1. A body immersed in a fluid will sink, if its specific gravity be greater than that of the fluid; if it be less, the body will rise to the top, and be only partly immersed; and if the specific gravity of the solid and fluid be equal, it will remain at rest in any part of the fluid in which it may be placed.

2. When a body is heavier than a fluid, it loses as much of its weight when immersed, as is equal to a quantity of the fluid of the same bulk or magnitude.

3. If the specific gravity of the fluid be greater than that of the body, then the quantity of the fluid displaced by the part immersed, is equal to the weight of the whole body. And hence, as the specific gravity of the fluid is to that of the body, so is the whole magnitude of the body to the part immersed.

4. The specific gravities of equal solids are as their parts immersed in the same fluid.

5. The specific gravities of fluids are as the weights lost by the same immersed solid.

Hence are drawn the following rules for ascertaining the specific gravities of both solids and fluids.

To find the specific gravity of a body.—This may be done generally by means of the hydrostatic balance, which is contrived for the easy and exact determination of the weights of bodies, either in air, or when immersed in water, or other fluid, from the difference of which the specific gravity of both the solid and fluid may be computed.

1. *When the body is heavier than water.*—Weigh it both out of water and in water; then say,

As the weight lost in water
Is to the whole or absolute weight,
So is the specific gravity of water
To that of the body.

2. *When the body is lighter than water.*—In this case attach to it a piece of another body heavier than water, so that the mass compounded of the two may sink together. Weigh the denser body and the compound body separately, both out of the water and in it; and find how much each loses in the water by subtracting its weight in water from its weight in air; and subtract the less of these remainders from the greater. Then use the following proportion:

As the last remainder
Is to the weight of the light body in air,
So is the specific gravity of water
To the specific gravity of the body.

3. *When the specific gravity of the fluid is required.*—Take a piece of some body of known specific gravity; weigh it both in and out of the fluid, and find the loss of weight by taking the difference of these two; then say,

As the whole or absolute weight
Is to the loss of weight,
So is the specific gravity of the solid
To the specific gravity of the fluid.

The following table exhibits the specific gravity of several of the most common bodies; it is extracted from a more extensive one given in Gregory's *Mechanics;* and other tables of a similar kind will be found in the works of Emerson, Muschenbroeck, Ward, Cotes, Martin, &c.

Table of Specific Gravities of Bodies.

SPERE, a screen across the lower end of ancient halls.

SPHERE, (from the Greek, *σφαιρα, a ball*,) a solid, whose surface is everywhere equally distant from a certain point within the solid; which point is called *the centre of the sphere.*

Every sphere is equal to two-thirds of its circumscribing cylinder; that is, it is equal to a cylinder, whose ends are circles, equal to a great circle of the sphere, and whose height is equal to the diameter of the same. Therefore,

To find the solidity of a sphere. Multiply the square of the diameter by .7854, and this product by the diameter of the sphere, and take two-thirds of the last product; or,—Multiply the cube of the diameter by .5236, and the product is the solid content.

To find the superficies of a sphere.—Multiply the area of the great circle by .4, and the project is the superficies.

Example.—To find the solidity of a sphere, whose diameter is 23 *feet,* 3 *inches.*

Here 23 : 3=23.25 in decimals.

The superficial content of the same sphere is 540.5625 + 4=2162.2500.

SPHERICAL BRACKETING, the forming of brackets to support lath-and-plaster-work, so that the surface of the plaster shall form the surface of a sphere. *See* PLASTERING.

The form of the bracketing depends upon the planes in which they are disposed, within the surface of a sphere: but, in all cases, the edges are circular, because the section of a sphere is a circle, according to any position of the cutting plane: the edges of the bracketing will be equal circles, when their planes intersect each other in the centre of the sphere; in this case, the edges require no bevelling: but if the planes of the brackets are disposed in a parallel way, the edges are all unequal circles, and the edges, which receive the lath, will be more oblique, as the planes of the circles are more remote from the centre of the sphere: therefore, the quantity of labour, and the waste of timber, will entirely depend on the disposition of the planes of the bracketing.

SPHEROIDAL BRACKETING, the bracketing prepared for a plaster-ceiling, whose surface is to form that of a spheroid.

As all the sections of a spheroid are either circles or ellipses, the edges of the bracketing are either circles or ellipses.

As a spheroid may be supposed to be generated by the revolution of a semi-ellipsis upon one of its axes; therefore, if the planes of the bracketing be disposed in parallel planes, perpendicular to the axis of the generating circle, the edges of the bracketing must be circles.

If the planes of the bracket be disposed in planes passing through the axis of rotation, the edges of the bracketing will be portions of an ellipsis, equal and similar to the generating semi-ellipsis.

If the planes of the bracketing be so disposed as to pass through a diameter of the great circle of the spheroid, viz., that circle perpendicular to and bisecting the generating axis; then all the ribs of the bracketing will be elliptic quadrants, bounded by two semi-axes and the quadrantal curve; one of the semi-axes will be equal to the radius of the great circle, and the other will be found upon the plane of the generating ellipsis.

SPHINX, a sculptured figure frequently found in Egyptian temples, and their approaches, representing a monster with the head and breasts of a woman, the wings of a bird, the claws of a lion, and the other parts of the body like a dog.

SPIRAL, (from the Latin, *spira*, involved,) a curve which makes one or more revolutions round a fixed point, and which does not return to itself. *See* VOLUTE.

SPIRE, a pyramidal acutely-pointed covering or roof, most usually found on towers of churches and on turrets. Spires are constructed either of stone or of wood, covered with lead, slate, or oak shingles. They were probably not introduced into England till some time after the Norman conquest. In the earliest examples, they are usually of the same plan as the tower, either square, circular, or octagonal, and are of no very great height. In early English examples of later date, they are sometimes of the same plans, but more frequently octagonal, and also of much loftier proportions; where an octagonal spire stands on a square tower, the angular spaces left unoccupied are covered by pinnacles, or by semi-pyramidal masses of masonry sloping against the spire. The outline is frequently broken by one or more tiers of small open windows, termed spire-lights, the faces of which are vertical, and therefore project out at the top from the sloping face of the spire; they are usually covered with gablets or sharp pediments, which in the later and more ornamented styles are often enriched with crockets, finials, pinnacles, &c. Spire-lights are frequently placed on the alternate faces of the spire in alternate tiers. Early English spires are usually what are termed *broach-spires;* that is to say, they spring directly from the edge of the tower, without the intervention of a parapet, whereas, in the later styles, the parapet is seldom omitted. In the Decorated and Perpendicular styles, the spire is more enriched, usually having angular pinnacles, and often flying-buttresses from the pinnacle to the spire; crockets sometimes adorn the angles of the spire, and ornamental bands divide it into several stages. Spires are terminated at the apex either with a finial or metal cross or vane, the latter being frequently in form of a cock, as an emblem of prayer and watchfulness. Spires of open work are not unfrequent in the larger continental churches.

SPITAL, an hospital.

SPLAYED, (from the old French, *disployer*, to spread abroad,) a term, in architecture, applied to whatever has one side making an oblique angle with the other: thus, the heading-joints of a boarded floor are frequently splayed in their thickness, as are also the jambs, or sides, of a window; in the latter case, the room may be lighted to the greatest advantage. The word *fluing* is sometimes applied to an aperture in the same sense as *splayed.*

SPRING BEVEL OF A RAIL, the angle made by the top of the plank, with a vertical plane touching the ends of the rail-piece, which terminates the concave side.

SPRINGED, in boarding a roof, the art of setting the boards together with bevel-joints, so as to keep out the rain.

SPRINGING COURSE, the horizontal course of stones from which an arch begins to spring; or the row of stones upon which the first arch-stones are laid.

The term is also applied to the bottom stone of the coping of a gable.

SQUARE, (from the Latin, *quadratus*, having four corners,) a term among workmen, applied to any material, when two of the sides stand perpendicular to each other. In joinery, the work is said to be *square-framed*, or *framed square*, when the framing has all the angles of its styles, rails, and mountings, square, without being moulded.

SQUARE, an instrument for trying whether an angle be a right angle, generally consisting of an outer and inner square, parallel to each other; the former for trying interior angles, the latter for exterior ones.

SQUARE-SHOOT. *See* WATER-SHOOT.

SQUARE-STAFF, a piece of wood, used for fortifying the angles of plaster-work intended to be papered over.

SQUARING HAND-RAILS, the method of cutting a plank to the form of a rail for a staircase, so that all the vertical sections may be rectangles. The squaring is the most difficult part in the execution of hand-rails, as the moulding and finishing must be regulated by it. To perform it accurately, the plank must be shot to the proper bevel, or edge; then, supposing it to be set to the pitch, a vertical line must be drawn on the edge, and the face-mould must be applied, first on one side of the plank, so that the two points may come close to the edge that is shot, and, one of them coinciding with the vertical face, lines are to be drawn by the edges of the mould on the surface of the plank. The mould is then to be applied to the other side, in the same manner, and lines drawn as before; after which, the plank is to be cut out between the lines thus drawn on both sides, great care being taken to keep the teeth of the saw perpendicular. The edges will then only want smoothing, and the top and bottom of the rail-piece will be brought to a level by the falling mould. *See* HAND-RAILING.

SQUARING OF A PIECE OF STUFF, the act of trying it up by the square, in order to make the angles right angles.

SQUINCH, a small arch thrown across the angles of square towers to support octagonal spires. The same object is sometimes effected by corbelling out at the angles, which has this advantage over the arch, that it does not tend to thrust apart the walls of the tower; this latter plan is termed the straight squinch.

SQUINT, an opening often found in the walls of churches, passing through them in an oblique direction, usually on one or both sides of the chancel-arch, so as to enable persons sitting in the aisles or transept to see the elevation of the host: where there are no chancel-aisles, there is often a projection on the exterior of the church through which the aperture is pierced. In Bridgewater church, Somersetshire, the perforation is carried through three walls in an oblique line, so as to enable persons in the porch to view the altar.

Some of these openings extend from the ground to a height of ten feet, or thereabouts, but they are usually two or three feet above the ground, and two or three feet high, by two wide; they are frequently plain, but sometimes highly enriched. They are more correctly termed *hagioscopes*.

STABLE, a house or shed for horses and cattle generally.

STADIUM, a Roman measure of length, nearly equivalent to an English furlong. Also an enclosed area in which the various athletic exercises were exhibited.

STAFF-BEAD, a vertical piece of timber placed on the exterior angles of the walls of apartments to preserve the arris, which, if made up of plaster, is liable to be broken; it is frequently moulded with a bead on the outer edge.

STAINED GLASS, pieces of glass stained of various colours, and arranged so as to form a variety of patterns or devices, and sometimes of pictorial representations.

The ancient Egyptians are said to have made and coloured small ornaments of glass, but glass does not seem to have been much used by any of the ancients; small pieces are found in Roman mosaics, and some larger plates have been discovered at Herculaneum, which some have supposed to have been used as window glass. According to Bede, glass was employed in the windows of Bishop's Wearmouth church, but it did not come into general use for some time afterwards, and was not used in private houses till A. D. 1180. Stained glass for windows, was probably in use as early as the ninth century, but no example exists in England of earlier date than the twelfth century, to which period belong the remains at Canterbury. These consist of panels of various forms, containing subjects on a deep blue or ruby ground, the spaces between the panels being filled up with mosaic patterns in which ruby and blue are the prevalent colours; the whole is surrounded with a border of foliage and scroll-work.

During the Early English period, the glazing consists of panels, circles, quatrefoils, and other forms, including that of the vesica piscis, and these contain subjects; the spaces between are filled with coloured mosaic patterns, and the whole contained in a border of leaves and scroll-work. Sometimes the entire space within the border is filled with scrolls, and foliage, on a deep blue or ruby ground, the scrolls, &c., being either of coloured glass, or only in black outline in plain glass; in the latter case, panels formed by strips of coloured glass are sometimes inserted. Quarry glazing, in which the windows are formed by lozenge-shaped pieces of glass, with a small pattern upon each, is first used in this style.

In the Decorated style, quarry glazing becomes of frequent use, and the panel system loses ground; where panels occur, the ground is covered with patterns of foliage of a more flowing and natural character than in the preceding style; the vine and ivy leaves are favourites. Sometimes the entire window is filled with such foliage, which is often only in outline, and frequently only some portions of the pattern are stained yellow. Quarries contain small patterns of leaves, rosettes, &c., sometimes in plain outline, but frequently coloured yellow; in foliage patterns, in which the vine and ivy leaves predominate, the stalks of the leaves are often so arranged, as to form one continuous flowing pattern throughout the window, and at other times, one edge of each quarry had a coloured stripe, so that when put together they each appeared surrounded with a coloured border. The entire design is surrounded, in most cases, with a running border of foliage and flowers. At this period, single figures surmounted by canopies, begin to appear, at first of small size, two or more being contained in one light, but afterwards they become larger, and were disposed one in each light.

In the Perpendicular period, this practice begins to increase, the figures and canopies are of a larger size, more than one being seldom contained in one light; at last whole windows containing several lights were filled with one large grouped subject. Quarries still continue in use, but the devices do not flow one into the other, consisting mostly of rosettes, flowers, fleurs de lis, and heraldic devices, the latter being very frequently and generally adopted in this style. Coloured inscriptions on bands or scrolls are frequently seen running diagonally, and at regular intervals, across windows, from top to bottom.

With the decline of Gothic architecture, stained windows fell into disuse; and with its revival, it is now occupying a great deal of attention, and is executed with considerable taste and skill.

STAIRCASE, a term applied to the whole set of stairs, with the walls supporting the steps, leading from one story to another. The same staircase frequently conducts to the top of the building, and thus consists of as many stories as the building itself.

When the height of the story is considerable, resting-places become necessary, which go under the name of *quarter-paces* and *half-paces*, according as the passenger has to pass a right angle, or two right angles; that is, as he has to describe a quadrant or a semicircle. In very high stories that admit of sufficient head room, and where the space allowed for the staircase is confined, the staircase may have two revolutions in the height of one story, which will lessen the height of the steps; but in grand staircases only one revolution can be admitted, the length and breadth of the space on the plan being always proportioned to the height of the building, so as to admit of fixed proportions.

In contriving a grand edifice, particular attention must be paid to the situation of the space occupied by the stairs, so as to give them the most easy command of the rooms.

With regard to the lighting of a grand staircase, a skylight, or rather lantern, is the most appropriate; for the light, thus admitted, is powerful, and the design admits of greater elegance; indeed, where the staircase does not adjoin the exterior walls, this is the only method by which light can be admitted.

In small buildings, the position of the staircase is indicated by the general distribution of the plan; but in larger edifices, this is not so obvious, but must at last be determined by considering maturely its connection with the other apartments.

STAIRS, (from the Saxon, *stæger*,) in a building, the steps whereby to ascend and descend from one story to another.

The breadth of the steps of stairs in general use in common dwelling-houses, is from 9 to 12 inches, or about 10 inches at the medium. In the best staircases of noblemen's houses, or public edifices, the breadth ought never to be less than 12 inches, nor more than 18. It is a general maxim, that the greater breadth of a step requires less height than one of less breadth: thus, a step of 12 inches in breadth will require a rise of $5\frac{1}{2}$ inches, which may be taken as a standard by which to regulate those of other dimensions; so that multiplying 12 inches by $5\frac{1}{2}$, we shall have 66; then supposing a step to be 10 inches in breadth, the height should be $\frac{66}{10}=6\frac{3}{5}$ inches, which is nearly, if not exactly, what common practice would allow. The proportions of steps being thus regulated, the next consideration is, the number requisite between two floors or stories, which will be ascertained by supposing the breadth of the steps given, say 10 inches each, as depending on the space allowed for the staircase, and this, according to the rule laid down, will require a rise of 7 inches nearly; suppose, then, the distance from floor to floor to be 13 feet 4 inches, or 160 inches: $\frac{160}{7}=22\frac{6}{7}$, which would be the number required; but as all the steps must be of equal heights, we should rather take 23 rises, provided the staircase-room would allow it, and so make the height of each somewhat less than 7 inches.

The most certain method of erecting a staircase is, to provide a rod of sufficient length to reach from one floor to the other, divided into as many equal parts as the intended number of rises; and try every step as it is set, to its exact height. The breadth of the staircase may be from 6 to 20 feet, according to the use or occupier of the building, or the form and proportions of the plan. If the steps be less than three feet in length, the staircase becomes inconvenient for the passing of furniture, as is frequently the case in small houses.

Though it is desirable to have such rules as are here laid down for regulating the proportions of the heights, breadths, and lengths of steps, architects and workmen cannot be so strictly tied to them, but that they may vary them as circumstances may demand.

Stairs, *Straight*, such as ascend in a straight line, and consist only of plane surfaces.

Stairs, *Winding*, those which turn round a solid newel, or circular well-hole; the latter either enclosed in a complete cylindric case, or semi-cylinder, at one end, adjoined to two parallel walls, which terminate upon an opposite wall.

In winding stairs the steps are formed narrower next to the well-hole than at the other end, where they adjoin the wall; these are termed *winders*.

Those steps which continue of the same breadth are termed *flyers*, in contradistinction to the winders.

A series, or number of flyers, connected together, is termed *a flight of steps*.

STALK, an ornament in the Corinthian capital, similar to the stalk of a plant, from which spring the volutes and helices; it is sometimes plain, and at others fluted.

STALL, (from the Saxon, *steal*, a shed,) a place, or division of a stable, for a single horse to stand and feed in. According to the number of these divisions, a stable is denominated a *one-stall*, *two-stall*, &c. *stable*.

Stall, a fixed seat, enclosed entirely or partially at back and sides, and frequently in an elevated position; to be seen at the sides of the choir, or chancel of parish and cathedral churches, in the latter of which, they are frequently covered with a lofty and rich canopy, with tabernacle-work, and richly carved on the sides and back, as also on the desk in front. They are appropriated to the officials and dignitaries of the church.

STANCHION, a term applied to any perpendicular support, such as the mullions of windows, &c.; also to the upright iron bar between the mullions, which is frequently terminated by a finial, or other ornamental top.

Stanchions, or Puncheons. *See* Studs.

STANDARDS, (from the Saxon, *standan*, to be on the feet,) the upright poles used by bricklayers in scaffolding.

Standards, in joinery, the upright pieces of a plate-rack, commonly placed above a dresser. When the edges of standards are cut into mouldings across the fibres of the wood, they are called *cut standards*.

Standards: the term is applied generally to upright supports, or upright pieces which are used to keep other pieces together; thus the upright ends of stalls or benches, into which the back and seat are fixed, are termed standards.

STAPLE, (Dutch,) a small bar of iron, pointed at each end, and bent so that the two ends may be parallel to each other, and of equal lengths; to be driven into wood, or into a wall, so as to form a loop for fastening a hasp, or bolt.

STARLINGS, in bridges and similar works, are the projections in front of the piers, usually pointed or rounded off at the ends, and employed to break the force of the current, and protect the piers from iniury.

STAVES, (from the Saxon, *stæf*, a staff) in joinery, the boards that are joined together laterally, in order to form a hollow cylinder, cylindroid, cone, or conoid, or any frustum of these bodies. The shafts of columns, in joinery, are frequently glued up in staves.

Staves are also small cylinders sometimes called *rounds*, for forming a rack to contain the hay in stables, out of which the horses eat.

STAY BAR, the horizontal iron bar placed across windows, to strengthen the mullions.

STEEL, (from the Saxon *stal*,) is made of the purest malleable iron by an operation called *cementation*, by which it acquires a small addition to its weight, amounting to about the hundred and fiftieth, or two hundredth part. In this state it is much more brittle and fusible than before. It may be welded like bar-iron, if it has not been fused or over cemented: but its most useful and advantageous property is, that of becoming extremely hard when heated and plunged into cold water; the hardness which it thus acquires is greater, as the steel is hotter and the water colder. The sign that should direct the mechanic in the tempering of steel, is the variation of colour which appears on its surface. If the steel be slowly heated, it exhibits a yellowish white, yellow, or gold colour, purple, violet, or deep blue. If the steel be too hard, it will not be proper for tools intended to have a fine edge, as it will be so brittle that the edge will soon become notched: and if too soft the edge will soon turn aside, even by very slight use. Some artists heat their tools, plunge them into cold water, and then brighten the surface of the steel upon a stone; the steel being then laid upon hot charcoal, or upon the surface of melted lead, or on a bar or piece of hot iron, it gradually acquires the desired colour, and must at that instant be plunged into water. If a hard temper be required, as soon as the yellow tinge appears, the piece is dipped again, and stirred about in the cold water.

In tempering tools for working upon metals, it will be proper to bring them to a purple tinge before the dipping. Springs are tempered by bringing the surface to a blue tinge. This temperature is also desirable for tools employed in cutting soft substances, such as cork, leather, and the like; but if the steel be plunged into water when its surface has acquired a deep blue, its hardness will scarcely exceed the temperature of iron. When soft steel is heated to any one of these colours, and then plunged into water, it does not acquire so great a degree of hardness as if previously made quite hard. The degree of heat required to harden steel varies in the different kinds. The best require only a low red heat; the harder the steel, the more coarse and granulated will its fracture be. Hardened steel has less specific gravity than the soft. The texture of steel is rendered more uniform by fusing it before it is made into bars, and in this state it is called *cast steel*, which is wrought with more difficulty than common steel, because it is more fusible, and will disperse under the hammer if heated to a white heat.

Every species of iron is convertible into steel by cementation; but the best steel can be made only from iron of the best quality, which possesses stiffness and hardness as well as malleability. Swedish iron has been long remarked as the best for this purpose.

The *cast steel* of England is made as follows: a crucible, about ten inches high, and seven in diameter, is filled with ends and fragments of the crude steel of the manufactories and the filings and fragments of steel works; they add a flux, the component parts of which are usually concealed. It is probable, however, that the success does not much depend upon the flux. This crucible is placed in a wind furnace, like that of the founders, but smaller, being intended to contain only one pot, and surmounted by a cover and chimney to increase the draught of air; the furnace is then entirely filled with coke, or charred pit-coal. Five hours are required for the perfect fusion of the steel. It is then poured into long, square, or octagonal moulds, each composed of two pieces of cast-iron fitted together. The ingots, when taken out of the mould, have the appearance of cast iron. It is then forged in the same manner as other steel, but with less heat and more precaution. Cast steel is almost twice as dear as other good steel; it is excellent for razors, knives, joiners' chisels, and all kinds of small work requiring an exquisite polish: its texture is more uniform than that of common steel, which is an invaluable advantage. It is daily more and more used in England, but it cannot be employed in works of great magnitude, on account of the facility with which it is degraded in the fire, and the difficulty of welding it.

STEEPLE, a spire or lantern; the pyramidal roof of a tower. By some the term is made to include both tower and spire, and by others is used indifferently for any lofty tower, with or without a spire.

STENCH TRAP, a valve to prevent the emission of effluvia from drains and sewers; they are of various forms.

STEPS, (from the Saxon, *stæp*,) the degrees of a staircase, by which we rise, consisting of two parts, one horizontal, called *treads*, the other vertical, called *risers*. When steps are placed round the circumference of a circle, or of an ellipsis, or any segments of them, they are called *winders:* but when the sides are straight, they are called *flyers*. The first or lower step, with a scroll wrought upon its end, according to the plan of the hand-rail, is called *the curtail step*.

STEREOBATA, or STEREOBATES, (from ςερεοβατης, *solid prop*,) in ancient architecture, the basis, or foundation, whereon a column, wall, or other piece of building, is raised. This answers pretty well to the continued socle, or basement of the moderns. Some confound it with the ancient *stylobata*, or *pedestal*; but, in effect, the stereobata is to the stylobata, what the stylobata is to the spire, or base of the column.

STEREOGRAPHIC PROJECTION OF THE SPHERE, that in which the eye is supposed to be placed in the surface of the sphere.

STEREOGRAPHY, (from ςερεος, *solid*, and γραφω, *to describe*,) that branch of solid geometry which demonstrates the properties, and shows the construction, of all solids which are regularly defined. It explains the methods for constructing the surfaces in plains, so as to form the entire body, or to cover the surface of a given solid; or, when a solid is bounded by plain surfaces, the inclination of the planes is determined by the rules of stereography. The sections of solids are also a branch of stereography; but this we shall refer to the article STEREOTOMY, with which it is more intimately connected.

Mr. Hamilton has denominated the principles of perspective by the name of *stereography;* but in this sense the term is too limited, as perspective is only a branch of the doctrine of solids, and extends only to the sections of pyramids and cones, and the representations of solids.

The eleventh and twelfth books of Euclid, which treat of the properties of solids, may be looked upon as the elements of this branch of geometry; and to them we shall refer our readers for the first elements to be acquired.

It is somewhat singular, that though the first principles of solids have long been demonstrated, no practical application to mechanical constructions has been made of them. The knowledge of solids is of the greatest importance in the constructive parts of architecture, as in masonry, bricklaying, carpentry, &c.

To be proficient in the art of construction, this branch of geometry is indispensable, and contains the very essence and foundation of the whole in abstract.

Definition 1.—*A solid* is that which has length, breadth, and thickness.

Definition 2.—The exterior surface of a solid is called its *superficies.*

Definition 3.—*A straight line* is perpendicular, or at right angles to a plane, when it makes right angles with every straight line meeting it in that plane.

Definition 4.—*A plane* is *perpendicular to a plane*, when the straight lines drawn in one of the planes, perpendicularly to the common section of the two planes, are perpendicular to the other plane.

Definition 5.—*The inclination of a straight line to a plane* is the acute angle contained by that straight line, and another drawn from the point in which the first line meets the plane, to the point in which a perpendicular to the plane drawn from any point of the first line above the plane meets the same plane.

Definition 6.—*The inclination of a plane to a plane* is the acute angle contained by two straight lines, drawn from any, the same point of their common section at right angles to it, one upon one plane, and the other upon the other plane.

Definition 7.—Two planes are said to have the *like inclination* to each other, which two other planes have, when the said angles of inclination are equal to one another.

Definition 8.—*Parallel planes* are such as do not meet each other, though produced.

Definition 9.—*A solid angle* is that which is made by the meeting of more than two plane angles, which are not in the same plane, in one point.

Definition 10.—*Similar solid figures* are such as have all their solid angles equal each to each, and contained by the same number of similar planes.

Definition 11.—*A prism* is a solid, of which the ends are similar and equal plane figures, and the sides parallelograms.

Definition 12.—When the ends of the prism are perpendicular to the sides, it is called *a right prism;* but if otherwise, it is termed *oblique.*

Definition 13.—A prism, whose sides and ends are equal squares, is called *a cube.*

Definition 14.—When the ends are parallelograms, the prism is called *a parallelopiped;* and when the planes of the parallelopiped are at right angles to each other, the prism is called *a rectangular prism.*

Definition 15.—When the ends of the prism are circles, it is called *a cylinder ;* but if the ends are ellipses, and alike situated, it is called *a cylindroid.*

Definition 16.—The straight line extended between the centres of the two bases is called *the axis.*

Definition 17.—A solid having any plane figure for its base, and its sides plain triangles terminating in the same point, is called *a pyramid.*

Definition 18.—A solid having a circle for its base, and terminating in a point, such that a straight line extended from any part of the circumference of the base to the terminating point may be in the surface of the solid, is called *a cone ;* and the surface which lies between the circumference of the base and the terminating point, is called *the conic surface.*

Definition 19.—If the plane of a circle be supposed perpendicular to a given plane, with its circumference or edge upon that plane ; and if there be a straight line standing on any other point perpendicular to the said plane; and if another straight line be made to move parallel to the plane on which the circle stands, so as always to touch the circumference and the straight line, beginning at any given point, and proceeding entirely round until it arrives at the same point; then the solid bounded by the circle, and the surface passed over by the straight line contained between the circumference of the circle and the straight line is called *a conoid;* and the surface generated by the straight line is called *a conoidal surface.*

Definition 20.—*A sphere* is a solid formed by the revolution of a semicircle upon its diameter.

Definition 21.—*The centre of a sphere* is the same with that of the semicircle.

Definition 22.—*The diameter of a sphere* is any straight line which passes through the centre, and is terminated both ways by the superficies of the sphere.

Definition 23.—*A cube* is a solid figure contained by six equal squares.

Definition 24.—*A tetrahedron* is a solid figure contained by four equal and equilateral triangles.

Definition 25.—*An octahedron* is a solid contained by eight equal and equilateral triangles.

Definition 26.—*A dodecahedron* is a solid contained by twelve equal pentagons, which are equilateral and equiangular.

Definition 27.—*An icosahedron* is a solid contained by twenty equal and equilateral triangles.

The solids defined in the last five definitions are called *the five regular solids.*

STEREOMETRY (from ϛερεομετρια, formed of ϛερεος, *solid,* and μετρον, *measure,*) that part of geometry which teaches to measure solid bodies, *i. e.*, to find the solidity, or solid content of bodies; as globes, cylinders, cubes, vessels, ships, &c. The methods see under the respective bodies; CYLINDER, GLOBE, SPHERE, &c.

STEREOTOMY, (from ϛερεος, *solid,* and τομη, *section,*) the science and art of cutting solids under certain specified conditions.

Stereotomy may be regarded as a branch of stereography, which is the science of solids in general. Mr. Hamilton has intitled his complete body of perspective, *Stereography,* which perhaps would have been more properly called *Stereotomy,* as the perspective representation of every object in nature is the section of a pyramid or cone of rays. But as it has not been the object of writers on perspective to show the rules for finding the sections of solids in general, under certain specified conditions of the cutting plane, nor of finding any other sections besides those of cones and pyramids, it is the express intention of this article to explain the general principles of the science for any given law, by which the surface of the solid may be constituted of straight lines, or that the surface may agree with the common section of two planes disposed in given positions. And as nothing of the kind has yet appeared, perhaps this attempt may be the more acceptable, particularly as in its principles the whole art of dialing is included, and the mechanical arts of masonry and carpentry. The art of stone-cutting, the squaring and cutting of timbers, and the formation of hand-rails, depend entirely upon the sections of solids.

Properties of Planes and Solids demonstrated in the eleventh book of Euclid's Elements, useful in Stereotomy.

Proposition I.—One part of a straight line cannot be in a plane, and another part above it.

Proposition II.—Two straight lines which cut each other are in one plane, and three straight lines which meet each other are in one plane.

Proposition III.—If two planes cut each other, their common section is a straight line.

Proposition IV.—If a straight line stand at right angles to each of two straight lines in the point of their intersection, it shall also be at right angles to the plane which passes through them.

Proposition V.—If three straight lines meet all in one point, and a straight line stands at right angles to each of them in that point, these three first straight lines are in one and the same plane.

Proposition VI.—If two straight lines be at right angles to the same plane, they shall be parallel to each other.

Proposition VII.—If two straight lines be parallel, the straight line drawn from any point in one to any point in the other, is in the same plane with the parallels.

Proposition VIII.—If two straight lines be parallel, and one of them at right angles to a plane, the other shall also be at right angles to the same plane.

Proposition IX.—Two straight lines which are each of them parallel to the same straight line, and not in the same plane with it, are parallel to each other.

Proposition X.—If two straight lines meeting each other be parallel to two others that also meet, but are not in the same plane with the first two, both couples will contain equal angles.

Proposition XI.—PROBLEM.—*To draw a straight line perpendicular to a plane, from a given point in space above the plane.*

Draw any straight line in the plane, and from the given point above the plane draw a second straight line at right angles to the first; from the point where the perpendicular meets the first line, draw a third straight line in the plane, at right angles to the first; and, lastly, from the given point in space draw a fourth line at right angles to the third; and the fourth straight line, thus drawn, will be perpendicular to the plane.

Proposition XII.—PROBLEM.—*To erect a straight line at right angles to a given plane from a given point in the plane.*

From any given point above the plane draw a straight line perpendicular to the plane, and through the given point in the plane draw a second line parallel to the first; which second line will be the perpendicular required.

Proposition XIII.—From the same point in a given plane there cannot be two straight lines at right angles to the plane upon the same side of it; and there can be but one perpendicular to a plane from a point above.

Proposition XIV.—Planes to which the same straight line is perpendicular, are parallel to each other.

Proposition XV.—If two straight lines, meeting each other, be parallel to two other straight lines, which also meet but are not in the same plane with the first two; the plane which passes through the latter is parallel to the plane which passes through the former two lines.

Proposition XVI.—If two parallel planes be cut by another plane, their common sections with it are parallels.

Proposition XVII.—If two straight lines be cut by parallel planes, they will be cut in the same ratio.

Proposition XVIII.—If a straight line be at right angles to a plane, every plane which passes through it will be at right angles to that plane.

Proposition XIX.—If two planes cutting each other be each of them perpendicular to a third plane, their common section will also be perpendicular to it.

Proposition XX.—If a solid angle be contained by three plane angles, any two of them are greater than the third.

Proposition XXI.—Every solid angle is contained by plane angles, which together are less than four right angles.

Proposition XXII.—If every two of three plane angles be greater than the third, and if the straight lines which contain them be all equal, a triangle may be made of the straight lines that join the extremities of those equal straight lines.

Properties of Solids.

In a prism, all parallel sections which cut the sides, are similar and equal figures; or, all parallel sections which would cut the plane of the base, if produced, are similar and equal figures.

In a pyramid, all the parallel sections which are not parallel to the plane of the base, are unequal similar figures.

The properties of a cone are numerous and interesting. If cut parallel to the plane of the base, the section is *a circle;* if in any direction through the apex, the section is *a plane right-lined triangle;* if the cone be cut by a plane inclined to the plane of the base, at any given angle, the section is *an ellipsis;* if cut by a plane parallel to any straight line within the solid passing through the apex, the section is denominated *an hyperbola;* and if cut by a plane parallel to another plane which touches the curved surface, the section, formed by this position of the cutting plane, is called *a parabola.*

For the purposes of stereotomy, we shall suppose the cone a right one; and consequently the abscissa of the curves, or sections, will bisect all the double ordinates at right angles.

Definition 1.—If any semi-conic section be supposed to revolve upon its abscissa, so as to perform an entire revolution, the surface generated by the curve-line is called *a conoid,* and the abscissa *the axis.*

Definition 2.—If the semi-conic section be a semi-ellipsis, the solid generated is called *an ellipsoid.*

Definition 3.—If the generating figure be a semi-parabola, the solid is called *a paraboloid.*

Definition 4.—If the generating figure be a semi-hyperbola, the solid is called *an hyberboloid.*

Definition 5.—All solids whatever, generated by revolving plane figures upon an axis, are called *solids of revolution.*

Definition 6.—All parallel sections of conoids are *similar figures.*

General Principles of Construction.

Definition.—Solid angles, which consist of three plane angles, are called *trihedrals.*

In the construction of trihedrals, besides the three plane angles which form the boundaries of the solid, there are the three inclinations. These inclinations are, by way of distinction, called *the angles;* the three boundaries are called *the sides;* and the sides and angles are indifferently called *parts;* any three of which, excepting the three angles, may be found by the following constructions:

Problem I.—*In a right-angled trihedral are given the two sides containing the right angle; to find the acute angles, and the side or hypothenuse which subtends the right angle.*

Figure 1.—Make the angle E B H equal to one of the given sides, and the angle E B F equal to the other; draw E H perpendicular to E B, and E I perpendicular to B F, cutting B F at F; from B, with the radius B H, describe an arc, cutting E I at I, and join B I; then B I is the hypothenuse: from E, with the radius E F, describe an arc, cutting E B in G, and join G H; then E G H is the angle contained by the hypothenuse and the side E B F, or the angle opposite the side E B H: or, make F I equal to G H, and join B I.

In the same manner the angle opposite the side of E B F may be found.

The reason will appear thus: raise the plane of the triangle B E F upon B E, so as to be perpendicular to the plane B E H; raise the triangle E G H upon E H, until E G fall upon E F; then the plane E G H will become perpendicular to B F; revolve the plane B I F upon B F, and F I will describe a circle, whose plane is also perpendicular to B F, from the point F; therefore, the plane of the circle and the plane E G H will be both in the same plane: therefore, since the point F coincides with G, the straight line F I may be made to coincide with G H; let this coincidence take place; and because F I is equal to G H, and the point G falls upon F, the point I will fall upon H; therefore, the straight line B I will fall upon B H; and the angle F B I, joining F B and B H, is the hypothenuse.

Again, it is evident from the planes thus raised, that the angle, E G H, contained by the planes F B E and F B I, and perpendicular to F B, their common intersection, is the measure of the angle contained by the planes F B E and F B I.

Problem II.—*Given one of the sides containing the right angle and the angle opposite; to find the remaining side which contains the right angle.*

Figure 2.—Let the given side be H B E: in B E take any point, F, and make E F H equal to the angle required; draw H E perpendicular to E B; from E, with the radius E F, describe an arc, F G; draw B G a tangent at G; and E B G is the side required. The demonstration is evident from the last.

Problem III.—*Given one of the sides containing the right angle and the inclination or angle adjacent; to find the remaining side which contains the right angle.*

Figure 2.—Make A B D equal to the given side; in A B take any point, E; draw E G perpendicular to B D, cutting it in G, and E H perpendicular to A B; make E F equal to E G, and E F H equal to the given angle; draw B H C, and A B C will be the measure of the plane angle opposite.

The following propositions show the construction of all the cases of trihedrals or spherical triangles, which are represented by right-lined angles. In each of the cases it will be found, that two of the sides of the spherical triangle are represented by the tangents of the arcs drawn from the same angle; and the angle included by these tangents is the measure of the spherical angle. The representation of the third side is a line joining the extremities of the tangents; the other two angles are measured by this proposition. If each of the three plane angles be denominated *a side,* and each of the three inclinations *an angle,* the geometrical construction will be the same as that of a spherical triangle, and the manner of expressing the data of the one is the same as expressing those of the other. The sides are always measured by the three plane angles of the solid angle.

Problem IV.—*Given two sides and the contained angle; to find the other parts.*

Figure 3.—Make the angle A B C equal to the contained angle; draw B D perpendicular to A B, and B E to B C; make B D and B E equal to each other, the angle B D A equal to one of the containing sides, and B E C equal to the other;

upon C, as a centre, with the distance C E, describe an arc, F; and upon A, as a centre, with the distance A B, describe another arc, cutting the former at F; join F A and F C; then the angle A F C will be the measure of the third side. Now if the triangle A B D be turned round the line A B, the triangle C B E round C B, and the triangle A C F round A C, until the points D, E, F, coincide, each of the two planes, A B D and C B E, will be perpendicular to the plane A B C; therefore, two of the sides of a solid angle will be given, one perpendicular to the other, to find the inclination of the vertical plane with that of the hypothenusal. Proceed, therefore, as in the last problem, and find the angle G H K, which will be the inclination of the two planes C B E and C A F. In the same manner may the inclination of the planes A B D and A C F be found.

Note.—The triangle A B C represents the spherical triangle, of which A B and B C are the tangents of two arcs; and the angle A B C is the spherical angle contained by the arcs, of which A B and B C are tangents.

PROBLEM V.—*The three sides of a spherical triangle being given; to find the angles.*

Figure 4. No 1 and 2.—Make the three angles, A B C, C B E, and E B F, equal to the three sides of the spherical triangle, that is, to contain the same number of degrees. On B, as a centre, with any radius, A B, describe an arc, A F; draw A C and F E tangents at A and F; join C E; draw the straight line G H equal to C E; on the centre G, with the tangent A C, describe an arc at I; and on the centre H, with the tangent F E, describe another arc, cutting the former at I. Join G I and H I; draw I K and I L perpendicular to I G and I H, making them equal to A B or B F; join K G and L H. Now if the triangles, G I K and H I L, be raised on the lines G I and H I, until the points K and L coincide; then each of the triangles, G I K and H I L, will be perpendicular to the triangle G I H. Proceed, therefore, as in the first Proposition, to find the angles, which, in the representation of the spherical triangle I G H, are represented by G and H.

Scholium.—Since each of the extreme angles may be made the middle angle in No. 1, the triangle G H I, No. 2, may be laid down in three different figures, each of which will have as many angles included by each pair of tangents. These three angles, made in each separate triangle, are the measures of the three spherical triangles; but this mode requires more lines than what are described in the above Proposition.

There is another method of finding the angles of a spherical triangle, when the three sides are given, pointed out by Bishop Horsley, at page 215 of his *Elementary Treatises.* The substance of it is as follows: Draw a right angle; make one of the legs equal to the difference of the cosines of the sides containing the required angle; the hypothenuse being equal to the chord of the third side. Upon the remaining perpendicular side, as a base, construct a triangle, whose two other sides are equal to the sines of the sides containing the required angle; then the angle contained by the sines will be the measure of the spherical angle. This may be very easily accomplished by means of a scale of sines and chords from Gunter's scale.

PROBLEM VI.—*Two angles and a side opposite to one of them, being given; to find the other two sides and the remaining angle.*

Figure 5.—Make the angle A B C equal to the spherical angle next to the given side; draw B D and B E perpendicular to B A and B C; make B D of any length, and B E equal to it; and make the angle B D A equal to the measure of the given side; draw A F perpendicular to B C, cutting it in F; make the angle F A G equal to the complement of the other given angle; on the centre F, with the distance F G, describe an arc, G H I; draw C H E a tangent to the arc at H, the same as in the second Proposition; join A C; and the angle C E B will be the measure of the included side. On the centre C, with the distance C E, describe an arc at K; and on the centre A, with the distance A D, describe another arc, cutting the former at K; join A K and K C; then will A K C be the measure of the third side of the spherical triangle.

PROBLEM VII.—*Given two angles, and the contained side; to find the other three parts.*

Make A B C, *Figure* 3, one of the given angles; draw B E perpendicular to B C; make D E C equal to the number of degrees contained in the given side; in B C take any point, G; draw G I perpendicular to C E, cutting it at I, and G K perpendicular on the other side of it; make G H equal to G I, and the angle G H K equal to the other given angle; draw C K A, as in Proposition III., and A B C will be a plane triangle representing the spherical one.

Now, because A B C is the angle included by the tangents, draw B D perpendicular to B A, and equal to B E, and join D A; then B D A is the measure of the side, of which A B is the tangent. On the centre A, with the distance A D, describe an arc at F; and on the centre C, with the distance C E, describe another arc, cutting the former at F. Join F A and F C; then A F C will be the measure of the third side.

PROBLEM VIII.—*Two sides, and an angle opposite to one of them, being given; to find the three remaining parts.*

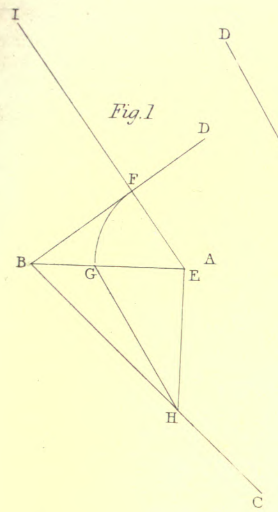
Figure 6.—Draw A C, representing the side adjoining the given angle, and A B perpendicular to it; make the angle A B C equal to the given side; in A C take any point, E; draw E D perpendicular to B C, cutting it in D, and E G perpendicular to A C; make E F equal to E D; and the angle E F G equal to the given angle; draw the line C G H; on A, as a centre, with the tangent of the other given side, describe an arc, K H; and if it cut the straight line C H in two points, H and K, join A K and A H; draw A I perpendicular to A H, and equal to A B; join I H; on the centre H, with the distance H I, describe an arc at M; and on the centre C, with the distance C B, describe another arc, cutting the former at M; join H M, K M, C M; then the angle C A K, or C A H, will be the measure of the spherical angle included by the tangents. The measure of the angle A H C, or A K C, representing the spherical angle opposite the given side, shown by the tangent A C, is found by Proposition I. The angle C M H, or C M K, is the measure of the remaining side, viz., that opposite the angle included by the tangents.

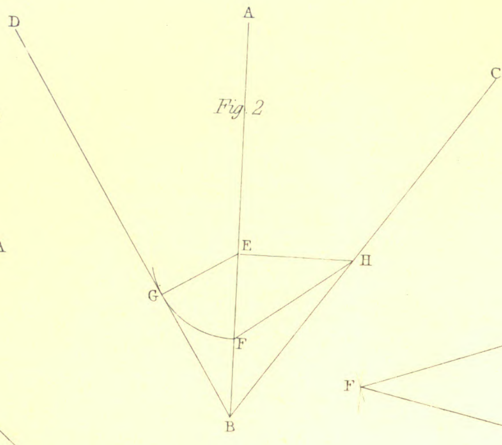
Note.—This case is not always ambiguous; for if A H be equal to, or greater than A C, the arc K H will only cut H C in one point; and, therefore, there can only be one triangle; or, if the angle A H C be a right angle, A H will only touch H C: and in this case also there can be only one.

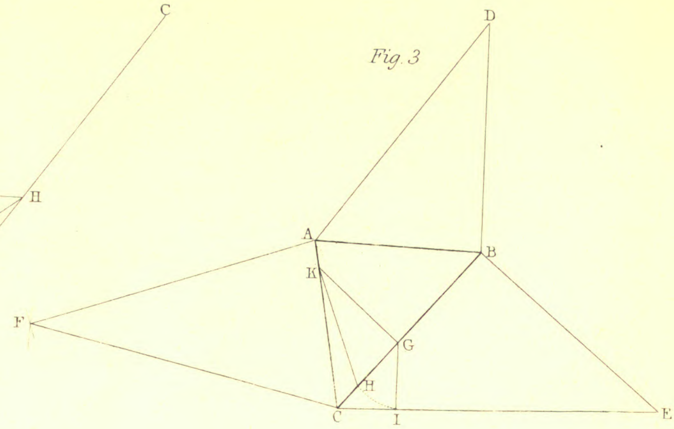
PROBLEM IX.—*The three angles of a spherical triangle being given; to find the three sides.*

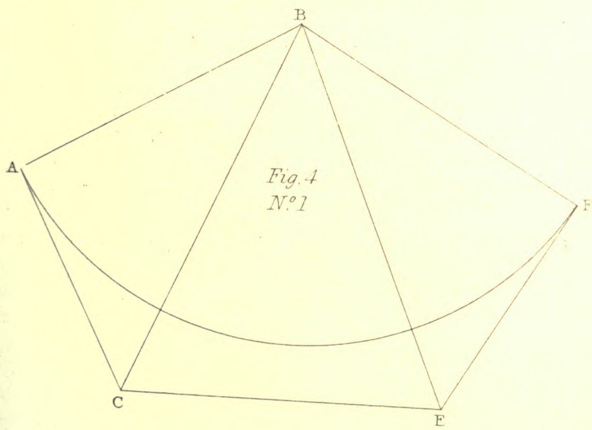
Take the supplements of each of the angles, and describe a triangle, by Proposition V., whose sides are equal to such supplements; and the measure of its angles will be the supplements of the sides of the triangle sought. This is demonstrated by writers on spherical trigonometry.

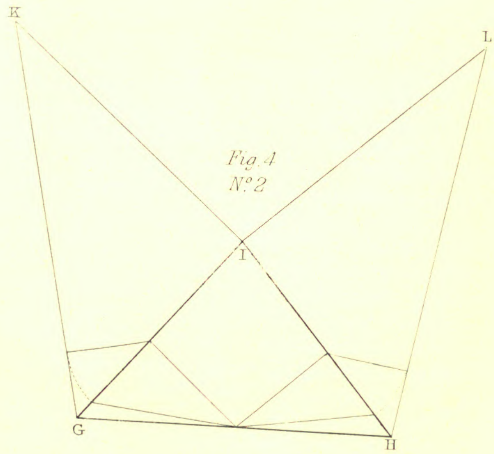
Though the author of this Dictionary has not given formal demonstrations of the preceding Propositions relating to the geometrical construction of spherical triangles, as it would have swelled the article too far, he hopes that enough has been said to enable any one, who has a clear conception of the parts of a spherical triangle, to describe the representation of it, and to find the measure of its parts in the most easy manner, without having recourse to the projection of the sphere, which frequently runs into conic sections, and, from their difficulty of description, renders the projection

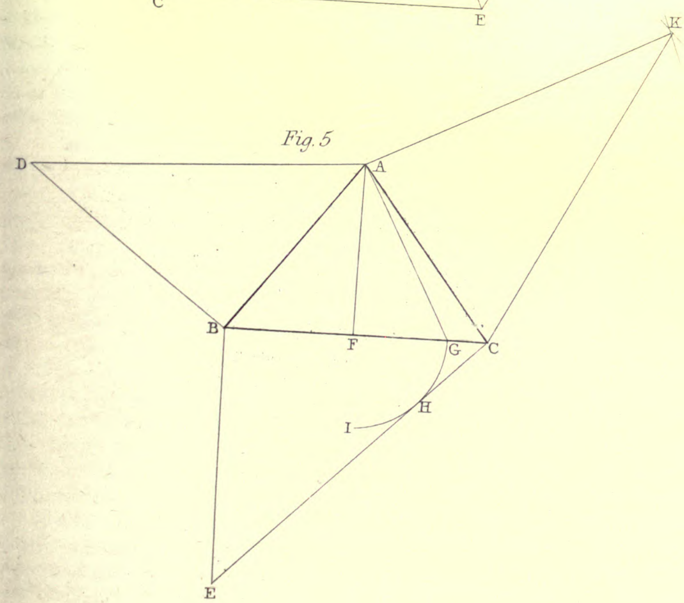


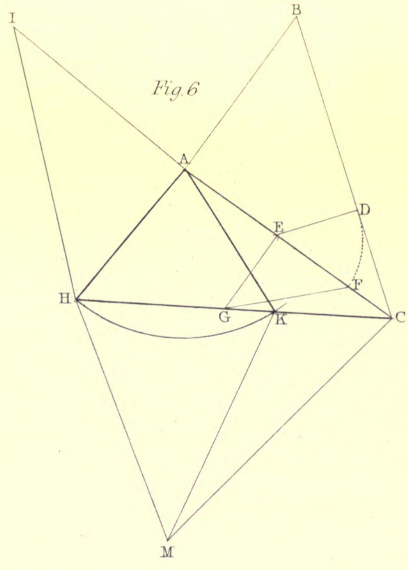












awn by P. Nicholson.

very inaccurate. The representation of the spherical triangle belonging to the preceding Propositions, is nothing else than a plane triangle, which is a tangent to the sphere at one of the spherical angles, and whose sides are bounded by the intersections of the planes of the three great circles of the sides of the spherical triangle; consequently, two of the sides of the representative triangle are always two tangents from the same spherical angle. The included angle by these tangents in the representative triangle is the measure of the spherical angle contained by the sides which the tangents represent. And the third side in the representative triangle is a line joining the extremities of the tangents, as has been already mentioned. In another point of view, the whole may be conceived to be a pyramid, whose sides are planes from the centre of the sphere, passing through the three arcs of the spherical triangle; and its base a triangle, a tangent to the sphere at one of the angles, which meets the sides. The vertical angles of the sides of this pyramid are the measures of the sides of the spherical triangle: the angles of the pyramid are the measures of the spherical angles: and the base of the pyramid is the representative triangle. Consequently, one of the angles of the pryamid is always perpendicular to the base. The angle intercepted by the two planes upon the base is equal to the inclination of the planes.

The triangle belonging to the preceding Propositions is such, that when all the parts are completed, the sides may be turned up upon the base, which is the representative triangle, until the edges of all the triangles forming the sides are united in one common vertex. A pyramid will then be formed, equal, similar, and situated like that above.

The Rev. George Walker, in his ingenious doctrine of the sphere, Proposition I. p. 258, shows, that "if there be a spherical triangle, and a plane quadrilateral figure be formed, two of whose sides are the secants, the other two the tangents of two of the sides of the spherical triangle, and the angle comprehended by the secants be measured by the spherical base, the angle comprehended by the tangents shall be the measure of the spherical angle opposite the base; the diagonals of the quadrilateral shall intersect each other at right angles; the segments of the diagonal joining the angle of the secants, and the angle of the tangents shall be the secant and tangent of the spherical perpendicular, drawn from the vertical angle to the base; the angle which this diagonal makes with the secants, shall be measured by the spherical segments of the base; and the angles which this diagonal makes with the tangents, shall be the measures of the spherical angles which the perpendicular makes with the sides." This theorem is very analogous to Problem V.; but the properties shown by it do not apply to the construction from any given data, nor can all the parts be found from any one datum; they may be very well applied when two sides and the contained angle are given, or when the three sides are given, by varying the triangle, as has been here shown, in order to find the other two angles; but this is both troublesome and inelegant. From what has been said, it will be easy to construct any solid similar to any other solid given, whose sides are planes, by constructing each solid angle, that is, by dividing it into as many solid angles, each consisting of three plane angles, wanting two, as the number of plane angles bounding the whole solid angle; then constructing the figure of any side, of which a plane angle of the described solid angle is one similar to the side of the solid given. From the several angles of this figure construct other solid angles in the same manner.

Problem X.—*Given the seat,* A B, *of the intersection in space of two planes, having a given inclination, and the intersection,* A C, *of one of them in a given plane,* Y; *also the inclination of the common intersection of the two planes to the plane* Y; *to find the intersection of the other plane with* Y.

Figure 7.—Make B A D equal to the inclination of the intersection of the two planes; from any point, D, draw D E perpendicular to A D, cutting A B at E; make E B equal to E D; draw E C perpendicular to A B; make the angle C B F equal to the inclination of the planes, of which the seat of their intersection is A B; let B F meet E C in F; and join A F; then will A F be the intersection required.

Or thus: Through any point, E, in A B, draw C E perpendicular to A B; make E A D equal to the inclination of the intersection; draw E D perpendicular to A D; make E B equal to E D; join B C; make the angle C B F equal to the inclination of the planes, which have A B for the seat of their intersection; let B F meet C E in F; and join A F; then will A F be the intersection required.

Demonstration.—Imagine the triangle A D E to be turned upon A E, until it becomes perpendicular to the plane, Y; let the plane Z be turned upon C E, until E B fall upon E D; that E B will fall upon E D is evident, since E B, in revolving upon E C, will always be in a plane passing through E perpendicular to C E; and E D is also in a plane passing through E perpendicular to C E; and since E B is equal to E D, E B must fall upon E D, and the point B upon D; and the plane A E D will be perpendicular to the two planes C E A and C E B; therefore A D will be perpendicular to the plane C E B; whence it is manifest, that C B F is in a plane perpendicular to the common intersection, and is the measure of the inclination of the planes.

Problem XI.—*Given,* I N, *the intersection of a plane,* W, *with another plane,* X, *and their inclination, the seat,* A B, *in the plane,* X, *of a line in space insisting at* A, *and the inclination of the line to the plane* X; *to find the section of the line in the plane* W.

Figure 8.—Through any point, B, in A B, draw B S perpendicular to I N, cutting I N at E; make the angle B E F equal to the inclination of the plane; draw B G perpendicular to B S; make B G the tangent of inclination to the radius A B; draw G F parallel to B S; through A, draw any two lines, A J and A K, cutting I N at J and K; make E S equal to E F; through S, draw V L parallel to I N; produce B S to P; make S P equal to F G; draw P V parallel to A K, and P L parallel to A J; and join K V and J L, cutting each other at *a;* and *a* will be the section of the line in the plane W, as required.

For, imagine the triangles B E C and C G F in the same plane to be turned upon B E, so that their plane may be perpendicular to the plane X; then B G will be perpendicular to the plane X, and the point G will fall in the line in space: imagine also the plane W to be revolved upon I N, until E S falls upon E F, as is evident for the same reasons as given in the first Problem, and the point S will fall upon F; then the line V L will become parallel to the plane. In revolving the plane W upon I N, imagine the plane Y to revolve upon V L at the same time, so that the plane Y may always continue parallel to the plane X, then V P will continue parallel to A K, and L P parallel to A J; then, as in perspective, X is the original plane, W the plane of the picture, Y the vanishing-plane, G or P the place of the eye coinciding therewith, I N the intersecting line, V L the vanishing-line, J, K, the intersecting points, V L the vanishing-point, and the original line would be a visual ray; therefore, by the theory of perspective, *a* is the representation of the point A.

Problem XII.—*The same things being given, and the constructive lines remaining as in the preceding Problem, as also the point a, the section of the line in space; to find* *the seat of the line in the plane* W, *and its inclination to the said plane.*

Figure 9.—Draw G Q perpendicular to E F, meeting E F in Q; in E P, make E T equal to E Q, and join T *a;* draw T R perpendicular to *a* T; make T R equal to Q G, and join R *a;* then will T *a* be the seat of the line in the plane W, and T *a* R its inclination to the said plane.

Demonstration.—For when E S is made to coincide with E F, as in the last Problem, the plane F C G will be perpendicular to the plane of the section W; but the line F C being now in the plane W, and Q G being perpendicular to F C, Q G will also be perpendicular to the plane W; but the point G, that is R, is a point in the line, whose seat is A B, and the point *a* is another point in the line, whose seat is A B; therefore, R and *a* are two points in the line, whose seat is A B; then join *a* R, which will be the part of the line in space on the other side of the plane W, and *a* T its seat.

Scholium.—This amounts to the same as when the seat and distance of the eye are given with respect to the original plane, and the position of a point in the said plane; to determine the seat and inclination of the visual ray.

PROBLEM XIII.—*Two straight lines,* A B *and* C D, *tending to an inaccessible point, being given; through a given point,* E, *to draw a third straight line, to tend to the same inaccessible point.*

Figure 10.—From any point, A, in A B, draw a straight line, A E, from A to the given point E, cutting C D in C; and through any other convenient point, B, draw B F parallel to A E, cutting C D in D; find D F, a fourth proportional to A C, C E, B D, and join E F; then will the lines A B, C D, and E F, tend to the same point of concourse.

Scholium.—It sometimes happens, that a number of lines radiate from the same point, and that from a given point it is required to radiate other straight lines so as to meet the radiations given in a given straight line: some, or many, of these radiations, according to their number, will be inaccessible; and though they may be all found by this Problem, yet if the several operations are combined in one, much trouble will be saved.

Figure 11.—Thus, let the radiations be A B, A C, A D, A E, A F, tending to the straight line B C; and let *a* be a given point, from which it is required to radiate other straight lines to meet or tend to the same points in B C, with those drawn from A. Join A *a*, cutting B C in G; and through any convenient point, C, in B C, draw F *f* parallel to A *a;* make C P equal to G A, and C Q in B C, produced to *o*, equal to G *a;* join P Q; let A D, A E, meet C F in D and E; draw D *m*, E *n*, F *o*, parallel to P Q, cutting R *o* at *m*, *n*, *o;* make C *d* equal to C *m*, C *e* equal to C *n*, C *f* equal to C *o;* draw *d a*, *e a*, *f a*, which are the lines required.

Example 1.—*Given the meridian,* A B, *in the plane of the horizon,* X, *the latitude of the place, the intersection,* I N, *of the plane,* W, *with the horizontal plane,* X, *and the inclination of the plane,* W, *to that of the horizon* X; *to construct a dial in the plane* W.

Figure 12.—In A B, take any point, A, for the foot of the style; then A B will be the seat of the style, or of the line tending to the pole; the latitude of the place is its inclination. Find *a*, the representation of A, that is, the section of the style of the dial in the plane W, by the eleventh Problem; produce A B to meet I N in D; draw D *a* in the dial plane W; then, by the twelfth Problem, find *a* T, the seat of the style in the plane W, and the angle of elevation T *a* R: and by the tenth Problem, find the intersections, U *a*, Y *a*, Z *a*, &c., of planes passing through the style, making angles respectively of 15°, 30°, 45°, 60°, &c., with the vertical plane passing through the meridian, A B; that is, with the plane whose intersection is T *a:* the inaccessible lines are also found by the last Problem; and the dial is constructed as required: *a* T is the seat of the style, whose intersection is T *a;* T *a* R its inclination; *a* D is the 12 o'clock line; and U *a*, Y *a*, Z *a*, &c., are the hour-lines.

Another method of finding the sub-style is thus: produce G Q to meet P E in H; join H A, which produce to N; and draw N *a*, the sub-styler line. Thus, upon one common principle, the sections of lines, planes, and solids, may be found. The sections of solids are found by means of the sections of planes; and the construction of a dial is only finding the sections of planes, whose positions are given. This method is, perhaps, of all others the easiest to consider and to construct.

Example II.—*Given the base,* A N Q R, *of a pyramid, in the plane* X, *and the whole seat,* A B, *of one of its angular lines, the intersection,* I N, *of the cutting plane* W, *and the inclination of the planes* W *and* X; *to find the section of the pyramid.*

Figure 13.—Find the vanishing line, V L, of the plane X, and the vanishing points, V and L, of the lines A R, N Q, A N, R Q; produce A R to K, N Q to M, A N to J, and R Q to L, to meet the intersecting-line I N; join K V and M V, also J L and L L; then *a n q r* will be the section of the pyramid insisting upon A N Q R.

Example III.—*To find the section of a prism, the same things as before being given.*

Figure 14.—Find the vanishing-points, V and L, of the lines A J and A K, and the representations, K V and J L, as before; draw L *r* parallel to J L, and M *n* parallel to K V; and *q n a r* will be the section of the prism required.

Plate 3. *Figure* I.—*To find the section of a right pyramid.* Suppose a trahedral, or solid angle, consisting of three plane angles, two of which are at right angles to each other; let the base of the solid be disposed in one of the planes which form the right angle, and let the cutting plane be the plane angle which subtends the right angle; let *x*, or G P F be the plane angle on which the base of the solid is to be placed; Y, or *g* P G, the other plane angle, standing perpendicular to the plane X; and *g* P *f*, or Z, the hypothenusal plane angle; the three angles being developed, or unfolded upon one plane. Here P F will be the intersection of the cutting plane with the plane of the base. In the plane X, let A B C D be the base of the pyramid parallel to the intersection, E P; find the centre, E; produce A D from each extremity, to meet P F in F, and P G in P; through E draw H parallel to A D, or B C, meeting P F at H, and P G at I; produce B C both ways, to meet P F at K, and P G at L; draw E N parallel to A D, meeting P G at N; produce A B to meet P G at M, and D C to meet P G at O; draw I Q and N R, each perpendicular to P G, and in length equal to the height of the pyramid; join G Q at L Q; also O R and M R; let P *g* be cut by G Q in *g*, I Q in *i*, L Q in *l*, O R in *o*, N R in *n*, and M R in *m*; transfer P F, P H and P K, to P *f*, P *h*, and P *k;* join *f g h k l;* parallel to P *f*, draw *m a* and *o d*, cutting *f g* at *a* and and *k l* at *b* and *c;* then the quadrilateral *a b c d* will be the section required.

Figure 2.—*To find the section when the base of the pyramid is oblique.*

Let A B C D be the base; find the points *g*, *i*, *l*, and F, H, as before; produce A B and D C to meet O F at M and N; transfer O F, O H, O K, O M, and O N, to O *f*, O *h*, O *k*, O *m*, O *n*, draw the diagonal B D, and produce it till it meet O F in T; transfer O T to O *t*, and produce O G and B D to meet each other; from the point of section draw a line, in the plane Y, perpendicular to O G, cutting O *g* produced; join *t* with the point of section; also join *g f*, *i h*, and *l k*, and let *g f* and *l k* cut

line drawn from t to the point of section in o g produced; join $b\ m$ and $d\ n$; produce $m\ b$ to meet $f\ g$ at a, and let $d\ n$ meet $l\ k$ at c; then will $a\ b\ c\ d$ be the section required.

Figure 3.—*To find the section of a right cone.*

Let the circle A B C D E F G H be the base. Find the centre of the circle, and draw through it G V, parallel to I O, cutting O P at V, and the circumference at G and C; through the same point draw R L, perpendicular to I O, cutting I O at L, O P at R, and the circumference at A and E; divide the quadrants A C, C E, F G, G A, into any number of equal parts, as two, through the points of division draw lines parallel to G V and R L; one on each side of, and parallel to A E, cutting O P in Q and S; and the other parallel to G C on each side of it, cutting O P in U and W; draw R Y at Z, each equal to the height of the cone; draw P Y, Q Y, S Y, T Y, cutting O p in p, q, r, s, t respectively; also draw T Z, U Z, X Z, W Z, cutting O p in x, w, u, t; make O i, O k, O l, O m, O n, respectively equal to O I, O K, O L, O M, O N; join $p\ i$, $q\ k$, $r\ l$, $s\ m$, and $n\ t$; draw $x\ a$, $w\ h$, $v\ g$, $u\ f$, $t\ c$, parallel to O i, cutting $r\ l$ at a and e; $k\ q$ at f and h, and $m\ s$ at b and d; then $a\ b\ c\ d\ e\ f\ g\ h$ will be the section required.

Figure 4, shows how the section of an oblique cone is found; the method is the same as for a right cone: except that the intersection, B C, must be placed parallel to the inclination; by which means the axis, G I, has the same inclination to B C, which the axis has to the plane of the base.

Plate 4, is exceedingly useful in finding the bevels of the stones of oblique cylindric arches, where the joints of the stones run in planes perpendicular to the axis of the cylinder.

We shall here begin with the most simple case, which is *figure* 2. Let A B represent the axis of the cylinder, and let B C represent the plane of the arch; draw A D perpendicular to A B, and make the angle, D A E, equal to the inclination of the bed of a stone with the horizon; from the centre, A, with any radius, A E, describe the arc E D. Draw E C and D F parallel to A B, and C F parallel to A D; join E F; then if A B be the under-side of the joint or bed in the intrados of the arch, the angle, A B F, will be the angle which the under-side of the joint makes with the face of the arch.

Figure 4.—Exhibits the bevels for a complete arch, consisting of seven joints.

Figure 1.—Shows the method of finding the joints when the plane of the sides of the arch are not perpendicular to the horizon. Let A B represent the axis of the cylinder as before, B C the insisting-line of the side of the arch: produce I C to F; draw F G perpendicular to F C; make the angle, I F I, equal to the inclination of the end of the arch, and the plane of the horizon.

Figure 3.—Shows the joints for a complete arch.

Plate 5. *Figure* 1.—Exhibits the method of finding the section of a cone upon the general principles, as explained in *Plate* 2 of this article.

Figure 2.—The lines for the section of a cylinder.

Figure 3.—The lines for the section of a cuneoid.

Figure 4.—Another method for finding the section of a cone, which is plain to inspection, the principles being nearly the same as before.

Figure 5.—Section of a right cone.

Figure 6.—Section of an oblique cylinder.

Figure 7.—Section of a right cylinder.

Figure 8.—Method of the intersection of a plane from three given points, and the heights upon these points.

Figure 9.—Method of finding the section of the segment of a cylinder.

The principles and methods for these having been previously explained, it is presumed that, by barely inspecting the figures, the methods of tracing them will be sufficiently obvious without having recourse to the references of the letters.

Figures 4, 5, and 6.—Method of finding the section of a right prism when the plane of the section is oblique to one of the sides of the prism, according to three given heights. *See* CYLINDER.

STERLINGS, *see* STILTS.

STILES, (from the Saxon, *stigele*,) in joinery, the vertical parts of a frame, into which the ends of the rails are fixed by mortises and tenons.

STILTED ARCH, an arch whose springing-line is above the impost, or which is raised, as it were, upon upright stilts or props.

STILTS, (from the Saxon *stælean*, supporters,) a set of piles driven into the ground-plot for the intended pier of a bridge; the tops of which being sawn to the low-water mark, the pier is raised upon them; a method formerly used, when the bottom of a river could not be laid dry. The stilts were surrounded, at a few feet distance, by a row of piles, with planks laid close to them, after the manner of a coffer-dam; this was called a *sterling*, or *jettee*; after which, loose stones, &c., were thrown into the space till it was filled up to the top; so as to form a kind of pier of rubble, or loose-work, which was kept together by the sides of the sterlings: the piling was then paved level at the top, and the arches were turned upon it. Most of the large old bridges in England were erected upon this method; but the inconveniences attending it are so great, that it is now quite exploded; for, on account of the loose composition of the piers, they must be made very large and broad, otherwise the arch would push them over, and fall down as soon as the centre was drawn. This great breadth of the piers and sterlings necessarily contracts the water-way so much, as not only to incommode the navigation through the arch, from the fall and quick motion of the water, but it also causes the bridge itself to be in danger, particularly in time of floods; besides this, there is great danger of the pier bursting out the sterlings, which are also subject to decay and damage, from the velocity of the water, and the passing of craft through the arches.

STOCK, (from the Saxon *stoc*,) a boring instrument, consisting of a double crank, so that one end may rest against the workman's breast, and the other upon the wood intended to be bored. It is provided with several steel cutters, called *bits*, of different dimensions, according to the holes to be made. It is, therefore, in London, called *stock and bits*, but in most country places, *brace and bits*.

STONE, (from the Saxon *ston*,) a hard mineral substance, not soluble in water, employed in the construction of edifices; of these there are various kinds, as described more largely under the article MATERIAL.

STONE ARCH, an arch constructed of stone: the general principles of the construction of which will be found under the article MASONRY.

STONE BRIDGE. In a former article, (BRIDGE) a general historical view has been taken, of the rise, progress, and present state, of bridge-building, exemplified in descriptions of the most celebrated edifices of the kind, in various parts of the world. Under the present head, the theory of the art will be principally considered; and we shall avail ourselves of the permission granted to us by the late Thomas Telford, Esq., to make considerable extracts from the able article on this subject, written by him for the Edinburgh Encyclopedia.

"The construction of a magnificent stone bridge, is justly looked upon as one of the greatest performances of the masonic art: for if we compare the enormous weight of a great arch, with the strength which the cohesion of the firmest cement can give, we readily admit, that it is only by the nicest adjustment and balancing of its parts, that they are hindered from instantly falling to pieces.

"Though there can be little doubt that the Romans, and latter Greeks, had paid some attention to this subject, from the beautiful specimens of their architecture which exist even in our times; yet, in none of their authors, either practical or scientific, is the smallest light afforded us respecting the principles upon which their practice was regulated.

"The architects of the middle ages, who constructed those great cathedrals, that are still the ornament of the chief cities in Europe, and the delight of the architectural antiquary, seem to have fondly indulged in the balancing of arches. They were, without doubt, directed by maxims which had been elicited from a varied and extensive practice; but whatever these were, they are to us unknown. None of these architects, though many of them were men of learning, seem ever to have committed to writing, either the history of any such erection, or the principles by which its construction was regulated. Nay, this knowledge seems rather to have been carefully kept secret, and regarded as a sort of mystery; a craft which was only to be communicated to the *brethren*, whose experience and skill had already qualified them to be initiated into the mysteries of the sublime degree.

"It does not appear that a knowledge of this subject could be acquired otherwise than by experience. The mathematical sciences were then little known, and we may see from the construction of the bridges of that age, that the priests, who were the only architects, have had in their eye, rather, the successive vaulting of a Gothic cathedral, than to have originally considered of the best way of forming a permanent and convenient road. It was only about a century ago, when Newton had opened the path of true mechanical science, that the construction of arches attracted the attention of mathematicians. Since that time, volumes have been written respecting the equilibrium of arches. It has been found one of the most delicate, as it is one of the most important, applications of mathematical science. Yet with all due deference to the eminent men who have prosecuted this subject, we are much inclined to doubt whether the greater part of their speculations have been of any value to the practical builder. He is still left to be guided by a set of maxims derived from long experience, and, as yet, little improved by theory. In truth, his works seldom fail, even where they differ furthest from the deductions of the theorist; and at all events, he finds that a much greater latitude is allowable than theory seems to warrant. He is therefore surely excusable in doubting of the justice of such theories, at least until they are more consonant to the approved practice.

"It is our intention, in the present article, to point out a new mode of considering this subject, to which, with great diffidence, we request the attention of the intelligent practitioner. It may indeed still be deficient, if not in some respects erroneous, but it will, we think, have this merit, that of being readily apprehended, and easily applied, without requiring much previous scientific information. Indeed, though we highly value the sublime geometry, we are inclined to think that the unnecessary parade of calculus in the application of science to the arts, has been one of the chief causes of the dislike which many able practical men of our country have shown to analytical investigation.

"Nevertheless, as many of our readers are well qualified to comprehend, and will naturally expect that we should point out, the modes of investigation usually pursued in this interesting subject, we shall previously, and in as succinct a manner as possible, endeavour to lay before them the commonly received theory of equilibration. From which, having cleared away the useless rubbish, if we can extract any proper materials, we may, like economical builders, make good use of them in our future structure.

"The first thing like a principle that we meet with is the assertion of the eminent Dr. Hook, that the figure into which a heavy chain, or rope, arranges itself, when suspended at the two extremities, being the curve commonly called the *catenaria*, is, when inverted, the proper form for an arch; the stones of which are all of equal size and weight.

"Now, as this idea, strictly just, has been very generally adopted, and affords some useful hints, it may be well worth while to examine it.

"*Figure* 1.—Let A B be a string or festoon of heavy bodies, hanging by the points A, B, and so connected, that they cannot separate although flexible. These bodies having arranged themselves in the *catenaria* A C B, conceive this to be turned exactly upside down. The bodies A and B being firmly fixed, then each body in the arch A D B, being acted on by gravity, and the push of its two neighbours, with forces exactly equal and opposite to the former, must still retain its relative position, and the whole will form an arch of equilibration.

"This arch, however, would support only itself; nay, a mere breath will derange it, and the whole will fall down. But if we suppose each spherule to be altered into a cubical form, occupying all the space between the dotted lines, the stability will be more considerable. And as the thrust from each spherule to its neighbour is in a direction parallel to the tangent of the arch at the point of junction, it is obvious, that the joints of our cubical pieces must be perpendicular to that, so as to prevent any possibility of sliding.

"Our arch is now composed of a series of truncated wedges, arranged in the curve of the *catenaria*, which passes through their centres; and we are disposed, with David Gregory, to infer, that when other arches are supported, it is only because in their thickness some *catenaria* is included.

"This curve is, indeed, the only one proper for an arch consisting of stones of equal weight, and touching in single points, but is not at all adapted to the arch of a bridge, which, independent of the varying loads that pass over it, must be filled up at the haunches, so as to form a convenient roadway. In this case, some further modification becomes necessary.

"*Figure* 2.—The haunch, E, of the arch A C B, bearing a much greater depth of stuff than the crown, it must be so contrived as to resist this additional pressure. Every variation of the line F G H, or extrados, will require a new modification of the curve A C B, or intrados, and the contrary. Accordingly, M. De la Hire has suggested a good popular mode of investigating this subject. Let it be required to determine the form of an arch of the span A B, and height C D, proper for carrying a road-way of the form F G H. Mark off upon a vertical wall, the points A, C′, B, inverting the required figure: suspend from A B an uniform chain or rope, so that its middle may hang a little below the point C′, and dividing the span, A B, into any number of equal parts, and drawing the perpendiculars *a b*, *c d*, &c., suspend from the intersections, *e*, *f*, bits of chain, *e b*, *f d*, &c., so trimmed, that their ends may fall on the line of the road-way; and it may be observed, that as those pieces, which hang near the haunch, will bring it down, the crown, C′, will thereby be raised into its proper position.

"But although this mechanical way of forming an equilibrated arch be founded upon principles sufficiently just, and be perhaps the simplest and best way in which the practical uilder could form the original design of such an arch; yet is it affords no general rules that may be applied to the construction of arches, we proceed to consider the same subject n a mathematical point of view.

"*Figure* 3.—And first, then, in the semicircular polygon, is it is called, where weights are hung on the thread A C′ C C″ B, which bring it into the position A C B, we have at each ingle three forces in equilibrio. Wherefore, by the principles of statics, they are to one another as the sines of the opposite angles; that is, the tension r C is to the tension l C, is sine l C W is to sine r C W, but the tension from C to l is the same as from C′ to r. Also, sine l C W is the same as sine r' C′ W′, since these angles are supplementary, C W, C′ W′ being parallel; therefore the tension r C is to the tension r' C′ is sine r' C′ W′ to sine r C W. *Or, the tension in each part of the chord is inversely as the sine of its inclination to the vertical.*

Again, we have as sin. d C l : sin. r C l : : tension r C : tension d C $= \frac{r \text{ C} \times \sin. r \text{ C } l}{\sin. d \text{ C } l}$; but as r C is inversely as sine r C d, therefore tension d C is as $\frac{\sin. r \text{ C } l}{\sin. r \text{C} d \times \sin. d \text{ C } l}$. Now, let an unlimited number of weights be hung from the chord, indefinitely near each other, and our polygonal thread becomes a curve; *Figure* 4 being in fact the curve of equilibration adapted to the weight which depends from it. The angles r C d and l C d become r' C d and l' C d, which are supplementary, and have equal sines, wherefore the product of these sines is the square of either. Also, as the sine of r C l or r C r' is as the curvature, or reciprocally as the radius of curvature, we have tension d C, or weight on C, inversely as rad. urv. $\times$ $\sin.^2$ inclination to vertical.

"This tension, in the present case, is usually produced by he gravity of the superincumbent materials, and may be neasured by the area contained between two indefinitely ear vertical lines E F, $e f$, *Figure* 4; but while the distance e is constant, the area F e will diminish with the sine of F e, as E e becomes more upright. To countervail this, we aust enlarge the depth E F in the same proportion as sine e F diminishes. And, therefore, we have E F inversely as ad. cur. $\times$ $\sin.^3$ F E e. *That is, the height of the superincumbent matter must be inversely as the radius of curvature, nto the cube of the sine of the inclination of the curve to the rtical.*

"Let us proceed to apply the theory to some practical ises.

"If the arch be the segment of a circle, then the radius of rvature is the same throughout, and the height will be inrsely as the cube of the sine of inclination to the vertical. nd from this we derive the following very simple construcon, for describing the equilibrating extrados of a circular ch, and which the reader, who has examined this subject, ll find much easier than those commonly given.

"*Figure* 5.—At any point, D, draw the vertical D d, and D from the centre C; then laying off D a equal to the thickss at the crown, draw the perpendiculars a b, b c, c d sucssively, D d is the vertical thickness at D, or d is a point in extrados.

"For it is evident, that D a : D b : : D b : D c : : D c : D d, cause of similar triangles; therefore, D a : D d : : rad. : ^{3} a D b, or inversely as radius to cube sine a b D. Now is the thickness at crown, and D d is therefore the thicks at D. *Figure* 6 is constructed in this way, and may ve as a specimen of the equilibrating extrados for a semiular arch. By reversing this operation, we may find the kness at the crown corresponding to a given thickness at other point. And here we may observe, that as D, *Figure* 5, approaches the extremity, D, of the semicircle, the line D d rapidly increases, until, at the point B, it is of an infinite length. But indeed this must evidently be the case with every arch which springs at right angles with the horizontal line; for the thrust of the arch should be resisted by a lateral pressure, and no vertical pressure can act laterally on a vertical line.

"We may also observe, that since the extrados or upper outline descends first on each side of the crown, and then ascends with an infinite arc, there is, for any thickness of the crown, a point on each side where the upper edge of the extrados is on a level with that on the crown. Thus, if B D $= 30^\circ$, its sine is half the radius. D a is therefore $= \frac{1}{8}$ of D d, so that if V v = D a be made $\frac{1}{14}$ of V C, the radius, we have the point d at the same level with V. Between this point, however, and the crown, there is a considerable depression, which is increased if the crown be made still thinner. On the other hand, if it be made thicker, the horizontal line drawn through the crown cuts the extrados much nearer the middle of the arch. It appears, therefore, that the circle is not well adapted for the purposes of a bridge, or a road, where the roadway must necessarily be nearly level; for no part of the extrados of the circular arch will coincide with the horizontal line. There is, indeed, a certain span, with a corresponding thickness at the crown, where the outline differs least from the horizontal; that is, an arch of about 54 degrees, with a thickness at the crown about $\frac{1}{4}$ of the span. But that is far too great for practical purposes.

"We may, however, extend the construction just given, even to those arches that are formed of portions of circles, differing in curvature. For the equilibrating extrados being first constructed for that portion of the arch in which the crown is, as far as the vertical line passing through the contact of the neighbouring curves, the thickness of the crown must be supposed to be enlarged, in proportion to the diminution of the radius of curvature, or the contrary, and, with this, proceed as before along the succeeding branch of the curve. This will, indeed, cause an unsightly break in the extrados, for which we shall not at present pretend to find any other remedy, than using materials of a different specific gravity.

"Those who wish to examine this subject farther, may consult Emerson's *Fluxions*, or Hutton's *Principles of Bridges*. We shall only observe here, that the extrados of the ellipsis, and of the cycloid, resemble that of the circle, having an infinite arc on each side at the springing; and indeed this, as has already been observed, is a general rule for all those curves which spring at right angles to the horizon. In the parabola the extrados is another parabola exactly the same, only removed a little above the other. In the hyperbola, the extrados is another curve, which approaches the interior arch towards the springing. None of these curves, therefore, can, with propriety, be employed for the arches of a bridge, though there may be cases where a single arch might, with propriety, be formed into a conic section.

"Mathematicians finding the circle, and other common curves, so little adapted to the arch of a bridge which has a horizontal roadway, have, in the next place, endeavoured to solve the converse of the problem, and give a rule for finding the intrados, or figure of the arch, which has the exterior curve a horizontal line.

"This problem can only be resolved by calling the fluxionary calculus to our aid. It is a case of the more general one to find the intrados when the extrados is given; and being the most useful case of that problem, fortunately admits of a solution comparatively easy.

"*Figure* 7.—We have already seen, that the load, D C, is inversely as rad. curv. × sine[3] inclination to vertical. Calling, therefore, as usual, the abscissa V E $= x$, C E $= y$, V C $= z$, we have C $f = \dot{x}$, f C $= \dot{y}$, C $c = \dot{z}$; and since C c : $c f$: : rad. : sin. inclin. at C; therefore the load D C is inversely as rad. curv. $\times \frac{\dot{y}^3}{\dot{z}^3}$. But as is well known, the rad. of curvature $= \frac{\dot{z}^3}{\dot{y}\ddot{x} - \dot{x}\ddot{y}}$; therefore, by multiplication, D C is inversely as $\frac{\dot{y}^3}{\dot{y}\ddot{x} - \dot{x}\ddot{y}}$, that is, directly as $\frac{\dot{y}\ddot{x} - \dot{x}\ddot{y}}{\dot{y}^3}$, or as $d\left(\frac{\dot{y}}{\dot{x}} \div \dot{y},\right)$ and is equal to $d\left(\frac{\dot{y}}{\dot{x}} \times \frac{\text{C}}{\dot{y}},\right)$ where C is a constant quantity, found by taking the real value of D C at the vertex, V, of the curve.

"Now, in the present case, calling A V $= a$, we have D C $= a + x$, (A V + V E,) therefore $a + x = \frac{\text{C}}{\dot{y}} \times$ flux. of $\frac{\dot{y}}{\dot{x}}$. Take $\frac{\dot{x}}{\dot{y}} = u$, and by integrating, we have $u = \sqrt{\frac{a\,2x + x^2}{\text{C}}}$, and therefore $\dot{y} = \left(\frac{\dot{x}}{u} =\right) \sqrt{\text{C}} \times \frac{\dot{x}}{\sqrt{2ax + x^2}}$; whence, by integration,

$y = \sqrt{\text{C}} \times \text{Lo.}\ (2ax + 2x^2 + 2\sqrt{2ax + x^2}) + \text{B}$. At the vertex $x = 0$, therefore $y = \sqrt{\text{C}} \times \text{Lo.}\ (2a)$. And consequently the ordinate $y = \sqrt{\text{C}} \times \text{Lo.}\ \frac{a + x + \sqrt{2ax + x^2}}{a}$.

"Lastly, to find the value of $\sqrt{\text{C}}$, we take some point of the extrados, where the ratio of x and y is known. For example, if the span, = 2 S, and height, = h, are given, we have $\text{S} = \sqrt{\text{C}} \times \text{Lo.}\ \frac{a + h + \sqrt{2ah + hh}}{a}$,

hence $\sqrt{\text{C}} = \text{S} \div \text{Lo.}\ \frac{a + h + \sqrt{2ah + hh}}{a}$,

and, finally, $y = \text{S} \times \frac{\text{Lo.}\ \frac{1}{a}\,(a + x + \sqrt{2ax + x^2})}{\text{Lo.}\ \frac{1}{a}\,(a + h + \sqrt{2ah + h^2})}$.

"We subjoin a table, calculated by Dr. Hutton from this formula, for an arch of 100 feet span and 40 feet rise, the thickness of the crown being taken at 6 feet. It is nearly of the same dimensions as the middle arch of Blackfriars Bridge, and which may answer for any arch where these dimensions are similarly related to each other.

"The curve of *Figure* 7 is accurately drawn to these dimensions, and may give an idea of the form of an equilibrated arch. It is not destitute of grace, and is abundantly roomy for craft.

"Such, then, is the analytical theory of equilibration: for a practical subject it does, we confess, appear abstruse.

"Let us turn, therefore, to another mode of considering this subject, which has been adopted by De la Hire, Parent, Belidor, and many others on the continent, and in our own country by the ingenious Mr. Atwood.

"The latter has, from the known properties of the wedge, and the elementary laws of mechanics, exhibited a geometrical construction for adjusting the equilibration of arches of every form.

"*Figure* 8.—The wedge A, if unimpeded, would descend in the direction V O, but is prevented by the reaction of B and B′, acting in the direction P Q and K I, perpendicular to the sides A G, Q D; and it is known, from the properties of the wedge, that if P Q, or K′ I, be to the weight of the wedge A, as D O is to D G, the wedge A will remain at rest. If also the wedge A be only at liberty to slide down G A, considered as a fixed abutment, then the force P Q alone will keep it in equilibrio. The force P Q being perpendicular to D O, has no tendency to make A slide either up or down on that line, but produce it towards N, making N M equal to P Q, then this force acting obliquely at N, may be reduced to two others, viz., M R perpendicular to A G, expressing the perpendicular pressure on the abutment of A, and R N expressing the force or tendency it has to make A slide upwards along A G. Again, take the vertical line A a, expressing the weight of A, and draw a H at right angles to A G; it is very evident, that A H expresses the tendency of A by its weight to slide down G A. A H is opposite, and is equal to N R.

"For, draw the perpendiculars D d and A p, then the triangles A a H, A G p, D G d, are evidently similar; and also the triangles O D d, O Q N, M N R, as they have always a common angle besides the right angle. Now, the force P Q, that is, M N, is to the weight of A, that is A a, as O D to D G, by supposition;

"And, A a : A H : : A G : A p : : D G : D d;

"Therefore, M N : A H : : O D : D d : : M N : N R.

"Or M N has the same ratio to A H, that it has to N R; that is, A H and N R are equal; or the tendency of A to slide downwards by its weight, is balanced by the tendency of M N to make it slide upwards; wherefore the section A remains at rest in equilibrio.

"Considering the whole arch as completed, with its parts mutually balancing each other, the force P Q, which is necessary for sustaining the wedge A, will be supplied by the reaction of the adjacent wedge B. Now, let it be required to ascertain the weight of B in proportion to A, so that they being adjusted to equipoise, may continue to be in equilibrio when left free to slide along K B. Since M R is the pressure produced by P Q, in a direction perpendicular to A G, we must add to this, H a, which is derived from the wedge A; therefore, make M n equal to H a, produce M R to Y, take Y Z equal to R n, draw Z W at right angles to K B; Y W is the force tending to make B slide up B K: take therefore B H′ equal to Y W, draw the perpendicular H′ b meeting the vertical B b in b; B b will represent the necessary weight of the wedge B, and the whole is so evident from the composition of pressures as to require no farther demonstration." Such is Atwood's construction; he has rendered the demonstration much more prolix, by the unnecessary introduction of trigonometry; and after showing how the weight of the sections C, D, &c., may be found in the same way, he goes on to reduce these weights and pressures to analytical and numerical values. He finds these in terms of the sines and tangents of the successive angles of inclination; but in reducing these to numbers, he has been led, by the accumulation of small errors, in that very operose way of proceeding, to give erroneous results; and into the singular mistake of conceiving, that the real expression of these values was only an approximation.

"The weight of the section C may be determined in the same way as the foregoing. But surely more simply thus: From C draw C S parallel to W Z, that is, at right angles to K O, and make it equal to W Z + H′ *b;* draw S *c* at right angles to L O, meeting the vertical C *c* in *c*, then C *c* represents the weight of C. From D draw D T parallel and equal to S *c*, draw T *d* perpendicular to D O, meeting the vertical D *d* in *d*, D *d* is the weight of D, and so on successively.

"Nay, instead of drawing D T parallel to S *c*, and T *d* perpendicular to D O, we may at once draw from S, S *d′* perpendicular to D O, which will cut off for us *c d′* = D *d*, the weight of the section D. It is of no consequence, although the lines of abutment do not all run to the same centre O.

"And thus we obtain a general construction for all the sections, which turns out abundantly simple; for upon any vertical line, *b′ e*, *Figure* 9, if *c b* be taken to represent the given weight of any section, C, and *c* T be drawn at right angles to C O, and *b* T at right angles to B O, meeting the other in T; then T *b* represents the pressure against the abutment O B, and T C the pressure against O *c;* and by drawing T *d* at right angles to D O, T *e* to E O, &c., we have the weights of the successive sections represented by *c d*, *d e*, &c., and the pressure on their lower abutments represented by T *d*, T *e*, &c.

"We may carry the same mode of determination to the other side of C, and pass the vertex of the arch. The divisions representing the weights of the sections will run upwards along the indefinite line *c b′*. The pressures on the abutments will be determined as before. Should the two sides of a section be parallel, the perpendiculars through T upon them will coincide; such a section, therefore, should have no weight. But should the two lines of abutment diverge towards the lower side, the line expressing the weight of that section will return upon the vertical, showing that such a section requires the reverse of weight, viz., a support from below. The line T V drawn horizontally through T, exhibits the horizontal pressure, which is uniform through the same equilibrated arch. But it is evidently greater, the less *b* T and *c* T are inclined to each other, the weight *b c* being constant, that is, the smaller the angle of the wedges, or sections. It also increases directly as the weight of the section C, &c. The line V *e* expresses the weight of the semi-arch, or perpendicular pressure on each pier; being the sum of the weights of all the sections in the semi-arch.

"Again, it is obvious that the angles *b* T *c*, or *c* T *d*, &c., are equal to the angles of the sections B O C, C O D, &c. If, therefore, the weight of any section, E, be given = *d e*, and the requisite angle of that section be required, everything else being known, we have only to join T *e*, and the line E *o*, being drawn perpendicular to T *e*, will exhibit the inclination of the lower abutment of the section; *d* T *e* is the angle of that section. And here it matters not where the point E be, that is, how great the base of the section be, provided the weight is equal to *d e*. We also see, that while the angles remain the same, and the weights proportional, it is of no consequence what the curve passing through the lower edges of the sections, or through their upper edges, may be, they may even be straight lines. According to this principle, the architect is not confined to given forms of intrados or extrados; he may take whatever curve appears most beautiful or useful: and, what is more, by the proper adjustment of the joints, *he may cast the ultimate pressure in any direction which he thinks most conducive to the strength of the edifice.*

"We now proceed to show the application of this investigation to some practical cases; and the first we shall consider, is that known by the common, though awkward name of the *flat arch;* one with which every mason is perfectly familiar, though it be seldom noticed by writers one quilibration.

"*Figure* 10.—A B *b a* is a structure of this kind, adjusted to this equilibrium, and resting on the abutments A *a*, B *b*. Its construction is exceedingly simple; nothing more is necessary than to draw all the joints, *m* M, *l* L, &c., to one centre, C: and the reason is obvious; for D K, K L, &c., are the differences of the natural tangents of the inclinations of the abutments, the perpendicular, C D, being radius; and the same thing is true in the line *d a*, and in every other parallel section. The surface, therefore, A *m*, M *l*, that is, the bulks or weights of the stones, are in the same ratio, and it is that which is required by the above principles. Also, if we assume the line of its base to represent the weight of any stone in the arch, for example, K D for half the keystone; then the perpendicular C D is the horizontal *thrust*, *drift*, or *shoot* of the arch. By increasing D C, or diminishing it, that is, by drawing the joints to a lower, or a higher centre, we may alter this thrust at pleasure. What if we should take C up to D? Some curious ideas occur here, but being chiefly speculative, we shall not now pursue them. They serve to connect this case very neatly with the lintel and the Egyptian arch, (or that formed by flat courses of stones gradually overlapping each other, until the opening be covered,) in each of which the horizontal thrust vanishes. We ought also to observe, that whatever weight of stuff lies on an arch of this kind, there is no change of design requisite, so long as the upper surface, or roadway, is horizontal. For being everywhere of the same height, the mass incumbent on any stone will be proportional to its base, viz., the back of that stone; since we must conceive the stuff to press vertically. It is therefore the same as if the whole arch had undergone a change of specific gravity; every pressure will be increased in the same proportion.

"The design of an equilibrated horizontal arch, or platband, being thus easily formed, it will not be difficult to extend it to a curve of any form; *a δ b b′ d′ a*,′ *Figure* 10, is an arch of this kind. It is a circular segment from the centre, C, to which the joints of the horizontal arch were directed; the two key-stones have the same weight and obliquity of abutment; consequently, the horizontal thrusts are the same. The other arch-stones being previously intended to have the same weight with those of the flat-arch, it is only necessary to draw the lines 1 1, 2 2, 3 3, parallel to M *m*, L *l*, K *k*, so as to produce this equality.

"This being merely a simple problem in mensuration, we shall not occupy the reader's attention with the solution of it. In the *Figure* referred to, we have divided the soffit, A B, of the flat arch into equal parts; all the stones, therefore, of that, as well as the curvilinear form, are of equal magnitude and weight, the angles of the arch-stones only, varying.

"The reader must have already observed, that when C D expresses the horizontal thrust, or pressure of the vertex, C M, C K, C L, &c. express the perpendicular pressures on the successive joints M *m*, K *k*, L *l*, &c. Now it is obvious, that K *k*, L *l*, &c. are proportional to C K, C L, &c.; for A D, *a d*, are parallel. Therefore, the vertical sides of the arch being parallel, the pressure on each joint of the flat-arch is always proportional to the surface of that joint, and the pressure on each square inch of joint throughout the arch is always the same. It may readily be found too, by dividing the horizontal thrust by the area of vertical section, D *d*. This is a most valuable property, for it secures uniformity of action in every part of the structure. But it is not to be found in the arch *a b d;* for there, the joints being nearly equal, the pressure on each increases as we descend from the vertex, and may, at the lower sections, be eventually so great as to overcome the cohesion of the materials.

"It may be objected to the straight arch, that acute angles, as A *a m*, B M *m*, are very apt to chip away, and weaken the arch. Now this is certainly true, but it has no connection with the doctrine of equilibration. There is, however, a very ingenious mode of remedying it; for if the upper and lower extremities of each joint be drawn to a centre, considerably below the former, or even if they be formed into vertical lines, as at N, *n*, it will materially strengthen the acute corners without injuring the equilibration. We may conclude, therefore, that a structure of this kind possesses every requisite that can be looked for in an equilibrated arch. But, before we take any further notice of it, we shall proceed somewhat farther with the applications of our theory.

"The segment *a δ b* was adjusted to equilibrium, with reference to the flat arch, upon the principle that the weight of the arch-stones was only to be provided for. In general, an arch of this kind is filled up at the flanks, so as to form a roadway as nearly as possible horizontal. We must, in that case, when considering the weight of each arch-stone, not lose sight of the difference of pressure upon it, arising from the varying height of the incumbent mass. Having, therefore, divided the back of the arch into sections, *d* 1, 1 2, 2 3, *Figure* 11, each containing one, two, or more arch-stones, and having drawn the vertical lines from these divisions to the line of roadway, we calculate the weight of the trapezoid of the stuff over each section; add this to the weight of the section; and divide the tangent line, or flat-arch, accordingly.

"We may even give a construction for this. The stuff over any section, 2 3, is proportional to the trapezoid, *t* 2 3 *v*, or nearly $t\,v \times s\,w$; for we need take no notice of the small segment of the circle between 2 and 3, but consider the arch as polygonal, in which case the mean height is *s w*.

"But 1 2, 2 3 being equal, we have *t v* or 2 *y* as sine of 2 3 *y* (*i. e.*) as sine of the inclination of the arch; wherefore, drawing the mean height, *w s*, and producing C *w* to meet the perpendicular *s x*, take the weights over the sections to be represented on the horizontal line, by lines equal to *w x* respectively; for *s w* is to *w x* nearly as 2 3 is to 2 *y*, and *t v*, at the vertex of the arch, is equal to 2 3; and since the weight of the arch-stone will be nearly constant, and that on the supposition that the weight over each section is represented by the trapezoidal space included between it and the roadway, let us assume the weight of the keystone, as represented by the part *d* P, and the others by similar additions. If we have an arch differing in gravity from the stuff which loads it, we can measure to a circle within or without the circle of intrados, P T *u* W. Draw, therefore, the horizontal line P *o*, and lay off P *a* equal to $\frac{1}{2}$ P *q* for the half keystone and its load, lay off, also, $a\,b = l\,n$, $b\,c = u\,x$, &c., and these divisions will represent the weight of the several sections, the superincumbent matter being included.

"This method is evidently only an approximation; we consider the principal load as arising from the mass incumbent on each section, or at least that the weights of the sections are proportional to these masses. It becomes pretty accurate, by taking *w* in the mean circle drawn between the soffit and back of the arch; and we might render it still more accurate, by giving the determination a fluxionary form, but we write at present for the practical builder, to whom the calculus is seldom known; besides, as the reader will see hereafter, we do not think the rigid determination of this matter as yet of much consequence.

"Having thus discovered the weights of the sections, and laid them off on the horizontal line, as if for a flat arch, and having, either from the given form of the keystone, or the horizontal thrust, drawn the angles of abutment which a flat arch would require, the joints of the arch in question are to be drawn parallel to these, and through the extremities of the proper sections, previously marked out, as above mentioned. If there be intermediate joints, they may either be drawn properly related to the others, or be separately discovered by a repetition of the construction.

"*Figure* 11.—For example, let C be the given centre for the keystone; draw C *a*, C *b*, C *c*, &c.; and through 1 draw the joint 1 R parallel to C *a*, also 2 T parallel to C *b*, and 3 W to C *c*, &c.: the arch would then be in equilibration.

"Thus we find, that, *by the proper adjustment of the joints to the weight of the section, we may form equilibrated arches, having soffits of any figure that may be thought proper*, and with any proportion of dead weight over them that circumstances may require. Let us now look at the converse of this Problem; where the inclinations of the joints being given, it is required to discover the mass or weight which must be allotted to each section, so as to preserve the whole in equilibrium.

"Pursuing the mode already employed, it is evident, that if we lay off from one centre the angles to be formed by the successive joints, or abutments, with the vertical line, a horizontal line drawn to cut them will represent, by its successive segments, the weights of the several sections; while, at the same time, the perpendicular let fall from the centre on this line will exhibit the horizontal thrust. If the arch, therefore, must be throughout of equal thickness, we have only to mark off upon the soffit, or rather upon the mean curve, segments proportional to those of the horizontal line. If the upper and lower outline of the arch be determined, we must divide it into trapezoids, having the same proportions; then draw the joints parallel to the lines expressing the given angles of inclination. Such joints will run to several different centres, thereby showing us, that their union in one is not at all necessary to the security of the arch, even should that be a portion of a circle.

"The position of the joints is usually given in a different way from that which we have just considered. In circular arches, they are generally formed by producing the radii from the centre; and in others they are commonly drawn perpendicular to the curve. Now, though we have just shown, that this is by no means necessary to the equilibrium, yet, as it is in reality the most convenient in practice, it may be of importance to attend to the effects likely to be produced by this modification.

"*Figure* 9.—We see that the tangents on the horizontal line rapidly increase as we pass outward, and we should therefore increase, in the same proportion, the weight of our sections. We cannot increase the base, as proposed above, for that is necessarily given by the position of the joints, but as we are still able either to increase the height, or the breadth of the sections, we may consider the effect of both these modes.

"Let it be required, then, to equilibrate a circular arch where the stones being all of equal thickness, with joints equally distant, are drawn all to one centre, we are only at liberty to increase the width of the roadway, or length of the horizontal courses.

"Considering each course of arch-stones as a prism of given base, a supposition sufficiently accurate, it is eviden that its magnitude or weight increases with the length only. But this weight must, from the principles already laid down, be as the difference of the tangents of its abutments; the length, therefore, must be in that ratio. Accordingly, we find the breadth at different distances from the vertex, in the same way with the weights of the sections: the breadth at 45° must be double, and at 55° must be about triple of that at the crown, and will increase still more rapidly afterwards. Proportions such as these may answer well in the short flight of steps for a flying staircase, but are quite unfit for our present purpose. When we recollect, however, that in a bridge, the extraordinary expansion towards the haunches is materially corrected by the increased pressure of the incumbent mass in that part, we are encouraged to proceed a little farther, and consider the effect of the second mode of effecting the equilibrium.

"*Figure* 11.—The pressure of matter upon each section has already been stated as proportional to $t\,v \times s\,w$; but $t\,v$ is the difference of the sines of the angular distances of the successive abutments from the vertex, and $s\,w$ is the mean versed sine added to the given thickness at the crown, when the roadway is horizontal. We have therefore the pressure as the difference of the sines $\times$ (mean versed sine $+$ thickness at vertex.) But these pressures are also, from the theory, as the difference of the tangents of these angular distances.

"In the common mode of building we must give the arch a sufficient thickness at the keystone, to resist the horizontal thrust, ensure stability, and bear the loads likely to come upon it. We must also cover this part with a certain thickness of gravel, or other matter, so as to form a roadway. The varying pressure of the wheels of a loaded carriage, when it is propagated through this stratum of gravel, will be so far diffused as not to disturb the stone immediately below it, nor injure the bridge by splintering away its corners. This thickness is made as small as possible, that the bridge may not be unnecessarily elevated, and the roadway is preserved nearly horizontal. The other courses of arch-stones, too, do not often differ much in thickness from that at the crown. But although these things are pretty constant, there is a considerable degree of latitude in filling up the space between the back of the arch and the roadway. It may be done with substances varying in density, from the lightest charcoal or pumice, open shiver, or chalk, to closely rammed clay, or even solid masonry; and it is not uncommon to make, in various ways, open spaces in the masonry of the spandrel, covering them above, so as still to support the roadway.

"It will, therefore, be proper for us to inquire, what is the density requisite over every section of an arch, where the thickness of the crown is given, the roadway horizontal, the arch of uniform thickness, and the angles of abutment of the several sections constant, that is, all drawn from the same centre; or, what is the same thing, let us suppose the structure built up to the horizontal roadway with parallel sides, and then inquire, what is the proportion between the pressure borne by each section in this way, and the pressure of equilibrium; we shall thereby discover the ratio in which the density of the backing must, if needful, be diminished; and the quantity of expansion necessary towards the springing of the arch, that the advantages of equilibration may be preserved, even in this state of things.

"Before we give a more rigid determination, we should wish to show the practical builder, that the solution of this problem may be easily approximated, by the help of the trigonometrical tables. For we may suppose the matter of the arch-stones to be the same in specific gravity with that which lies above it; and as there can be no impropriety in considering the arch as polygonal, from joint to joint, our mean versed sine is only half the sum of those at the two joints. The supposition is not strictly accurate, but it is sufficiently near: greater strictness would only serve to render the calculation more complicated without making it more useful.

"It was customary in the construction of bridges, to fill up the haunch with solid matter, such as gravel earth, or the like, until a roadway of a proper slope was procured. Where the arches were small, this might not be attended with any perceptibly bad effect, provided the arch-stones were of a good depth. But the necessity of lightening the haunches, has been forced upon the attention of builders, whenever large arches have been attempted.

"In all probability, the first inventors of this mode of building, besides employing it with the view of equilibrating the arch by lightening the part over the haunches, had also an idea of steadying it by the lateral abutment. They appear to have considered the spandrel walls as a sort of hoops, that would keep the parts of the arch together, and hinder any stone from moving, by their great friction, inertia, and mutual abutment. Hence various ingenious modes have been employed for locking them into the back of the arch-stones, propagating the pressure through, and securing them from sliding away at the bases.

"They indeed act in this way; nevertheless the equilibration of the arch should be attended to in their construction, that every unnecessary strain may be avoided. The thickness of these walls may be varied indefinitely, and the vacant spaces made in any proportion to the solid parts. The walls ought to be near each other, that their effect may be felt over the whole arch, and perhaps they should spread out towards the bottom; but this is not so very necessary, for the courses of arch-stones break joint with each other, and the inequality of pressure in one course is immediately corrected by being propagated to the succeeding.

"We have now determined a method of constructing an equilibrated arch for sixty degrees on each side of the vertex; and this method, so far from having anything unusual, is even strictly analogous to that which is adopted by the practical builder. Why then cannot we keep pace with him throughout, and give a construction for the entire semicircle? No difficulty is felt by the mason in that case. He constructs such arches every day. Nay, they are not only the most common, but the most ancient of all arches. But the reader must have ere now observed, that our theory is in this particular defective. The enormous expansion of the roadway, or the infinite height of superincumbent matter, which it seems to require when the joints are nearly horizontal, are altogether preposterous and impracticable. We are sure they are unnecessary; for many semicircular arches have existed from the time of the Romans, and are still in good order. What is more, the failure of such arches near the springing, where they differ farthest from the theory, is a most unusual, and, indeed, unheard of phenomenon. Is our theory erroneous, then, or is it only defective? There is no reason for distrusting any of the consequences we have hitherto deduced. They are mathematically derived from an unquestionable principle, the action of gravity. But we have not yet considered all the causes of stability. The lateral resistance of the masonry, or other matter behind the arch, acts powerfully in preventing any motion among its parts; and independently of that, the friction of the arch-stones, assisted by the cohesion of the cement, affords a great security to the structure. We have even seen a semicircular ring of stones, abandoned to itself without any backing, and stand very well; long enough, at least, to admit of the other work being leisurely applied to it. Here was no lateral pressure; no equilibration: why did not the lower courses yield to the pressure propagated from above, and slide off? It was only their friction that could retain them. It is greatly increased by this very pressure. And it is unquestionable, that a ring of polished blocks in that situation would not have hung together for a moment. The force of friction, therefore, makes so important a part of our subject, that it deserves a separate inquiry. Let us see how it may be estimated.

"When a mass of matter is moved along other matter of the same kind, the resistance produced by friction has been usually stated at $\frac{1}{3}$ of the weight. That of freestone, indeed, is supposed to be greater than $\frac{1}{3}$, perhaps it is $\frac{1}{2}$. And in the case to which we are going now to apply it, there can be little doubt, that, aided by the inertia of the stones, and the cohesion of the cement, the friction is even much more. But this force is inert; and we are at present inquiring, how far we are benefitted by it in promoting the stability of our structure. It will, therefore, be proper to underrate it, at least until we discover how far we are warranted to say it must be beneficial.

"*Figure* 12.—Let L, M, N, exhibit the three sections (10° each) of an arch, which we may conceive equilibrated above the section L, or 60° from the crown. Draw L T, expressing the direction and magnitude of the ultimate pressure, perpendicular to the upper surface of L. In like manner, T V is the horizontal thrust, and V L the weight of matter over L to the vertex. Draw the perpendicular T *y b*; T L is the direction of the ultimate pressure when propagated to the lower surface of L; *y* L is its tendency to make L slide upwards along the joint. Now it is evident, that, if *y* L has to *y* T a less ratio than the friction has to the pressure, L will not move. Nay, what is more, L will itself have some weight. Take L *a* to represent it, which, in the case of equal sections, = the tangent *x z*. Draw T *a* for the ultimate pressure in the lower surface of L, and *a b* for the force to be resisted by friction, in this case equal to .1343, or about $\frac{2}{15}$ of the pressure, and of course less than the friction, which will at least be one-third of the same.

"Since L does not move upon the section M, they are to be considered as one solid mass, and we pursue the pressure through the section M. For this purpose, lay off *a c* for the weight of M, draw the perpendicular T *d*, and the parallel *c d* to the joint M O, *c d* is the force opposed to friction in that joint, and still is less than one-third of T *d*, the pressure being, in the case of equal sections, = .2796, or about $\frac{11}{40}$. Lastly, lay off *c e* for the weight of the lowest section, N, and draw as before. It is evident, that *e f*, the force opposed by friction here, is just equal to T V, the horizontal thrust, as might have been concluded without any investigation. In the case of equal sections, its proportion to T *f* or V *e*, the weight of the semi-arch or perpendicular pressure, is as .4425, or about $\frac{7}{16}$, which is probably more than the friction will oppose without other assistance.

"If, therefore, the friction on the horizontal bed at the springing be not equal to the thrust of the arch, we must increase it, as by dowelling it, for example, into the lower stones, or by backing it with other masonry, or by increasing the pressure on that joint, without altering the thrust of the arch, which may be done by thickening, or loading the arch just over the springing. And here the theorems for the extrados of equilibration come to our aid; for we see, that any quantity of matter may be laid over the springing-courses, and, far from disturbing the arch, it will tend to increase its stability.

"It may not be improper to inquire, what are the conditions for equilibrating an arch by means of the friction of its segments alone? that is to say, what are the alterations practicable in the position of the joints, or in the weights over the several sections, until the tendency of each section to slide is just balanced by the friction at its lower surface?

"Whether we inquire into the position of the joints, or the weight that may be applied, there are two cases; for the friction being an inert force, will resist the stone in sliding either upwards or downwards.

"I. Let it be required to determine the position of the joints in an arch, when each section is just prevented from sliding outwards by the friction at its lower surface.

"*Figure* 13.—Let the arch spring from a horizontal joint, as N *n*, where, of course, the friction acting in V N, is just equal to the horizontal thrust, and must therefore have to T *n′* or V N the weight of the semi-arch, the ratio which friction has to the incumbent pressure, say $\frac{1}{3}$. T N is the direction of the absolute pressure at the abutment N *n*. Take M M the weight of the section N, T M is the pressure on the joint of M, and making M T *m* similar to N T *n′*, M *m* will also represent the extreme friction in that joint, and T *m* its load, and so on successively. Wherefore, if T *m*, T *l*, &c. be found, the joints of the arch may be drawn at right angles to these lines respectively, and every stone will be exactly in the predicament of N, that is, just kept by its friction from sliding away.

"The positions of T *m*, T *l* may be readily discovered; for the angle *n′* T *m* must be equal to N T M. If, therefore, we make T *a* equal to T N, draw the tangent *a w*, and making *a b*=N M, and joining T *b*, we have *a* T *b*=N T M. And, in this manner, taking *a b*, *b c*, &c. for the weights of the successive sections from the scale, and drawing lines from T, the joints may be formed perpendicular to the lines thus drawn.

"*Figure* 14.—But a more convenient construction perhaps would be, to take the horizontal thrust, or quantity of friction in the vertical line C *d*, lay off the weight of the semi-arch *d a*, draw C *a*, make C *x* equal to it, also *x z*, mark off the weight of the sections along *x z*, and through the divisions draw lines from the centre; the joints required are parallel to these lines.

"II. Let it be required, in the next place, to determine the other limit to the position of the joints, or that in which each section is just prevented from sliding in, by the friction on its lower bed.

"Here it is evident, that as the friction acts precisely opposite to its direction in the former case, the joints may have on the opposite side, exactly the same degree of obliquity to the position of equilibrium. Draw, therefore, the tangent *v y* parallel to *a* C, cut it with C *v* equal to *a* C, lay off the weights of the sections along *v y*, and draw lines from C; these lines will exhibit the positions of the joints, which of course may be drawn parallel to them. We have marked these two limits of position in three joints of the half-arch above the same figure, assuming the friction at one-third, and taking the first section of 30° as equal to the thrust; and any other arch might have been introduced as well as the circular. Any of the lines in the triangle C *d a*, makes with the corresponding line in C *y v*, or in C *z x*, an angle equal to *a* C *x*, that is, when the friction is one-third of the pressure, equal to 18° 26′; and when the friction is one-half, this angle is 26° 34′. The position of any joint, therefore, may vary, in the former 18° 26′, and in the latter case 26° 34′, on either side of the position of equilibrium, before any sliding can take place among the sections. Nay, the friction of polished freestone is even more than one-half, perhaps it is two-thirds, of the pressure, which would give 33° 4′. And it is proper to observe, that this is not confined to the annulus of arch-stones, but holds equally with whatever weight the sections may be loaded. We may observe, then, that, in any arch, the position of the joints may be varied about 20°, perhaps 30°, from that of equilibrium, before any derangement can arise from the sliding of the arch-stones.

"This is a most important conclusion, and leads to extensive practical consequences. It affords a true explanation of the facility with which arches are everywhere constructed, even by the common country mason.

"For this reason, therefore, we approve highly of the practice, which we believe is very general among artificers, we mean that of backing up the arch with solid masonry, for several courses above the springing. If great security is thought necessary, cement, being a compressible substance, ought to be sparingly employed in the vertical joints at the back of the arch-stones.

"The friction of the sections of the arch, as it permits a considerable variation to take place in the position of the joints, will also admit of a considerable deviation from the load which is necessary for equilibrium over any point of the curve.

"It would not be difficult to investigate the extent to which this variation of weight might be carried. But we shall at present only remind the reader, that, as we find a variation of 20° practicable in the position of the joints, he may conclude that each section will admit of its load being altered to that which would suit a point in the curve 20° on either side of it.

"One thing only remains to be considered in this department of our subject, which is, the lateral pressure likely to arise on the back of the arch, from the materials employed to raise the structure to the horizontal line.

"If the materials employed here be only a solid mass of masonry, it is not easy to see, everything being steady, how it can act in any other way than in the vertical direction. If, however, a motion takes place in the arch, the mass of materials lying nearly over the springing, when the arch is not very different from a semicircle, will have such an enormous friction, if well built and bonded together, as would appear equal to the resistance of any pressure that is likely to be opposed to it. And when the arch is a segment much smaller than a semicircle, the rules we have already given for its equilibration must be considered. But, instead of solid courses of masonry, the haunches of arches are often filled up with coarse gravel, or shiver, and sometimes with mere earth or sand. Materials of this description do by no means act by mere dead weight. They have a tendency to slide down towards a horizontal position; and, of course, possess, in some slight degree, the *quaquaver sum* pressure of a fluid. This may act on our arch in a manner altogether new, and produce strains for which hitherto we have made no provision. We shall first consider the back of the arch as filled up with a fluid substance, as water. The pressure in every part will be in a direction perpendicular to the curve, and will be proportional to the depth. A pressure perpendicular to the curve will be equivalent, in effect, to a vertical pressure, which exceeds it in the ratio of the secant of the inclination to the vertical. Of course, the pressure at the springing, when all is equilibrated, must be equal to the horizontal thrust in a semicircular arch.

"Though the action of sand, gravel, or mould, in situations such as this, be not exactly the same with that of water, in following the laws of hydrostatical pressure; yet these materials resemble water, and may be conceived to hold the middle place between the fluid and the solid backing. In some respects they are more advantageous than the fluid. They are stiffer, so to speak, affording a lateral abutment to the arch, if it is likely to yield; and as the parts have a great friction among themselves, it will require a much greater pressure, acting horizontally, to make the matter rise, than in the case of a fluid. We must not, however, be too confident. Materials of this kind are compressible; and we have already seen that very slight shifts are attended with dangerous consequences. At the same time, we need not be much afraid of a trivial departure from exact equilibration; for it is not likely that materials of this kind will act with the powerful effort of hydrostatical pressure.

"But there is another case, where matter of this kind is likely to be attended with more pernicious effects than even a fluid of equal density would be. We mean, when the back of the arch is gorged up with water from land-floods: if the backing be open gravel, or shiver, we have superadded to its weight that of the whole quantity of water admitted into the structure. This, even if it acts equally on both sides, must be a dangerous experiment on any arch; but where it is confined to one side, as is generally the case, and between lofty side-walls, the effects are likely to be serious indeed. Accordingly, the builder forms gutters in the side-wall to let off the water ere it collect;—a practice which is in general highly useful, but which, in the case of sand, clay, or mould, is of small service. The water enters into such matter by its capillary attraction; and fills it to the upper surface, in spite of our gutters. It of course expands it, and this with a force which we cannot measure, but which we are sure is very great. Here the friction of the parts, which was so useful in the former instance, proves extremely hurtful. For as the matter cannot easily rise, and probably the adhesion of its particles is increased by the water, the expanding force becomes an enormous hydrostatical pressure acting perpendicularly on the side-walls and extrados of our arch, and which in all probability they may not sustain.

"The dangerous consequences of this mode of backing are, in some degree, prevented by ramming the layers of matter, especially if it consists of mould or the like: or, by puddling them, so as to form a mass impervious to water. And here we should observe, that as this ramming will produce an extraordinary lateral pressure, we must attend to equilibration, as we rise along the arch, and secure the side-walls by thickening them below or curving them horizontally or vertically.

"The thickness of the arch-stones is an important department of the theory of arches. It is natural that we should endeavour to make them as small as possible. That will diminish the expense of the structure, lessen the pressures in the arch, and increase the security at the springing. But there is an evident limit to this diminution; for though we take every pains to render the joints close, the stones may come at length to be so small as to crush by the thrust of the arch. This is, indeed, a curious branch of inquiry. It depends intimately upon the corpuscular actions of the particles of stone; a subject on which, we regret to say, our information has been hitherto very scanty.

"The question evidently depends on the amount of the tangential pressure. At the crown this is the horizontal thrust. We shall suppose all the joints to be duly drawn to equilibration, the sections fairly abutting on each other, and no weakness arising from acute angles.

"Stone, it is said, will carry from 250,000 to 850,000lb. avoirdupois per foot square, and brick 300,000lb. They have been made practically to carry one-sixth of this, and even more. The pillar in the centre of the Chapter-house at Elgin carries upwards of 40,000lb. on the square foot, and there was formerly a heavy lead roof on it. It is a red sandstone, and has borne this pressure for centuries.

"We shall therefore take 50,000lb. per foot as a load which may be safely laid on every square foot in the arch.

A cubic foot of stone weighs about 160lb. per foot; and brick weighs less. Suppose, therefore, the arch to be one foot thick at the crown, and the keystone one cubic foot, it will bear a horizontal thrust of 50,000lb. that is, $312\frac{1}{2}$ times its weight.

"But, 50,000 : 160 : : R : Tang. 11′ 0″ 3‴, which will be the angle of the keystone in that case. So that an arch of $312\frac{1}{2}$ feet radius, or a semicircular arch of 625 feet span, might bear to have a keystone of a foot deep, without risking its being crushed more than in structures which have already stood for many years. And this may be called the limit of stone-arch building; for if we double the depth of the stone, we will thereby double the weight also, and its ratio to the horizontal thrust will still be the same. Indeed this limit does not much exceed what has been actually executed. A considerable portion of the bridge of Neuilly is an arch of 250 feet radius; and Gautier mentions a platband in the church of the Jesuits at Nismes, the camber of which, after settling, would make it a portion of an arch of 280 feet radius. The length or span is $26\frac{1}{2}$ French feet, the rise only 4 inches, and therefore the diameter of its circle would be 560 English feet.

"'This singularly bold platband was made under the conduct of Père Mourgues, after the design of Cubisol, an able architect. The stones are 1 foot thick, their depth is 2 feet towards the key, and 2 feet 4 inches at each end. It had a camber given it of about 6 or 7 inches, and descended near 3 inches on striking the centres.'"—*Gautier.*

"We see, that the horizontal pressure does not determine the vertical thickness of the arch-stone. But as we pass down the arch, it is plain that the butting surfaces must increase in proportion to the increasing tangential pressure.

"At sixty degrees from the vertex, granting that the arch is equilibrated, the depth of the arch-stones must be doubled; and though the equilibration be carried no farther, yet, at the springing or horizontal joint, a small increase will still be necessary. The ratio will soon be found. To the square of the weight of the semi-arch, add the square of the horizontal thrust, the square root of the sum is the pressure at the springing. If we divide this by the horizontal thrust, it will give the thickness at the springing, compared with that which is necessary at the crown. Or if we divide it by $312\frac{1}{2}$, it will give the smallest depth of joint which should be used at the springing. The thrust and weight are supposed to be given in solid feet. If given in pounds, divide the above quotient by 160, or divide at once by 50,000.

"If we calculate upon the same principles, the depth of arch-stone at the spring-course of a semicircle of 100 feet span, 10 feet thick at the crown, we shall find it to be 5 feet, and at the crown the depth may be 19 inches. In the great arches of the bridge of Neuilly, the thickness at the crown is about 4 feet 8 inches, the span 128.2 feet, and height 32. The horizontal thrust is great, the crown being drawn with a radius of 150 feet; consequently, this arch would require a depth at springing of about 4 feet. But when the centre was struck, the crown of this arch descended 23 inches, which has rendered it a portion of a much larger circle, and has greatly increased the horizontal thrust.

"The piers and abutments of a bridge must be so constructed, that each arch may stand independent of its neighbours. For though, by the mutual abutment of arch against arch, the whole may rest upon very slender piers, if once the structure is erected; yet, as they must be formed singly, and are exposed to many accidents, it will be best to contrive them, so that the destruction of one arch may not involve in it that of the whole.

"Some of the writers on the principles of bridges, in treating this department of their subject have found it necessary, by the help of the higher calculus, to find the centre of gravity of the semi-arch. The solution of the problem, we are convinced, so far as it is useful in practice, lies much nearer the surface.

"The reader has already frequently seen, that the ultimate pressure may, in every case, be reduced to two others, viz., the weight of the semi-arch above, and the horizontal thrust. In the equilibrated arch, this pressure is directed perpendicularly to the joints of the sections; and these being usually drawn at right angles to the curve, the pressure is in the direction of the tangent to the arch. Hence, we have often called it the tangential pressure. Upon this principle, however, when the curve springs at right angles to the horizon, an infinite pressure is required in the vertical direction,—a supposition which cannot have place in practice. We must accordingly call in the assistance of friction in that case; a force which may be set in opposition to the horizontal thrust, and which, increasing with the superincumbent weight, very fortunately keeps pace also with what it is intended to oppose.

"Granting, then, that the friction is so contrived, upon the principles already explained, that there is no danger of any slide at the horizontal or springing-joint; it will be readily admitted, that no slide is likely to take place in any horizontal course below that, till we arrive at the foundation; for the disturbing force is constant, but the friction increases as we descend.

"*Figure* 15.—Our principal care then must be, that the pier does not overset, by turning on the farther joint, E, O its base, as a fulcrum. Take a in the horizontal joint, A a as the centre of pressure; draw a V to represent the weight of the semi-arch, and V T the horizontal thrust; then T a is the ultimate pressure; and if, when produced, it falls within the base of the pier, it is perfectly obvious that it can never overturn it. And this is altogether independent of the weight of the pier: for if that were a mass of ice, immersed to the springing in water, the case would be exactly the same.

"But the pier itself has a considerable stability, arising from its own weight; and even though the direction of the ultimate pressure of the arch alone pass out of the base, the tendency to overturn the pier may be balanced by its weight. This weight may be supposed concentrated in the centre of gravity of the pier, and of course to act in the vertical line which bisects it.

"Its effect will be nearly found by laying off in that line from the point q, where the direction of the ultimate pressure of the arch intersects it, $q\ r =$ the weight of the pier, and taking $q\ s =$ the ultimate pressure $= a$ T, and completing the parallelogram, the diagonal drawn from q will represent the direction and magnitude of the united pressure of the arch and pier. This is not strictly accurate; it would be so if a and q coincided, which is the case with a single arch standing on a pillar: but in general, the ultimate pressure is still more favourable than this. Its direction at any point is in the tangent of a curve, which approaches the vertical as we descend, since the proportion arising from the weight of the pier increases with its height.

"In order to find analytical expressions for these forces, let the horizontal thrust of the arch $= t$. The weight of the half-arch $= a$, and that of the pier $= p$, the height of the pier to the springing of the arch $= h$, the breadth at the base $= b$.

"1. Then the horizontal thrust acting in A G, tends to overturn the pier, and its force round the fulcrum, E, will be represented by multiplying it by the perpendicular distance A D, viz., $h \times t$.

Fig. 14.
Fig. 15.

"2. The weight of the pier acts in the direction B C, and its effect will be represented by multiplying it by the leverage C E, viz., $p \times \frac{1}{2} b$.

"3. The arch acts with the leverage E K, which is not equal to the breadth of the pier, by the part K D = A H, say one-half of the depth of the joint at the springing. This will never exceed one-fourth of the breadth, when two different rings of arch-stones rise from the same pier, unless the pier widen below. Call E K, therefore, $= \frac{3}{4} b$.

"We have now $h\,t = \frac{1}{2}\,b\,p + \frac{3}{4}\,b\,a$; whence,

"1st, $b = \dfrac{h\,t}{\frac{1}{2}\,p + \frac{3}{4}\,a} = \dfrac{4\,h\,t}{2\,p + 3\,a}$, and consequently,

to find the least breadth of the pier at its base, divide the horizontal thrust by half the pier added to three-fourths of the half-arch. Multiply the height of the pier by the quotient.

"2d, $h = \dfrac{b\,(\frac{1}{2}\,p + \frac{3}{4}\,a)}{t}$, that is,

the height of a pier to the springing, having a given base and weight, is found by adding the half-pier to three-fourths of the arch, multiplying by the breadth of the base, and dividing by the horizontal thrust.

"3d, $p = \dfrac{h\,t - \frac{3}{4}\,b\,a}{\frac{1}{2}\,b} = \dfrac{2\,h\,t}{b} - 1\tfrac{1}{2}\,a$;

or the weight of the pier cannot be less than the excess of the horizontal thrust multiplied by twice the height of the pier, and divided by the base, above one and a half times the semi-arch.

"In the above determination it may be observed, that we consider the weight of the pier as independent of its base. Now, though it may be said with propriety, that the weight of the pier cannot be known until we know its thickness, which is the very thing sought, yet a little consideration will show, that we may give different magnitudes to piers which have equal bases, and that, either by altering the outline of their sides, the density of their structure, the gravity of their materials, or the weight of solid matter over them, we may therefore, when the base is given, apply the weight necessary to keep the pier in equilibrio, provided this does not require the pier to be any more than a solid mass up to the roadway. Should the base assumed admit of the pier being much less than the solid parallelopiped, we may diminish it in various ways: as, 1st, By opening arches over the pier, where, in case of floods, we will procure an addition to the water-way; a practice very usual in the ancient structures: or 2d, By tapering the pier towards the springing of the arches, or by making each pier only a row of pillars in the line of the stream, arching them together at top; a mode which may perhaps be objectionable in a water-way, but which would have a very striking and light effect in land-arches. Something of this kind has been done by Perronet, at the Pont St. Maxence.

"When piers indeed are to be exceedingly high, as in the columns which are sometimes employed in supporting a lofty aqueduct, the best way is to make them hollow, and give them stability, by enlarging the base. They will, in that case, press less on the foundations, be less expensive, and they may be greatly stiffened by hooping.

"Indeed, it is not usual to make piers solid all the way up to the road; the spandrel-walls are carried back so far as to unite with those of the neighbouring arch, are locked together by a cross wall just over the middle of the pier, having also walls longitudinally, and the whole arched or flagged over from spandrel to spandrel just under the roadway.

"Nevertheless, as the case of solidity will enable us to assign a limit to the breadth of piers, which it may be proper to be acquainted with, we shall proceed in that investigation.

"The weight of the pier in that case will be as the rectangle under its height and thickness, expressing the weight of arch and pier by the cubic feet of stone. The pier indeed will be somewhat more; for the sterlings, or breakwaters, at each end, will add something to its stability; and this will be still farther increased in proportion to the horizontal push, if the whole bridge be wider at the foundation than at top, as is very common. Excluding these collateral advantages, we shall consider the whole as rectangular, and then the stability may be found in the longitudinal section. We have already $b = \dfrac{h\,t}{\frac{1}{2}\,p + \frac{3}{4}\,a}$, and in the case of a parallelogram $\frac{1}{2}\,p = \frac{1}{2}\,b\,(h + c)$, c being the height from springing to the roadway. By substitution, there arises $\frac{1}{2}\,b^2\,(h + c) + \frac{3}{4}\,a\,b = h\,t$; and by resolving this quadratic equation,

we have $b = \sqrt{\dfrac{2\,h\,t}{h + c} + \left(\dfrac{3\,a}{4\,(h + c)}\right)} - \dfrac{3\,a}{4\,(h + c)}$

or thus, $b = \dfrac{\sqrt{2\,(h + c)\,h\,t + \frac{3}{4}\,a\,|^2} - \frac{3}{4}\,a}{h + c}$, as a formula

for the thickness of solid piers to support equilibrated arches; and it must be observed, that if the arch be understood to act otherwise than at three-fourths the thickness of the pier, this co-efficient may be altered accordingly.

"When the arch is a segment less than a semicircle, a greater thickness of pier becomes necessary. For, the span continuing the same, we must either make the arch a part of a circle of greater radius, which would increase the horizontal thrust, or we must, in order to obviate that, diminish the thickness at the crown. In either case the weight of the arch is diminished, and with it the assistance which it gives to the stability of the pier.

"There is an interesting subject of inquiry, which might not be unappropriately noticed here; we mean the lowest versed sine that can be used for arches in proportion to the span. We conceive this, however, as in a great measure a practical question. We have already given some idea of the greatest possible arch of stone, or brick; a segment of that circle may, of course, be employed in any situation, but the piers (if the arch be of considerable span and height to the springing) must be made very great. Indeed, the investigation depends intimately on the thickness of piers. We ought to know the dimensions of the largest pier that can be trusted, and this, we conceive, depends chiefly on the care of the mason; for stone, and especially cement, is a compressible substance; and when an arch is very flat, a very small yielding at the springing produces an enormous depression at the crown, insomuch that there may be reason to dread, lest the arch pass down below the horizontal line, and fall to pieces before the stability of the abutments can be acted upon. A compression in the joints is equivalent to a yielding at the abutments, and appears equally difficult of remedy.

"In great horizontal thrusts, where the segment is flat, the immersion of the pier in water comes to have an important effect. On the weight of the pier, in those cases, the stability chiefly depends, and a deduction from that of two-fifths must be compensated by enlarging the thickness.

"But, indeed, the immersion of the pier, if it be very tall, that is, if the depth of water be great in proportion to the span, will demand attention, although the arch should not be very flat. In such a case, the stability arising from the pier is often as great as that which is derived from the weight of the arch. It can seldom be greater, and consequently can seldom require, an addition of more than one-fifth of that breadth, which would be sufficient were there no immersion.

"But although the total immersion, even of a lofty pier, will seldom require any great alteration in the thickness, there is yet another circumstance which well deserves attention. Bridges are often built, especially in a tideway, with the arches springing below the high waters; we have in that case a diminution from the weight of the arch itself; but unless the keystone be under water, the horizontal thrust is unchanged; we must, accordingly, in our calculation, make the same diminution for that part of the arch which is thus immersed, as we did in the above example for the piers. The result will oblige us still more to increase the thickness of pier.

"On the whole, we may conclude from this investigation respecting the piers, that the increase of breadth which may be, and usually is, given to the pier, is of much less importance, on account of the weight that is thereby gained, than by its increasing the length of that arm of the lever, whereby the weight of the whole resists the effect of the horizontal thrust oversetting it.

"Instead, therefore, of building up the pier with perpendicular sides, we should think it more advisable to begin the foundation of the pier on a base much wider than usual, and from thence, by regular recesses, or otherwise, gradually to diminish it, until, at the springing of the arch, it does not exceed the depth of the two arch-stones, while the outline of the pier may be a curve of any shape that is most pleasing. Many advantages would, in our opinion, be obtained by this construction: the water-way will be enlarged; the pier equally strong; the stability equally great, nay, much greater than usual; and the chance of the foundations being hurt in floods will be greatly diminished; and all this with a smaller quantity of materials."

It is manifest, that before an arch of equilibration can be destroyed, the pressure applied must be so great as to overcome the resistance offered by the friction of the adjoining voussoirs, or the adhesive power of the cements; and be it remembered, the greater the pressure, the greater also is the friction. We give the following as a method of discovering the extent of license allowed in practice, on account of this quality in the materials employed.

To find the quantity of friction in individual instances,— Place the stone to be used upon a platform of the same material, and raise up one end of the platform, until the least additional elevation would cause the stone to slide down, and measure the angle of elevation so found.

Now the effect of friction is this, that instead of being compelled to place the joints of the voussoirs in the position assigned them by theory, we may place them in any position on one side of it, provided the joints fall within an angle from their theoretical position, not greater than the angle of elevation, determined as above; or if the joints of the voussoirs are maintained in their original position, we may allow a proportionate variation in their weight. On this account very great latitude is allowed in construction, for we may depart very far from the rules laid down from theory, before we can endanger the stability of the edifice.

Dr. Robison is of opinion, that the voussoirs may be considered as a solid mass, and that the principal object to be attended to, is that the arch should be made so flat, as to admit the same straight line being drawn in such a manner as to pass through some point in every voussoir on either side of the keystone, and where this is impracticable, he recommends that the straight line should be carried through as many arch-stones as possible, and that the arch should be carefully loaded at the intersection of such lines, considering each number of voussoirs passed through by one line as a separate block of stone. Generally, he supposes, that the pressure at the crown, is communicated in a straight line through as many stones as one straight line will pass through. All suggestions, however, on this subject, must be attended with considerable doubt and difficulty, as we are almost entirely ignorant of the method by which the communication and distribution of pressure is regulated, and even, in many cases, of the nature of the materials employed.

In accordance with the intention expressed by us in our article on Bridges, we now proceed to give a description of the principal stone bridges erected over the Thames, commencing with Westminster, as being the oldest. The first stone for that bridge having been laid on January the 29th, 1739, by the Earl of Pembroke, and the bridge itself being entirely completed on the 10th of November, 1750.

Westminster Bridge was built according to the designs, and under the superintendence of, a Swiss architect, named Labeyle, who, in its construction, adopted the practice of forming the foundations by means of caissons, instead of driving piles into the ground, or making use of coffer-dams, according to the general custom. This he effected in the following manner:—Large timber cases, consisting of a strong platform, or raft, surrounded by sides, were made water-tight, and floated on the surface of the Thames to such places as the piers of the intended bridge were eventually to occupy. In these, when firmly moored in proper position, the masonry of the piers was commenced: the caissons gradually sinking in the water as the masonry advanced, until at length they finally settled on the bed of the river; the sides of the caissons were then removed, to be used elsewhere, and the piers, which were built of Portland stone in blocks, each of which was at least a ton in weight, and many of them weighing as much as five tons, were carried up to the springing of the arches. These blocks of stone were cemented together with Dutch tarras, besides being connected with each other by iron cramps fastened with lead.

The building of this bridge occupied nearly twelve years, owing to the plan that had been adopted in laying the foundation; in consequence of which, one of the piers sunk so much, as seriously to endanger the stability of the structure, and it was found necessary to put another in its place; this circumstance greatly enhanced the cost of construction, and the various sums expended amounted to £389,500. It appears that materials of this bridge, to the value of £40,000, are constantly under water. The caisson on which the first pier was erected, contained 150 loads of timber, on which were laid 3,000 cubic feet, or nearly three tons of solid stone.

Westminster Bridge is 1,220 feet long, and is 44 feet wide, including the foot-path for passengers on either side of the carriage-way; it consists of 13 large, and two small arches, 14 piers, and two abutments. The arches spring at about 2 feet above low-water mark, they are all semi-circular. The centre arch is 76 feet span, and the others decrease on either side by 4 feet, so that the arches near the banks of the river are only 52 feet span. There are, besides, the two small arches each of 25 feet span.

The piers are 70 feet in length, and terminate in cut-waters, pointing up and down the stream. Those which support the centre arch are each 17 feet wide, and every successive pier is diminished a foot in breadth, so as to leave a water-way in the clear of 870 feet.

There was formerly a handsome stone balustrade, which formed the parapet of the bridge on either side, and over every pier there was a bay or recess, covered in with a kind of half cupola; while over the central arch, a rectangular space increased the width of the bridge by means of a projection towards the water.

The soffits of the different arches in this bridge, were carefully turned in Portland-stone. Over this, another arch was formed of Purbick-stone, well bonded with the preceding, and so arranged as to make the thickness of the double arch about the haunches four times that at the crown. The spandrels were constructed with barrel and intermediate arches, so as to maintain the edifice in equilibrio.

When Old London Bridge was taken down, and a more uninterrupted outfall was thus afforded to the stream, the bed of the Thames became considerably deepened, and the foundations of the different bridges which had been previously constructed, were thereby more or less affected. Westminster Bridge suffered particularly from that cause; for, owing to the very insecure substructure on which it was founded, its piers have been gradually giving way for years; and, in consequence of the inequality of yielding which has taken place, the entire bridge is now in a deplorably dilapidated condition. It has been deemed absolutely necessary to prop up several of the arches by centerings, to remove the weight over others, and in order to prevent a too manifest appearance of the unsightly breaks which have taken place in the roadway, the stone balustrade has been replaced by a temporary wooden fence or parapet.——To our thinking, the repairs which it has lately undergone, were effected in a most injudicious manner. In the first place, the system of propping up some of the arches, and allowing others to sink freely, was highly prejudicial to the stability of the bridge; and indeed one of the arches was only partially supported, so that the remaining portion separated from it, and sunk several inches, to the imminent peril both of its real and apparent efficiency. Again, the uselessness of facing the piers with new stone, at a time when the entire demolition of the structure became inevitable, must be evident to every one who will give the subject but a passing consideration.

As, however, this bridge is to be taken down very shortly, and a handsome modern structure will ere long supply its place, we do not think it necessary to say more on this subject at the present time.

Next in point of date among the stone bridges of the Thames, is that of Blackfriars, which was commenced in the year 1760, and finished in 1770, by Robert Mylne, a Scotch engineer, who had just before returned from Rome, where he had been pursuing his studies, and where he had earned a well-deserved reputation; having received a silver medal from the Roman Academy, which he deposited, together with several coins of George the Second, in the foundations of the bridge.

Blackfriars Bridge is about 1,000 feet in length, and about 43 feet wide, including a carriage-way of 28 feet, and two raised footpaths for pedestrians, each 7 feet in width; it is built of nine nearly semi-elliptical arches, of which the centre one is 100 feet, and the others decrease in span, as they are placed nearer the banks of the river, being respectively 98, 93, 83, and 70 feet, by which it will be seen that there is a water-way of 788 feet in the clear. The roadway is a uniform curve, being the segment of a very large circle.

The architecture of this bridge is exceedingly beautiful, and great taste is displayed in the design; the bays over each of the piers being supported by Ionic columns, which give a light and graceful character to this really handsome edifice; and it is to be regretted, that the materials of which it is composed are of so perishable a nature. In consequence of the curved roadway, the entablature of the columns is not made horizontal; and the consequent inequality in the height of the columns, is a marked defect in an æsthetic point of view. The parapets of this bridge are formed by a very handsome stone balustrade, 4 feet 10 inches in height; so that, while the security of persons passing over the bridge is amply assured, the view both up and down the river is uninterrupted. The expense of constructing Blackfriars Bridge amounted to £152,840.

The plan of forming the foundations by means of caissons, was unfortunately again resorted to in this case, and although short piles were driven into the bed of the river on which the bottoms of the caissons were made to rest, still the scouring process to which the channel of the Thames has been subjected of late years, has seriously affected the stability of the piers, and the change which has consequently taken place in the form of some of the arches, plainly point out the necessity of constructing a new bridge for this reach of the river at no very distant period.

Waterloo Bridge is one of the finest stone bridges constructed over the Thames; its bold, solid style of architecture being admirably suited to the character of a bridge over a large and important river, where massiveness and strength, combined with taste in design, have been judiciously and pleasingly combined; and when to these considerations are added the circumstance of its having a roadway perfectly level throughout, we may safely come to the conclusion, that it is one of the most successful specimens of bridge-building which has ever been produced. The celebrated Canova was loud in its praises, and extolled it as the *beau-ideal* of such constructions.

It was built by the late eminent engineer Rennie, who submitted two plans, one with seven arches, and the other nine; the latter was adopted, and the first stone of the new structure was laid in the October of 1811. The foundations he formed by means of coffer-dams, composed of three rows of piles one within the other, at a distance of about 3½ feet between the rows; the intermediate spaces having been carefully filled in with well-rammed clay. The water was then pumped out of the coffer-dam, and piles a foot square, and about 20 feet long, were driven into the bed of the river. A framework of timber was then constructed on the top of those piles, and the spaces between the pile-heads, to a depth of about a foot and a half, were filled in with stones tightly packed, and well grouted with liquid mortar. A floor of beech-planking, six inches in thickness, was bolted to the timber frame-work, on which the masonry of the piers and abutments was then commenced.

The entire surface-work of this bridge was built of Cornish granite, and the interior consists principally of Craigleith sandstone, well bonded, and cemented by a grouting of mortar. The spandrels of the arches were left hollow, to avoid an undue loading of the haunches, with the exception of six transverse brick-walls, for the purpose of supporting the roadway.

All the arches of the bridge are the same—semi-elliptical in form, 120 feet in span, and having a rise or versine of 35 feet. This allows a clear waterway of 1,080 feet. The piers are 87 feet long, from the extremity of one cut-water to another; they are 30 feet in width at the foundations, and diminish to 20 feet at the springing of the arches. Over each pier there is a rectangular recess, which is supported by Doric pillars, these, together with an open stone balustrade, give a certain degree of lightness to the edifice, without interfering with its characteristic solidity.

The entire length of Waterloo Bridge, including its approaches, which are built on land-arches, at either side of the river, is 2,456 feet.

This bridge took only six years to construct; and it was so carefully put together, every stone having been accurately put into its place, and so well driven home, that on removing the centres, the arches did not sink more than an inch and a half at the crown; which is truly wonderful, when their immense span is taken into consideration.

Waterloo Bridge was built by a Joint-Stock Company, empowered by act of Parliament to raise a million of money; to pay off which, and reimburse its proprietors, a small toll is levied from passengers; and now that the South Western Railway is completed as far as the Waterloo-station, the traffic over the bridge, and consequently the returns derived from the tolls, have been considerably augmented.

London Bridge was built somewhat to the west of the site formerly occupied by Old London Bridge, an antiquated stone structure, that was erected about the beginning of the 13th century, by Peter of Colechurch, who combined the professions of architect and priest: he died in the year 1205, and was buried in a crypt within the centre pier of the old bridge, over which there was a chapel dedicated to St. Thomas à Becket.

The contractors for the building of the new bridge, Messrs. Jolliffe and Bankes, under the superintendence of Mr. (now Sir John) Rennie, the engineer, drove the first pile of a coffer-dam for the south pier, on the 15th of March, 1824.

The general form of the dam was elliptical. Three rows of piles shod with iron, and many of them measuring between 80 and 90 feet, were driven into the ground, and after being bolted together by means of walings, the spaces between them were puddled with clay, &c.; wooden stays or props were also placed between the different rows of piles and the interior space of the dam, strongly truss-framed between longitudinal beams. This coffer-dam having been completed, the first stone of the new bridge was laid by the then Lord Mayor of London, in the presence of H. R. H. the Duke of York, on the 15th of June, 1825.

Piles of beech-wood were driven into the natural bed of the river, consisting of stiff blue clay, to the depth of about 20 feet; two rows of horizontal sleepers, about a foot square, were laid on the tops of those piles, and these again were covered by a planking of beech, 6 inches in thickness; and on this flooring the foundations of masonry were laid. The same system was adopted for all the piers and abutments.

The construction of centering for the arches was the next step in this great undertaking. Each centre was composed of ten frames, joined together on the principle of the diagonal truss—each frame rested at either end on a pile driven into the river. The ten frames were then boarded over with planks placed within 2 or 3 inches of each other. In consequence of a difference in size in the arches, it was necessary to have four sets of centres.

On these centres the arches were turned in the ordinary manner, and in the spandrels hance-walls were built, longitudinally, so as to oppose the thrust of the arches without overloading the haunches. On the top of those walls heavy blocks of stone were bedded, and on these were laid stone landings, upon which was placed a layer of tarras, and over that again, the puddling, on which the roadway was formed. The first arch was keyed in on the 4th of August, 1827, and the last on the 19th of November, 1828.

The approaches on either side of the bridge were carried on arches over some of the streets running along the banks of the river. The arch over Thames-street, in particular, is worthy of attention, being very flat, having been constructed over the roadway and both the footpaths of Thames-street, and the centering for it had to be so made as to leave an uninterrupted passage for vehicles and pedestrians; it was entirely supported by struts ranged along the junction, between the carriage-way and footpaths, and the abutments of the arch; on these the wedges were placed upon which the centering was made to rest.

The only alteration in the original plan of Mr. John Rennie, the engineer who designed the work, was the addition of 6 feet to the roadway, and an increased height of 2 feet in the abutment arches. The alteration in the width of the roadway was loudly insisted on by the public; and the government ordered that the additional cost it would necessitate, should be met by a public grant to the amount of £42,000. The additional height in the side arches was proposed by the present Sir John Rennie, on whom the execution of the work had devolved on the demise of his father. This great undertaking was entirely completed on the last day of July, 1831, after having been about seven years and a-half in the course of construction.

London Bridge is composed of five semi-elliptical arches, four piers, and two abutments. The centre arch is 152 feet span, having a rise of 29 feet 6 inches above high-water mark. The two arches next to this are each 140 feet in span, and rise 27 feet 6 inches. The two abutment arches are 130 feet in span, and rise 24 feet 6 inches. The two piers which support the centre arch are each 24 feet wide, and the others 22 feet in width.

The line of roadway, which is the segment of a great circle, the rise being only 1 in 132, is marked externally by a modillion cornice, over which there is a close parapet wall in place of the open balustrade which we have mentioned connected with the other three stone bridges.

The abutments are each 73 feet at the base. On either side of these are two straight flights of steps, 22 feet in width.

The entire length of the bridge, from the extremities of the abutments, is 928 feet; and the clear water-way is 690 feet. The carriage-way is 35 feet wide, and each of the footpaths 9 feet.

This admirable bridge was built of the best Aberdeen, Penryn, and Heytor granite; and the quantity of stone used in its construction amounted to 120,000 tons. In addition to this, many of the arches forming the approaches were built of brick. The cost of construction for the bridge itself was but little over half a million of money; but the expense of making new approaches, purchase of land for the same, and cutting through valuable and important premises, increased the expense considerably; and the various sums expended on the new bridge, and the different improvements it rendered necessary, came to nearly two millions sterling; to which amount the government, however, contributed to a considerable extent.

London Bridge was opened to the public on the 1st of August, 1831, by King William the Fourth, who proceeded in state by water, to be present at the inauguration ceremony, attended by the most distinguished personages connected with his court; and the king took the opportunity of complimenting the citizens of London on the "skill and talent" which they had displayed in "many magnificent improvements," and especially in the successful accomplishment of that splendid undertaking. The day's festivity was concluded by a princely banquet, which was served up on London Bridge; and that beautiful erection, admirable in design—simple in appearance—but substantially useful in its character, became thenceforward public property, and was freely thrown open, without toll or restriction, for the use and benefit of the entire nation.

Skew Bridges may fairly come under the head of Stone

Bridge; for though they are frequently built of brick and other materials, the vast majority of such constructions are either formed of stone, or stone and brick combined.

Oblique, or Skew bridges, have been introduced contemporaneously with railways; for few bridges of the kind were constructed anterior to that time. We hear, indeed, of one having been thrown over the river Mugone, at Florence, so early as the year 1550; but the true principles on which oblique bridges depended were not previously known or studied, as their application to general purposes was rarely, if ever, absolutely called for, until the plan of rapid locomotion, which the system of railways gave rise to, made their use constant, and in many cases indispensable.

In the construction of oblique bridges, the main object to be kept in view is to bring the thrust of the arch into such a position as will enable the abutments, or piers, properly to counteract it; and the most effective way of so doing, and at the same time the most simple, is found to be by making the direction of the courses at right angles to the face of the bridge.

There have been various methods suggested for building these bridges; but the one most commonly adopted, is to form the arch by regular spiral courses, all parallel to one another, and so arranged, that any section taken at right angles to the axis of the cylindrical segment which constitutes the arch, shall exhibit the coursing-joints tending in a radial direction to the centre of the cylinder at the point of section. All the voussoirs are rectangular in plan, both on the extrados and intrados, with the exception of those on the faces of the bridge, because a spiral line, touching the outer edge of both abutments, would form a curve of contrary flexure, falling partly within and partly without the line bounding the arch. In this case, the face-line will evidently not be parallel to the heading-joints of the voussoirs, which, therefore, will be of a constantly varying shape and size on the faces of the bridge. Again; it is important to remark, that in this particular system of construction, the joints of the voussoirs are not, properly speaking, straight lines on the elevation of the arch, but segments, whose chords should all tend to a common centre, which, in every case, must be more or less below the axis of the cylinder, according to the angle of the skew bridge.

One of the best works on the subject of skew bridges, was written by Buck, wherein formulæ are given, from which all the dimensions of skew arches of every kind may be arrived at with mathematical accuracy, and the principles of their construction are clearly and correctly explained. Nicholson published two admirable works on this important department of bridge-building—one in 1828, entitled, "A Practical Treatise on Masonry and Stone-cutting;" and the other in 1839, called, "A Treatise on the Oblique Arch." To him we are indebted for the first sound exposition of the principles on which such constructions are founded; and from the practical bearing of this, as of all his works, it was of the greatest use in presenting the subject to men's minds in a correct and intelligible point of view, and setting it forth in its proper light.

The method of forming oblique arches, as above explained and treated of by Buck and Nicholson, supposes the arch to be a segment of a circle on the square section. It is not, however, necessary that such should be the case; the form of the arch may be elliptical on the square section, in which case the elevation is a much flatter ellipse, according to the amount of skew; as it is clear that the minor semi-axis is constant, while the major semi-axis will increase with the skew; and this arch may be again modified by making the joints of the voussoirs perpendicular to the radius of curvature on the square section, instead of making them tend to the axis of the cylindrical segment.

Many changes of this kind have been recommended and tried, with varying success, by Messrs. Hart, Adie, Roebuck, and several others.

Stone Columns, such columns as are constructed of stone; in which, the fewer the joints, the better the appearance. If columns are necessarily composed of more than one piece, from the difficulty of procuring stones of sufficient magnitude, they ought to consist of three, five, or some odd number; more especially if the joints be few in number, than when they are many.

In columns constructed of several pieces, a mould must be made for every joint; and in setting the pieces, a sheet of thin milled lead, well bedded in white-lead, ought to be inserted between the joints, so as to come within about three-quarters of an inch of the convex surface of the column.

In the act of building, the diminishing rule ought to be applied to every course as it is set; and when the whole column is completed to its height, it ought to be tried again, and all the inequalities in the height reduced to the regular curve; for it is hardly possible, even though constructed by the best workmen, that some irregularities should not occur: and, at the same time, the circularity, or roundness, of the column ought to be attended to.

The most accurate method of fluting columns is, to cut the flutes after the columns are built, and brought to the curve; but in performing this, great care ought to be taken to prevent the chipping of the stone at the joints; which is best avoided by working each adjoining stone, or piece, from the joint, at least so far as to be out of danger of splitting the part of the stone next to it.

Stone Stairs, those constructed of stone. When stone stairs are supported by a wall at both ends, nothing difficult can occur in the construction; in these the inner ends of the steps may either terminate in a solid newel, or be tailed into a wall surrounding an open newel. Where elegance is not required, and where the newel does not exceed two feet six inches, the ends of the steps may be conveniently supported by a solid pillar; but when the newel is thicker, a thin wall surrounding it would be cheaper.

In the stairs of a basement story, where there are geometrical stairs above, the steps next to the newel are generally supported upon a dwarf wall.

Stone geometrical stairs have the outer end fixed in the wall, and one of the edges of every step supported by the edge of the step below, and constructed with joggled joints, so that they cannot descend in the inclined direction of the plane, nor yet in a vertical direction; the sally of every joint forms an exterior obtuse angle on the lower part of the upper step, called *a back rebate*, and that on the upper part of the lower step, of course an interior one, and the joint formed of these sallies, is called *a joggle*, which may be level from the face of the risers, to about one inch within the joint. Thus is the plane of the tread of each step continued one inch within the surface of each riser, and the lower part of the joint is a narrow surface, perpendicular to the inclined direction, or soffit, of the stair at the end next to the newel.

In stairs constructed of most kinds of stone, the thickness of every step at the thinnest place of the end next to the newel, need not exceed two inches for steps of four feet in length, measuring from the interior angle of every step perpendicular to the rake. The thickness of steps at the interior angle should be proportioned to the length of the step: but allowing the thickness of the steps at each interior angle to be sufficient at two inches, the thickness of steps at the interior angles will be in inches half the length of the steps in feet: thus, a step of five feet long would be two inches and a half at that place.

The stone platforms of geometrical stairs, viz., the landings, half-paces, and quarter-paces, are constructed of one, two, or several stones, as they can be procured. When the platform consists of two or more stones, the first platform stone is laid upon the last step that is set, and one end is tailed in and wedged into the wall; the next platform stone is joggled, or rebated, into one set, and the end also fixed into the wall, as that and the preceding steps are; and thus with every stone in succession, till the platform is completed. If there is occasion for another flight of steps, the last stone of the platform becomes a spring stone for the next step, and the joint is to be joggled, as well as those of the succeeding steps, in the same manner as in the first flight. Geometrical stairs, executed in stone, depend upon the following principle: that everybody must, at least, be supported by three points placed out of a straight line, and consequently, if two edges of one body in different directions be secured to another, the two bodies will be immovable in respect to each other. This last is the case in a geometrical stair: one end of a stair stone is always tailed into the wall, and one edge either rests on the ground itself, or on the edge of the preceding stair stone, whether it be a plat or step. The stones of a platform are generally of the same thickness as those forming the steps.

Stone Walls, such walls as are constructed of stone.

The modern methods of constructing stone walls, with a description of the materials employed, have already been given under the head Masonry; we shall, therefore, confine this article to the construction of walls used by the ancient Greeks and Romans.

Vitruvius has left us an account of the construction of the walls of the ancients as follows: "The sorts of walls are the *reticulated*, (*Figure* 1,) and the ancient, which is called *the uncertain*, (*Figure* 2.) Of these, the reticulated is the handsomest, but the joints are so ordered, that all the parts of the courses have an infirm position; whereas, in the uncertain, the materials rest firmly one upon the other, and are interwoven together; so that they are much stronger than the reticulated, though not so handsome. Both sorts are formed of very small pieces, that the walls, being saturated with mortar, may endure the longer; for the stones, being of a porous and spongy nature, absorb the moisture from the mortar; and when there is an abundance of mortar, the wall, having more humidity, will not so soon decay, but will, on that account, be rendered more durable; for as soon as the humidity is extracted from the mortar by the suction of the stones, then the lime and sand separating, the cement is dissolved, and, the mortar, no longer uniting the materials, the walls soon become ruinous. This may be observed in some tombs near the city, which are built with marble, or hewn stone, and the internal parts rammed with rubble stones; the mortar being by length of time drained of its humidity by the suction of the stones, and the union of the joints being dissolved, they separate and fall to ruin.

"To avoid this error, the middle space (*Figure* 2) must be strengthened with abutments of the red hewn-stone, or bricks, or common flints, built in walls two feet thick, and bound to the front with cramps of iron fixed with lead; for the work being thus built in a regular manner, and not laid in promiscuous heaps, will remain without defect; and being, by the orderly arrangement of the courses and joints, firmly united and bound together, it will not be liable to fractures, nor will the abutments suffer it to fall to decay. For this reason, the walls of the Greeks are not to be despised; for though they do not use smooth or polished materials, yet where they discontinue the square stones, they lay the flints, or common hard stones, that they use, in the same manner as bricks are generally laid, bonding the courses together with alternate joints, and thus making their works strong and durable.

"These walls they build in two manners; one is called *isodomum*, (*Figure* 3,) and the other *pseudisodomum*, (*Figure* 4.) Isodomum is when all the courses are of an equal thickness; and pseudisodomum when they are unequal. Both these sorts are firm; first, because the stones themselves are of a compact and solid nature, and do not absorb the moisture from the mortar, but preserve its humidity to a great age; and, secondly, being situated in regular and level courses, the mortar is prevented from falling, and, the whole thickness of the wall being united, it endures perpetually.

"Another sort is that which they call *emplecton*, (*Figure* 5 and 6,) which is also used by our villagers. The faces of the stones, in this kind, are smooth; the rest is left as it grows in the quarry, being secured with alternate joints and mortar; but our artificers, quickly raising a shell, which serves for the faces of the wall, fill the middle with rubble and mortar; the walls, therefore, consist of three coats, two being the faces, and one the rubble core in the middle, (*Figure* 5 and 6.) But the Greeks do not build in that manner; they not only build the facing courses regularly, but also use alternate joints throughout the whole thickness, not ramming the middle with rubble, but building it the same as the face, and of one united coat they construct the wall; besides this, they dispose single pieces, A, which they call *diatonos*, in the thickness of the wall, extending from one face to the other, which bind and exceedingly strengthen the walls. Those, therefore, who would build works of long duration, must attend to these rules, and make use of such methods of building; for the smooth polish, and beautiful appearance of the stones, will not prevent the wall from being ruined by age."

STOOTHINGS, a term used in the north of England, and perhaps in some parts of the south of Scotland, for battening to walls.

STORY-POSTS, upright timbers, disposed in a story of a building, for supporting the superincumbent part of the exterior wall, by means of a beam over them. They are chiefly used in sheds and workshops. Story-posts should have a solid wall below, or they should stand upon a strong wooden sill, or upon inverted arches, or upon large stones, with their ends let into sockets. When the distance between story-posts is considerable, they should have two braces on either side; and these should be resisted at the top by a straining-beam, and at the bottom by joggles cut in the posts themselves; the upper surface of the straining-beam should also coincide with the lower surface of the upper beam, or bressummer. In cases where the distance between the story-posts is still greater than above supposed, not only braces and straining-beams are to be employed, but every interval should be arched upon the top of the bressummer.

Story-Posts, or Prick-Posts, as they are called in old books on architecture, are used in wooden buildings, between the stories, to support the floors.

Story-Rod, a measure used in staircasing, in length equal to the height of the story; or from the upper surface of the boards of one floor to the under surface of those of the next; it is divided into as many equal parts as there are to be risers in the stair, for the more accurately carrying up the steps.

STOUP, a stone bason, frequently found in the porches and at the entrances of our old churches, and employed to contain holy water, with which the worshippers sprinkled themselves upon entering the church. This was a relic of a very ancient practice observed in the early church, and the holy-water stoup seems to have been a substitute for the foun-

tain which existed in the atria of the early churches. The stoup, or *benatura*, in our old churches, is of small size, usually situated in an arched recess, and of similar form to the piscina, which, however, has its place by the side of an altar, and was used for a different purpose. Many examples still exist of various forms, and of different degrees of ornamentation.

STRAIGHT-JOINTED FLOOR, a floor in which the joints are continued from one end of the apartments to the other; and where the heading-joints are not in the same straight line, as in folded floors.

STRAINING-PIECE, or STRUTTING-PIECE, a piece of timber acting in opposition to two equal and opposite forces at its extremities, for the purpose of preventing their nearer approach towards each other. Principal rafters, camber-beams, hip-and-valley rafters, collar-beams, or straining-beams, auxiliary rafters, or principal braces, struts, studs, and story-posts, are all of this description. Straining-pieces are distinguished as beams or sills by the term *beam* or *sill* immediately following the word *straining;* as *straining-beams*, *straining-braces*, or *straining-sills*.

STRAINING-SILL, or STRUTTING-SILL, a beam that is both a straining-piece and a sill.

STRAP, (from the Dutch, *stroppe*,) in carpentry, an iron plate placed across the junction of two or more timbers, either branched out or straight, as may be found requisite, and each branch bolted, or keyed, with one or more bolts, or keys, through each of the timbers, for the purpose of securing them together. When one piece of timber stands upon another, so as to form two right angles on the same side of the standing-piece, the strap is most frequently made to go round the cross-piece, and to embrace the two opposite sides of the standing-piece, which may be bolted, or keyed, with one or two bolts passing through the tails of the strap. When it is inconvenient to make a strap embrace both opposite sides of the timbers, it is necessary that a branched strap should be placed upon each side, and every timber must be bolted to the opposite branches.

When two pieces of timber press upon each other, and one of them extends on both sides of the joint, a strap is unnecessary: but where neither extends beyond the joint, it is necessary to have one. All ties having shoulders abutting against transverse pieces at the ends, whether the angle formed by the transverse pieces be right or oblique, should be strapped to those pieces.

STRATA, the layers of earth, sand, gravel, clay, chalk, stone, and other substances, which form the crust of the earth. A knowledge of geological strata is very necessary in all extensive building-operations.

STRENGTH OF MATERIALS, the force which any material is capable of resisting before it breaks, whether from pulling, compressing, squeezing, or from being twisted, or from bending by a force applied laterally.

As the laws of resistance are the same, whatever be the material employed, under the specific name of *Strength of Timber*, the reader will find ample satisfaction, at least as far as regards useful knowledge in its application to practical architecture.

STRENGTH OF TIMBER, the resistance that a bar, or beam, is capable of exerting against a superior power, before it breaks, whether the force be applied in its longitudinal or transverse direction, or by twisting. The theory of this subject, illustrated by various examples, will be found in the following Propositions :—

PROPOSITION I.—*The force which elastic strings, or fibrous bodies, &c. exert, when drawn or compressed in a direction of their length, is proportional to the increased or contracted space to which they are lengthened or shortened.*

As the extension or contraction of bodies, when drawn out or compressed by superior forces, depends entirely on the law of corpuscular attraction; and as this law has not yet been developed, it does not, therefore, come within the limits of demonstration: but from numerous experiments on different elastic bodies, it has been sufficiently proved, that when these bodies have been stretched by forces at each end, the additional lengthening was always as the force applied, except when near the point of breaking, where the force was something less than in that proportion; and when compressed by forces, this law has been found to hold equally, except where the compressing forces were enormous; in which case, the contracted spaces were less than the proportion of the force; the truth may, therefore, be looked upon as sufficiently established.

Remark.—Dr. Robert Hook was the first who attended to this subject, and assumed this law as a property of bodies.

PROPOSITION II.—*If a beam be supported at the two ends, and a force, or weight, applied to the middle of it, the deflection of the beam, or space through which it bends, will be as the force applied, nearly.*

This proposition may be determined from the law of elasticity and attraction, supposing them once established; but, perhaps it will be more easily determined by experiment; and the analogy is the same with regard to the deflection in this, as it is in the preceding Proposition, with respect to the increase or decrease of length; and it is found also in this, as in the extended state of the other, that when the beam is nearly upon the point of breaking, a less proportion of weight is required, than the space through which the beam descends. Therefore this Proposition may also be looked upon as sufficiently established.

PROPOSITION III.—*If a solid be supported by four forces, of which two and two are parallel: then, in each pair of parallel forces, one force is equal to the other, and its direction contrary.*

Plate I. *Figure* 3.—Let A B C D represent the section of a solid, supported in the plane of its section, in the parallel directions A G, C P, and A F, C S, by four forces, H, P, I, L, three of which may be weights going over the pulleys G, F, S. Join A C; then let the weight P be represented by the part C M, and complete the parallelogram C M N O; make A R equal to O C; produce G A to K; and complete the parallelogram A K R Q. The point C is now sustained by the three forces, C O, C N, C M, and the point A by the three forces A Q, A R, A K; and the forces A R and O C being equal, and opposite in the same straight line, they mutually balance each other. Now the triangles A K R and O N C are similar, and A R is equal to O C; therefore A K and O N are equal; that is, A K is equal to C M, as A Q is to C N; but A K and C M are the forces at H, as P and A Q and C N are the forces at I and L; therefore the forces at H and P are equal to each other, as are also the forces at I and L. Now, as the string C P is in a state of tension, and as any two of the three angles P C S, S C A, A C P, are greater than two right angles, the lines C S and C A are in a state of tension; and because A C is in a state of tension, A G and A F are so likewise; because any two of the three angles G A F, F A C, C A G, are greater than two right angles; therefore the forces in each pair of parallel lines, A G, C P, A F, and C S, act equal and contrary to each other.

Corollary.—If the body be a prism, and A B C D a section parallel to one of its faces; and if the directions of the forces be in the lines A B, B C, C D, D A, then the force at P, or the contrary force at H, is to the force L, or its contrary force I, as the breadth of the prism to the length; for as the triangles O N C and A D C are similar, O N : N C : : A D : D C.

Definition.—*Power* is the weight, or force, employed to break a beam.—*Momentum of Power*, *mechanical energy*, or *stress*, *upon a given section of a solid*, the force which a power has to produce fracture at that section, which forms the fulcrum of a lever acted upon by such power.

Corollary.—Hence the strain is as the momentum of power.

PROPOSITION IV.—*If, instead of the weights* I, L, H, *as in the last Proposition, the points* A *and* D, *Figure* 4, *be supported by two springs*, A G *and* D H, *in the direction* A B *and* D C, *parallel to the horizon, and by a prop* D F, *perpendicular to it; and if* A D *be divided into any two parts*, A E *and* E D, *then will* $P \cdot CD = ED \cdot f + EA \cdot f$; *that is, the momentum of power is equal to the sum of the momentum of tension and compression, where f is the tension of the upper spring, or the compression of the lower.*

For, by the *Corollary* of the last Proposition, $f : P :: CD : DA$; therefore $P \cdot CD = f \cdot DA$; but $ED \cdot f + EA \cdot f = AD \cdot f$; therefore $ED \cdot f + EA \cdot f = P \cdot CD$.

Corollary 1.—Hence, if a prismatic rectangular beam, A B C D, projecting from a wall, be loaded with a weight, P, sufficient to balance the resistance of the fibres at the place of fracture; there will be a certain line in that place, on which the beam will turn as on an axis, and all the fibres from that line to the upper surface will be extended in the ratio of their distances, whilst all those below will be compressed in the same ratio towards the lower surface.

Corollary 2.—Hence, if E be the quiescent axis, the forces of all the fibres in a state of tension will be equal to $EA \cdot f$; and those in a state of compression will be equal to $ED \cdot f$; their whole resistance, therefore, is equal to $EA \cdot f + ED \cdot f$, that is, equal to the weight, or power, P, multiplied by its distance, D C, from the wall, the momentum of power.

PROPOSITION V. *Figure* 5.—*If a beam be supported by the two ends*, A, B, *and a weight*, W, *be applied over the middle section*, C D; *then will the momentum of power occasioned by the weight*, W, *to overcome the resistance of the beam, be equal to half the weight*, W, *multiplied into half the length of the beam.*

For the beam is under the same circumstance as if it had been supported by three forces in parallel directions; and because the weight, W, is in the middle of the beam, each of the props must support half of it. Now the part D B may be considered as if acted upon by a power at B, equal to half the weight, W, drawing it upwards, while the other part, A C, is fixed in the same manner as if built in a wall; therefore, by the last Proposition, the force to balance the resistance made by the fibres at the section, C, will be equal to $\frac{W}{2} \times DB$.

Corollary 1.—Hence, if the weight, W, be given, the strain at C will be as the length, A B.

Corollary 2.—Hence it is also evident, that in beams of the same dimensions of breadth and depth, the strain by their own weight is as the square of the length; because the weight is as the length.

Corollary 3.—The greatest strain is where the weight is applied.

Corollary 4.—If there are two beams, having equal weights placed upon them, so as to divide them into segments of equal ratios, the strain in each will be as its length.

Corollary 5.—Hence the strain in a beam fixed in a wall, from any weight hung to its end, is equal to the strain in a beam of twice the length, with double the weight, supported at the ends.

PROPOSITION VI. *Figure* 6.—*If a beam*, A B, *be supported in four points*, A, B, C, D, *and a weight*, W, *appended to the middle of the part* C D *at* F, *it will carry twice as much as if it were only supported by the two middle points* C D.

For, suppose the beam cut through at the section E, then, by *Corollary* 5 of the last Proposition, the strain at C, from a weight at E, will be equal to the strain in a beam of double the length; therefore it will require the same weight to break the parts E C and E D, at C and D together, when cut at E, as it would when C D is whole, and supported at C and D only: therefore, to break all the three sections C, E, D, at once, it will require twice that weight.

PROPOSITION VII. *Figure* 7.—*If a weight*, W, *or any force, act perpendicular to the length of a beam, supported at the two extremities*, A *and* B, *the strain at the section*, C, *on which the force acts, will be equal to the rectangle of the two segments into the weights, divided by the length; that is, as* $\frac{AC \cdot CB \cdot W}{AB}$.

For, by the property of the lever, $AB : AC :: W :$ the force at $B. = \frac{AC \cdot W}{AB}$; but the strain at C, from a force acting at B, is as the distance and force applied; that is, $BC \cdot \frac{AC \cdot W}{AB} = \frac{AC \cdot CB \cdot W}{AB}$.

Corollary 1.—In beams of equal lengths, the strain at the section, C, is as the rectangle of the two segments and the weight.

Corollary 2.—In beams of equal lengths, having equal weights applied, the strain in each is as the rectangle of the two segments only.

Corollary 3.—If the force applied be in the middle, the strain will be as the square of the length.

Corollary 4.—The greatest strain of a beam is in the middle, because the greatest rectangle is there.

PROPOSITION VIII. *Figure* 8.—*The strain on any section*, D, *of a beam resting on two props*, A *and* B, *occasioned by a second force applied perpendicularly upon another section*, C, *is equal to the rectangle of the two extreme segments into the weight, divided by the length; that is*, $\frac{AC \cdot DB \cdot W}{AB}$, *equal to the strain at* D.

For, by Proposition VII., the strain at C is $\frac{AC \cdot CB \cdot W}{AB}$; but the strain at C is to that at D as B C to B D; therefore, $BC : BD :: \frac{AC \cdot CB \cdot W}{AB} : \frac{AC \cdot BD \cdot W}{AB}$ equal to the strain at D.

Corollary 1.—Hence, the strain at D, from a weight, W, placed at C, is equal to the strain at C, from the same weight, W, placed at D.

Corollary 2.—Hence, the strain of a beam at any section, from an equal weight placed upon any other section, is as the rectangle of the two exterior segments directly, and length reciprocally.

Corollary 3.—Hence, in the same beam, from the same weight, the strain at any section, D, by the weight at C, is as the rectangle of the two exterior segments.

PROPOSITION IX. *Figure* 9.—*If a weight be equally diffused throughout any part*, B C, *of a beam*, A D, *the strain at either end*, C, *of the diffused part, is to the strain at the same place, from the same weight being suspended there, as* A B + A C *to twice* A C.

Let the weight of the part B C be represented by W, and conceive W to be accumulated in its centre of gravity, E;

STRENGTH of TIMBER.

then, by the last Proposition, the strain at C from the weight W is $\frac{AB+\frac{1}{2}BC.CD.W}{AD}=\frac{2AB+BC.CD.W}{2AD}=\frac{(AB+AC.)CD.W}{2AB}$; and, by Proposition VII., the strain at C, supposing W to be suspended there, is $\frac{AC.CD.W}{AD}$.

Now, $\frac{(AB+AC.)CD.W}{2AD}:\frac{AC.CD.W}{AD}::AB+AC:2AC$.

Proposition X. *Figure* 8.—*The strain of a prismatic beam supported at the two ends,* A *and* B, *by its own weight at any section,* C, *is equal to the rectangle of the two segments into the weight of the beam, divided by twice its length; that is,* $\frac{AC.BC}{2AB}$.

Conceive the parts A C and C B of the beam to be accumulated in their centres of gravity, F and G. Let W equal the weight of the whole beam; the weight of the part A C will be $\frac{AC.W}{AB}$, and the weight of the part B C will be $\frac{BC.W}{AB}$. By Proposition VIII., the strain at C, from the weight of the part, A C, is $\frac{AF.CB}{AB}\times\frac{AC.W}{AB}=\frac{AF.CB.AC.W}{AB^2}$, and the strain at C, from the weight of the part B C, is $\frac{GB.AC}{AB}\times\frac{CB.W}{AB}=\frac{GB.AC.CB.W}{AB^2}$.

Therefore the whole strain at C will be

$$\frac{AF.CB.AC+GB.AC.CB}{AB^2}\times W=\frac{(AF+GB.)AC.CB.W}{AB^2}.$$

Now, $AF+GB=\frac{AB}{2}$; therefore, the whole strain by the whole weight, is $\frac{AC.BC.W}{2AB}$.

Corollary 1.—Hence, the strain of a beam at any point, C, from a weight suspended there, is double what it would be at the same point, C, from the same weight being uniformly distributed over it; because, by Proposition VII. the stress is $\frac{AB.BC.W}{AB}$, and by Proposition X. it is $\frac{AB.BC.W}{2AB}$.

Corollary 2.—Because, in the same beam, W and A B being given, the strain at any point, C, is as rectangle of the two segments A C and C B.

THE SAME BY FLUXIONS.

Let w = W, equal to the whole weight of a = A C, b = B C, l = A B, and x any indeterminate part, A P. Then the weight of $AP=\frac{wx}{l}$, and the fluxion of $\frac{wx}{l}=\frac{w\dot{x}}{l}$ equal to the weight acting at P. Then, by Proposition VIII., the strain at C, from a weight acting at P, is $\frac{bx}{l}\times\frac{w\dot{x}}{l}=\frac{bwx\dot{x}}{l^2}$; therefore, by taking the fluent, the strain at C, from the whole weight of A P is $\frac{bwx^2}{2l^2}$. So the strain at C, from the weight of B C, will be found to be $\frac{ab^2w}{l^2}$; therefore, the whole strain tending to break the beam at C is $\frac{ba^2w+ab^2w}{2l^2}$ $=\frac{\overline{a+b}\times abw}{2l^2}$; but $a+b=l$; therefore, $\frac{a+b\times abw}{2l^2}=\frac{abw}{2l}=\frac{AC\times CB\times W}{2AB}$

Proposition XI. *Figure* 10.—*If a prismatic beam,* A B, *be fixed in a wall at* A; *the strain at any section,* C D, *from its own weight will be as the square of the distance,* B C, *of that section from the extremity.*

The strain which the weight of the part B C occasions at the section C D, is the same as if the whole weight of B C were collected in its centre of gravity, F, and the length of the lever, C F.

Let W represent the whole weight of A B; then, because the beam is prismatic, the weight of the part B C will be $\frac{BC.W}{AB}$; therefore, by Proposition IV., *Corollary* 2, the strain at C is $CF\times\frac{BC.W}{AB}=\frac{BC}{2}\times\frac{BC.W}{AB}=\frac{BC^2.W}{2AB}$; but in the same beam, W and 2 A B are given quantities, consequently, the strain at the section C D is as BC^2.

Proposition XII. *Figure* 11.—*To determine the relative strength of a rectangular prismatic beam,* A B C D, *projecting horizontally from a wall, supposing the beam to be incompressible at the fulcrum.*

Let A B C D be considered as a longitudinal section, and let A B be the section of fracture; let A B C be considered as a bent lever, whose fulcrum is at B; A B, B C, the two arms; and P the power employed to overcome all the resistances in the section A B. Now, in the act of breaking, all the fibres in A B will be stretched, and this the more in the same ratio as they are more remote from the axis of fracture passing through B; and those at A will break first. Let f be a force just sufficient to destroy the cohesion of a fibre: also, let l equal the length, d equal the depth, b equal the breadth or horizontal dimension, and x equal any indeterminate distance from B; then, because the tension of any fibre is as its extension (by Proposition I.) and the extension as the distance of the fibre from the axis of fracture, $d:x::f:\frac{fx}{d}$ the force or tension of a fibre; therefore, the force of all the fibres in the breadth is, $\frac{fbx}{d}$; but the momentum of any force applied to a lever, is that force multiplied by its distance from the fulcrum, consequently, $\frac{fbx}{d}\times x=\frac{fbx^2}{d}$, the momentum of the fibres in the breadth; and the sum of all these momenta upon the lever x is the fluent of $\frac{fbx^2\dot{x}}{d}=\frac{fbx^3}{3d}$; and when $x=d$, $\frac{fbx^3}{3d}=\frac{fbd^2}{3}$; now, the momentum of the power is P l, therefore, $Pl=\frac{fbd^2}{3}=bd^2\times\frac{f}{3}$, or $P=\frac{bd^2}{l}\times\frac{f}{3}$.

THE SAME WITHOUT FLUXIONS.

The momentum of the fibres in the breadth is $\frac{fbx^2}{d}$ as above; but $\frac{bx^2}{a}$ is the section of a pyramid, having b and d for the dimensions of its base, and for its altitude a, at the distance x from the vertex; now, the sum of all the $\frac{b\,x^2}{a}$, in the altitude d of the pyramid, is equal to the whole pyramid; but every pyramid is one-third of a prism, having the same base and altitude, or it is equal to one-third of the base multiplied by its altitude, namely, $\frac{b\,d}{3} \times a$; that is, d times $\frac{b\,d}{3}$ are equal to the sum of as many times $\frac{b\,x^2}{d}$; consequently, the sum of all the $\frac{f\,b\,x^2}{d}$, or the whole momentum of resistance, is $\frac{f\,b\,d^2}{3}$, as above; therefore, $P\,l = \frac{f\,b\,d^2}{3} = b\,d^2$, or $P = \frac{f\,b\,d^2}{3\,l} = \frac{b\,d^2}{l} \times \frac{f}{3}$.

Corollary 1.—Because $P = \frac{b\,d^2}{l} \times \frac{f}{3}$, and $\frac{f}{3}$ is a given quantity, P is as $\frac{b\,d^2}{l}$; that is, the power is as the breadth and duplicate ratio of the depth directly, and length reciprocally.

Corollary 2.—Because $P\,l = b\,d^2 \times \frac{f}{3}$, and $\frac{f}{3}$ is a given quantity, $P\,l$ will be as $b\,d^2$; that is, the power, or weight, multiplied by the length, is as the breadth multiplied by the square of the depth.

Corollary 3.—In square timber, the power multiplied by the length is as the cube of the breadth or depth.

Corollary 4.—Because $P = \frac{b\,d^2}{l} \times \frac{f}{3}$, and $\frac{f}{3}$ are given, the force, or power, required to break similar prisms is as the square of their corresponding dimensions.

PROPOSITION XIII. *Figure* 11.—*To determine the relative strength of a prismatic rectangular beam, projecting horizontally from a wall, supposing it to turn round some intermediate axis, in the section of fracture.*

Let A B C D be a longitudinal section of the beam, parallel to two vertical sides; now it has been shown, by Proposition IV. *Corollary* 1, that here is a certain line passing through some point, E, on which the beam turns in the act of bending, or breaking: that all the fibres above this line are in a state of tension, while those below are in a state of compression; and that the compression or extension of any fibre is as its distance from that line; it also appears, that $P \cdot CB = AE \cdot f + EB \cdot f$; where f is the whole force of extension or compression. Let m equal the extension of a fibre in the upper part, at the instant of breaking; n equal the compression of a fibre in the lower surface at the same instant; and let b equal the breadth of the beam; $a = AE$, $e = EB$, $l = BC$, $x =$ any indeterminate part of A E, or a, from E towards A: then, since, by Proposition I. the force of a fibre is as the distance to which it is extended or compressed, $a : m :: x : \frac{m\,x}{a}$, the force of a fibre at the distance x; but the energy, or resistance, of this force, is as the length of the lever, x, upon which it acts; consequently, as $\frac{m\,x^2}{a}$, and the sum of all the resistances in the breadth, is $\frac{m\,b\,x^2}{a}$, the whole resistance of the extended fibres in x is the fluent of $\frac{m\,b\,x^2\,\dot{x}}{a} = \frac{m\,b\,x^3}{3\,a}$; and when $x = a$, then $\frac{m\,b\,x^3}{3\,a} = \frac{m\,b\,a^2}{3}$. In the same manner, it may be shown, that the sum of all the resistances of the compressed fibres is $\frac{n\,b\,e^2}{3}$, and, therefore, the whole sum of all the extended and compressed fibres is $\frac{m\,b\,a^2 + n\,b\,e^2}{3} = AE \cdot f + EB \cdot f = l\,P$.

Now, if the ratio of m to n be known, that of a to e will also be known; for $f\,a = \frac{m\,b\,a^2}{3}$, $f = \frac{m\,b\,a}{3}$, and $f\,e = \frac{n\,b\,e^2}{3}$. $f = \frac{n\,b\,e}{3}$, therefore $\frac{n\,b\,e}{3} = \frac{m\,b\,a}{3}$, or $n\,e = m\,a$, consequently, $n : m :: a : e$. Hence, it will be seen, that the distance of the axis of fracture depends on the nature of timber. Now, let $d = a + e$, the depth of the beam, and let a and e be equal to each other, then will m and n be also equal to each other; and $\frac{m\,b\,a^2 + n\,b\,e}{3} = \frac{m\,b\,d^2}{6} = \frac{m}{6} \times b\,d^2 = P\,l$, or $P = \frac{b\,d^2}{l} \times \frac{m}{6}$.

It will readily appear, that all the Corollaries in the preceding Propositions will equally flow from this; it may, nevertheless, be observed, that the relative strength of such beams as are equal rectangular prisms of homogeneous texture, upon supposition, is only one-half of what is expressed in the former.

The celebrated Galileo, who first undertook the discovery of the law of resistance, supposes that at the place of fracture the body breaks at once, so that the whole of the fibres resist with their ultimate force: a supposition that would be correct, were the matter of bodies of a homogeneous and unelastic texture.

Mariotte, an eminent French philosopher and mathematician, who first corrected the Galilean notion of equal resistances made by the fibres of a beam at the section of fracture, having observed that all bodies bend before they break, considered the fibres as so many bent springs, which never exert their utmost force till stretched to a certain distance. But the axis of fracture was still considered as in the convex side of the beam. Now, as it has been shown, that timber in a state of bending, or breaking, is both compressed and extended, it follows that this axis cannot be in the convex surface, but must have some indeterminate situation between the upper and lower superficies. To compare the three suppositions with each other: in the act of breaking, the resistance of a fibre, according to Galileo, is a constant force in the section of fracture; therefore, let f denote the force of a fibre, then its momentum will be $f\,x$, and the sum of all the $f\,x$ will be the fluent of $f\,x\,\dot{x} = \frac{f\,x^2}{2}$, and the sum of all the $\frac{f\,x^2}{2}$ in the breadth will be $\frac{f\,b\,x^2}{2}$; and when $x = d$, the depth, $\frac{f\,b\,x^2}{2} = \frac{f\,b\,d^2}{2}$, for the relative strength. Now, it has been shown in Proposition XII., which is that of Mariotte, that the relative strength is $\frac{f\,b\,d^2}{3}$, and by Proposition XIII., it is $\frac{f\,b\,d^2}{6}$, by substituting f for m; but $\frac{f\,b\,d^2}{2}$, $\frac{f\,b\,d^2}{3}$, and $\frac{f\,b\,d^2}{6}$, are to each other as 3, 2, 1; hence, the relative strength of beams, according to the system of Mariotte, is two-thirds of Galileo's; while, according to the supposition of the axis fracture being in the middle of the beam, the relative strength is only one-third of Galileo's, or half of Mariotte's.

It is worthy of notice, that, although the relative strength is very different on the three suppositions, yet in each it is as the breadth, duplicate ratio of the depth, and reciprocal ratio of the length. This relation is the most important; and, if exactly true, would answer every purpose: for, by having the weight that a piece of timber of any given dimensions will carry, that which a piece of timber of any other given dimensions would bear, might be ascertained, without paying any attention to the absolute strength.

A very commodious formula may be had from this analogy, as follows:—

Suppose a piece of timber, a foot in length and an inch square, would carry w pounds; let l be the length of any other piece of timber in feet, b the breadth, and d the depth in inches; and let w be the weight in pounds that these dimensions will carry; then $\mathrm{w} = \frac{b\, d^2\, w}{l}$, for, by this analogy, $\frac{1 \times 1^2}{1}$, or $1 : \frac{b\, d^2}{l} :: w : \mathrm{w}$; therefore, $\mathrm{w} = \frac{b\, d^2\, w}{l}$.

That is, the strength of any piece of timber is equal to the relative strength of a piece of timber a foot in length and an inch square, multiplied into the breadth and square of the depth, divided by the length.

Example.—Suppose a piece of timber a foot in length and an inch square, would carry 500 pounds, how much will a piece eight feet in length and five inches square carry? Here $w = 500$, $b = 5$, and $d = 5$; therefore,

$$\frac{b\, d^2\, w}{l} = \frac{5 \times 5^2 \times 500}{8} = 7812.5.$$

In pieces of timber of the same length, the relative strength, being as the breadth and square of the depth, differs but in a very small degree from that which actual experiment gives; but in order to show how far the practical carpenter may confide in the rule just found from the theory, we have two sets of experiments, made on oak timber, one by the celebrated French engineer Belidor, on a small scale, the other by M. De Buffon, much more extensive, with which the result found by rule may be compared. The pieces tried by Belidor were sound, evenly-grained oak, and tolerably well seasoned; and the relative strength resulting from the various dimensions tried, are exhibited in the following Table; where, it must be observed, the lengths are in the second vertical column, under L, on the left, and the other dimensions in the columns under the initials B and D. The weight required to break the beams is given in lbs. in the fifth column. Three pieces of each dimensions were tried, and the mean taken. The experiments were of two kinds; one set with the ends loose, the other with the ends firmly fixed.

In the following table—

No. 1 and 2 show the strength to be as the breadth.

No. 1 and 3, as the square of the depth.

No. 1 and 4, nearly as the reciprocal of the length.

No. 4 and 5, nearly as the breadth multiplied into the square of the depth.

No. 1 and 5, nearly as the breadth multiplied into the square of the depth, divided by the length.

The two lower numbers, 7 and 8, show the increase of strength derived from fastening the two ends. By comparing No. 1 with No. 7, and No. 4 with No. 8, the strength of the loose bar to that of the fixed one, appears to be in the ratio of 2 to 3; but the theory shows it to be in the ratio of 1 to 2, that is, as 2 to 4; though a difference in the manner of fixing may produce this deviation.

Table I.

N.	L.	B.	D.	lb.	Medium.	
1	18	1	1	400 415 405	406	Ends loose.
2	18	2	1	810 795 812	805	
3	18	1	2	1570 1580 1590	1580	
4	36	1	1	185 195 180	187	
5	36	2	2	1550 1620 1585	1585	
6	36	1⅜	2½	1665 1675 1640	1660	
7	18	1	1	600 600 624	608	Ends fixed.
8	36	1	1	285 280 285	283	

The following Table is an abstract of experiments on beams of four inches, by Buffon. The first column contains the length of the bar in the clear, between the props. The second, the weight of the bar, the next day after it was felled, in pounds. The third column exhibits the number of pounds necessary for breaking it in the time shown by the fifth column. Column the fourth shows the inches bent in the act of breaking; and the fifth, the time required to break each beam. Two bars of each length were tried, and each of the first three pairs were cuts of the same tree.

Table II.—*Experiments on Beams Four Inches Square.*

Length of Bar in Feet.	Weight of Bar in lbs.	lb. to break Bar.	Inches bent in breaking	Time in breaking
7	69 56	5350 5275	3.5 4.5	29 22
8	68 63	4600 4500	3.75 4.7	15 13
9	77 71	4100 3950	4.85 5.5	14 12
10	84 82	3625 3600	5.83 6.5	15 15
12	100 98	3050 2925	7. 8.	

The cut next to the root was always found to be the heaviest, stiffest, and strongest; and from this invariable coincidence of weight and strength, M. De Buffon recommends, as an unerring rule, to make choice of timber by its weight. He finds, that this was always the case when timber had grown vigorously, forming thick annual layers; but observes, that this is only during the advances of the tree to maturity; for the strength of the different circles approaches gradually to an equality, during the healthy growth of the tree.

M. De Buffon also made experiments on other sizes of timber of a square section. Thr medium of two pieces of the same length and section were taken; and the following Table exhibits the results of those mediums. The lengths are contained in the vertical column on the left hand, and the dimensions of the section, or scantling, are expressed at the top, in inches.

The experiments on the five-inch bars were considered, by M. De Buffon, as a standard, he having both extended their number, and tried other pieces of the same length. He found, after repeated trials, that oak timber lost much of its strength in seasoning, to secure uniformity; and therefore, he caused it all to be felled at the same time of the year, squared the day after, and tried on the third day; which gave him an opportunity of observing a very curious phenomenon. For when the weights were laid quickly, and were nearly upon the point of breaking, a sensible smoke was observed to issue from the ends with a sharp hissing noice, which continued while the beam was bending. This evidently shows, that it must have been compressed throughout its whole length.

TABLE III.

L.	4 In.sq.	5 In.sq.	6 In.sq.	7 In.sq.	8 In.sq.
7	5312	11525	18950	32200	47649
8	4550	9787½	15525	26050	39750
9	4025	8308½	13150	22350	32800
10	3612	7125	11250	19475	27750
12	2987½	6075	9100	16175	23450
14		5300	7475	13225	19775
16		4350	6362½	11000	16375

20		3225	4950	8375	11487½
22		2975			
24		2162½			
28		1775			

In the above Table, the weight of the beams is not taken into the account; therefore, to make a just comparison with the theory, it will be necessary to add half the weight of each beam to itself. The half-weights will be found in the following Table, in the same manner as in the preceding; the lengths being contained in the first vertical column, and the dimensions of the section at the top.

TABLE IV.

L.	4 In. sq.	5 In. sq.	6 In. sq.	7 In. sq.	8 In. sq.
7	28.777	44.965	64.750	88.131	115.111

22		3116			
24		2316			
28		1954			

By taking the weights in the above Table, corresponding to the seven-feet lengths as a standard, the following Table may be calculated, by making the succeeding weights follow in the reciprocal ratio of their lengths.

Table VI.

L.	4 In. sq.	5 In. sq.	6 In. sq.	7 In. sq.	8 In. sq.
7	5340	11570	19014	32288	47764
8	4672	10123	16637	28252	41793
9	4153	8998	14788	25112	37149
10	3738	8099	13309	22601	33434
12	3115	6749	11091	18834	27826
14	......	5785	9507	16144	23882
16	......	5061	8318	14126	20897
18	......	4499	7394	12556	18574
20	......	4049	6654	11300	16717
24	......	3681	......	......	......
28	......	3374	......	......	......

By comparing this table with the fifth, it will be found, that the strength of beams decreases in a ratio much more than that of the reciprocal ratio of the length; and it would also appear, that the greater the dimensions, the more rapid will the decrease be; for, taking any two numbers as a ratio of any given dimension of section, belonging to any two different lengths, and comparing them with that of a greater dimension of section immediately following, of the same length, the fourth number resulting will be greater than that which is found by experiment, thus:
11570 : 3352 : : 19014 : 5510, which should only be 5135;
19014 : 5135 : : 32288 : 8719, which should only be 8626; and
32288 : 8626 : : 47764 : 12760, which should only be 11815.

The preceding theory will not account for this great deviation from rule. It is probably owing to our ignorance of the law of attraction, by which the particles of fibres are held together, and of the law by which the fibres slide longitudinally on each other; but in order to show this more particularly, all the five-inch bars in Table V., as far as the twenty-feet lengths, are taken as standards, and a set of numbers are found in proportion to the cubes of the sides of their sections; the result of these calculations are exhibited in the following Table: where the sign + subjoined to any number, shows that an addition is to be made to the number, in order to make it equal to that found by experiment; and in like manner, the sign — subjoined to any number, indicates a deduction to be made from that number.

Table VII.

L.	4 In. sq.	5 In. sq.	6 In. sq.	7 In. sq.	8 In. sq.
7	5923—	11570	19992+	31748+	47320+
8	5037—	9838	17000—	26995—	40296—
9	4282—	8365	14454—	22953—	34263—
10	3680—	7189	12422—	19726—	29446—
12	3149—	6152	10630—	16881—	25198—
14	....	5389	9312—	14787—	22073—
16	....	4452	7692—	12216—	18235—
18	....	3815	6592—	10468—	15626—
20	....	3353	5793	92000—	13734—

The columns in the succeeding Table contain the differences between the above and Table V. of experiments, corrected by the half-weights; the + shows that the number to which it is prefixed, is to be added to that found by rule, and the sign — denotes, that the number to which it is prefixed, is to be abstracted from what is found by rule.

By comparing the different lengths of the five-inch beams with those of the other scantlings, they will be found to be much too strong; for the numbers in the other columns are all in excess, except two: but by reducing the five-inch bars about the twentieth part of their strength, a set of numbers may be calculated, not greatly differing from those found by experiment. In each of the succeeding horizontal columns, the excess of those found by rule, at an average, is continually greater than what is given by experiment; which shows that the different lengths have an effect upon the strength, and, therefore, in two pieces of the same length, the relative strength is not in the same proportion as in two other pieces of different lengths, but of the same dimensions of section. Hence, as the length is greater, the strength, in advancing from a less dimension to a greater, is continually less than that of the cube of their sides. Experiments on timber are too few, and too anomalous, to afford any certain means of correction.

It has been found, that by adding 1245 to each of the weights in the column of five-inch bars, a set of numbers may be generated nearly in the proportion of the inverse ratio of the lengths; and, therefore, if s denote the relative strength, w the weight found by experiment necessary to break a beam of five inches square, L its length, and l the length of any other beam; the strength of this latter will be expressed by $\frac{\overline{w + 1245} \times L}{l} - 1245$. From this formula, by making $L = 7$, and $w = 11570$, the weight found, by experiment, necessary to break the seven-inch beam, the numbers in the following Table have been calculated. The first column contains the lengths; the second, the result of calculation; the third, the weight found to break each beam, taken from Table V.; and the fourth, the difference between those found by rule, and those given by experiment.

TABLE IX.

1st.	2nd.	3rd.	4th.
7	11570	11570	0
8	9968	9838	130
9	8722	8365	357
10	7725	7189	536
12	6230	6152	78
14	5162	5389	227
16	4361	4452	91
18	3738	3815	77
20	3240	3353	113
22	2832	3116	284
24	2492	2316	176
28	1958	1954	4

From the above rule, which is only applicable to the five-inch bars, another more general one has been derived; which is, $s = \frac{651\ b\ d^2}{l} - 10\ b\ d^2$.

This formula is founded on the following observations: a constant number may be added to each column, which will increase the numbers therein contained in the reciprocal ratio of their lengths: the constant additive number of one column is to that of another as the cube of the side of the beams of the former to the cube of the side of the beams of the latter; therefore, $5^3 : 1^3 :: 1245 : 9.96$, or 10 nearly, for the additive number to a bar of an inch square. Again, $5^3 : 4^3 :: 1245 : 6.37$, or 6.40 nearly, for the additive number to a beam of four inches square; consequently, the relative strength of a piece of a foot in length, and an inch square, taking 5312 for a radical number, is $\frac{5312 + 640 \times 7}{64} - 10 = 641$.

The relative strength of a piece in general will, therefore, be $\frac{651\ b\ d^2}{l} - 10\ b\ d^2$, or, in square beams, $\frac{651\ b^3}{l} - 10\ d^3$.

Example.—What weight will be required to break an oak beam twenty feet long and eight inches square?

$$\frac{651 \times 8^3}{20} - 10 \times 8^3 - 11545.$$

That the reader may judge properly of the application of this rule, the following Tables have been calculated. The first contains the numbers according to calculation; the second, the differences between the first Table and the Table of experiments; where it may be observed, that six, seven, and eight-inch beams differ less and less from the experiment, as the beams are longer: the greatest difference is in the seven-inch beam of seven feet long, which is something greater than one-ninth, and less than experiment.

This rule is sufficiently exact for practical purposes, as in most cases it gives a solution within the fifteenth part of what would result from experiment: though the principle upon which it is founded cannot be admitted to be just, for when the length is 65.1 the quantity $\frac{651\ b\ d^2}{l} = 10\ b\ d^2$, and, consequently, the strength would be nothing.

28	....	+ 119	....	....	....

The succeeding Table is calculated upon other principles, viz. that the strength is as the breadth and square of the depth, and reciprocally as the fourth root of the fifth power of its length; and that the mean relative strength of a bar of oak, one foot in length, and an inch square, is found to be 1,000 lb. nearly; therefore, let s be the relative strength of a piece of timber, b the breadth, and d the depth; then $s = \frac{1000\ b\ d^2}{l^{\frac{5}{4}}}$. This formula is exceedingly easy; and the arithmetical operation will be much simplified by the use of logarithms. The radical number, 1000, is founded on Buffon's experiments, and is reduced to a piece of one foot long and an inch square, by the last given note. Mr. Emerson says, a piece of good oak, an inch square and a yard long, supported at both ends, will bear in the middle, for a very little time, 330 lb. avoirdupoise, but will break with more than that weight: now, upon the supposition that the strength is reciprocally as the length, the section being the same, 1 : 3 : : 330 : 990, for the strength of a piece of oak one foot long and an inch square, which is nearly 1000 lb., but as $3\frac{5}{4}$ is greater that 3, and almost equal to 4, we have $330 \times 4 = 1320$, instead of 1000; so that Emerson's timber is stronger than Buffon's.

M. De Buffon uniformly found, that two-thirds of the weight necessary to break a piece of timber, in a few minutes impaired its strength, and frequently broke it at the end of two or three months: the half of that weight brought it to a certain degree of curvature, which did not increase after the first minute or two; and this, he found, might be borne for any length of time; but when the weight was removed, the timber had acquired a curvilinear figure. One-third of the weight appeared to have no effect; and, when properly seasoned, the timber recovered its rectilinear figure, after being loaded several months. Therefore, when the strength of a piece of timber is known, according to any of the preceding methods, and if it is applied to any mechanical purpose, in bearing or supporting a heavy body, it ought to have sufficient strength to bear thrice, or rather four times, the weight to be applied.

Several reasons may be assigned for the irregularity of experiments; some pieces, even from the same tree, might be much stronger than others. M. De Buffon says, that healthy trees are always strongest at the root. The ligneous coats might not be disposed in the same way, and their resistance is always greater when perpendicular to the force applied, than when in an horizontal direction. The trunk of a tree is composed of many hollow cylinders, each formed in the annual growth; these are only united by a soft medullary substance; and when the tree is brought to a square, or cut into beams, the portions of the ligneous cylindric coats at the angles, present but a very small resistance.

A bar of small size, such as an inch square, cut out of a large tree, may have its annual plates nearly in planes, disposed perpendicularly to one of its sides, and, consequently, it will be as much stronger, or weaker, than the largest square beam cut out of a tree of the same size and texture, as the force is applied to the side, or edges, of the plates. M. De Buffon found, from repeated trials, that the strength of a bar, with its plates in the direction of the breaking force, was to that of a bar with its plates perpendicular to it, as 8 to 7, nearly.

From what has been said, and exhibited in the foregoing Tables, it appears that the resistance of timber increases in a ratio somewhat less than the square of the depth, and somewhat greater than in the reciprocal ratio of the length.

The cohesion of timber is probably of a nature different from that of metal, and is subject to greater inequalities: which inequalities are occasioned either by the soil in which the tree was reared, the growth of the tree, or the part from which it is cut.

To what has already been said, the following practical remarks may be added.

Mr. Petit, on the authority of his own experiments, and those of M. Parent, declares that the utmost strength of a square inch of oak, by pulling in the direction of its length, does not exceed 8640 lb., whereas Muschenbroeck makes it 17,300 lb., but by experiments tried at the Royal Military Academy, Woolwich, the strength of oak has been found but little exceeding 9,000 lb., its specific gravity being 774. The writer of the article, Strength of Materials, in Rees's *Cyclopædia*, observes, that "We have not this datum in either of the above cases; yet we conceive it to be a very important one, as we have always found the strength of wood of the same kind, to depend a great deal upon the weight, or specific gravity. The same experiments give for the strength of ash 17,000 lb. and fir from 10,000 lb. to 13,000 lb., both considerably different from Muschenbroeck's tabular results." The same writer, or experimenter, adds, that "an oak rod of an inch surface requires a weight of about 9,000 lb. to produce fracture; while the same, or a similar rod, fixed in a wall, and acted upon at the distance of a foot, is broken with a weight of 132 pounds."

He farther remarks, that "a beam of fir, 6 feet long and 2 inches square, supported at each end, broke with 744 lb.; and the mean of several experiments of similar pieces of the same dimension, fixed at each end, required 1,105 lb.; while the fragments of the same, 3 feet long, broke with one end in a wall, required at a medium 400 lb."

Upon the experiments of Buffon and Belidor, this writer observes, that "Another discrepancy between theory and experiment is, where the strength ought to be inversely as the length; it shows itself in the above experiments, but is very remarkable in those of M. De Buffon; and though our preceding remarks will explain very satisfactorily this deviation, we are almost afraid to offer it as an illustration, after seeing it treated as an inexplicable paradox by some writers of the first eminence. We have seen that if W be the computed weight, independent of the deflection, the absolute weight will be W cos. D, D being the angle of deflection; and as this deflection, both from theory and practice, is found to increase as the square of the length; it follows, that when the length is quadrupled, the depth of the deflection will be sixteen times greater; that is, the sine of the angle of deflection will be sixteen times more in one case than in the other, while the radius will be only four times longer; and therefore the angle in the one case about four times what it is in the other, (supposing, in a rough way, the angle to vary as the sine). Consequently, if $W \times \cos. D$ is the weight which breaks the shorter beam, $\frac{1}{4} W \times \cos. 4 D$ ought to be that which breaks the longer one, and this, we presume, will nearly, if not entirely, account for the decrease of the strength in Buffon's experiments. We cannot perceive but that this reasoning is perfectly legitimate, yet we are astonished that it should not have occurred to so keen a mathematician as the one to whom we have alluded, or to some one of the writers on this subject; and on this account we offer it with some hesitation."

This excellent writer concludes thus: "Our limits will not admit of reporting here the nature of the experiments, nor the calculations founded upon them, which led to this determination; but we hope soon to see them laid before the public in another form. We can only give here the result, which, as far as it is at present ascertained, is as follows:

"The centre of tension and centre of compression are nearly, or exactly, coincident with the centre of gravity; and the neutral line, whatever may be the figure of the section, is so posited, that the rectangle of the area of tension into the distance of its centre of gravity from the said line, is to the rectangle of the area of compression into the distance of its centre of gravity, as 1 to 3.

"From which theorem, the neutral line for any formed beam may be determined, and the absolute strength may then be found as follows, *viz.* Let d denote the distance of the centre of tension, and l the length of the beam, all in inches; D the angle of deflection, and f the strength of direct cohesion on a square inch; then, without considering the increased length of lever,

"1. When a beam is fixed at one end,

$$W = \frac{2 f a d}{l \cos. D}.$$

"2. When the beam is supported at both ends,

$$W = \frac{8 f a d}{l} \times \cos. D.$$

"3. When the beam is fixed at both ends,

$$W = \frac{12 f a d}{l} \times \cos. D.$$

"And when the beam is fixed at one end at any angle, formula I will still apply; only increasing or decreasing the angle of deflection by the quantity of the first angle of inclination, according as that inclination is downwards or upwards.

"And when the beam is supported, or fixed, at both ends, and either resting obliquely, or acted upon by an oblique force, the two latter formulæ become,

"4. For the beam supported at each end,

$$W = \frac{8 f a d}{l} \times \frac{\cos. D}{\cos. I}.$$

"5. For the beam fixed at each end,

$$W = \frac{12 f a d}{l} \times \frac{\cos. D}{\cos. I};$$

where I denotes the angle, which the direction of the force makes with the direction of the beam.

"*Note* 1.—It should have been observed, that the preceding theorem for determining the neutral line, is principally drawn from experiments on fir beams. A different ratio than 1 : 3 may be necessary in other kinds of wood, but at present that ratio has not been found.

"*Note* 2.—The deflection, D, as we have before observed, is not a necessary datum in estimating the strength of timber, for any practical purposes of building, &c., it is merely introduced in order to reconcile the theory with the result of experiments made upon the absolute and ultimate strength, in which cases, particularly in long beams, it becomes an important quality, and must not be omitted; and in all cases where it is required, it must be drawn from some prior experiment on the same kind of wood, by means of the following theorem, viz.

"Let l, d, D represent the length, depth, and deflection, of any beam; l', d', the length and depth of any other beam, whose deflection, D′, is required; then $D' = \frac{l' d D}{l^2 d'}$.

"*Example* 1.—*The strength of direct cohesion on a square inch of fir being* 13,000 *lb., required the weight necessary to break a rectangular bar,* 30 *inches long,* 2 *inches deep, and* 1 *inch in breadth, when fixed at one end in a wall, and the weight acting at the other: the deflection, computed from other experiments, having been found to be* 5 *inches.*

"First find the neutral line: here, since the section is a rectangle, the centre of tension and compression are each on the centres of their respective areas; therefore call the depth of tension x, the depth of compression will be $2 - x$, which also denote these areas; and we must have, therefore,

$$\frac{x^2}{2} : \frac{(2-x)^2}{2} :: 1 : 3;$$

or $3 x^2 = 4 - 4 x + x^2$ or $x^2 + 2 x = 2$.
Whence $x = -1 + \sqrt{3} = .732 = a$;

also $\frac{.732}{2} = 366 = d$;

tan. of deflection $= \frac{5}{30} = \frac{1}{6} = .16666666$.

When the angle $D = 9° 34'$, and its cosine $= .9860$; therefore, by formula 1,

$$W = \frac{2 f a d}{l. \cos. D} = \frac{2 \times 13,000 \times .732 \times .366}{30 \times .986} = 235 \text{ lb.}$$

"*Example* 2.—*Required the weight that would break the same beam, when supported at each end, rejecting the deflection, which is very inconsiderable.*

"By Formula 2,

$$w = \frac{8 f a d}{l} = \frac{8 \times 13{,}000 \times .732 \times .366}{30} = 928 \text{ lb.}$$

"*Example* 3.—*Required the weight that would break the same beam, fixed at each end.*

"Rejecting the deflection, we have, by Formula 3,

$$w = \frac{12 f a d}{l} = \frac{12 \times 13{,}000 \times .732 \times 366}{30} = 1492 \text{ lb.}$$

"*Note.*—We have assumed 13,000 for the force of direct cohesion; this, however, rather exceeds the greatest strength of fir, which varies from 10,000 to about 13,000 lb.

"*Example* 4.—*Assuming the direct cohesion at* 13,000, *and the specific gravity of fir at* 720; *how long must a beam be, that is two inches deep and one inch broad, which, when fixed, with one end in a wall, will just break with its own weight?*

"Let x be the required length of the beam in inches; its weight will be $\frac{2\,x \times 720}{1728}$ ounces, or $\frac{90\,x}{1728} = \frac{5x}{96}$ pounds; and this weight will have the same effect as if it acted all at one point on the centre of the beam, or at the distance $\frac{1}{2}\,x$.

"Hence, by substituting $\frac{5x}{96}$ for w, in Formula 1, we have $\frac{5x}{96} = \frac{2 \times 13{,}000 \times .732 \times .366}{\frac{1}{2}x}$; or $5\,x^2 = 192 \times 2 \times 13{,}000 \times .732 \times .366 = 133{,}728$; whence $x = \sqrt{\frac{133728}{5}}$ inches, or 47 feet.

"In this case, the angle of deflection is not introduced.

"When the deflection is considered, as it should be in this case, we find it to be, from the data of Example I., and the theorem for the deflection, as $30^2 : 5 :: \frac{1}{4}x^2 : \frac{5\,x^2}{3600}$; whence the cosine $= \sqrt{\left(1 - \frac{25\,x^2}{(1800)}\right)}$; and the above equation becomes $\frac{5x}{96} = \frac{2 \times 13{,}000 \times .732 \times .366}{\frac{1}{2}x\sqrt{\left(1 - \frac{25\,x^2}{(1800)^2}\right)}}$; which produces a cubic equation, whence the value of x may be determined.

"Mr. Banks, after many experiments made, at various times, on the real and comparative strength of oak, fir, and iron, has deduced the following inferences: the worst, or weakest, piece of dry heart of oak, one inch square and one foot long, bore 660 lb., though it was much bent, and 2 lb. more broke it. The strongest piece he tried, of the same dimensions, broke with 974 lb. The worst piece of deal bore 460 lb.; but broke with little more. A bar of the weakest kind of cast-iron, of an inch square and a foot long, would break with 2190 lb.

"The following are some of the experiments he mentions; (see Banks *On the Power of Machines.*)

"*Experiment* 1.—Two bars of cast-iron, once inch square and three feet long, were placed upon a horizontal bar, so as to meet in a cap at the top, from which was suspended a scale; these bars made each an angle of 45° with the base-plate, and of course formed an angle of 90° at the top; from this cap was suspended a weight of 7 tons, which was left for sixteen hours, when the bars were a little bent, but very little.

"*Experiment* 2.—Two bars of the same length and thickness, were placed, in a similar manner, making an angle of 22½° with the base-plate; these bore 4 tons upon the scale; a little more weight broke one of them, which was observed to be a little crooked when first put up. In this case the pressures would be as the sines of the angles of elevation, viz., as 3826 to 7071, and as 3826 : 7071 : : 4 tons : 7.6 tons; that is, if the second bars broke with 4 tons, the first ought to have taken 7.6 tons to break them; and it is likely that such would, if tried, have been the case.

"*Experiment* 3.—Another bar was placed horizontally upon two supporters, exactly three feet distant, which bore 6 cwt. 3 qrs. or 675 lb. but broke when a little more was added.

"*Experiment* 4.—The same experiment repeated with the same result.

"*Experiment* 5.—The bearings were 2 feet 6 inches apart, the bar broke with 9 cwt.

"Three more experiments were tried at three feet, the average result was 6 cwt. 2 qrs. and 6½ lb.

"Mr. Banks made some experiments on the strength of cast-iron, at Messrs. Aydon and Elwell's foundery, Wakefield. The iron came from their furnace at Shelf, near Bradford, and was cast from the air-furnace; the bars, one inch square, and the props exactly three feet distant; one yard in length weighed exactly 9 lb. or one about half an ounce less, the other a very little more; they all bent an inch before they broke.

	lb.
1. The first bar broke with	963
2. The second bar with	958
3. The third bar with	994
4. A bar made from the cupola	864
5. A bar equally thick in the middle, but the ends formed into a parabolic form, weighing 6 lb. 3 oz.	874

"The same gentleman, after many other experiments, concludes from the whole, that cast-iron is from 3½ to 4½ times stronger than oak of the same dimensions, and from 5 to 6½ times stronger than deal.

"We shall only observe here, (says the writer of the Strength of materials, in Rees's *Cyclopædia*,) that Mr. Banks's pieces of oak exceed very considerably the specimens we had an opportunity of trying, while his fir falls something short of ours."

The following Tables of Experiments on the strength of various materials under different circumstances will be found useful. They are extracted principally from Tredgold, to whose works, and those of Barlow, we would refer for further information :

Cohesion of a Square Inch, pulled asunder in a direction perpendicular to the Length of the Fibres.

The following remarks respecting the strength of cast and wrought iron, with the various Tables of Experiments, are extracted principally from the elaborate work on Tubular Bridges, by Mr. Edwin Clark, to which we would refer the reader for much valuable information on this subject. A further list, showing the strength of various materials in general use, will be found useful; it is obtained from the same source.

Mr. Telford commenced his experiments upon iron by proving what force would pull asunder, lengthwise, pieces of iron from $1\frac{1}{2}$ inches to $\frac{1}{20}$th of an inch in diameter. The experiments were made upon those of the largest diameter, by means of an excellent hydrostatic machine, and in those of the smaller by attaching weights perpendicularly, and repeating them at various times.

He then made several experiments upon different diameters, from $\frac{1}{10}$th to $\frac{1}{20}$th of an inch drawn horizontally, and with different degrees of curvature; and this was performed between points 900, 225, 140, and 139 feet 6 inches apart, and was repeated 200 times. In the experiments made upon $\frac{1}{10}$th of an inch and under, the wire was drawn over pulleys; sometimes both ends were fixed, and sometimes one end only, the other having weights attached perpendicularly, to show the effects when compared with those loaded upon the curved part of the wire; these last were disposed at $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{3}{4}$ divisions of the distance over which it was stretched. These experiments being completed, it was ascertained what blow would break the wire when stretched nearly horizontally and at different curvatures, which was done by dropping weights from a given height. The several wires were weighed, and the weight of 100 in length of each noted.

The result of the experiments was, that a bar of good malleable charcoal iron, 1 inch square, will suspend 27 tons, and that an iron wire, $\frac{1}{10}$th of an inch in diameter, 200 feet in length, weighing 3 pounds 3 ounces, will suspend 700 pounds; and that the latter, with a curvature or versed sine of $\frac{1}{50}$th part of the chord line, will support $\frac{1}{10}$th of the weight suspended perpendicularly, when disposed equally at $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$, its length, and with a curvature of $\frac{1}{20}$th of the chord, it will bear $\frac{1}{3}$ of the aforesaid perpendicular weight disposed in a similar way. A wire, $\frac{1}{10}$th of an inch in diameter, drawn very tight between points, 31 ft. 6 in. apart, resisted the impulse of 20 pounds weight, falling from a height of 7 ft. 9 in.

A bar of good English malleable iron, 1 inch square, will suspend from 27 to 30 tons before it breaks, and will bear from 15 to 16 tons before its length is at all extended. With a curvature of $\frac{1}{20}$th of the length, malleable iron, besides its own weight, sustained $\frac{1}{3}$ of what broke it perpendicularly. An inch bar would therefore bear $\frac{1}{3}$ of 15 tons without deranging its parts; but it is better in practice to assume that an inch square in action should only bear 4 tons.

General Observations.

The tenacity of good Baltic fir is very remarkable; sound rods of this material will bear an ultimate tensile strain of 5 tons per square inch, the specific gravity of which being from $\frac{1}{2}$ to $\frac{3}{4}$ of that of water, so that it will be about $\frac{1}{2}$ or $\frac{3}{4}$ immersed when floating in that liquid; the weight may be taken generally at about 45 lbs. per cubic foot, or nearly one-tenth that of wrought-iron, while the ultimate strength amounts to one-fourth. Thus a tension-rod of wrought-iron will be $2\frac{1}{2}$ times as heavy as a tension-rod of Baltic fir of the same strength, and of four times the sectional area.

Its elasticity is about one-fifteenth that of wrought-iron; i. e. a bar one inch square is extended on $\frac{1}{150000}$th of its length per ton of direct tensile strain.

The difficulty of connecting timber longitudinally, is a complete bar to the use of deal in cases of tensile strain, in greater lengths than it is naturally produced; the balks imported vary from 40 to 60 and 70 feet in length, being from 12 to 16 inches square.

In practice, wrought-iron should not be strained beyond 10 tons per square inch, and deal $2\frac{1}{2}$ tons per square inch.

An ordinary round rod of wrought-iron, 1 inch in diameter, bears tensilely 16 tons, and weighs 8 lbs per yard.

For a round rod of any diameter, the square of the diameter, taken in greater inches, is the breaking weight in tons.

Half this quantity is the weight in lbs per yard. Thus the breaking weight of a round bar 5 inches, or 20 quarter-inches in diameter, will be 20 × 20 or 400 tons, and the actual weight will be half 400 or 200 lbs. per yard.

A rod will be perceptibly damaged by half this strain, which can never be safely exceeded, one-third being sufficient in practice.

The strength of chain-cable is thus easily arrived at, the strength of a link being double that of the bar from which it is forged.

It is usual technically to denominate chains by their diameter, thus a five-eighth chain is a chain made from a bar $\frac{5}{8}$ inch in diameter.

The following approximations will be found very convenient in estimating the weight and strength of chains, the ultimate tensile strength of the material being taken at 16 tons per circular inch, or 20 tons per square inch of section.

1. The square of the diameter in eights, will be the weight of the chains in lbs. per fathom.

2. The square of the diameter in eights, divided by 2, will be the breaking weight in tons. Thus the breaking-weight of a $\frac{5}{8}$ chain will be half 25 tons = $12\frac{1}{2}$ tons, and the actual weight will be 25 lbs. per fathom of 6 feet.

N. B.—A chain will be perceptibly damaged by half this strain, which can never be safely exceeded, one-third being sufficient in practice.

The strength of ropes is very uncertain, their size is generally denominated technically by their circumference in inches; and the following approximations will be very correct for ordinary tarred hempen rope:—

1. The square of the circumference in inches, divided by 10, will give the practical strength in tons, which will be about half their breaking-weight.

2 The square of the circumference, divided by 4, will roughly give the weight in lbs. per fathom. Thus the useful strength of a 5-inch rope will be $\frac{25}{10}$ or 2.5 tons, the ultimate strength being 5 tons; and the weight of a tarred 5-inch rope will be $\frac{25}{4}$ or $6\frac{1}{4}$ lbs. per fathom.

A rope of 10 inches in circumference, and a chain of $\frac{6\cdot3}{8}$ths diameter, will each bear practically about 10 tons, taking half the breaking-weight, and the weight of the former will be 25 lbs., and of the latter, $39\frac{1}{2}$ lbs. per fathom.

Transverse Strength of a Slab of State from the Penrhyn Quarries.

A slab of slate 2 feet 10 inches broad, 4 inches thick, and 4 feet between the bearings, failed with $24\frac{1}{2}$ tons distributed over 15 inches at the centre of the span.

A slab of cast-iron of the same dimensions would scarcely support five times as much, and would be above two and a half times as heavy. This material forms a valuable flooring for bridges.

Transverse Strength of Timber.

To avoid any anomalies in deducing the strength of large beams of timber from experiments on small battens, the following experiments were made on the transverse strength of whole balks of American red pine timber selected from the scaffolding employed in erecting the tubes.

These beams were exactly 12 inches square and 17 feet long, the distance between the bearings being 15 feet. They were broken by actual weight suspended on a scale from the centre of the beams.

Dry timber from the butt end of the balk:—

Weight of the beam, 5 cwt. 2 qrs. 5 lbs. or 36.5lbs. per cubic foot.

Breaking weight, 14.82 tons.

Dry timber from the top of the balk:—

Weight of the beam, 5 cwt. 17lbs. or 33.9lbs. per cubic foot.

Breaking weight, 13.24 tons.

Results of Experiments made with actual Weight on Materials used in the Britannia Bridge, January, 1848.

(*Brickwork.*)

	lbs. per sq. in.
No. 1. 9-inch cube of cemented brickwork (Nowell and Co.,) No. 1 (or best quality), weighing 54 lbs., set between deal boards. Crushed with 19 tons 18 cwt. 2 qrs. 22 lbs. . . .	= 551.3
No. 2. 9-inch brickwork, No. 1 weighing 53 lbs., set in cement. Crushed with 22 tons 3 cwt. 17 lbs.	= 612.7
No. 3. 9-inch brickwork, No. 3 weighing 52 lbs., set in cement. Crushed with 16 tons 8 cwt. 2 qrs. 8 lbs.	= 454.3
No. 4. 9¼-inch brickwork, No. 4 weighing 55½ lbs., set in cement. Crushed with 21 tons 14 cwt. 1 qr. 17 lbs.	= 568.5
No. 5. 9-inch brickwork, No. 4 weighing 54½ lbs., set between boards. Crushed with 15 tons 2 cwt. 12 lbs.	= 417.
Mean	521.

Note.—The three last cubes of common brick continued to support the weight although cracked in all directions; they fell to pieces when the load was removed. All the brickwork began to show irregular cracks a considerable time before it gave way.

The average weight supported by these bricks was 33.5 tons per square foot, equal to a column 583.69 feet high of such brickwork.

(*Sandstone.*)

No. 6. 3-inch cube red sandstone, weighing 1 lb. 14⅜ oz., set between boards (made quite dry by being kept in an inhabited room). Crushed with 8 tons 4 cwt. 19 lbs.	= 2043.
No. 7. 3-inch sandstone, weighing 1 lb. 14 oz., set in cement (moderately damp). Crushed with 5 tons 3 cwt. 1 qr. 1 lb.	= 128.5
No. 8. 3-inch sandstone, weighing 1 lb. 15½ oz., set in cement (made very wet). Crushed with 4 tons 7 cwt. 21 lbs.	= 1085.
No. 9. 6-inch cube sandstone, weighing 18 lbs., set in cement. Crushed with 63 tons 1 cwt. 2 qrs. 6 lbs.	= 3924.8
No. 10. 9¼-inch cube sandstone, weighing 58½ lbs., set in cement (77½ tons were placed upon this without effect = 2042 lbs. per inch, which was as much as the machine would carry).	
Average crushing weight	2185.

All the sandstones gave way suddenly, and without any previous cracking or warning. The 3-inch cubes appeared of ordinary description; the 6-inch was fine-grained, and apparently tough, and of superior quality. After fracture, the upper portion generally retained the form of an inverted square pyramid about 2½″ high, and very symmetrical, the sides bulging away in pieces all round. The average weight of this material was 130 lbs. 10 oz. per cubic foot, or 17 feet per ton.

The average weight required to crush this sandstone is 134 tons per square foot, equal to a column 2351 feet high of such sandstone.

(*Limestone.*)

	lbs. per sq. in.
No. 11. 3-inch cube Anglesey limestone, weighing 2 lbs. 10 oz., set between boards. Crushed with 26 tons 11 cwt. 3 qrs. 9 lbs.	= 6618.

This stone formed numerous cracks and splinters all round, and was considerably crushed; but, upon removing the weight, about two-thirds of its area were found uninjured.

No. 12. 3-inch limestone, weighing 2 lbs. 9 oz., set between deal boards. Crushed with 32 tons 6 cwt. 1 lb.	= 8039.

This stone also began to crack and splinter externally with 25 tons (or 6220 per inch), but ultimately bore as above.

No. 13. 3-inch limestone, weighing 2 lbs. 9 oz., set in deal boards. Crushed with 30 tons 18 cwt. 3 qrs. 24 lbs.	= 7702.6
No. 14. 3 separate inch cube limestone, arranged in a triangle, weighing 4½ oz., set between deal boards. Crushed with 9 tons 7 cwt. 1 qr. 14 lbs.	= 6995.3
All crushed simultaneously.	
Average	7579.
	7338.5

All the limestones formed perpendicular cracks and splinters a considerable time before they crushed. Weight of the material from above = 165 lbs. 5 oz. per cubic foot, or 13½ feet per ton.

The weight required to crush this limestone is 471.15 tons per square foot, equal to a column 6433 feet high of such material.

(*Single Bricks of different qualities.*)

No. 15. A single brick, No. 1 (Nowell and Co.), weighing 8 lbs., bedded flat in cement. Crushed with 17 tons 19 cwt. 1 qr. 7 lbs. .	= 1022.
No. 16. A single brick, No. 3. Crushed with 13 tons 11 cwt. 1 qr. 6 lbs.	= 750.
No. 17. A single Birkenhead brick, 9 × 4½″, weighing 7 lbs. 14 oz., bedded in cement. Crushed with 32 tons 2 cwt. 17 lbs. . . .	= 1775.8
No. 18. A single Buckley mountain brick, 9½″ × 4½″, weighing 9 lbs. 2 oz., bedded in cement. Crushed with 40 tons 13 cwt. 15 lbs.	= 2130.3

These last experiments not being on cubes, only serve for comparisons among themselves. The bricks were completely crushed into powder. The cement used in all the above experiments invariably began to crack away round the edges as soon as a very moderate weight was applied.

STRETCHED OUT, a term applied to a surface that will just cover a body, and is extended in such a manner that all its parts are in a plane, or may be made to coincide with a plane.

STRETCHER, a term applied to bricks or stones so placed in a wall that their longest side shall be parallel to the face of the wall; those bricks, on the contrary, which have their longest dimension in the heart of the work, perpendicular to the surface, are termed *headers* or *through-bricks.*

STRETCHING COURSE, in walling, a course of stones, or bricks, laid with their longest dimensions in a horizontal line parallel to the face of the wall: it is exactly the contrary of *a heading course*, where the breadths of the stones, or bricks, are laid in a straight line parallel to the face of the wall.

STRIÆ (Latin), the fillets or rays which separate the furrows, or grooves, of fluted columns.

STRIGES (from the Latin *striga*, a ridge), the channels of a fluted column.

STRIKING, STICKING, or RUNNING A MOULDING, in joinery, is the shaving away the superfluous part of the wood, till the section be of the required figure.

STRIKING is also applied to the drawing of lines by the square on the face of a piece of stuff for mortises, and cutting the shoulders of tenons, &c.

STRIKING is also used for the drawing of lines on the surface of a body.

STRIKING A CENTRE, the removal of the centre after the completion of the arch it had supported during the building, and during the time necessary for the mortar to consolidate.

STRING-BOARD, in wooden stairs, a board placed next to the well-hole, and terminating the ends of the steps. The face of string-boards follows the direction of the well-hole, whether it be prismatic or an inverted cone. String-boards are sometimes glued in several thicknesses, with the fibres of the wood running in the direction of the steps; sometimes they are wrought out of the solid, like a hand-rail, the grain of the wood being in the same direction; and they are sometimes also glued up like columns, viz., having the fibres vertical. Brackets are most frequently placed upon the string-boards, and mitred into the risers.

STRING-COURSE, a narrow continuous horizontal moulding or plat-band, projecting slightly from the face of the wall.

STRING-PIECE, the piece, or pieces, of timber, put under the flying steps of a wooden stair, for their support, and covered with the lath and plaster forming the soffit of the stair.

STRIX, (Latin,) a channel in a fluted column.

STRUCK, an architectural expression, when anything of a temporary kind is taken away, which had been used for the support of some part of the building during its erection; as the centre of a vault, &c. *See* STRIKING.

STRUTS, in a truss, are one or more pair of oblique straining-pieces, each pair tending and pressing to a point below either of their extremities, and making equal angles with the horizon, though in contrary directions. Every strut is a brace; but every brace is not a strut. Braces may meet on either side of their extremities, above or below them; but struts only meet or tend to the same point downwards, as already defined.

Struts occur most frequently in roofs, and braces in partitions. Braces, when they occur in roofs, are called *principal braces*, *auxiliary rafters*, *cushion rafters*, or *discharging braces:* when they occur in the same frame, they are used in opposition to each other; though it would be as well to have a separate term to express the idea of braces when they meet upwards, as, in this way, there could be no ambiguity of expression.

STRUTTING BEAM, or STRUT BEAM, a term used by old writers in carpentry, for what is now called *straining beam*, or *collar beam.*

STRUTTING PIECE. *See* STRAINING PIECE.

STUCCO, (from the French, *estoc.*) *See* CEMENT, MORTAR, and PLASTERING.

STUDS, (from the Saxon *studer*, a post,) the posts, or quarters, in partitions, placed eleven or twelve inches distant; the term is frequently used in London and in Somersetshire. The studs go also under the various names of *uprights* and *quarters*, in London.

STUD PARTITIONS, the same as quarter partitions.

STUD WORK, or BRICK-NOGGING, a wall consisting of brick-work, built between studs, or quarters, chiefly used in thin walls, or partitions, for greater strength than when bricks are used without studs. *See* BRICK-NOGGING.

STUFF, (from the Dutch, *stofe*,) a general term for the wood upon which joiners work.

STYLE, or STILE, the upright supports of a frame.

STYLOBATE, the substructure of a classic temple below the base of the columns, or the platform on which the building was elevated. This consisted either of a series of steps continued all round the temple, or of a podium or wall, which admitted of access to the temple at one end only.

SUB-BASE, a second base below the first or true base.

SUBNORMAL, or SUPERPENDICULAR, the distance upon the axis between the foot of the ordinate and a perpendicular to the curve, or its tangent.

In all curves, the subnormal is a third proportional to the subtangent and the ordinate; and in the parabola it is a constant quantity, being equal to half the parameter of the axis.

SUB-PLINTH, a plinth below the true plinth, and on which the latter stands.

SUB-PRINCIPALS, the same as auxiliary rafters, or principal braces.

SUMMER, a large stone, the first that is laid over columns and pilasters, in beginning to make a cross vault; or that stone, which being laid over a piedroit, or column, is made hollow, to receive the first haunce of a platband.

SUMMER, a large piece of timber, which being supported by two stone piers, or posts, serves as a lintel to a door, window, &c.

SUMMER, a beam of timber tenoned into a girder, for supporting the ends of joists on both sides of it. The distinction of the large beams of a carcase floor is, that *bressummers* are disposed in exterior walls; *girders* lie across the building; and the *summers* divide the floor in the middle, and are laid perpendicular to girders, or parallel to the bressummers.—Summers are now seldom or never employed in building.

SUMMER is also a Warwickshire term for a girder.

SUMMER-HOUSE, a house situate in a garden, or on some pleasant sequestered spot, on an estate, for the purpose of retiring to in the summer.

SUMMER-TREE, a beam full of mortises for the ends of joists to lie in, and to which the girders are framed. *See* BRESSUMMER and GIRDERS.

SUNK SHELVES, have a groove consisting of two sides, to prevent the plates from sliding off, when set up on edge.

SUPERCILIUM, in ancient architecture, the uppermost member of the cornice, called by the moderns, *corona*, *crown*, or *larmier*. It is also used for a square member under the upper torus, in some pedestals.

SUPERSTRUCT, (Latin,) to build one thing upon another.

SUPERSTRUCTURE, the upper portion of a building raised upon the foundations.

SUPPORTERS, images to bear up, or serve instead of posts, &c., in a building. The posts themselves are sometimes so called.

SURBASE, the mouldings of a room, immediately above the base, with the dado between.

SURMOUNTED ARCH, that which has its springing line below the level of the centre from which it is struck.

SURVEYING, the practice of measuring the areas and defining the boundaries of plots of land, estates, houses, &c., in such a manner as to be able to transfer a correct representation of the same to a plan showing the relative position and proportionate dimensions of the various parts with reference to each other. In other words, the plan is made to present, on a small scale, a delineation of the surface of the area surveyed.

The principal instruments employed in surveying are the theodolite and chain; the former for measuring angles, and the latter for lines. It is usual to divide the plot to be surveyed into a number of triangles, as convenient, and, when the chain only is used, which is probably the more accurate method, to measure the three sides of each triangle, which at once determines its form and dimensions. If, however, the theodolite be also used, one or more of the angles are measured thereby, and one or more sides determined by the chain; in this case, the form and dimensions of each triangle may be determined by trigonometrical formulæ. In surveying large tracts of country, it is usual to fix or determine the relative position of some of the more conspicuous points by a system of triangulation, and from these fixed points, as a basis, to determine or fill in the remainder of the plan. Several other instruments are employed in these operations, but the two above-mentioned are the principal.

SURVEYING WHEEL. *See* PERAMBULATOR.

SUSPENSION BRIDGE. This kind of construction is, perhaps, the simplest and most easily erected of all bridges; we find examples of it spoken of in remote times, and there are few countries in the world where it may not be seen under some form or other. In England we now have many splendid bridges of this description, in which the combined labours of practical experimentalists and scientific theorists have produced monuments of surprising skill and admirable daring.

The principle on which suspension bridges are constructed, is exactly the reverse of that on which the stability of arched bridges depend. In the latter case, the force of gravity is, by an ingenious arrangement, made to counteract the natural tendency of all bodies to fall towards the earth; and a *compressive* force is called into play, by which the several parts of the bridge are kept in their proper positions, provided the materials have been properly disposed, and are sufficiently strong to bear the requisite crushing force.

In suspension bridges, on the contrary, the roadway is supported by ropes or chains attached to towers and abutments, so that the *tension* of the materials employed is *principally*, although not altogether, acted upon, and the platform is sustained by the excess of their tensile powers above the weight (their own included) with which they are loaded. These bridges were not constructed to any great extent until the commencement of the present century; up to that period they were of rather a primitive character. We hear, indeed, of one built in China about the year 65 A.D., and of several suspended bridges in South America and the Indies, in which the chains were formed of ropes or barks of trees plaited or interwoven together, so that the roadway was in the form of a catenary curve; still, even in those countries we have instances of the roadway or platform being placed horizontally, and suspended from the ropes or chains by intermediate rods. Among the first Iron Suspension bridges put up in this country was the Winch Bridge crossing the river Tees near Middleton. It was merely intended for foot-passengers, being only 2 feet in width, although 70 feet long. In 1816, a Wire Suspension bridge was built over the Gala Water, of upwards of 100 feet span, at a cost of only £40; and another over the Tweed at Peebles in the following year, also of iron wire, and about the same span, for £160.

In 1820, Captain Sir Samuel Brown built a Suspension Bridge over the Tweed, in an ingenious and novel manner, for which he had obtained a patent in 1817. Instead of making the main iron chains, intended for the support of the bridge, in the form of ropes, as had been hitherto done, he constructed those chains by links of iron several feet in length, with holes formed at either end, through which he joined them together by means of bolts. This bridge, called the Union, is situate close to Berwick-on-Tweed, and has a span of 449 feet. It is supported upon 12 chains disposed in pairs, and placed one above the other 3 deep, formed by links of round iron 2 inches in diameter, and each 15 feet long, connected with one another by intermediate short links also of iron. The suspending rods are of an oval section, and are placed 5 feet apart, every one being attached to a joint of one of the three main chains, which are made to break joint, so as to admit of this arrangement. These suspension rods support the roadway, which is formed of timber. This bridge cost £50,000. In the following year, this engineer built the Newhaven Pier, which is constructed on the same principle, having three openings, each 209 feet span; and afterwards the Chain Pier at Brighton, which runs out into the sea a distance of upwards of 1,000 feet, having four openings, each 225 feet span. In the year 1823, a bridge of the kind was erected by Sir Isambert Brunel, with two spans, each 122 feet; and the year after (1824) Tierny Clarke constructed the much-admired Suspension Bridge over the Thames at Hammersmith, spanning the river by an opening of 422 feet, which has stood remarkably well.

Next in order of time is the far-famed Suspension Bridge erected by Telford over the Menai straits, for the purpose of carrying the Holyhead road, and thus connecting the Island of Anglesea with the mainland. This splendid work of art was completed in the year 1825, having been about six years in course of construction. It consists of one opening of 570 feet span. The roadway being 100 feet above the level of high-water. The chains are formed of flat bars of iron 10 feet long, $3\frac{1}{2}$ inches deep, and nearly an inch thick. There are four rows of chains, each consisting of four tiers of bars ranged one above the other, so that, in all, there are 16 chains; to these, which are passed over the tops of two lofty towers placed at either side of the straits, and fastened at either shore into the solid rock, bars an inch square are attached, 5 feet apart, for the purpose of supporting the roadway, which has two carriage-ways, each 12 feet wide, and a central footway 4 feet in width. The entire weight of this suspended platform, including the 16 chains, is about 2,186 tons. The Conway bridge, over the river Dee, is also a Suspension Bridge, and was built by Telford about the same time; it has a span of 327 feet, and likewise carries the great Holyhead road. Sir Samuel Brown then erected, in the year 1829, the Montrose Suspension Bridge over the Esk in Scotland, with a span of 412 feet, and a roadway 12 feet wide. This bridge was all but destroyed during a great storm which took place in 1838; the platform not having sufficient rigidity to withstand the unequal force of the wind. The engineer, Rendel, however, has restored the bridge, and it is thought that such a disaster cannot again take place.

In the year 1829, M. Navier, an able French engineer, to whom we are indebted for a valuable work on Suspension Bridges, constructed the Pont des Invalides, on the suspension principle, over the Seine at Paris, with a span of 236 feet, and a deflection in the catenary formed by its chains, of about 26 feet. The Fribourg Bridge, which spans the valley of the Sarine in Switzerland, is one of the most splendid wire bridges ever built. It was constructed by Mr. Challey between the years 1832 and 34. It has a span of 870 feet, and the platform is 167 feet above the surface of the water, which runs at the bottom of the valley. This platform is suspended from four iron-wire ropes, two on each side of the bridge. The ropes are composed of 80 wires, each $\frac{1}{12}$ of an inch diameter, tied up by coils of wire at regular intervals; these chain-ropes are made fast to the rock on either side, after passing over the tops of the towers. Suspension rods are then hung upon the chain-ropes, to which the joists forming the roadway are fixed; the cost of this magnificent and truly wonderful structure did not amount to more than £24,000.

SWALLOW-TAIL, a particular way of fastening together two pieces of timber, so strongly, that they cannot fall asunder. It is much the same as DOVE-TAIL.

SWELLED COLUMN. *See* COLUMN.

SYMBOLICAL COLUMN. *See* COLUMN.

SYMMETRY, (from the Greek, *συν*, *with*, and *μετρεω*, *to measure*,) the harmony, proportion, or uniformity between the parts of a building and the whole.

SYSTYLE, a building where the pillars stand thick, but not quite so thick as in the pycnostyle, the intercolumniation being only two diameters, or four modules, of the columns.

T.

TABERN, a local word for cellar.

TABERNACLE, a casket composed of marble, precious stones, or metal, placed upon the altar in churches, and employed to contain the consecrated wafer; also any casket for containing holy relics, vessels, &c. The term is further applied to decorated niches, with enriched canopies, &c.; a collection of such work is termed *Tabernacle-work*.

TABLE, or TABLET, a flat surface or panel of various forms, but usually rectangular, either plain, or charged with ornament of some kind. They are frequently made to project from the wall, and are termed *raised tables*.

The term is also applied to continuous horizontal mouldings; thus we have *bench*, *corbel*, *water tables*, *&c.*

TABLE CORBEL, a curious horizontal ornament, used, in Gothic architecture, for a cornice.

TABLE, *Projecting*, as its name imports, is a table projecting from the naked of a wall.

TABLE, *Raised*, the same as PROJECTING TABLE.

TABLE, *Raking*, one that is not perpendicular to the horizon.

TABLE, *Rusticated*, a table of which the surface is rough, from being broken with the hammer, frosted, or vermiculated.

TABLE, *Water*, one that inclines to the horizon, for throwing off water; this kind is mostly used in buttresses, and other parts of Gothic edifices.

TABLE, in perspective, the same as *the plane of the picture*, being the paper or canvass on which a perspective drawing is made, usually perpendicular to the horizon. In the theory of perspective, it is supposed to be transparent, for the more easily comprehending the subject.

TABLE OF GLASS, in glass-works, and among glaziers, a circular plate of glass, being its original form, before it is cut, or divided into squares. Twenty-four tables make *a case*.

TABLED, a term applied to anything cut into tables.

TABLET, the same as TABLE.

TABLING, a term used in Scotland for the coping of the wall of very common houses; also a method of scarfing timbers.

TACKS, small nails, for fastening and stretching cloth upon a board, &c.

TÆNIA, or TENIA, a small square fillet at the top of the architrave, in the Doric capital.

TAIL, *Swallow*. *See* SWALLOW-TAIL.

TAIL-IN, to fasten anything into a wall at one end, as the steps of a stair; this expression is similar to what, in joinery, is called *housing*.

TAIL TRIMMER, a trimmer next to the wall, into which the ends of joists are fastened, in order to avoid flues.

TAILING, the part of a projecting stone, or brick, inserted in a wall.

TAILOIR, a term used by some writers, in imitation of the French, for the ABACUS.

TALON, (French,) the same as OGEE; being either the cima-recta or cima-reversa: according to some authors, it is a kind of astragal, used as a crowning. The word is not used in England.

TALUS, or TALUT, the slope or inclination of a wall, whereby, reclining at the top, so as to fall within its base, the thickness is gradually lessened according to the height. Among workmen, this is called *battering*; and the wall itself is said *to batter;* but when the wall inclines beyond the perpendicular of its base, it is called *hanging*. The term *talus* is mostly restricted to fortifications.

TAMBOUR, (a French term, derived from the Arabic, *tambor*, a drum,) a word applied to the naked of a Corinthian or Composite capital, or to that part from which the ornaments are supposed to project.

TAMBOUR, is also applied to the wall of a circular temple, which is surrounded with columns.

TAMBOUR, a place enclosed with folding-doors, to break the current of air from without, at the entrance of churches, or other similar buildings.

TANGENT, (Latin, *tangere*, to touch,) in geometry, a line or surface which touches another without cutting it. The term is more especially applied in trigonometry to the line drawn, touching the circumference at the commencement of the arc, and terminated by the secant, which is drawn through the centre and the end of the arc.

TANK, a large vessel, or reservoir, to contain water.

TAPERING, a term expressive of the nature of a solid contained between two opposite planes inclined towards each other. Thus, the wedge, the pyramid, the frustum of a pyramid, the cone, and the frustum of a cone, are all tapering solids.

TAPESTRY, hangings of wool, silk, and other materials, and ornamented with embroidery of various kinds of needle-work, employed as decorative coverings to the walls of ancient houses.

TARRACE. *See* TERRACE.

TARRAS, or TERRAS, a strong mortar or plaster, of great use in aquatic works. *See* CEMENT, MORTAR, and PLASTER.

TASSELS, (from the French,) in common country houses, the pieces of timber that lie under the mantel-tree.

TAXIS, the same with the ancients that ORDONNANCE is with the moderns, and described by Vitruvius, as that which gives every part of a building its just dimensions, according to its uses.

TEAZE-TENON, a tenon upon the top of a post, with a double shoulder and tenon from each, for supporting two level pieces of timber at right angles to each other.

TEINT, (from the French,) a wash of any colour upon paper.

TELAMONES, the Roman term for the figures or images of men supporting a cornice or other projection. By the Greeks they were called ATLANTIDÆ, ATLASES, and PERSIANS.

TEMOIN, (from the French,) in fortification, a pillar, or mound of earth, left by the workmen in digging, to show how much has been removed, and what they are to have for their labour.

TEMONES, (from the Greek, τεμνος,) in ancient temples, the place where the image stood.

TEMPERED, a term applied to such bricks as are easily cut and reduced to a required shape.

TEMPLE, (from the Latin *templum*,) a building erected in honour of some deity, whereat the people met for religious worship. Clemens Alexandrinus and Eusebius refer the origin of temples to the sepulchres for the dead: Herodotus and Strabo will have the Egyptians to have been the first who raised temples to the gods: others say, that the portable temple, or tabernacle, made by Moses in the desert, was the first of the kind, and these hold it to have been the model of all others. The first temple erected in Greece is ascribed to Deucalion by Apollonius; as the first in Italy is said to have been built by Janus, or Faunus. In antiquity, we meet with many who would not build temples to their gods, for fear of confining them to too narrow bounds. They performed sacrifices and other religious rites in all places indifferently, from a persuasion, that the whole world is the temple of God, and that he requires no other. This was the doctrine of the Magi, followed by the Persians, Scythians, Numidians, and many other nations mentioned by Herodotus, Cicero, and Strabo. The Persians, who worshipped the sun, believed it would be injurious to his power to enclose within the walls of a temple him who had the whole world for his habitation; and hence, when Xerxes ravaged Greece, the Magi exhorted him to destroy all the temples he found. The Athenians would erect no temple to Clemency, who, they said, was to live within the hearts of men, not within stone walls. The Bithynians and Germans had no temples, but worshipped on mountains and in woods.

Temples were built and adorned with all possible splendour and magnificence; and this partly out of reverence for their respective deities, and partly to create an awe for them in those who came to pay their devotions. The temples were built after that manner which different votaries thought most agreeable to their Gods; for instance, the Doric pillars were sacred to Jupiter, Mars, and Hercules; the Ionic to Bacchus, Apollo, and Diana; and the Corinthian to Vesta; though there are instances of these being used in the same temples; such were some of those dedicated to Minerva, which had pillars of the Doric, Corinthian, and Ionic orders. Wherever a temple stood, if the situation of the place would permit, it was so contrived, that the windows, on being opened, might receive the rays of the rising sun. The front was towards the west, and the altars and statues were placed towards the other end, that the worshippers, on entering, might have their faces towards them, it being a custom among the heathens to worship with their faces towards the east. If the temples were built by the side of a river, they were to look towards the banks of it; if near the highway, they were to be so ordered, that travellers might have a fair prospect of them, and pay their devotions to the god as they passed: those built in the country were generally surrounded with groves. In the front of the temple was the porch, in which, according to Casaubon, was placed the holy water, in a vessel of stone or brass, with which all who were admitted to the sacrifices were sprinkled; beyond this porch it was not lawful for the profane or polluted to pass; this led into the body of the temple, where was the *adytum*, or sacred place, into which none entered but the priests. Belonging to each temple there was a vestry, which seems to have been a treasury both for the temple itself, and for such also as had a mind to secure their wealth in it, as was done by Xenophon, who committed his treasures to the custody of the priest of Diana, at Ephesus.

Temples are thus described by some of the ancients: first, the whole edifice; secondly, the altar on which the offerings were made; thirdly, the porch in which usually stood an altar, or an image; and lastly, the place upon which the image of the chief god was erected. This idol was originally only a rude stone; and Themistius tells us, that thus they all continued till the time of Dædalus, who first gave them feet. In after-ages, when the art of graving and carving was invented, those rude lumps were changed into figures resembling living creatures, generally men. The material of these statues, among the Greeks, was generally wood; and it has been observed, that those trees which were sacred to any particular deity, were thought most acceptable for his statues: thus, Jupiter's were made of oak; Venus', of myrtle; Minerva's, of olive; Hercules', of poplar, &c. Sometimes they were the work of the lapidary, and consisted of common or of precious stones; at other times of black stone, indicating the invincibility of the gods: marble and ivory were frequently made use of, sometimes clay and chalk; and, last of all, brass, silver, gold, and other metals. The place of the images was in the middle of the temple, where they stood on pedestals raised above the height of the altar, and enclosed with rails.

The most ordinary form given to temples was that of a long square; though sometimes they were of a circular form. Those which were of the former shape were generally twice as long as broad, and their cella had generally, on the exterior, porticos, which adorned sometimes only the front façade, sometimes both the front and back façade, and, at others, were carried all round the four sides. The enclosed part of the temple was called the *naas domos selias*, or *cella*. The front portico was termed *frons*, *pronaos*, *prodomos*, *anticum*: the back part, when it had an entrance and portico, was termed *posticum* and *opisthodomus*. Above the entablature of the two columns of the two façades was the *tympanum*, or *actos*.

The façades of temples had always an even number of columns, either four, six, eight, or ten; and from these numbers they received the names of *tetrastyle*, *hexastyle*, *octostyle*, or *decastyle*. On the two sides the columns were generally an odd number. The Grecian and Roman architects, however, were not agreed as to the disposition of the columns on the sides. When the façade had six or eight columns, the Greeks placed on each side thirteen or seventeen. Examples of this are seen in the small temple at Pæstum, in the temples of Juno Lucinia, and of Concord, at Agrigentum, in that of Jupiter Nemæus between Argos and Corinth, in that of Theseus, and the Parthenon at Athens, and in several others. The Romans, on the contrary, reckoned by the intercolumniations, and, according to Vitruvius, they gave to each side twice the number of intercolumniations of the façade, so that a temple, which had six or eight columns in front, would have on each side eleven or fifteen. Thus the temple near Mylassa had six columns on the façade, and eleven on each side; that of Fortuna Virilis, at Rome, had four in front, and seven on each side. Sometimes, however, the columns at the side are an even number, and either double, or not double, of those at the front. Thus the temple of Jupiter Panhellenius, in the island of Ægina, had six in front and twelve on each side. The temple of Ægesta in Sicily, as well as the grand temple at Pæstum, have six columns in front, and fourteen on each side. Some temples at Selinus have six columns in front, and on the sides of one of them twelve, one fourteen, and another sixteen. The greatest temple in this city had eight in front, and sixteen on each side.

Temples are classified by Vitruvius into seven different kinds, determined according to the disposition of the columns: viz., the temple *in antis*, *prostylos*, *amphiprostylos*, *peripteros*, *dipteros*, *pseudo-dipteros*, and *hypæthros*.

The temple *in antis* is the most simple in form, consisting only of the cella, with a portico formed by the projection of the side-walls beyond the end-walls of the cella, the ends of the projections being enriched with capital and base similar to a pilaster; between the antæ were two columns, one on either side of the entrance. These temples were devoid of columns on the flanks, and are termed *astylar*, or devoid of columns. The *prostyle* temple had columns only on its front or fore side. The *amphi-prostyle* had columns both before and behind, and was also tetrastyle. The *peripteral* or *peristylar* temple was surrounded on all sides by a colonnade, and, according to Vitruvius, had six columns in the front, and eleven in the flanks, including those at the angles; the space between the peristyle and walls of the cella was of the width of one intercolumniation. The number of columns in the flanks of Grecian hexastyle peripteral temples does not appear to have been regulated by the number in the fronts; it has been believed it always exceeded double that of those in the front; but in the temples of Ægina, Pæstum, Argos, Syracuse, Ægesta, and Selinus, it generally exceeds the double by two or more. Peristylar temples are of two kinds, those with a single row of columns on each side, and those which have two rows, and which are distinguished as *dipteral*. These were octostyle in the fronts, with fifteen columns in the flanks, the walls of the cella ranging with the columns at the ends which were third in order from the angles. The *pseudo-dipteral* differed from the dipteral only in omitting the innermost of the two ranges of columns which surrounded the cella. The peripteral, dipteral, and pseudo-dipteral temples all presented the same general appearance, but in the second some advantage was obtained over the first in the extended width of the fronts, but more especially in the variety of effect in shadow and perspective, and in the extension of sheltered space which was gained for ambulatories. In the third kind, the second advantage was lost, but the last was considerably increased by the clear space gained by the omission of the inner row of columns; in fact, this arrangement was similar to the first, with the exception that the space between the cella and the colonnade was twice as great.

The *hypæthral* temple was open at top, and exposed to the air. Of this latter description, some were decastyle, others pycnostyle; but they all had rows of columns within, forming a kind of peristyle, which was essential to this sort of temple. The last kind was the *monopteral* temple, which was round, and without walls, having its dome supported by columns. Sometimes, however, we find circular *astylar* temples.

TEMPLET, a mould used in masonry and brickwork, for the purpose of cutting or setting the work. When great nicety is required, two templets should be used, one for moulding the end of the work, and its reverse for trying the face. Where many stones or bricks are required to be done with the same mould, the templets ought to be made of copper.

Templet, a short piece of timber, sometimes laid under a girder, more particularly in brick than in stone buildings.

TENAILLE, (French,) in fortification, a kind of hornwork.

TEN-FOOT ROD, a rod used for measuring out grounds or long lengths in building.

TENON, (from the French *tenir*, to hold,) a projecting rectangular prism formed on the end of a piece of timber, to be inserted in a mortise of the same form.

Tenon-Saw, a saw with a brass or steel back for cutting tenons. *See* Saw.

TENSION, (from the Latin *tendo*, to stretch,) the degree that a piece of timber is strained by drawing it in the direction of its length.

TENSION ROD, a rod usually of wrought iron, employed to tie together any two parts of a structure which have a tendency to separate or be thrust asunder. Such are the tie-rods employed to tie the ends of the principals of a roof together, also such as are used to tie walls together to prevent their bulging, &c.

TEOCALLI, a name given to the ancient pyramidal structures of Mexico.

TEPIDARIUM, one of the apartments in a Roman bath.

TERM, (from the Latin *terminus*, a bound,) in Geometry, the same as *boundary*, or *limit*.

TERMINUS, a trunk, or pedestal, adorned at the top with the figure of the head of a man, woman, or satyr, whose body seems to be enclosed in the trunk, as in a sheath, which usually tapers downwards.

TERRA-COTTA, baked earth. This material has been much used in building and modelling both in ancient and modern times; many specimens of bas-reliefs and other ornaments in terra-cotta have been found in Herculaneum and Pompeii.

TERRACE, (from *terra*, earth,) an area raised before a house, or other building, above the level of the ground, for walking upon. The word is sometimes used for a balcony, or gallery.

Terrace-Roofs, those that are flat on the top.

TERRAS. *See* Tarras.

TERREPLAIN, in fortification, the platform, or horizontal surface of the ramparts.

TESSELATED PAVEMENT, a rich pavement of mosaic work, made of curious small square marbles, bricks, or tiles, called *tesselæ* or *tesseræ*. *See* Mosaic.

TESSERA, (from τεσσαρα, or τεσσερα, *four*,) a cube or die.

Tessera, a composition for covering flat roofs, recently invented.

TESTER or TESTOON, a flat canopy over a pulpit, &c.

TESTUDO, (from the Latin,) the horizontal vault of a church; an arched roof.

TESTUDINAL CEILINGS, or ROOFS, a word used by Vitruvius for such roofs as are in the form of the back of a tortoise.

TETRADORAN, a kind of bricks used by the Greeks. *See* Brick.

TETRAGON, (from τετρα, *four*, and γωνια, *a corner*,) a plain figure consisting of four sides and as many angles.

TETRAHEDRON, a regular solid comprehended under four equilateral and equal triangles.

TETRASPASTUS, (from $\tau\epsilon\tau\rho\alpha$, *four*, and $\sigma\pi\alpha\sigma\sigma\omega$, *to draw*,) a machine containing four pulleys.

TETRASTYCHE, a gallery with four rows of pillars.

TETRASTYLE, (from $\tau\epsilon\tau\rho\alpha$, *four*, and $\sigma\tau\upsilon\lambda o\varsigma$, a *pillar*,) a building, or portico, with four columns in front; or a building with four pillars on a side.

THATCH, a roof or covering formed of reeds, straw, and other similar materials.

THEATRE, (from $\vartheta\epsilon\alpha\sigma\theta\alpha\iota$, *to see*,) a building used for the performance of plays, and other scenic representations.

The magnitude of a theatre must depend upon the number of spectators, and the style in which the exhibitions are intended to be got up. It would not be easy to describe in words all the apartments necessary to the construction of a theatre, nor their uses, or proportions to each other, as these must depend upon arbitrary circumstances; but the following abstract of the report of Mr. Wyatt, the architect of the present Drury Lane Theatre, with a description of the plan, will furnish a valuable elucidation.

"In arranging the design which I submitted to the committee for rebuilding Drury Lane Theatre, and which the committee have done me the honour to adopt, I have been guided principally by the considerations which are explained under the four following heads, namely: First, the size, or capacity, of the theatre, as governed by the width of the proscenium, or stage-opening, and by the pecuniary return to be made to those whose property may be embarked in the concern. Secondly, the form or shape of the theatre, as connected with the primary objects of distinct sound and vision. Thirdly, the facility of ingress and egress, as materially affecting the convenience of those going to every part of the house respectively; as well as their lives in cases of sudden accident and alarm. Fourthly, decorum among the several orders and classes of the visitants to the theatre, as essential to the accommodation of the more respectable part of those visitants, and consequently of great importance to the interests of the theatre." [Mr. Wyatt here details, under their respective heads, the space requisite for the various departments of the theatre; and then proceeds thus to the comparative width of the stage openings.] "The annexed statement of the dimensions of the stage-opening of several large theatres will be sufficient to show, that 35 feet is a very moderate width for that opening.

[The statement alluded to by Mr. Wyatt, is as follows:

Parma, 40 feet; Turin, 39; Bordeaux, 39; Argenta, at Rome, 36; Milan, 40; San Benedetto, at Venice, 40; Theatre Francais, at Paris, 40; Theatre Italien, at Paris, 33; present Theatre at Covent Garden, 37; late Theatre in Drury Lane, 46, afterwards reduced to 33 feet.]

"And although it appears, in that statement, that the stage-opening, in the theatre that was lately burnt down in Drury-lane, was laterally two feet less than that proposed in my plan, this fact is not to be received as a criterion for the dimensions most suitable to that part of a theatre; for, in the late theatre, the stage-opening was originally 46 feet; but, upon an alteration which was subsequently made in the proscenium (for the purpose of introducing stage-doors,) the breadth was reduced to 33 feet; not because a greater breadth than 33 feet was considered to be inconvenient and improper, but because the reduction to that breadth of 33 feet afforded an opportunity of combining, with the alteration above specified, the introduction of some private boxes in a part of the proscenium which would otherwise have been lost space.

"Having assumed that the size, or capacity of the theatre, must depend principally upon the width of the scene opening, and having stated the reasons for the limit which I have applied to that opening, I have next to remark upon the size of the house, as it relates to the pecuniary return for the capital embarked in the concern. It is proposed, that the largest return which can be obtained, consistently with a due attention to the interests of the public, is the legitimate right of the proprietors, and, consequently, that (after having determined the width of the stage-opening upon a suitable scale) the most capacious form which can be possibly constructed to admit of distinct vision and sound, is the form which ought to be chosen. It appears to be a very popular notion at present, that our theatres should be very small, but if that popular notion be suffered to proceed too far, it will tend, in every way, to deteriorate our dramatic performances, by depriving the proprietors of that revenue which is indispensable to defray the heavy expenses of such a concern, and to leave a reasonable profit to those whose property may be embarked in the undertaking. It should be remembered, that the unavoidable expenses attendant on any theatre of a superior order in London, (whatever be the dimensions of that theatre,) must of necessity be very great; and that less than a certain return for those expenses cannot maintain such a theatre to any good effect. Assuming the boundary which has been described as the limit of the stage-opening, and confining the front boxes (which is absolutely necessary for purposes of vision or sound) within a given distance from the front line of the stage, it is quite unquestionable, that a segment of a circle, including three-fourths of an entire circle, contains the most capacious area which can be formed within those given points; and, therefore, if that form be also one which is well adapted to distinct vision and sound, it ought, upon the principle before stated, to be chosen in preference to any other. It should be remembered, that the remarks which I am now offering, apply to the size or capacity of the theatre, as relates to the pecuniary return for capital embarked; the subject will be hereafter considered in its relations to sound and vision; in the meantime, viewing it as the form which is capable of containing the greatest number within the given limit, I shall assume it as that which the proprietors are entitled, for their own interest, to adopt. A theatre consisting of three-fourths of a circle, with a proscenium according to my plan, which shall limit the stage-opening to 35 feet, will contain, in four different heights, 78 boxes, holding 1004 persons; with four boxes (of larger size than the rest) next to the stage on each side of the theatre, capable of containing 188 spectators, in addition to the 1004 before mentioned, amounting, in the aggregate, to 1,192 persons, or

	£	s.	d.
persons, or	£417	4	0
A pit, containing 911 persons, or	159	8	6
A two-shilling gallery for 482 persons, or . .	48	4	0
A one-shilling ditto for 284 persons, or . . .	14	4	0
Total.	£639	0	6

exclusive of four private boxes in the proscenium, and 14 in the basement of the theatre, immediately under the dress-boxes. Suppose the four private boxes in the proscenium to be appropriated to the managers, and certain other persons connected with the theatre who shall pay no rent for those boxes, the remaining 14 private boxes will let as follows: namely, the 12 smaller ones for £300 each, and the two larger ones for £500 each, for the season, (being at the rate of £23 per night for 200 nights) which, together with the foregoing amount, produces an aggregate total of £662 6s. 6d. Adverting to all the foregoing circumstances, I have no doubt that the advantages of the form which I have adopted will readily be admitted, as far as the form relates to the capacity of the theatre, and to the financial considerations attending thereon; and I shall therefore, having shown what appears to be the best form with respect to size and capacity, now proceed to the second head of the discussion, namely, the former shape of the theatre, as connected with the objects of distinct vision and sound.—1st. With reference to distinct sound, the safest method in deciding upon the shape of a theatre appears to be, to adopt a form which is known to be in itself capable of conveying sound with facility; to construct that form of materials which are of a conductive nature; and to avoid all breaks and projections on the surface of such form, which can tend to interrupt or impede the progress of the sound when once conveyed to any part of it. It is generally admitted that a circular enclosure, unobstructed by breaks and projections, possesses the power of conveying sound with facility, and that wood is the material which combines the greatest number of desirable qualities, as to conduction, resonance, &c. &c. It does not absorb the sound so much as some materials, and does not conduct it so much as others; which medium is acknowledged to be an advantage to the clear and distinct conveyance of sound. That wood is sonorous, and capable of producing soft, clear and pleasing tones, is sufficiently demonstrated by the effect of it in musical instruments.—I shall take it for granted that whatever be the form of the theatre, it ought in every part to be confined within the limit to which the voice is known to be capable of expanding: and, certainly, I hazard nothing in assuming, that the nearer the shape shall conform to those proportions which would be described by the natural expansion of the voice, the more equally the sound will be heard in all parts of the theatre. After reading Mr. Saunders's account of the experiments upon the voice, which he describes in his *Treatise on Theatres*, I was induced to try the same experiments myself, and after changing the relative positions and distances of the speaker and hearer, in a variety of ways, and after several repetitions of each experiment, the result corresponded as nearly as possible with the statement given by Mr. Saunders, and clearly proved to me, that the natural expansion of the human voice, when moderately exerted, will be in the proportion of about two-ninths farther in a direct line, than it will laterally; and that being distinctly audible on each side the speaker, at a distance of 75 feet, it will be as plainly heard at a distance of at least 92 feet in front of the speaker declining in strength behind him, so as not to be clearly heard at much more than 30 feet from his back. Upon this principle, I have in my design made the widest of the area of the theatre, upon the level of the dress-boxes, 58 feet, allowing 9 feet 6 inches for the depths of the boxes: upon that floor, a projection of 18 inches more than is given to any of the boxes above, making together, 67 feet 6 inches between the extremity of the stage on one side, and the back wall of the boxes on the opposite side. But it should be remembered, that the speaker will not at any time be placed laterally, at the very extremity of either side of the stage, and even if he were to be sometimes so situated, the distance between him and the opposite side of the house, would be eight feet within the expansion of the voice in a lateral direction, and 27 within its limits in a direct line. Referring to all the considerations connected with the foregoing remarks, I have no hesitation in believing, that the circular form is preferable to any other form. And having, upon the principles above stated, fixed a limit for the diameter of that form, I next come to those considerations connected with sound, which ought to operate upon the longitudinal dimensions of the theatre, or upon the space from the front line of the stage, to the boxes immediately facing that line.

"It has already been stated, that the natural expansion of the human voice is about 75 feet in a lateral direction on each side of the speaker; and as it is evident the space between the front line of the stage, and the boxes immediately facing that line, may at times constitute the lateral direction of the voice, according as the actor's face shall be turned more or less towards either of the sides of the theatre, the utmost distance from the front of the stage to the back-wall of the boxes facing the stage, ought not to exceed 75 feet; or the limit to which the voice is capable of expanding in its lateral direction. For if, calculating upon the actor's face being turned (as in general it would be) towards the front of the house, the distance between that part of the house and the most advanced line of the stage, were to be considered as invariably the direct line of the voice, and were accordingly to be extended 92 feet, (the expansion of the voice in a direct line,) the consequence would be, that upon a sudden turn of the actor's head, what had before been the direct line of the sound would then become its lateral direction, and those persons, sitting at the front boxes at the distance of 92 feet from the actor, would be 17 feet beyond the reach of his voice.

"There is a form approaching very nearly to that which I have chosen, which some persons might, perhaps, on the first view of it, be disposed to prefer; I mean a semicircle, with the sides continued parallel to each other, instead of converging by continuing the circular line to three-fourths of the circle, as I have done. But upon examination, this form will be found ineligible, because it involves an extension of the stage-opening to an inadmissible width, without affording any advantage as an equivalent for that defect.—I have already stated, that the extreme distance from the front line of the stage to the back-wall of the boxes facing the stage, according to my plan, is 53 feet 9 inches; in the late theatre in Drury Lane, it was 74 feet, or 20 feet 3 inches more than mine: in the old theatre in Covent Garden, (I mean as it was built in 1730,) the distance between the front of the stage and the back of the wall of the front boxes, was 54 feet 6 inches, or 1 foot 3 inches more than mine: in the old Opera House, built by Sir John Vanburgh, in the Haymarket, it was 66 feet, or 12 feet 3 inches more than mine.—In most of the foreign theatres, it is very much greater than in my plan. At Milan it is 78 feet, or 24 feet 3 inches more: in the theatre of San Carlos, at Naples, it is 73 feet, or 19 feet 3 inches more: at Bologna it is 74 feet, or 20 feet 3 inches more: in the present theatre of Covent Garden, it is 69 feet 8 inches, or 15 feet 11 inches more. The advantages of which difference between the theatre now building in Drury Lane, and those I have just mentioned, in point of distinct sound, are obviously not less than they are with respect to vision, and they are in both so evident, that they need not be here detailed. It may be right to remark, that the theatre at Bourdeaux is exactly of the form which I have chosen; and that theatre is always quoted as one in which the voice is better heard than in almost any theatre in the world.—Before I conclude this part of the subject, I shall mention one more point, which bears very seriously upon the distinctness of sound in a theatre, namely, the uniform depth from the front to the back of the boxes throughout the house: it has hitherto been invariably the practice in our theatres, to carry the boxes facing the stage to a much greater depth than those on the sides of the theatre; and, by so doing, to produce a great difference between the form of the wall immediately at the back of the boxes, and that of the breast-work, or front of those boxes.

"Having stated my observations with respect to the advantages in point of sound which I conceive to be attendant on the circular form, I shall now offer a few remarks upon its comparative and positive merits with respect to vision. In entering on this branch of the subject, I should wish to anticipate a question, which may possibly arise in the minds of some persons, why we should not, in the form of our theatres, adopt the semicircle, which was generally in use among the ancients, and which has evidently great advantages with respect to vision? The answer to this is, that the semicircle requires either that the stage-opening should be of enormous width, or that the size of the house should be extremely small, and therefore it is inadmissible in our theatres. It is inadmissible on the first point, namely, the enormous width of the stage as to opening, for the reasons which have been already shown (under the first head) upon that subject: and it is equally so upon the second point, because it is impossible to maintain a good theatre in this metropolis upon such a revenue as would accrue from an extremely small house. So long as the public taste for spectacle shall continue (and it is not likely to cease) all the objections to increasing the stage opening, and with it the magnitude and expense of the scenery, must remain in force. The Greeks and Romans, in their theatres, made use of scarcely any change of scenes, and their performances were given gratis to the public; consequently, their theatres were not subject to many of those considerations which are attached to ours. Under these circumstances, therefore, the semicircle is totally inadmissible for a principal theatre in London. The oval and the horse-shoe, as well as some flat-sided forms, have been supposed to be very advantageous in point of vision; but it is evident, that in the oval, a large proportion of the spectators must be placed with their backs inclining towards the scene, and that in all of them (if the house be not of extremely small dimensions) the front boxes must be at a great distance from the stage; for, in proportion as the sides shall approximate each other, the front must recede, provided the circumference be not varied.

"The fact is, there is no object connected with the formation of a theatre, which, in all its bearings, is of more importance than that that part of the house which faces the scene should be within a moderate distance of the stage; unless that be the case, it is obvious that a very large proportion of the spectators must be excluded from a clear and distinct view of that play of the features which constitutes the principal merit of the actor in many of the most interesting scenes. If the actor's merit in that particular be not fairly appreciated, he must, of course, be deprived of a proportionate share of the applause which might otherwise be bestowed on him, and this mortifying want of encouragement, bringing with it a gradual and progressive defect of zeal and emulation, cannot fail in the end to reduce the number of good actors, and materially to injure the state of dramatic performances.

"For the sake of argument, let it be supposed for a moment, that an oval, or horse-shoe, or flat-sided figure, is the best for side-vision, and the fact will then be, that, although in adopting either of those forms, provision may be made for the better accommodation of spectators sitting on the sides of the theatre, that accommodation will be given to them at a serious expense to those sitting in the front, for, while it will enable those who may sit on the sides of the house to see a greater proportion of the stage in cases of spectacles, (though not in ordinary,) those who are placed in the front will be proportionately excluded from that distinct view of the actor's countenance which is not less desirable than to be within the reach of his voice. But in point of fact, the oval, horse-shoe, or flat-sided theatre, is not so well calculated even for side-vision, as that which I have chosen; for there is one consideration of very great importance to each of these forms, and which appears entirely to have escaped observation, although obvious on reflection, namely, that although in either of them, the spectators who sit in the front row of the boxes on each side of the house, may be enabled to see rather more of the stage when extended to an extraordinary depth, those who sit in the back-seats in all the boxes above stairs, (which it should be remembered constitute in point of extent the greater part of the house,) will see considerably less of the stage than in a theatre of circular form; where, of course, the sides of the theatre will, from their swelling-shape, recede from the stage much more than in either of the others; for nothing can be more unquestionably true, than that the more the boxes on each side shall advance towards the centre-line of the theatre, the more must they necessarily overhang the stage, and all the objects on the stage; and that the more they shall overhang those objects, the more perpendicular the rays of sight (especially from the upper part of the boxes) must become, and, consequently, the less those who sit on the back-rows of the upper boxes will be able to see of the performance on the stage. In proportion as the point of sight shall be at a greater distance from the stage, the visual rays will have an oblique direction towards the stage; and a greater proportion of the breadth, as well as depth of the stage, than appears in the plan, will be opened to view in all situations. However, the comparative advantage which has been stated, namely, of seeing one-fifth more of the breadth of the stage, will belong to the circular form, a fact which I wish to impress upon the mind of the reader. There is an exemplary instance of this in the House of Commons; for, from the second row of seats on the side-gallery, (taking a position opposite the side of the table, or speaker's chair,) it is impossible to see the speaker, or any part of the floor of the house, although the whole of the seats on the opposite side of the house, upon a level with the speaker, and even below him, (being farther removed from the point of sight,) are perfectly visible; whence it is evident, that the more the position of the spectator shall recede from a perpendicular point with respect to the objects below him, the more those objects will be opened to his view: and while it is thus clear, even for the purposes of side-vision, that the oval, horse-shoe, or flat-sided theatre, is inferior to the circular form, it is, on the other hand, impossible for prejudice itself to resist the proof, that in the form I have chosen, namely, three-fourths of a circle, a much larger proportion of the whole house will be placed immediately in front of the scene, than could be the case in either of the other three forms which have been named. Impressed by the importance of all the foregoing considerations, I determined to adopt, in my design for a theatre, the form I have described; and although I was aware at the time when my drawings and model were first made, that a certain proportion of the spectators in the boxes nearest to the stage, would have but an imperfect view of the stage, I considered that as an unavoidable inconvenience in all theatres, and not greater in that projected by me, than all others; while on the other hand, the form which I had chosen, possessed many advantages which could not be derived from any other shape.—The angles, however, to which I allude, in the boxes nearest to the stage, having appeared to several persons, who saw my model, as an imperfection to the design, and those persons seeming to view the defect more in its positive than in its comparative bearing upon the perfection of a theatre, I was led to reconsider, most attentively, this particular part of the design; and after a great deal of reflection, and a variety of experiments, I determined to alter the shape of that part of the theatre adjacent to the stage, by opening the proscenium from the back, instead of from the front of the boxes. The scene (excepting in cases of spectacle) is seldom extended in depth beyond 30 feet from the front line of the stage.

"In the theatre of Parma, (which is particularly celebrated both for sound and vision,) the frontispiece of the stage-opening is placed at a distance of no less than 40 feet from the termination of the spectatory, for the purpose of opening a view of the scene to the spectators sitting nearest to the stage; and the width of the stage-opening in that theatre, with a view to the same desirable object, is extended to 39 feet, exceeding by 4 feet the width which is given to that opening of my design.

"In discussing this subject, I have hitherto confined myself to those considerations connected with the form of the theatre, which appertain directly to the two primary objects of distinct sound and vision; and I trust, that I have shown completely, that there is no admissible form so well calculated to secure those objects, as that which I have adopted in my design. But there is another consideration of great importance, which appertains to the form which I have chosen, and which does not relate to either of the objects above mentioned; namely, its decided superiority over every other form in point of beauty, for a circle is a form which will never weary or distress the eye.

"In building our early theatres in this country, little attention seems to have been bestowed upon the means of favouring sound or vision: in the form of those theatres, their sides were either entirely parallel, or diverging but little from each other; and if those theatres had not been confined to very small dimensions (such as would not be consistent with the present population and condition of the metropolis) there can be no doubt that their form would have been found to be extremely defective. The first gradation of improvement in this respect, appears to have been the introduction of the oval, and the horse-shoe, by rounding of the angles of the former shape, and thus we have been approaching gradually to that form which I now propose, and which deviates as little from the Greek and Roman amphitheatres, as the state of circumstances will admit. The original theatres of Drury Lane and Covent Garden, as well as the old Opera House, and Foote's theatre in the Haymarket, were all flat-sided; the latter (never having been rebuilt) is so to this day. The late theatre in Drury Lane was nearly oval, and the present Opera House is in the form of a horse-shoe.

"There is one other point in a great degree connected with the form and proportions of the theatre, to which I must advert, before I entirely conclude this part of the subject; namely, the height of the ceiling. In forming my design, it has been my object to avoid raising the ceiling beyond the proportion which I think it ought, for the sake of the symmetry, to bear to the open area which it is to cover: that proportion is, in my opinion, about three-fourths of the diameter of that area, but not less. I do not believe that the height of the ceiling can in any degree injure or affect the sound of the voice in the lower parts of the theatre; it may materially assist in conducting the sound into those parts of the house which are nearest to it: but it must, in every theatre, be much too high to act as a reverberator, or sounding-board, to the lower parts of the house. If this were not the fact, the voice would be quite indistinct and inaudible in a cathedral church, where the roof is at a vast height: the form of that roof, not calculated for direct reverberation of sound, and the person uttering the sound at the reading-desk, placed in a situation by no means so well calculated to convey the sound of his voice generally among his auditors, as that in which an actor upon the stage is placed: yet we know, that even under all these circumstances, the voice is heard in most of the cathedral churches quite as well as it is in many chapels; which is a positive proof that a low ceiling is not essential to the strength and clearness of sound in a theatre. If it were necessary to support this opinion, the whispering gallery in St. Paul's cathedral would serve as an additional proof, that sound may be distinctly heard in a large enclosed area (provided that area be in itself so constructed as to facilitate the conveyance of sound) without any direct reverberation from above; the great height of the dome above the floor of the whispering gallery, together with the large aperture in the centre of the dome itself, are sufficient to demonstrate, that the extraordinary effect of sound in the whispering gallery, is in no degree produced by reverberation from above. Under this conviction, I have been influenced in the height at which I have fixed the ceiling, by the proportion which appeared to me to be most in symmetry with the area to be covered by that ceiling. I feel confident, that upon a serious and impartial attention to the facts and deductions contained in the foregoing pages, it will be admitted, that the form which I have adopted is the best form: 1st, as to size and capacity; and 2nd, as to distinct sound and vision."

The following are the Dimensions of the Interior of Drury Lane Theatre.

The stage-opening, 35 feet.

The widest part of the area, upon the level of the dress boxes, 58 feet.

Depth of the dress boxes, 9 feet 6 inches.

Depth of the three upper tiers of boxes, 8 feet.

From the front line of the stage to the front of the dress boxes, in the widest part, 44 feet 3 inches.

Theatre, among the ancients, a building encompassed with porticos, and furnished with seats of stone, or marble, disposed in the area of a semicircle, and ascending, by degrees, over each other, for the use of the spectators to behold the performances. The orchestra, or place where the musicians performed, was situate in front of the spectators. The stage, or place where the actors performed, was called *the orchestra*. The area beyond this was called *the proscenium*, or *pulpitum*. At the extremity of the proscenium stood *the scena*, a large front, adorned with the orders of architecture; and, behind, was the place where the actors made themselves ready, called *the postscenium*. *See* Amphitheatre.

THEODOLITE, an instrument for taking angles, whether in a horizontal or in a vertical plane.

If 29 half-degrees of the horizontal circle be taken for the length of an arc on the vernier, and this arc be divided into 30 equal parts, the vernier will show to a single minute, by observing when a coincidence takes place between a division of the vernier and one of the horizontal circle, or limb.

THEOREM, (Greek,) a proposition which requires to be demonstrated.

THEOTHECA, (Greek, θεος, *god*, and θήκηα, *repository*,) the receptacle for the consecrated host; it is of various forms and sizes, but usually of the most costly materials. The same as *Monstrance* or *Remonstrance*.

THOLE, the knop or scutcheon in the midst of a timber vault.

THOLOBATE, that part of a building on which a cupola is raised; the base of a cupola.

THOLUS, the name given to buildings of a circular form. Vitruvius employs the term to signify the roof of a circular building.

THOROUGH FRAMING, the framing of doors and windows: a term not much used at present.

THOROUGH-LIGHTED ROOMS, those which have windows on two opposite sides.

THRESHOLD OF A DOOR, the sill. *See* Sill.

THROAT. *See* Gorge, and Gula.

THROATING, the channel cut on the underside of a stone, &c., to prevent the further passage of rain, which is here collected, and drips off the building.

THROUGH-STONE, a bond stone; one which runs through the heart of the work.

TIE, (from the Saxon, *tian*, to bind,) a timber, string, chain, or iron rod, connecting two bodies together which have a tendency to diverge from each other. The tie-beams, diagonal ties, and truss-posts, are ties. Braces may act either as ties or straining-pieces: straining-pieces are preferable to ties, for these cannot be so well secured at the joints as straining-pieces.

Tie-Beam, the beam which connects the bottom of a pair of principal rafters, and prevents them from bursting out the wall. *See* Tie and Truss.

Tie-Rod. *See* Tension-Rod.

TIERCE POINT, the vertex of an equilateral triangle. Arches, or vaults, of the third point, which the Italians call *de terzo acuto*, are such as consist of two arcs of a circle intersecting at the top.

TIGE, a term used by the French for the shaft of a column.

TILE, (from the Saxon, *tigle*,) an artificial stone, or broad thin brick, made of dried earth, and burnt in a kiln, used in covering buildings. *See* Brick.

Tiles have various names, according to their surface, shape, or situation.

Those of a rectangular form, with a plane surface, are denominated *plane tiles* and *crown tiles*: their dimensions are about 10½ inches long, 6 inches broad, and five-eighths of an inch thick. A plane tile weighs from 2 lb. to 2½ lb.

Those of a cylindric form are denominated *ridge tiles, roof tiles*, or *hip tiles*, and are used in covering the ridges of houses. Their dimensions are, in length, about 12 inches, in breadth 10, and in thickness five-eighths of an inch. The weight of a ridge tile is about 4½ lb. Tiles which are placed on the angle formed by the two sloping sides, are called *hip tiles*.

Tiles to be placed in gutters, have a form adapted to their situation: the weight of a gutter tile is the same as that of a ridge tile.

Tiles of a rectangular outline, with a surface both concave and convex, are denominated *pan tiles;* these have no holes, but are hung on the lath, by means of a ledge, formed in their making, at their upper ends: they are usually 14½ inches long, and 10 broad. They weigh from 5 lb. to 5¼ lb.

Tile-Creasing, two rows of tiles placed horizontally under the coping of a wall, and projecting about three inches from the surface, for discharging the rain-water therefrom.

Tiles, Encaustic, decorative tiles formed of different-coloured clays, arranged so as to form a variety of patterns. The ground is usually red, and this being stamped with some pattern, the recess is filled in with clay of various colours, frequently white, the whole being afterwards glazed over with a yellow glaze. Frequently each tile presents a complete pattern, but at other times a pattern is composed of four or more tiles arranged in juxtaposition. Such tiles are mostly used in ecclesiastical buildings, and are often interspersed in regular order amongst tiles of a plainer description, by which means their beauties are more fully displayed.

TILING, the act of laying tiles for the covering of a building, which may be done either with plane tiles or pan tiles. Plane tiling is preferable to pan tiling. Plane tiles are laid at a 6-inch gauge, with or without mortar; and pan tiles at an 11 or 11½ inch gauge, though some use a gauge of 12 inches, but this distance is too great.

From the frequent repairing of tiled roofs, and their fiery appearance, slating has now become the general covering, and tiling is seldom used except for common cottages, sheds, and out-houses, as being more expensive to keep in repair than slating.

TIMBER, (from the Saxon, *timbrian*, to build,) in carpentry, a piece of wood for supporting some part or parts of the building, or to give strength to any part thereof.

Timbers, in a building, support parts of the fabric in three different ways, viz., by lateral strain, by tension, and by compression.

Timber, wood felled and seasoned for the purpose of building. Many kinds of woods are useful for building purposes, but those most frequently employed are oak, fir, and pine; but before entering into the peculiar properties of these, it will be as well to give some idea of the structure and growth of trees in general.

Upon observing the transverse section of the stem or trunk of a tree, the wood will be found to be composed of numerous concentric layers or rings, which are more or less defined in different trees. Where the rings are well defined, they will be found to consist of two parts, the outer being hard, compact, and of a dark colour, while the inner is of a lighter tint, more soft and porous. In the centre of the tree is the pith, and on the exterior the bark, and it will be observed, that the concentric rings become more soft, and contain more sap as they recede from the pith, the more compact layers nearest the pith being termed heart-wood.

The structure of a tree appears to be composed of minute vessels for conveying nutriment from the roots; the space between these vessels being occupied by cells, which are engaged in performing the function of secretion. The vessels in the growing tree convey the sap in a liquid state from the roots to the leaves, whence it descends in a less liquid state through the bark, and is at last deposited in an altered state between the bark and the last year's wood, forming a new layer of bark and sap-wood, the old bark being pushed outward, and the inner layers being compressed, probably in an equal degree. The sap begins to ascend in the spring of the year, and flows principally through the annual rings next the bark, which contain most sap-wood. In its ascent, it would appear to dissolve some part of a substance which had accumulated in the vessels during the preceding winter, for the nourishment of the buds, leaves, and new wood; and this accounts for the viscous state of the sap on its descent. As the leaves expand, the sap ceases to flow, and the bark again adheres to the wood, and, from the middle of June to the middle of August, there appears to be a pause in vegetation; but after this period, the sap again begins to flow.

As this process goes on from year to year, the fluid parts of the interior of the wood, are absorbed by the new wood and leaves, and the vessels through which they flow, being pressed more closely together by the growth of new wood, become harder and harder, until at last the sap-wood is converted into heart-wood; for it would appear, that there is nothing of the character of solid fibres in wood, the more compact parts being composed solely of the linings of the vessels and cells deprived of their moisture, and packed closely together. When trees arrive at this stage of existence, that is to say, when the sap-wood has become heart-wood, and the greater part of the moisture has been expelled, they are in a fit state to be felled for the purposes of building. The best time for felling is in mid-winter or midsummer; for in the former the sap has ceased to flow, and in the latter it is expended in the production of leaves. Besides the concentric rings, another series of lines may be observed with more or less facility in the sections of various trees;

these lines radiate from the centre, and are termed medullary rays; they produce that beautiful flowered appearance in the oak, to which the name of silver grain has been given.

It will not be necessary here to treat of the seasoning of timber, as that subject has been treated on in another place. *See* SEASONING OF TIMBER.

If timber be properly seasoned, and kept in a dry situation, with a free circulation of air, it will last for several centuries, but even under the most favourable circumstances it gradually deteriorates, it loses its elastic and coherent properties, and becomes brittle at last. If it be kept immersed in water, it will also last a very considerable period; but it is not uninjured, for if it be taken out and dried, it becomes brittle, splits, and cracks in every direction. Alternate changes of dryness and moisture is very injurious to timber, and under such conditions it rapidly decays, as may be observed in the upper part of piles driven in a tidal river, viz., that part which is contained between high and low water. Moisture, combined with a certain degree of heat, about 45 degrees, will gradually decompose timber, especially when exposed to the air. This rot is usually divided into two kinds, the wet and dry rot; these, however, are both produced by the same causes, the only difference being that the former takes place when there is a free evaporation, the latter when the evaporation is imperfect; the one takes place when there is a free circulation of air, the other when the air is confined.

The best method of preserving timber, and preventing decay from any of the above causes, is by proper seasoning, but it must be thoroughly seasoned, partial seasoning being of little avail. A coating of paint, tar, or other preparation, will help to defend the wood from injury by external causes, but will be of no service if any moisture remain in the interior, for it will only prevent its escape, and thus hasten decay. Paint is also useless, unless fresh coats be repeatedly applied, for it is as liable to decay as the timber itself, and therefore requires to be constantly renewed. If the paint be sanded over, it will be found much more durable than common painting. A very good preparation consists of linseed oil and tar put on boiling, the wood being first thoroughly heated; this will sink into the wood, and close up all the pores. Charring the wood will be found an excellent method, and is in many respects better than some of the above. No composition should, however, be applied till the timber has been well seasoned, for to inclose the natural juices of the wood, is to render its rapid decay certain.

Description of Woods.—Of oak there are several kinds, two of which belong to England—the common British oak, and the sessile-fruited oak. The first is found in the temperate parts of Europe, and is that which is commonly met with in the south of England. The wood has often a reddish tinge, and the larger septa are very numerous, producing large flowers; the grain is tolerably straight and fine, and free from knots. It splits freely, and makes good laths for plasterers and slaters; and is decidedly the best kind of oak for joists, rafters, and for any other purposes where stiff and straight-grained wood is required. The second kind is found in the temperate parts of Europe, and in the north of England; it is of a darker colour than the preceding, and the larger septa are fewer in number; the grain is smooth and glossy. It is heavier, harder, and more elastic, and is apt to warp and split in seasoning; it is tough, and difficult to split.

The Dursault oak is a native of France and the south of England, but it is not so strong nor of so firm a texture as the above. The wood of the Austrian and American species is not very valuable; the former being comparatively soft and the latter coarse-grained. The mountain red oak, from Canada, is useful for many purposes, but is light and spongy, and not very durable. The white oak, also from America, is more valuable, being tough and pliable, and more durable than the other species.

The colour of oak is a fine brown of various shades; that inclined to red is the most inferior kind. The transverse septa are usually large and distinct, but are smaller and less distinct in the stronger kinds of wood. The texture is alternately compact and porous.

Oak is particularly adapted for situations exposed to the weather, and makes the best wall-plates, ties, templets and king-posts, but is liable to twist and warp when drying.

Beech is not much used for building, and soon rots in damp situations; in dry situations it is more durable, but is liable to be injured by worms; it is best adapted for piles and other works where it is constantly immersed in water. It is stronger and tougher than oak, but not so stiff. The colour is whitish-brown, of different shades; the texture is very uniform, and the septa smaller than in oak.

Alder has much the same qualities as beech, being very durable in water, but rotting when exposed to damp, and subject to worms in a dry state. The colour is reddish yellow of different shades, and nearly uniform; the texture is very uniform, with larger septa of the same colour as the wood. It is soft, and works easily.

Of plane trees, that from America is very durable in water, but they are not much used for building purposes. The colour and structure is similar to that of the beech, but in this case the septa are more numerous.

Chesnut may be used in many places as a substitute for oak, the wood is hard and compact; when young it is tough and flexible, but when old it is brittle and often shaky. It does not shrink and swell much, and is easier to work than British oak, and contains only a small proportion of sap wood.

The wood of chesnut is so much like that of oak, that it has frequently been mistaken for it; it has, however, no large transverse septa, and in old wood the sap-wood is whiter, and the heart-wood browner, than in oak.

Ash is superior to any other British timber for its toughness and elasticity; it is tolerably durable in a dry situation, but soon rots when exposed to damp or alternate changes of wet and dry. It is too flexible for the timbers of buildings, and in old trees is of a brittle nature. The colour is oak brown, the veins being darker than in oak; in young trees, however, the colour is lighter. The texture is alternately compact and porous, the rings being strongly marked; there are no large septa.

Elm is not much used for building; it is very durable in water, as also when perfectly dry, but will not stand exposed to the weather. It is difficult to work, but not liable to split; it twists, shrinks, and warps much in drying. The heart-wood is generally darker and redder than that of oak, and the sap-wood of a yellowish or brownish white; it is porous and cross-grained, but has no large septa.

The common acacia is very durable; it is equal or superior to oak in stiffness and toughness, and is very valuable for fencing. The colour is a greenish yellow, with a slight tinge of red in the pores, and is, in structure, alternately compact and very porous, so that the rings are very distinct; it has no large septa.

There are several species of poplars, of which the Lombardy, black, and common white, are mostly esteemed. They are all very durable when preserved in a dry state; and the aspen or trembling poplar will last a considerable time exposed to the weather. They are not well adapted for large timbers, but are well fitted for flooring, where there is no great wear, they do not take fire readily.

The colour is of a yellowish or brownish white, one side of the annual rings being a little darker than the other. The wood is of a uniform texture, and has no large septa.

Red or yellow fir is the produce of the Scotch fir, and is common in the north of Europe, in Scotland, Russia, Denmark, Sweden, Norway, and Lapland. It is very durable; and its lightness and stiffness render it superior to any other material for beams, girders, joists, rafters, and framing in general. It is also much used for joiners' work, both external and internal, being cheaper and more readily worked than oak. The wood from cold climates is stronger than that from warmer situations. The colour is of a reddish or honey-yellow, and of various degrees of brightness; the layers are well marked, the one part being soft and light-coloured, the other hard and dark: in the best timber the rings are thin, not more than $\frac{1}{10}$th of an inch in thickness. The inferior kinds have thick annual rings; in some kinds the dark parts of the rings are of a honey-yellow, the wood, heavy, and filled with soft resinous matter, feels clammy, and chokes the saw. In other inferior kinds it is spongy, contains less resinous matter, and leaves a woolly surface after the saw.

White fir, or deal, is the produce of different varieties of spruce fir, and is imported from the north of Europe, and from America. Of Norway spruce, a great quantity is imported from Christiana in deals and planks, which are very highly esteemed. The American wood is not so resinous as that from Norway; it is tougher, less heavy, and generally more liable to twist in drying. It is of two kinds, white and black spruce, the latter producing the best wood. White deal is very durable in a dry state, and is much used for internal joiners' work.

The colour is yellowish or brownish white; the hard part of the annual ring a darker shade of the same colour, often has a silky lustre, especially in the American and British-grown kinds. Each annual ring consists of two parts, the one hard and the other softer. The knots are generally very hard. The clear and straight-grained kinds are often tough, but not very difficult to work, and stand extremely well when properly seasoned.

The Weymouth, or white pine, is a native of North America, and is imported in large logs, often more than 2 feet square, and 30 in length: it is one of the largest and most useful of the American pines. The wood is light and soft, and is said to stand the weather tolerably well. In joinery it is much used for mouldings and other work, where clean straight-grained wood is desirable; but it is not durable, nor fit for large timbers, being very liable to take the dry-rot. The colour is brownish yellow, and the texture more nearly uniform than that of any other of the pine species, and the annual rings not very distinct.

The pitch pine is a native of Canada. It is very resinous and heavy, but not very durable: it is also brittle when very dry. It is of a redder colour than the Scotch pine, feels sticky, and is difficult to plane.

The silver fir is a native of the mountains of Siberia, Germany, and Switzerland, and is common in British plantations. The wood is of a good quality, and much used on the continent both for carpentry and ship-building. The harder fibres are of a yellow colour, compact and resinous; the softer nearly white. It is light and stiff, and does not bend much under a considerable load; consequently floors constructed of it remain permanently level. It is subject to worm.

Of the larch there are three species; one European, and two American. The wood is extremely durable in all situations, even when exposed to damp and weather; it is adapted for both internal and external work, and especially for flooring boards, which are subject to much wear; also for doors, shutters, &c.

The wood of the European larch is generally of a honey-yellow colour, the hard part of the annual rings of a redder cast; sometimes it is brownish white. In common with the other species of pine, each annual ring consists of a hard and soft part. It generally has a silky lustre, and its colour is browner than that of the Scotch pine, and it is much tougher. It is more difficult to work than Riga or Memel timber, but the surface is better when once it is attained. It bears driving bolts and nails better than any other kind of resinous woods. When it has become perfectly dry it stands well, but warps much in seasoning.

The following table, showing the comparative strength, stiffness, and toughness of various woods, taking English oak at 100 as a standard, is compiled from Tredgold, from whose work the above observations are principally extracted:—

Name of Wood.	Strength.	Stiffness.	Toughness.
Common English Oak	100	100	100
Riga Oak	108	93	125
American Oak	86	114	64
Dantzic Oak	107	117	99
Beech	103	77	138
Alder	80	63	101
Plane Tree	92	78	108
Sycamore	81	59	111
Green Chesnut	68	54	85
Ash	119	89	160
Elm	82	78	86
Unseasoned Acacia	95	98	92
Spanish Mahogany	67	73	61
Honduras Mahogany	96	93	99
Walnut	74	49	111
Teak	109	126	94
Abele Poplar	86	66	112
Lombardy Poplar	50	44	57
Cedar	62	28	137
Foreign Fir	80	114	56
Mar Forest Fir	61	49	76
English-grown Fir	60	55	65
Christiana Deal	104	104	104
American White Spruce	86	72	102
British-grown Norway Spruce	70	81	60
Weymouth Pine	95	99	103
Pitch Pine	3	82	92
Larch	103	79	134

For further information on this head, see STRENGTH OF MATERIALS.

TIMBER BRIDGE. *See* WOODEN BRIDGE.

TIMBER MEASURE, 43 solid feet make a ton of timber, and 50 feet a load.

TIMBER PARTITIONS, are board and brace, or quarter or stud partitions. Board and brace partitions are made of narrow boards, or battens, with a thin board between every two battens inserted into their edges: the batten is about half the width of a board.

TIN, a very useful metal, found principally in Cornwall. It is of a silvery-white colour, with a very slight shade of yellow; it is very soft and malleable.

TING, a Chinese temple. *See* CHINESE ARCHITECTURE.

TINNING. The process of covering other metals with tin for the purpose of preventing rust or oxydation. The practice was very commonly adopted in mediæval metal-work.

TOMB. The custom of interring the dead seems to be more ancient than that of burning, and in many countries we find that great pains were taken to preserve them by embalming and similar methods. The practice of burning the bodies would seem to be of later date, and at no period of time universal; under these circumstances, however, the ashes were usually preserved with great care in some structure set apart for that especial purpose. Great reverence has always been shown for the bodies of the departed; a feeling which has been exhibited in different manners, according to the time and place: the interment would appear to have been always connected with some religious rite. In some places, the bodies were simply inhumed or deposited in the earth without any erection above them, save that of a tumulus of earth; in others, they were embalmed at great expense, and placed in structures of greater or less magnificence; whilst in others again they were deposited in natural caves or excavations beneath the surface of the earth.

Perhaps no people have ever expended greater care upon their dead than the Egyptians, a fact which may be readily accounted for by the tenets of their religion. This nation was accustomed to adopt both the latter practices, as is manifest by their building those vast structures, the pyramids, which have been proved to have been erected for the purpose, as well as by the existence of an extensive range of excavations below the surface of the ground. Of the latter, as well as of the pyramids, will be found an account under the article EGYPTIAN ARCHITECTURE, and of the PYRAMIDS, under that article.

Many sepulchral grottos have been found in the plains of Etruria. They are hollowed out of a rock, sometimes disposed in the form of a cross, or with three wings, and sometimes squared in different proportions. Doors have been formed to lead from one grotto to another; sometimes they are above each other. These grottos are not very deep, and the interior is often adorned with paintings. In Campania, also, several tombs have been discovered, containing Etruscan vases. They are represented as being formed by an enclosure of cut stones, and covered with a sort of roof or flagstone shelving on both sides. The dead body was stretched out on the ground, the feet turned towards the entrance of the sepulchre, and the head ranged against the wall, from which were suspended, by bronze nails, vases of terra-cotta, whilst others of a similar kind were disposed around the body.

At Agrigentum, the tombs are a sort of troughs ranged one above another, sometimes arched, or chambers with rent-holes in the roof, only two inches apart from each other. In some parts of Greece and Italy are sepulchral chambers excavated in the rock, and formed like a bell, as at Amphissa. In the valley of Ispica, in Sicily, Denon found tombs, formed out of a hollow stone, upwards of 5 feet long and 15 inches wide.

Tumuli, or large mounds of earth, are of very ancient date, and are to be found in various situations. They are frequently found encompassed by a large square wall, as that of Alyattes in Lydia, of Ægyptus in Arcadia, and of Phocus in Ægina besides many others in Greece and Asia, and in western Scythia. In one, with a circular wall, which was opened between Smyrna and Pergamus, were found galleries and chambers. One of the tumuli in the plain of Athens having been opened, was found to contain a chamber finely constructed of large blocks of stone, in which was a vase of terra-cotta, with figures and inscriptions.

Of a similar kind, though of smaller dimensions, were those mounds which are termed barrows, and which are common in many parts of Europe and Asia. "The Russians, in effecting a practicable road to China, discovered, in fifty degrees north latitude, between the rivers Irtish and Obalet, a desert of very considerable extent, overspread in many parts with tumuli or barrows." One of the largest of these barrows was opened by the Russian government, and was found to contain the body of a prince. "After removing a very deep covering of earth and stones, the workmen came to three vaults constructed of stones of rude workmanship. That wherein the prince was deposited, which was in the centre, and the largest of the three, was easily distinguished by the sword, spear, bow, quiver and arrow which lay beside him. In the vault beyond him, towards which his feet lay, were his horse, bridle, saddle, and stirrups. The body of the prince lay in a reclining posture upon a sheet of pure gold, extending from head to feet, and another sheet of gold of the like dimensions was spread over him. He was wrapped in a rich mantle, bordered with gold, and studded with rubies and emeralds. His head, neck, breast, and arms naked, and without any ornament. In the lesser vault lay the princess, distinguished by her female ornaments. She was placed reclining against the wall, with a gold chain of many links set with rubies round her neck, and gold bracelets round her arms. The head, breast, and arms were naked. The body was covered with a rich robe, but without any border of gold or jewels, and was laid on a sheet of fine gold, and covered over with another. The four sheets of gold weighed forty pounds. The robes of both looked fair and complete, but, upon touching, crumbled into dust." The tombs near Pergamus in Asia Minor are cones of earth with chambers or vaults constructed in the interior. The tomb of Anthridates in the Crimea, is an immense tumulus of hemispherical form, constructed with huge masses of stone of an irregular shape, heaped together without the aid of cement of any kind. This kind of construction is the same as that to be found at Tyrus and Mycene, and is supposed to have been of very ancient date. *See* PELASGIAN ARCHITECTURE.

The Romans do not seem to have adopted this kind of sepulchre, for although tumuli have been discovered in this country containing articles of Roman workmanship, yet our best antiquaries do not allow such to have been the burial-places of the Romans themselves, but rather of Romanized Britons, or of Britons engaged in their service. The general characteristics of a Roman place of interment in Britain, appear to consist simply of the plain grave, with one or more stone pillars bearing an inscription, and sometimes a sculptured device. At Chatham hill in Kent, a Roman sepulchre was discovered, of which the walls were composed of rubble-stone and hard mortar; the wall first discovered was 30 feet in length, and intersected by three apartments with their walls. One apartment which was complete, was 9 feet 3 inches by 7 feet 3 inches, with the inside of the walls covered with fine white plaster, on which were painted stripes of black and red. The urn containing the ashes of the deceased, was deposited on a pavement within the sepulchre, and round it were several vessels of different size and shape, pateræ, &c. A Roman sepulchre, discovered about two hundred and fifty yards from the wall of the city of York, was an oblong room with a ridged roof, covered with hollow Roman tiles; it was about 3½ feet long within, and contained several urns all standing on a tiled pavement. A burial-vault was discovered in Oxfordshire, which in the part explored was 20 feet long by 18 wide, and 8 high from the planking-stones. The human remains were laid in partitions of a dissimilar width, which crossed the vault from east to west, and were built with Roman red tiles, about 8½ inches square. The partitions were 2½ feet deep, and generally about the width of modern graves. Roman urns and other vessels were discovered among the rubbish. There were two tiers of sepulchral recesses, and above were a range of planking tiles covered with mortar and sand, in which was set tesselated work, supposed to have formed the flooring of a temple." In the year 1807, a Roman vault containing a scarcophagus, was discovered in the suburbs of York. The sarcophagus, which contained a skeleton, was cut out of a single grit-stone, and covered with a blue flagstone; its length was 7 feet; breadth 3 feet 2 inches; depth 1 foot 6 inches; thickness 4 inches. Near the vault, an urn of red clay was discovered, containing ashes and fragments of burnt bones. Stone coffins of a similar character, containing bones accompanied by urns, &c., have frequently been discovered. Coffins of brick also occur.

The tumuli, not unfrequently discovered in this island, are to be attributed for the most part to the Britons, as is often evidenced by the weapons, &c. found within them. The Saxons, however, it is probable, still continued the practice, though not for a very long period; their barrows are distinguished from the British by being devoid of any remains of garments, &c.; they are found in clusters, and are of the bell-shaped form. Those with cistvaens, urns, cups, beads, weapons in wooden scabbards, bosses of shields, &c. are British. The cistvaens, just mentioned, consist of three or four stones placed edgeways, and covered by another at the top. Several Saxon barrows are still to be seen in Lower Saxony. The custom of interring the body commenced to be practised by the Saxons, in all probability, upon their conversion to Christianity: their coffins were either of wood or stone, the latter being reserved for persons of wealth and influence; they were at first made of several stones, set round with one at the bottom, and one for a cover at the top, similar to the British cistvaens, but they were afterwards formed of a single stone, hollowed out, with a slab for a cover. In the earlier periods, the bodies of all persons were interred in the cemetery which surrounded the church, but in a short time, persons of rank, and ecclesiastics, began to be buried within the church; and, in such cases, the top of the coffin was generally level with the pavement, of which, indeed, it formed a part.

After a time, the tombs began to assume a different form, and became gradually of a more costly and imposing character. From the plain stone chest we come to that with a coped covering; and then we find the lid sculptured with some ornament, most frequently with a cross, plain or floriated. Next, we arrive at the raised tomb, which became more and more ornamented; and at last we have them covered with rich canopies, and embellished with the most minute and delicate carving. Some tombs in our larger churches and cathedrals still exist as specimens of the most elaborate workmanship of our ancient artificers. Stone tablets, inlaid with brass, were for some time common; the brasses which were engraved, represented the deceased in his usual costume, sometimes surrounded with a canopied niche, also of engraved brass, let into the slab, and usually having a border of inlaid brass round the edge of the slab, containing an inscription relative to the title of the deceased. Floriated crosses, and other figures, were sometimes inlaid in a similar manner; and, occasionally, the brasses were enriched with coloured enamel. Remains of brasses are very common, few old churches being without them.

During the whole of this period, burials in the church-yard were still common, tombs within the church being reserved for the great and noble. The church-yard stones were, of course, of a more simple description, being either of wood or stone, and most usually in the form of a cross, varying, however, greatly in design and outline.

After the Reformation, sepulchral monuments, together with architecture, began to decline in taste and execution; in design, they follow the prevailing style of architecture; and we find Italian details gradually introduced. Effigies were common; and it is not uncommon to find, during the Stuart period, effigies of an entire family on one tomb. Brasses were still prevalent, though of less beautiful design and workmanship. After this, the Italian, or rather Elizabethan style, was thrown aside, and we find groups of sculpture, of classic design, more or less successful, some of very extensive dimensions; in fact, at one time, size seems to have been the principal recommendation, as will be evident to any one visiting our cathedrals, where he cannot but lament the introduction of huge monstrosities, equally vicious in design and execution; and for the sake of these, too, he will see windows and arches blocked up, delicate workmanship defaced, and the whole effect of a grand design marred, if not destroyed. The ill taste displayed in the designs, and the monstrous adulation portrayed in the inscriptions of the monuments of the last century and a half, is enough to shock the feelings of any man who pretends to modesty or common sense. We are glad to see a better taste reviving in the present day.

Mr. Gough has classified the tombs of this country under eight different heads as follows:—

1st Form.—Coffin-shaped stone, prismatic and plain at the top.

2nd Form.—Prismatic and carved at the top, with crosses plain and fleury, as that of Theobald, Archbishop of Canterbury, in 1160, and that of Bishop Glanville, near the altar in Rochester Cathedral.

3rd Form.—Tables with effigies or sculpture, as that of Robert Duke of Normandy, in Gloucester Cathedral, with effigy cross-legged, in a coat of mail, A. D. 1134; King John, in Worcester Cathedral, 1213; Prelates in pontifical habits, first in half-relief, afterwards complete effigies, as Herbert Walter, Archbishop of Canterbury, 1205; Knights and nobles in armour, &c., as Longspee, Earl of Salisbury, 1226.

4th Form.—Tombs with festoons or arches over them, as those of Henry III., Edward I., Queen Eleanor, Edward the Black Prince, Henry IV., &c. This class was succeeded by more lofty tombs, with arches, crochets, pinnacles, finials, &c.

5th Form.—Tombs in chapel burial-places, consisting mostly of open screens, with doors, altar, monuments, piscinas, niches, &c., several of which are seen in the cathedrals of Wells, Salisbury, Exeter, &c.

6th Form.—Inlaid with brass, representing figures of the deceased, and inscriptions either in cameo or intaglio. These are mostly of the 14th century. Many fine specimens are engraved and published by Cotman.

7th Form.—Against walls, which chiefly occur since the Reformation.

8th Form.—Detached buildings, as domes, obelisks, columns, and equestrian statues.

TONDINO, a round moulding, representing a ring. *See* Torus.

TONGUE, (from the Saxon *tung*,) a projecting part on the edge of a board, to be inserted in a groove ploughed in the edge of another. Instead of a tongue wrought out of the edge of the solid board, sometimes both the edges to be joined are ploughed, and a tongue is made equal to the sum of the depths of both grooves, and being inserted into one of them, they are then driven home to each other. It is very difficult to glue two edges that are grooved and tongued together, unless the tongue be made very slack, on account of the difficulty of rubbing them. Work that is tongued should not be fastened with glue; white-lead and oil should be used in preference.

TOOLS, (from the Saxon *tol*,) implements used by artificers in the reduction of any material to its intended form.

The tools employed by the different professions of artificers in building are chiefly carpenters' tools, bricklayers' tools, joiners' tools, masons' tools, slaters' tools, and tilers' tools.

The bricklayers' tools have already been described under the article Bricklayer, it only remains here to give the reference to the Plate:

Figure 1.—The *trowel.*

Figure 2.—The *brick-axe.*

Figure 3.—The *square.*

Figure 4.—The *bevel.*

Figure 5.—The *jointing-rule.*

Figure 6.—The *jointer.*

Figure 7.—The *hammer.*

Figure 8.—The *raker.*

Figure 9.—The *line-pins.*

Figure 10.—The *rammer.*

Figure 11.—The *pickaxe.*

Figure 12.—The *camber-slip.*

Figure 13.—The *banker*, with the *rubbing-stone* placed upon it.

The carpenters' tools having been more slightly noticed, we shall here show their uses as they are referred to in the Plate.

Figure 1.—The *axe*, used in chopping timber by a reciprocal circular motion, with the cutting edge of the axe in a vertical plane.

Figure 2.—The *adze*, used in chopping timber by a reciprocal motion in a given plane, which is generally that of a vertical plane, but with the cutting edge describing a cylindric surface.

Figure 3.—The *socket-chisel*, used in mortising large timbers; and as the mortise is commonly bored by the auger, the chisel is generally less than the breadth of the mortise.

Figure 4.—The *mortise-gauge*, with a double tooth, made temporarily to serve only for the framing in hand.

Figure 5.—The *square*, used in forming right angles, and taking any kind of angles by observing the numbers on the sides of the square.

Figure 6.—The *plumb-rule*, used in setting work perpendicular.

Figure 7.—The *level*, used in setting work horizontal by means of the double square.

Figure 8.—The *auger*, for boring pin-holes, or holes in mortises, for the more easy cutting with the socket-chisel.

Figure 9.—The *hook-pin*, used in drawboring, or in bringing the parts of a large frame together.

Figure 10.—The *crow-bar*, for moving large pieces of timber.

References to Joiners' Tools. See Joinery.

Plate I. *Figure* 1.—The *jack-plane; a* the stock; *b* the tote, or handle, which being open on one side, is called *a single tote; c* the iron; *d* the wedge; *e* the orifice, where the shavings are discharged. *See* Plane.

Figure 2.—The *trying-plane.* The parts are the same as those of the jack-plane, except that the hollow of the tote is surrounded with wood, and on this account it is called *a double tote.*

Figure 3.—The *smoothing-plane*, without a tote, the hand-hold being at the end of the plane.

Figure 4.—The *iron.* No. 1, Front view of the cover for breaking the shavings, screwed on the top of the iron, to prevent the tearing of the wood. No. 2, Front of the iron without the cover, showing the slit for the screws which fasten the cover to the iron. No. 3, The profile of the iron and cover screwed together.

Figure 5.—The *wedge*, for lightening the iron. No. 1, The longitudinal section of the wedge. No. 2, Front, showing the hollow below, for the head of the screw.

Figure 6.—The *sash-fillister*, for throwing the shavings on the bench; *a* head of one stem; *b* tail of the other; *c* iron; *d* wedge; *e* thumb-screw, for moving the stop up and down; *f f* fence for regulating the distance of the rebate from the arris. *See* Plane.

Figure 7.—The *moving-fillister*, for throwing the shavings on the bench. No. 1, Right-hand side of the plane: *a* brass stop; *b* thumb-screw of ditto; *c d e* tooth; the upper part *c d*, on the outside of the neck, and the part *d e*, passing through the solid of the body, with a small part open above *c* for the tang of the iron tooth; *f f* the guide of the fence. No. 2, Bottom of the plane turned up: *a* the guide of the stop; *f f* the fence, showing the screws for regulating the guide; *g g* the mouth and cutting edge of the iron.

Figure 8.—The *plough*, being the same in every respect as the sash-fillister, except the sole, which is a narrow iron. *See* Plane.

Figure 9.—The *mallet.*

Figure 10.—The *hammer.*

Figure 11.—The *side hook*, for cutting the shoulders of tenons.

Figure 12.—The *work-bench: a* the bench-hook; *b b* the screw-cheek; *c c* handle of the screw; *d* end of the guide.

Plate II. *Figure* 1.—The *stock*, into which is fixed a *centre-bit.*

Figure 2.—No. 1, The *gimlet;* No. 2, The lower part, at full size.

Figure 3.—No. 1, The *bradawl;* No. 2, The lower end turned edgewise; No. 3, The lower end turned sideways.

Figure 4.—No. 1, The *paring chisel;* No. 2, The lower end turned edgewise with the basil.

Figure 5.—The *mortise chisel.* No. 1, The side; No. 2, The front; No. 3, The lower end, with the basil.

Figure 6.—The *hand saw. See* Saw.

Figure 7.—The *tenon saw;* generally backed with iron.

Figure 8.—The *sash saw;* generally backed with brass.

Figure 9.—The *compass saw*, for cutting in the direction of a curve-line.

Figure 10.—The *key-hole saw: a* the pad, in which is inserted a spring and two screws for fixing the saw to any length.

Figure 11.—The *square: a b c* the outer square; *d e f* the inner square; *a d e* the stock, or handle; *b c f e* the blade.

Figure 12.—The *movable bevel: a b* the stock; *b c* the blade.

Figure 13.—The *gauge: a a* the stem; *b b* the head, which moves; *c* the tooth, for cutting a sharp line on the surface of the wood. *See* Gage.

Tools, *Masons'*, are: 1. The *peck*, or *cavil*, for breaking and dressing the stone to any determinate size. 2. *Points*, from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch, for quickly reducing the prominent parts of a stone.

3. The *chisel*, from half an inch to two inches in breadth.

4. The *tool*, from two inches to two and a half or three inches in breadth.

5. The *mallet.*

As points will reduce the solid more than chisels, so will a narrow chisel reduce the solid more than a broad one; but the broader the chisel, the smoother the work; and hence broad chisels, or tools, are always used in the finishing of work. The tools here enumerated belong to the journeyman; but the master requires many others of a more extensive nature, as cranes, and other machines for hoisting up stones.

Tools, *Plasterers'*. *See* Plasterer.

TOOLS.

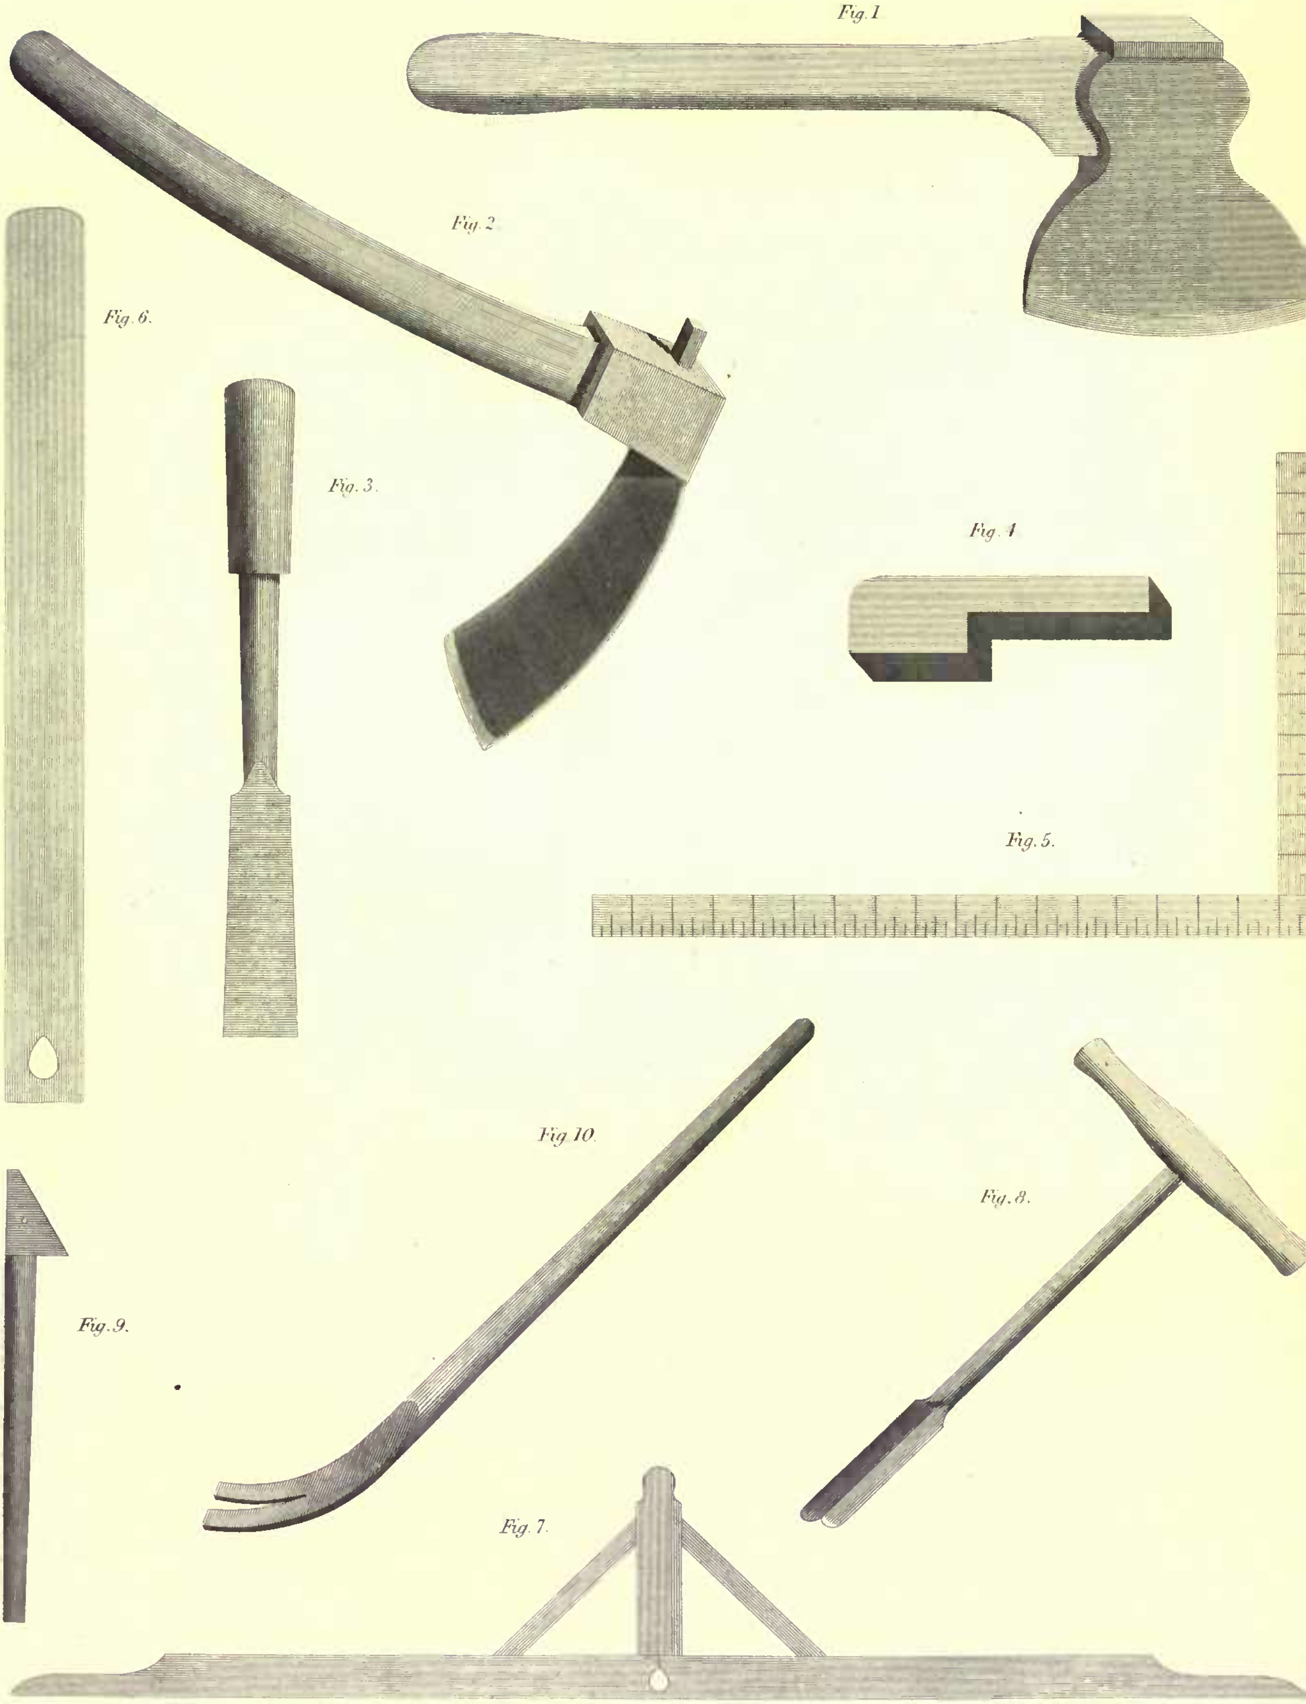
CARPENTER'S TOOLS.

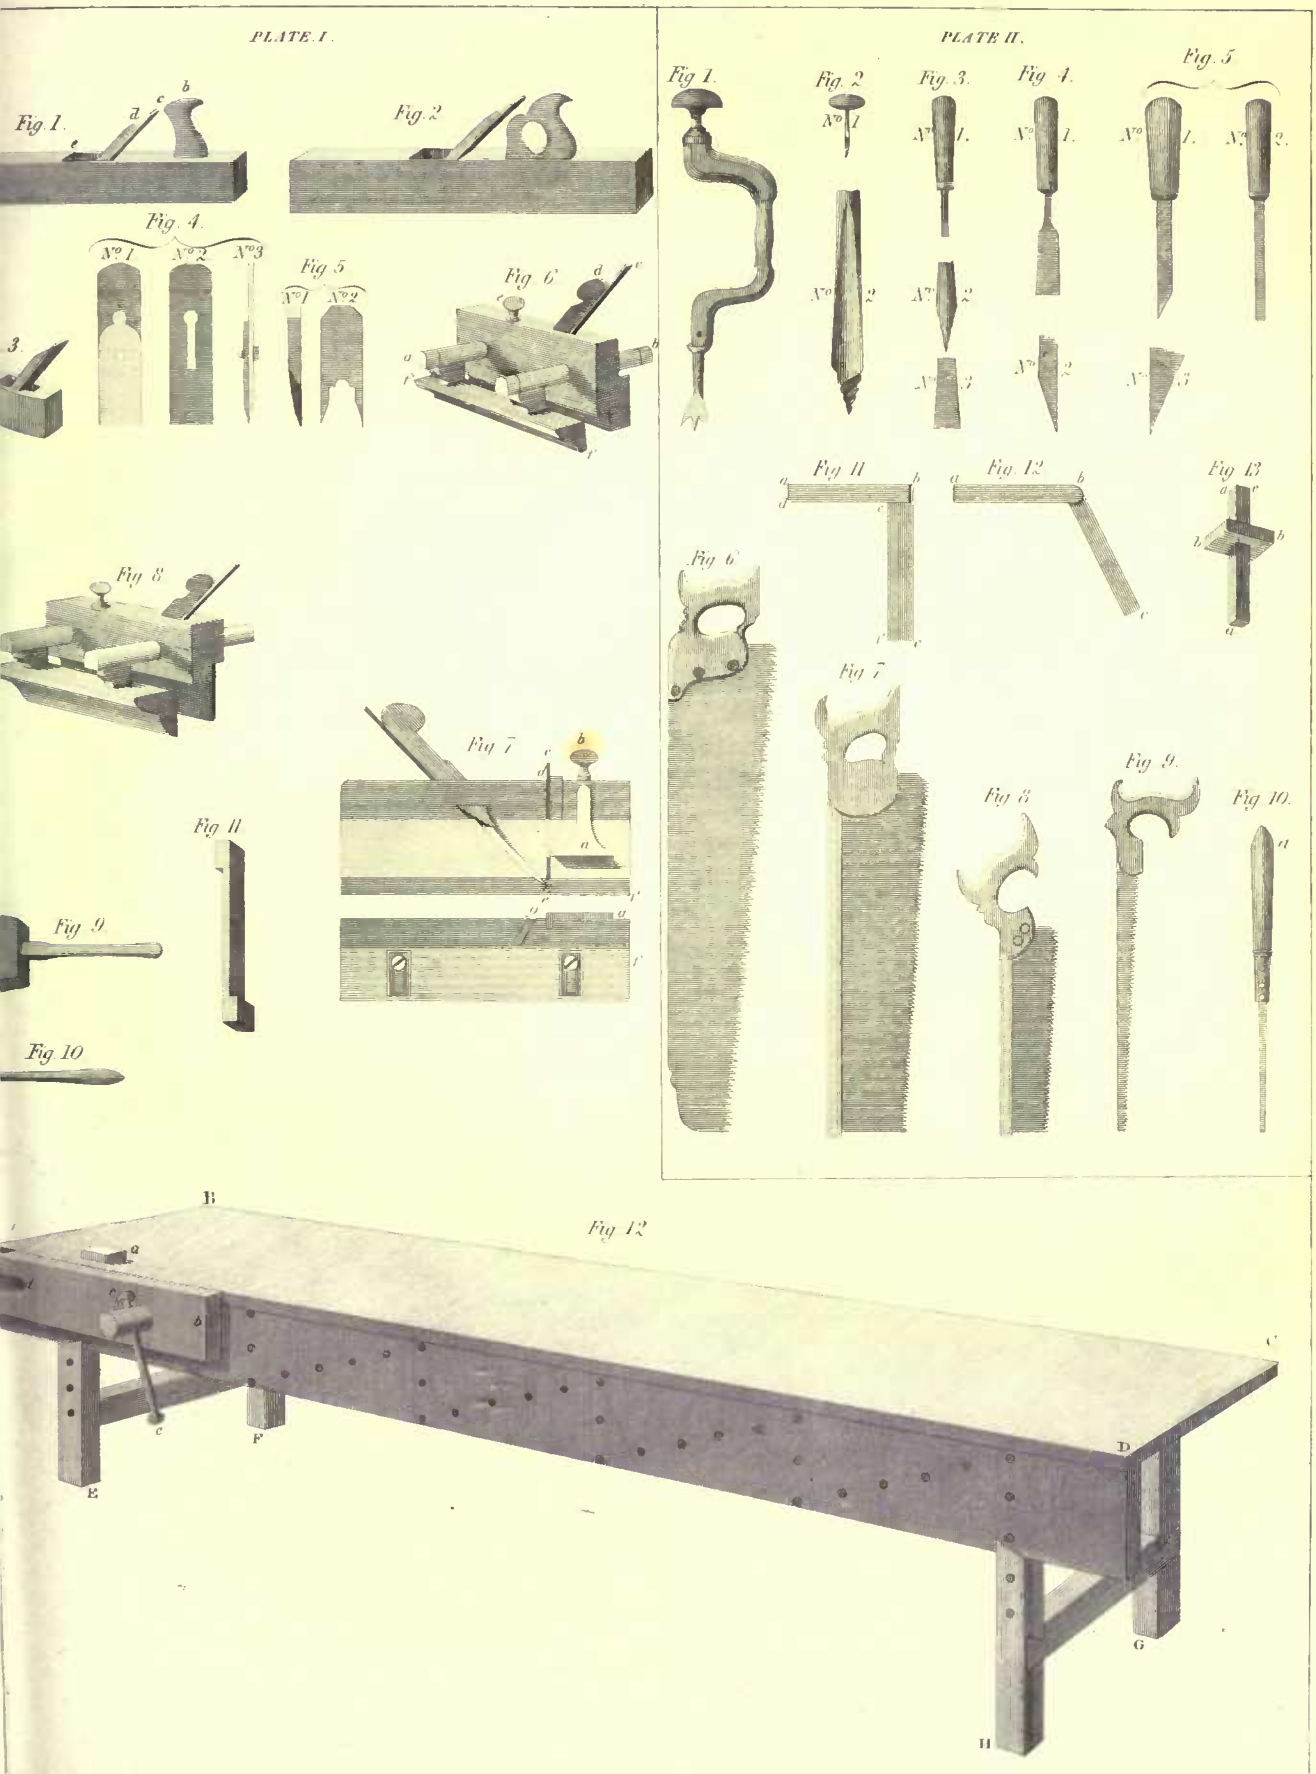


Drawn by M. A. Nicholson.

Engraved b

TOOLS.

BELONGING TO JOINERS.



Tools, *Plumbers'*. *See* Plumber.

Tools, *Slaters'*. *See* Slating.

Tools, *Tilers'*, are: 1. The *lathing hammer*, with two guage marks; one mark is placed at 7 inches, the other at 7½. This tool is used both for lathing and tiling.

2. The *lathing staff*, of iron, in the form of a cross, to stay the cross laths, and clinch the nails.

3. The *tiling trowel*, to take up the mortar and lay it on the tiles. It differs from the brick trowel in being longer and narrower.

4. The *bosse*, made of wood, with an iron hook to hang on the laths, or on a ladder for holding the mortar and tiles.

5. The *striker*, a piece of lath about ten inches long, for separating and taking away the superfluous mortar at the breeches of the tiles.

6. The *broom*, to sweep the tiling after it is strook.

TOOTH, the iron or steel point in a guage, which marks the stuff in its passage, or draws a line parallel to the arris of the piece of wood.

Tooth Ornament, a sculptured ornament common in and characteristic of buildings of the early English style of architecture. It consists of a sculptured flower of four leaves, disposed in a pyramidal form; the centre, where the leaves join, projecting above the general surface, to which it is applied as a decoration. It is commonly inserted in hollow mouldings, disposed either at intervals, or more frequently in close proximity one to the other. Its origin is naturally derived from the junction of two Norman zig zag mouldings meeting at an arris. *See* Dog-tooth Moulding.

TOP BEAM, the collar-beam of a truss: it has also been called *wind-beam*, or *strut-beam*. Collar-beam is now generally used, the other names being either antiquated or not much employed. *See* Collar-Beam.

Top Rail, the uppermost rail of a piece of framing, or wainscoting, as its name imports.

TORSEL, or Torsil (from the French *torse*,) a piece of wood laid into a wall, for the end of a timber, or beam, to rest on. *See* Tassels.

TORUS, or Tore, (Latin,) a large moulding, of a semicircular section, used in the bases of columns. The only difference between an astragal and a torus is in size, the astragal being small, and the torus large.

Torus for a Bulwark, a large semicircular moulding, used in the base of a fortified edifice.

TOWER, a building of great height in proportion to its horizontal dimensions, usually forming an adjunct to a larger building, and employed as a belfry, stronghold, watch, or beacon. Amongst the Romans, structures of this kind do not seem to have been very numerous; and when employed, they were not very lofty: they were of various forms. In the castles of the feudal ages, towers were very necessary; the keep usually consisted of a large square tower, with smaller ones at the angles, which were generally elevated above the central one. Sometimes, however, the keep is circular, and occasionally of irregular forms. Towers are also common at the entrances of other positions in fortifications. Churches are seldom found without an addition of this nature, either with or without a pyramidal spire. Church towers are sometimes detached from the main building, but most frequently adjoining; they are of various forms, designs, and proportions, and are found in every position, except at the east end of the chancel. Cathedrals and larger churches frequently have more than one tower, the most usual number being three, one at the intersection of nave and transept, and two others at the west end; sometimes the transepts are flanked with towers, as at Exeter. Smaller churches have only one tower which is variously situated, but as a rule, at the west end of nave, or in cruciform churches at the intersection. *See* Castle, Church, Cathedral, Gothic Architecture, and Round Tower.

TOWN, (from the Saxon, *tun*,) a collection of houses, walled round about for the defence of its inhabitants.

During the feudal system, when many inhabitants lived together, a wall surrounding their habitations was necessary, and now, though this system is abolished, and the surrounding walls have either gone to ruin, or have been taken down to extend the boundaries for habitation, the collection of houses still retains the name of *town*.

Town-Hall, a public hall in which the business of a town is transacted. It answers in some respects to the ancient basilica.

TRABS, (from the Latin *trabs*, a beam,) in ancient carpentry, those beams which are now called *wall-plates*, or *rising-plates*, for supporting the rafters.

TRACERY. That kind of pattern traced in the head of a Gothic window or panel by the divergence and intersection of the mullions.

The origin of this kind of work is to be observed in the works of the close of the 12th century, from which period it was gradually developed into its more perfect form. At a very early period it became customary to enclose two small arches within one larger one; and when this form came to be applied to windows, it must naturally have been observed that the tympanum, or blank space, contained between the larger arch and the heads of the smaller ones, offered a very favourable opportunity for increasing the lighting area by perforating it either wholly or partially: in fact, it appeared to form part of the window; and the idea of making it really so must readily have occurred to many persons; as a blank space, it is heavy, and rather offensive to the eye.

The first advance towards the development of tracery then occurred in this way; the tympanum was relieved by being pierced with an aperture in the form of a circle, quatrefoil, or some other simple figure, and sometimes the spandrels were treated in a similar manner. To this method of perforation the name of *plate*-tracery has been applied, while that in which the sides of the adjacent openings are always parallel, so that the patterns of the openings appear to be formed by the intersection of bars, is termed *bar*-tracery. This latter form arose, naturally enough, from the former, by the multiplication of the piercings, or apertures, till at last the plate disappeared, save what was just sufficient to separate the openings. Sometimes we find bar and plate tracery in the same window, which shows one stage in the development of the former.

At first, the bar-tracery was disposed in simple geometrical patterns, to which the name of *geometrical*-tracery has been given. This term, however, is scarcely appropriate, as all tracery is described geometrically, although not composed of the more common or regular geometrical figures, such as circles, squares, triangles, &c., of which the so-called geometrical tracery was mostly composed. The *flowing*-tracery is designed with greater freedom, and curve-lines of variable curvature are made to flow gracefully one into the other, branching off in various directions, and forming, in their progress, an infinite variety of patterns, the apertures so produced being, for the most part, in the shape of a leaf. Regular geometrical figures are sometimes found combined with the last system. As we near the Perpendicular period, the curves gradually become straight, the bars assume a vertical position, and are at last divided horizontally by transoms.

In all the above instances, the practice of cusping the various figures is very common, such ornamentation being seldom omitted. When the tracery is of a complicated character, we find a sort of subordination observed amongst the less significant members; thus, the principal compartments of a window are divided by large bars, consisting of a large assemblage of mouldings, of which only a portion are employed in the bars which form the sub-divisions.

The Gothic buildings of France are noted for a peculiar form of tracery, termed *flamboyant*, from its flame-like appearance. It is similar to some examples of our flowing-tracery, but differs in this, that the leaf-like openings always terminate in a sharp point at the top, and thus assume rather the appearance of flames.

Tracery is employed, not only in windows, but also in screens, panels, &c., even when not pierced.

TRAIL, a running, or continuous, enrichment of leaves or flowers, with their tendrils or stalks, &c. Such enrichment is common in Gothic mouldings.

TRAMMEL, a rod of wood or metal, having sliding pieces, to which are affixed points, with which to describe large circles, or set off long distances.

TRANSEPT, that portion of a cruciform church which extends across the main body of the building, and usually separates the nave and choir. Thus, the nave and choir running from west to east, the transept will have its direction from north to south, and in the plan forms the shorter arms of the cross, projecting more or less beyond the nave and chancel aisles. Sometimes double transepts occur east and west of each other, as at Canterbury and Lincoln cathedrals; occasionally we find one at the extreme west, as at Ely; and also at extreme east, as at Durham and Peterborough. *See* Cathedral, Church.

TRANSITION, a term applied to certain classes of architectural examples, which appear to form a connecting link between two well-defined styles. It is especially applied to those buildings which are intermediate between the Norman, or Romanesque, and the Pointed styles. *See* Gothic Architecture.

TRANSOM, (from the Latin *transenna*, a cross beam,) in joinery, a horizontal piece, framed across a double-lighted window. When a window has no transom, it is called *a clear story window.*

Transom, a horizontal mullion, dividing a window into two stages in height. Transoms were not generally in use previous to the Perpendicular period of Gothic architecture, but are occasionally found in spire-lights of both Early English and Decorated buildings, where they seem to have been requisite for the purpose of strengthening the window. They are also very common in domestic buildings of all periods, and in those of later date almost universal, the lights beneath being usually arched and cusped.

TRANSTRA, the horizontal timbers in the roof of Roman buildings.

TRANSVERSE, (from the Latin *trans*, over, and *verto versus*, to turn,) lying in a cross direction.

Transverse Strain, the strain against a piece of timber side-ways, by which it is more easily bent, or broken, than when compressed, as a straining-piece, or drawn in a direction of its length, as a tie.

TRANSYTE, a narrow or triforial passage.

TRAPEZIUM, (from τραπέζιον,) a plane figure with four unequal sides and angles. As every rectilinear figure may be divided into as many triangles, wanting two, as the figure has sides; a trapezium, which is a right-lined figure of four sides, may be divided into two triangles by a diagonal. Therefore, to find the superficial content, find the area of each triangle, and the sum of these areas is that of the trapezium.

TRAVELLING-CRANE, a very useful machine for hoisting materials in the erection of a building. It consists of a crab fixed on a carriage, which is movable upon rails to any part of a building where it may be required.

TRAVERSE, (from the Latin *traversus*,) to plane a board in a direction transverse to the fibres, in order to straighten it in that direction.

Traverse, a gallery or loft of communication, such as those found in large churches.

TREAD OF THE STEP OF A STAIR, the horizontal part of the step.

TREBEATION, the same as Entablature.

TREFOIL, an ornament much used in Gothic architecture, consisting of a figure of three cusps disposed within a circle, and enclosing a space similar in form to the three-leaved clover. Trefoils, however, are not invariably disposed within a circle; any cusped figure which encloses a tri-lobed space is termed a trefoil, even if it have only two cusps.

TRELLIS WORK, a reticulated framing, made of thin bars of wood, used in rural architecture. Any reticulated work.

TRESSEL, or Trussel. *See* Trussel.

TRIANGLE, (from the Latin *tres*, three, and *angulus*, a corner,) a plane figure of three sides, and consequently as many angles. In measuring, all rectilinear figures must be reduced to triangles; and in constructions for carpentry, all frames of more than three sides must be reduced to triangles, to prevent a revolution round the angles.

TRIANGULAR COMPASSES, such compasses as have three legs, or feet, by which any triangle, or three points, may be taken off at once. *See* Instruments.

TRICLINIUM, a hall, or apartment, used by the ancients. *See* Cyzicene.

TRIFORIUM, the gallery contained in the space between the vault and timber-roof of the aisles of a church; presenting towards the interior a continuous arcade, situate between the lower arcade and the clere-story.

TRIGLYPHS, (from τρεῖς, *three*, and γλυφάς, *a channel*, or *furrow*,) the tablets in the Doric frieze, chamfered on the two vertical edges, and with two channels in the middle called glyphs, or carvings. In the Grecian Doric, the triglyph is placed upon the angle; but in the Roman, the triglyph next the angle is over the centre of the column.

TRIGONOMETRY, (from τρεῖς, *three*, γονια, *a corner*, and μετρεω, *to measure*) the art of measuring the unknown parts of a triangle, from the remaining parts being given.

Trigonometry, is either *Plane*, or *Spherical*. *Plane* trigonometry is the arts of measuring the unknown parts of a plane rectilinear triangle. This, on many occasions, might be of considerable use to the architect and engineer, in ascertaining certain distances and dimensions, which might otherwise be very inconvenient to obtain. Indeed, it is founded upon such obvious principles, that when once understood it can never be forgotten.

Every triangle consists of six parts, *viz.* the three sides and the three angles: any three of these six parts, except the three angles, being given, the rest may be ascertained.

Definitions.

Definition 1.—The chord of an arc is a straight line, A B, joining its two extremities.

Definition 2.—The sine of an arc is a straight line, B C, drawn from one extremity perpendicular to the diameter drawn through the other extremity of the arc, A B.

Corollary.—Hence, the sine of an arc is the same as the sine of its supplement; the supplement being an arc of such dimensions as will, together with the original arc, make an arc of 180°, or, in other words, a semicircle: thus, an arc of 120° is the supplement of an arc of 60°, and *vice versa*, because 60° + 120° = 180°. Similarly, the complement of an arc is an arc of such dimensions as, together with the original arc, to make an arc of 90°; thus, an arc of 50° is the complement of an arc of 40°, and *vice versa*.

Definition 3.—The tangent of an arc is a straight line, A D, drawn from one extremity of the radius, A C, perpendicular to the same, A C, terminated at the other extremity by a continued radius drawn through the other extremity, B, of the arc A B.

Definition 4.—The secant of an arc is a straight line, D C, passing through one extremity of the arc and the centre, and terminated by the tangent, which passes through the other extremity.

The versed sine is that part of the radius which is intercepted between the foot of the sine and the beginning of the arc.

The co-tangent and co-secant are respectively the tangent and secant of the complement.

Definition 5.—The sine, tangent, or secant of an angle, is the same as that of the arc intercepted.

As trigonometry is chiefly performed by proportion, and as all proportion consists of multiplication or division, or both, and since multiplication and division is best performed by logarithms, we shall here give a short sketch of the nature and construction of logarithms.

The sum of the logarithms of any two numbers, x and z, is the logarithm of their product. Let X be the logarithm of x, and Z the logarithm of z; then taking the exponents of the power of a constant root for the logarithm, we have $x = a^{X}$, and $z = a^{Z}$.

Therefore $x z = a^{X} a^{Z} = a^{X + Z}$; therefore X + Z is the logarithm of $x z$; that is the sum of the logarithms of any two numbers is the logarithm of their product.

Corollary.—Hence, if $x = z$ the logarithms of x^2 is 2 X or of $z^2 = 2$ Z.

In the same manner the logarithm $x y z$ will be found to be X + Y + Z, and consequently the logarithm of $x^3 = 3$ X; therefore, universally, the logarithm of a power is the logarithm of the root multiplied by the index of the power.

The difference of the logarithms of any two numbers, x and z, is equal to the logarithm of their quotient; since $x = a^{X}$ and $z = a^{Z}$, therefore $\frac{x}{z} = \frac{a^{X}}{a^{Z}} = a^{X - Z}$; therefore, X—Z is the logarithm of $\frac{x}{z}$.

The logarithm of the nth root of any number, x, is the logarithm of that number divided by n.

Since $x = a^{X}$; by taking the nth root of both sides, we have $x^{\frac{1}{n}} = a^{\frac{X}{n}}$; but $\frac{X}{n}$ is the logarithm of $x^{\frac{1}{n}}$. And in the same manner we find the logarithm of the nth power of any number, x, is n times the logarithm of that number, for $x = a^{X}$; raise both sides to the nth power, then will $x^n = a^{nX}$; therefore n X is the logarithm of x^n.

To determine two such functions of two quantities, $x + 1$ and $z + 1$, so that if the same operation be separately performed upon $x + 1$ and $z + 1$, and upon their product, the sum of the functions of $x + 1$ and $z + 1$, may be equal to the function of their product:

I. That is, $\phi\,(x + 1) + \phi\,(z + 1) = \phi\,[(x + 1)\,(z + 1]] = \phi\,(1 + x + z + x z)$.

II. Assume $\phi\,(1 + x) = a + b x + c x^2 + d x^3 +$, &c.

III. Therefore, $\phi\,(1 + z) = a + b z + c z^2 + d z^3 +$, &c. And by the same operation we obtain,

$$\text{IV. } \phi\,[1 + (x + z + x z)] = a + \begin{matrix} b x \\ b z \end{matrix} + (b + 2c)\,x z + \begin{matrix} c x^2 \\ c z^2 \end{matrix} \begin{matrix} (2c + 3d) \\ (2c + 3d) \end{matrix} \begin{matrix} d x^2 \\ x^2 z \\ x z^2 \end{matrix} +, \text{\&c.}$$

and by adding No. II. and No. III. together, we obtain,

$$\text{V. } \phi\,(1 + x) + \phi\,(1 + z) = 2a + \begin{matrix} b x \\ b z \end{matrix} + \begin{matrix} c x^2 \\ c z^2 \end{matrix} - \begin{matrix} d x^2 \\ d z^2 \end{matrix} +, \text{\&c.}$$

Then comparing the co-efficients of IV. and V. we obtain,

$$a = o,\ b = b,\ c = -\frac{b}{2},\ d = \frac{b}{3},\ e = -\frac{b}{4}, \text{ \&c., whence we obtain,}$$

$$\text{VI. } \phi\,(1 + z) = b\,(z - \frac{z^2}{2} + \frac{z^3}{3} - \frac{z^4}{4} + \text{\&c.,}) \text{ which is the logarithm of } 1 + z.$$

Let M $= b$, substitute $-z$ for x, in the series VI. and we obtain,

$$\text{VII. } L'\,(1 - z) = M\,(-z - \frac{z^2}{2} - \frac{z^3}{3} - \frac{z^4}{4} -, \text{\&c.})$$

Subtract No. VII. from No. VI. and we obtain,

$$\text{VIII. } L'\,(1 + z) - L'\,(1 - z) = 2M\,(z^1 + \frac{z^3}{3} + \frac{z^5}{5} + \frac{z^7}{7} +, \text{\&c.,}) \text{ or,}$$

IX. $L'\,\frac{1+z}{1-z} = 2\,M\,(z + \frac{z^3}{3} + \frac{z^5}{5} + \frac{z^7}{7} +, \&c.)$

In VI. substitute $\frac{\dot{x}}{x}$ for z, and we obtain,

X. $L'\,\frac{x+\dot{x}}{x} = M\left(\frac{\dot{x}}{x} - \frac{\dot{x}^2}{2\,x^2} + \frac{\dot{x}^3}{3\,x^3} - \frac{\dot{x}^4}{4\,x^4} +, \&c.\right)$ or,

XI. $L'\,(x+\dot{x}) - L'\,x = M\left(\frac{\dot{x}}{x} - = \frac{\dot{x}^2}{2x^2} + \frac{\dot{x}^3}{3x^3} - \frac{\dot{x}^4}{4x^4} +, \&c.,\right)$ and, by transposition, we obtain,

XII. $L'\,(x+\dot{x}) = L'\,x + M\left(\frac{\dot{x}}{x} - \frac{\dot{x}^2}{2x^2} + \frac{\dot{x}^3}{3x^3} -, \&c.\right)$

In IX. substitute $\frac{\dot{x}}{x}$ for z, and we obtain,

$L'\,\frac{x+\dot{x}}{x-\dot{x}}\ 2\,M\left(\frac{\dot{x}}{x} + \frac{\dot{x}^3}{3x^3} + \frac{\dot{x}^5}{5x^5} + \frac{\dot{x}^7}{7x^7} +, \&c.\right)$

In IX. for z substitute $\frac{v-1}{v+1}$, and we obtain,

XIII. $L'\,v = 2\,M\left(\frac{v-1}{v+1} + \frac{(v-3)^3}{3\,(v+1)^3} + \frac{(v-1)^5}{5\,(v+1)^5} + \frac{(v-1)^7}{7\,(v+1)^7} +, \&c.\right)$

This series will always converge, whatever be the value of v; but as v is greater, the degree of convergency becomes less, and, therefore, the logarithms of small numbers may be easily found; but, in the computation of large numbers, the calculation would extend to too great a length to be of any practical utility. In order, therefore, to save trouble, it becomes necessary to derive the logarithm of one number from that of another.

In XIII. for v substitute $v + 1$, and we obtain,

XIV. $L'\,(1+v) = 2\,M\left(\frac{v}{1\,(v+2)} + \frac{v^3}{3\,(v+2)^3} + \frac{v^5}{5\,(v+2)^5} +, \&c.\right)$

In IX. substitute $\frac{x}{2-x}$ for z, and we obtain,

XV. $L'\,\frac{1}{1-x} = 2\,M\left(\frac{x}{2-x} + \frac{x^3}{3\,(2-x)^3} + \frac{x^5}{5\,(2-x)^5} +, \&c.\right)$

In XIII. let $v = \frac{z+\dot{z}}{z}$, and we obtain,

XVI. $\frac{z+\dot{z}}{z} = 2\,M\left(\frac{\dot{z}}{1\,(2z+\dot{z})} + \frac{\dot{z}^3}{3\,(2z+\dot{z})^3} + \frac{\dot{z}^5}{5\,(2z+\dot{z})^5} +, \&c.,\right)$ therefore,

XVII. $L'\,(z+\dot{z}) - L\,z = 2\,M\left(\frac{\dot{z}}{(2z+\dot{z})} + \frac{\dot{z}}{3\,(2z+\dot{z}^3)} +, \&c.\right)$ therefore,

XVIII. $L'\,(\,z+\dot{z}\,) = L'z + 2\,M\left(\frac{\dot{z}}{(2\,z+\dot{z})} + \frac{\dot{z}^3}{3\,(2\,z+\dot{z})^3} +, \&c.\right)$

Practical Example.

The logarithm of 18 being 1.255273, to find the logarithm 19 by the series XIX.

Here $z = 18, \dot{z} = 1$;

therefore, $L'\,19 = L\,18 + 2\,M\left(\frac{1}{37} + \frac{1}{3\,(37)^3} + \frac{1}{5\,(37)^5} +, \&c.\right)$

$= L'\,19 + 2 \times .4342945\left(\frac{1}{37} + \frac{1}{3\,(37)^3} + \frac{1}{5\,(37)^5} +, \&c.\right)$

$2 \times .4342945 = .868589 \qquad (37)^2 — 1369.$

```
                (1369)   ( 3)
37) .868589 ( .023475  (. 17

 .023480 sum
```

add 1.255273 the log. 18.

the sum 1.278753 is the logarithm of 19.

To find the logarithm of 2 from *Series* XIX. Here $z=1$ and $z=1$, and by substituting the numbers, the series becomes

$$\text{Log. } 2 = 0+.86858896\left(\frac{1}{3}+\frac{1}{3.3^3}+\frac{1}{5.3}+\frac{1}{7.3^7}+\&c.\right)$$

work, therefore, as follows:

3) .86858896			
9) .28952965	÷ 1	=	.28952965
9) 3216996	÷ 3	=	.1072332
9) 357444	÷ 5	=	71488
9) 39716	÷ 7	=	5673
9) 4412	÷ 9	=	490
9) 490	÷ 11	=	44
54	÷ 13	=	4

.30102996 which is the logarithm of 2 nearly. By only adding .00000004, we should have .30103, which is the number to be found in the common tables of logarithms. And lastly, by reverting the series,

$$\text{L}'\,(1+x) = \text{M}\left(x-\frac{x^2}{2}+\frac{x^3}{3}-\frac{x^4}{4}+,\ \&c.\right) \text{ we obtain}$$

$$x = 1 + \text{A}x + \frac{\text{A}^2x^2}{1.2} + \frac{\text{A}^3x^3}{1.2.3} + \frac{\text{A}^4x^4}{1.2.3.4} +,\ \&c., \text{ which}$$

is the value of the number x when the logarithm of x is given. Here $\text{A} = \frac{1}{\text{M}}$.

Trigonometrical Formulæ.

The circumference of a circle being divided into 360 degrees, of which 90° forms a right angle, affords us a ready means of connecting angular space with lines, for the dimensions of an angle will vary directly as the arc, and inversely as the radius. Thus if we make the sides containing any angle of equal length, and measure the width of the opening, as also the length of either side, we shall be able to find the number of degrees contained by the angle. Now we know with sufficient accuracy for all practical purposes, the number of times which a radius is contained in its circumference, which is 2 × 3.14159, &c.; and by this proportion, we shall be enabled to find our angle.

For instance, suppose the width of the opening to measure 52.359 feet, and the length of the side 100 feet, then 100 × 3.14159 = 314.159 gives the length of the semicircumference, or an arc of 180°. Then $\frac{314.159}{52.359} = 6$ gives the number of times which the arc to be found, is contained in an arc of 180°; therefore $\frac{180°}{6} = 30°$ is the measure of the angle required.

The following Table gives the value of the sine, cosine, &c. in terms of each other, so that if one be given, the other may be found.

$$\text{Sin. A} = \sqrt{1-\cos.^2\text{A}};$$
$$\text{Cos. A} = \sqrt{1-\sin.^2\text{A}};$$
$$\text{Vsin. A} = 1-\cos.\ \text{A};$$
$$\text{Tan. A} = \frac{\sin.\ \text{A}}{\cos.\ \text{A}};$$
$$\text{Cot. A} = \frac{\cos.\ \text{A}}{\sin.\ \text{A}} = \frac{1}{\tan.\ \text{A}};$$
$$\text{Sec. A} = \frac{1}{\cos.\ \text{A}} = \sqrt{1+\tan.^2\text{A}}$$
$$\text{Cosec. A} = \frac{1}{\sin.\ \text{A}} = \sqrt{1+\cot.^2\text{A}}$$

The following numerical values of the sine, cosine, tangent, and secant, of 30° 45° 60° 120° are of frequent use. They are calculated to radius = 1.

30°.

The chord of 60° = 2 sin. 30°
But chord of 60° = rad. = 1.

$$\therefore \sin 30 = \frac{1}{2}.$$

$$\text{Cos. } 30 = \sqrt{1-\sin.^2 30} = \sqrt{1-\frac{1}{4}} = \frac{\sqrt{3}}{2}.$$

$$\text{Tan. } 30 = \frac{\sin.\ 30}{\cos.\ 30} = \frac{\frac{1}{2}}{\frac{\sqrt{3}}{2}} = \frac{1}{\sqrt{3}}.$$

$$\text{Sec. } 30 = \frac{1}{\cos.\ 30} = \frac{1}{\frac{\sqrt{3}}{2}} = \frac{2}{\sqrt{3}}.$$

45°

Since sine of an arc = cosine of its compliment;

$$\therefore \sin.\ 45 = \cos.\ \overline{90-45} = \cos.\ 45.$$

But $\sin.^2 45 + \cos.^2 45 = 1$;

$$\therefore 2\sin.^2 45 = 1;\ \text{or } \sin.\ 45 = \frac{1}{\sqrt{2}} = \cos.\ 45.$$

$$\text{Tan. } 45 = \frac{\sin.\ 45}{\cos.\ 45} = \frac{\sin.\ 45}{\sin.\ 45} = 1$$

$$\text{Sec. } 45 = \frac{1}{\cos.\ 45} = \frac{1)}{\frac{1}{\sqrt{2}}} = \sqrt{2}.$$

60°

$$\text{Sin. } 60 = \cos.\ \overline{90 - 60} = \cos.\ 30 = \frac{\sqrt{3}}{2}.$$

$$\text{Cos. } 60 = \sin.\ \overline{90 - 60} = \sin.\ 30 = \frac{1}{2}.$$

$$\text{Tan. } 60 = \frac{\sin.\ 60}{\cos.\ 60} = \frac{\frac{\sqrt{3}}{2}}{\frac{1}{2}} = \sqrt{3}.$$

$$\text{Sec. } 60 = \frac{1}{\cos.\ 60} = \frac{1}{\frac{1}{2}} = 2.$$

120°

Since the sine of an arc = sine of its supplement, and the cosine of an arc = — cosine of its supplement;

$$\text{Sin. } 120 = \sin.\ 60 = \frac{\sqrt{3}}{2}.$$

$$\text{Cos. } 120 = \cos.\ 60 = -\frac{1}{2}.$$

$$\text{Tan. } 120 = \frac{\sin.\ 120}{\cos.\ 120} = \frac{\frac{\sqrt{3}}{2}}{-\frac{1}{2}} = -\sqrt{3}.$$

$$\text{Sec. } 120 = \frac{1}{\cos.\ 120} = +\frac{1}{-\frac{1}{2}} = -2.$$

The above, as we observed, are calculated for a circle whose radius = 1, but if we require their value in a circle of any other radius, it can be readily obtained, for we have this rule to transform formulas, computed to a radius unity, into others computed to a radius (r); write, for sin. A, cos. A., &c. $\frac{\sin.\ A}{r}$, $\frac{\cos.\ A}{r}$ &c., and the values of the sin. A, and cos. A, &c. so found, will be in terms of the radius (r).

Also if we know the numerical values of sin. A, and cos. A, to radius unity, and we wish to have them to a radius (r), we must multiply the numerical value by (r);

For $\frac{pn}{r} = \sin.\ A$; $\therefore pn = r \sin.\ A$

or sin A to radius $r = r \times \sin.\ A$ to rad. = 1.

Ex. Find the numerical value of sin. 30 to rad. 10.000.

sin. 30 to rad. unity $= \frac{1}{2} = .5$;

$\therefore$ sin. 30 to rad. 10.0000 = 10.000 × .5 = 5000.

We may here observe, that in any right-angled triangle, the sine of one of the acute angles $= \frac{\text{altitude}}{\text{hypothenuse}}$, the cosine $= \frac{\text{base}}{\text{hypothenuse}}$ and the tangent $= \frac{\text{altitude}}{\text{base}}$.

The sine and cosine of any two unequal arcs of the same circle being given; to find the sine of any multiple of the lesser arc.

Let E K be any arc of a circle, which being divided into two arcs, E F the less and F K the greater, draw the radii E C, F C, and K C; make F D equal to F E, and join D E cutting C T at L: draw E M, L O, F G, and D H, perpendicular to C K, cutting C K in M, O, G, and H: parallel to C K draw D S, cutting L O at S, and L N cutting E M at N: then let r = C E = C F = C K, let the arc F K be called B, and the arc E F be called A; then F G is the sine of B, C L the cosine of A, C G cosine of B, and E L the sine of A: then, by similar triangles,

C F : F G : : C L : L O, that is,

$$r : \sin' B : : \cos' A : LO = \frac{\sin' B \times \cos' A}{r}.$$

Again, by similar triangles,

C F : C G : : E L : E N, that is,

$$r : \cos' B : : \sin' A : EN = \frac{\cos' B \times \sin' A}{r}.$$

Now E M = sin' (A + B) = N M + E N = L O + E N; therefore, by addition,

$$\sin' (B - A) = \frac{\sin' B \times \cos' A + \cos' B \times \sin' A}{r}$$

Again, D H = sin' (B — A) = L O — E N; therefore, by subtraction,

$$\sin' (B - A) = \frac{\sin' B \times \cos' A - \cos' B \times \sin' A}{r}.$$

These formulæ may be simplified by putting $r = 1$, thus:

Form. 1. $\sin' (B + A) = \sin' B \times \cos' A + \cos' B \times \sin' A$.

Form. 2. $\sin' (B - A) = \sin' B \times \cos' A - \cos' B \times \sin' A$;

add these formulæ together, and we obtain,

Form. 3. $\sin'(B + A) + \sin' (B - A) = 2 \times \sin' B \times \cos' A$;

therefore, $\sin' (B + A) = 2 \times \cos' A + \sin' B - \sin'(B - A)$.

Let $B = (n - 1)$ A; then will

$\sin' n A = 2 \times \cos' A \times \sin' (n - 1) A - \sin' (n - 2) A$, which is a general theorem.

Now in this general theorem, let n be put successively equal to 1, 2, 3, 4, &c., and we obtain,

s' 1 A = s' A.
s' 2 A = 2 × c' A × s' A.
s' 3 A = 2 × c' A × s' 2 A — s' A.
s' 4 A = 2 × c' A × s' 3 A — s' 2 A.
s' 5 A = 2 × c' A × s' 4 A — s' 3 A, &c.

where s' signifies the sine of the quantity that follows, and c' the cosine of the quantity that follows it.

In the last article, put $2 A = a$; $\therefore A = \frac{a}{2}$.

$$\therefore \sin.\ a = 2 \sin.\frac{a}{2}.\cos.\frac{a}{2};$$

$$\text{and } \cos.\ a = 1 - 2 \sin.^2\frac{a}{2} = 2 \cos.^2\frac{a}{2} - 1,$$

by which formulas we find the sine and cosine of an arc in terms of the sine and cosine of half the arc.

A great variety of formulas may be deduced from the general formulas; the following are the most important:

Adding 1 and 2 together—

sin. (A + B) + sin. (A — B) = 2 sin. A cos. B.

And similarly, also, we have—

cos. (A + B) + cos. (A — B) = 2 cos. A cos. B,
sin. (A + B) — sin. (A — B) = 2 sin. B cos. A,
cos. (A — B) — cos. (A + B) = 2 sin. A sin. B.

Let $A+B=m$, and $(A-B)=n$;

$$\therefore A=\frac{m+n}{2} \text{ and } B=\frac{m-n}{2}, \text{ and}$$

$$\sin. m+\sin. n=2\sin.\frac{m+n}{2}.\cos.\frac{m-n}{2}$$

$$\cos. m+\cos. n=2\cos.\frac{m+n}{2}.\cos.\frac{m-n}{2}$$

$$\sin. m-\sin. n=2\sin.\frac{m-n}{2}.\cos.\frac{m+n}{2}$$

$$\cos. n-\cos. m=2\sin.\frac{m+n}{2}.\sin.\frac{m-n}{2}.$$

Again—

since $\sin.(A+B)=\sin. A\cos. B+\sin. B\cos. A$
and $\sin.(A-B)=\sin. A\cos. B-\sin. B\cos. A$

therefore,

$$\sin.(A+\,)\sin.(A-B)=\sin.^2A\cos.^2B-\sin.^2B\cos.^2A$$
$$=\sin.^2A(1-\sin.^2B)-\sin.^2B(1-\sin.^2A)$$
$$=\sin.^2A-\sin.^2B$$
$$=(\sin. A+\sin. B)(\sin. A-\sin. B)$$

$\cos.(A+B)=\cos. A\cos. B-\sin. A\sin. B$
$\cos.(A-B)=\cos. A\cos. B+\sin. A\sin. B$

$$\cos.(A+B)\cos.(A-B)=\cos.^2A\cos.^2B-\sin.^2A\sin.^2B$$
$$=\cos.^2A(1-\sin.^2B)-(1-\cos.^2A)\sin.^2B$$
$$=\cos.^2A-\sin.^2B=(\cos. A+\sin. B)\times(\cos. A-\sin. B).$$

Again—

$\sin.(A+B)=2\sin. A\cos. B-\sin.\overline{A-B}$
$\cos.\ A+B\ =2\cos. A\cos. B-\cos.\overline{A-B}$

Hence, if we have three arcs, $A+B$, A, and $\overline{A-B}$, given in arithmetic progression, the sine and cosine of $A+B$ may be found from the sines and cosines of A and $A-B$. Thus, to find $\sin. A+B$, multiply $\sin. A$ by $2\cos. B$, and $\sin. A-B$ by $(-1,)$ the sum of the products will be $\sin. A+B$; and to find $\cos. A+B$, multiply $\cos. A$ by $2\cos. B$, and $\cos. A-B$ by (-1), and add the results together. The expression $2\cos. B-1$, is called the scale of relation; and $\sin. A+B$, $\sin. A$, and $\sin. A-B$ are called terms of a recurring series.

Since $\sin.(A+B)+\sin.(A-B)=2\sin. A\cos. B$,
and $\cos.(A+B)+\cos.(A-B)=2\cos. A\cos. B$.

For B put a, and for A put $n\,a$;

$$\therefore A+B=n\,a+a=\overline{n+1}.a$$
$$A-B=n\,a-a=\overline{n-1}.a;$$

$\therefore \sin.(n+1)a+\sin.(n-1)a=2\sin. n\,a\cos. a$
and $\cos.\overline{n+1}\,a+\cos.(n-1)\,a=2\cos. n\,a\cos. a.$

Let $n=2$; $\therefore n+1=3$, and $n-1=1$

Therefore,

$$\sin. 3a+\sin. a=2\sin. 2a\times\cos. a=2(2\sin. a\cos. a)\cos. a$$
$$=4\sin. a\cos.^2a=4\sin. a(1-\sin.^2a)$$
$$=4\sin. a-4\sin.^3a;$$
$$\therefore \sin. 3a=3\sin. a-4\sin.^3a$$

and $\cos. 3a+\cos. a=2\cos. 2a\cos. a.$

$$=2(2\cos.^2a-1)\cos. a.$$
$$=4\cos.^3a-2\cos. a.$$
$$\therefore \cos. 3a=4\cos.^3a-3\cos. a.$$

These formulas for $\sin. 3a$, and $\cos. 3a$, give the values of the sine and cosine of triple the arc in terms of the sine and cosine of the simple arc.

128

To find the sine and cosine of an arc in terms of the sine of twice the arc.

$$\cos.^2A+\sin.^2A=1$$
$$2\sin. A.\cos. A=\sin. 2A;$$
$$\therefore \cos.^2A+2\sin. A\cos. A+\sin.^2A=1+\sin. 2A;$$
$$\text{and } \cos.^2A-2\sin. A\cos. A+\sin.^2A=1-\sin. 2A.$$

$$\therefore \cos. A+\sin. A=\pm\sqrt{1+\sin. 2A}$$
$$\cos. A-\sin. A=\pm\sqrt{1-\sin. 2A}$$

$$\therefore \cos. A=\tfrac{1}{2}\left\{\sqrt{1+\sin. 2A}\pm\sqrt{1-\sin. 2A}\right\}$$
$$\sin. A=\tfrac{1}{2}\left\{\sqrt{1+\sin. 2A}\pm\sqrt{1-\sin. 2A}\right\}$$

When A is $<45°$, $\cos. A$ is $>\sin. A$, and we must use the upper signs; but when $A>45°$, $\sin. A$ is $>\cos. A$, and we must use the lower signs.

These values for $\cos. A$ and $\sin. A$ are termed formulas of verification; for, by means of them, we are enabled to test or verify the accuracy of results obtained by other processes.

Thus, to find $\sin. 15°$,

$$\sin. 15=\sin.(45-30)=\sin. 45\cos. 30-\sin. 30\cos. 45$$
$$=\frac{\sqrt{3}}{2\sqrt{2}}-\frac{1}{2\sqrt{2}}=\frac{\sqrt{3}-1}{2\sqrt{2}}$$

Then, in the formula, let $A=15$;

$$\therefore 2A=30 \text{ and } \sin. 2A=\frac{1}{2} \text{ and } \overline{1+\sin. 2A}=\frac{3}{2}, \overline{1-\sin. 2A}=\frac{1}{2};$$

$$\therefore \sin. 15=\frac{1}{2}\left(\sqrt{\frac{3}{2}}-\sqrt{\frac{1}{2}}\right)=\frac{\sqrt{3}-1}{2\sqrt{2}},$$ the same result as before.

The utility of the preceding formulas may be shown in finding the numerical values of some arcs.

$$\sin.(45+A)=\sin. 45\cos. A+\sin. A\cos. 45$$
$$=\frac{1}{\sqrt{2}}(\cos. A+\sin. A).$$
$$\cos.(45+A)=\cos. 45\cos. A-\sin. 45\sin. A$$
$$=\frac{1}{\sqrt{2}}(\cos. A-\sin. A).$$

Let $A=30$; $\therefore \cos. A=\frac{\sqrt{3}}{2}$, and $\sin A=\frac{1}{2}$;

$$\therefore \sin. 75=\frac{\sqrt{3}+1}{2\sqrt{2}}, \text{ and } \cos. 75=\frac{\sqrt{3}-1}{2\sqrt{2}}.$$

Next let $A=90$; $\therefore \cos. A=0$, and $\sin. A=1$

$$\therefore \sin. 135=\frac{1}{\sqrt{2}}, \text{ and } \cos. 135=-\frac{1}{\sqrt{2}}.$$

To find the sine and cosine of 18° and 36°

$$5\times 18°=90°;\ \therefore 3\times 18°=90°-2\times 18°$$
$$\therefore \cos.(3\times 18°)=\cos.(90°-2\times 18°)=\sin.\overline{2\times 18°}$$

But $\cos.\overline{3\times 18}=4\cos.^3 18-3\cos. 18,$
$\sin.\overline{2\times 18}=2\sin. 18\cos. 18;$

$\therefore 4\cos.^3 18-3\cos. 18=2\sin. 18\cos. 18.$

Let $8=x$;

$$\therefore 4(1-x^2)-3=2x, \text{ or } 4x^2+2x=1$$
$$\therefore x^2+\frac{x}{2}+\frac{1}{16}=\frac{1}{4}+\frac{1}{16}=\frac{5}{16}$$
$$\therefore x=\frac{\sqrt{5}-1}{4}=\sin. 18=\cos. 72.$$

But,

$$4(1-x^2) = 4 \cos.^2 18 = 2x + 3 = \frac{\sqrt{5}-1}{2} + 3 = \frac{5+\sqrt{5}}{2}$$

$$\sqrt{1-x^2} = \cos. 18 = \frac{\sqrt{5+\sqrt{5}}}{2\sqrt{2}}$$

THEOREMS. (*The figures, as marked on the Plate, are according to the numbers of the Theorems.*)

Theorem 1.—*The sides of any plane triangle are as the sines of the angles opposite to them.*

Figure 1.—Let A B C be a triangle; upon B C let fall the perpendicular A D: from B A and C A take B E and C H, equal to each other; on B, with the radius B E, describe the arc E F, cutting B C at F; on C, with the radius C H, describe the arc H I cutting B C at I; draw E G and H K parallel to A D, cutting B C at G and K; then will E G be the sine of the arc E F, or of the angle E B F; and H K will be the sine of the arc H I, or of the angle H C I: now, let B E and C H be called radius, denoted by R, and let E G be called the sine of angle B, and H K the sine of angle C; then, by similar triangles,

B A : A D : : B E or C H : E G.

Again, by similar triangles,

A D : A C : : H K : H C or B E;

therefore,

B A : A C : : H K : E G;

that is,

B A : A C : : sin' C : sin' B.

Therefore, the sides of triangles are as the sines of their opposite angles.

Theorem 2.—*In any plane triangle, as the sum of the two sides is to their difference, so is the tangent of half the sum of the opposite angles to the tangent of half their difference.*

Figure 2.—Let A B C be a plane triangle; from B C cut off B D equal to B A, and join A D; bisect the angle A B C by the straight line B E; then will B E also bisect A D; let F be the point of section, and let B E meet A C in E; through F draw F G parallel to A C, cutting B C in G; then by similar triangles, B C E and B G F,

B G : G C : : B F : F E.

But D C is the difference of the sides B A and B C; and because D F : F A : : D G : G C; but D F and F A are equal, whence D G and G C are equal; therefore, D G or G C, is half the difference of the sides; now half the difference of the sides, added to the lesser side, is half the sum of the sides. It is evident, that B A D is half the sum of the angles C A B and B C A, and D A C is half their difference; now, by considering A F as radius, B F will be the tangent of the angle B A F, or B A D, and F E the tangent of the angle F A E, or D A C; therefore, as B G, half the sum of the two sides, is to G C, half their difference, so is B F, the tangent of the half sum of the opposite angles, to F E, the tangent of half their difference; and, consequently, as the sum of the two sides is to their difference, so is the tangent of the half sum of the opposite angles, to the tangent of half their difference.

Theorem 3.—*In any plane triangle, if a perpendicular be let fall upon the longest side from the opposite angle; then, as the sum of the segments of the longest side, or base, is to the sum of the other two sides, so is the difference of the sides to the difference of the segments of the base.*

Figure 3.—In the triangle A B C, left fall the perpendicular A E upon B C; about A as a centre with the distance, A C, of the shortest side, describe a circle: produce B A to meet the circumference in G; then will B G be the sum of the two sides, and B F their difference; also, B E and E C are the segments of the base, and B D their difference; now, by the property of the circle, B G × B F = B C × B D;

whence, B C : B G : : B F : B D;

that is, as the longest side, B C, is to B G, the sum of the other two sides, so is B F the difference of the sides, to B D, the difference of the segments of the base.

When two angles of a triangle are given, the third angle is found by subtracting the sum of the two given angles from 180°, or two right angles; and, consequently, if one of the acute angles of a right-angled triangle be given, the remaining angle will be found, by subtracting the acute angle from 90; for, in this case also, two angles are given, *viz.*, one of the acute angles and the right angle; and these being subtracted from two right angles, or 180, the other acute angle will be found.

Various propositions might be given, but the preceding are sufficient for every case of plane trigonometry.

The analogies of plane trigonometry may easily be deduced from those of spherical trigonometry; the former being particular cases of the latter.

Proposition.—The sum, s, and difference, d, of two quantities, x and y, being given; to find the quantities themselves.

$$\text{Let } x + y = s$$
$$x - y = d$$

add these equations together, and $2x = s + d$ or $x = \frac{s+d}{2}$; subtract these equations from each other, and $2y = s - d$, or $y = \frac{s-d}{2}$; whence x, the greater of the two quantities, is half the sum and difference of these quantities; and y, the lesser, is half of the difference between the sum and difference; or, in other words, the half sum added to the half difference, gives the greater quantity; and the half sum subtracted from the half difference, gives the lesser quantity.

Solutions of the three cases of oblique-angled triangles.

Every plane triangle consists of six parts, the three sides and the three angles; three of these parts must always be given, and of these given parts one at least must be a side; to find the remaining three parts.

Case 1.—*Two angles and a side being given, to find the remaining sides.*

As the sine of the angle opposite the given side is to the sine of the angle opposite the required side, so is the given side to the required side.

In the oblique-angled triangle, A B C, given the angle A 59°, the angle C 52°15′, and the side A B 276.5, to find A C and B C.

We shall find

angle B = 180° − (52° 15′ + 59°) = 68° .45,

as the sine < C 52° 15′	9.89801
is to sine of < B 68° 45′	9.96942
so is the side A B 276.5	2 44170
	12.41112
to the side A C 325.9	2.51311

To find B C.

As the sine of < C 52° 15′	9.89801
is to the sine of < A 59°	9.93307
so is A B 276.5	2.44170
	12.37477
to B C..........299.8	2.47676

GEOMETRICAL CONSTRUCTION.

From a scale of equal parts draw A B = 276.5, and by the protractor, or line of chords, make angle A 59°. Now the triangle cannot be constructed without having the angle B;

therefore subtract the sum of angles A and C from 180° which gives angle B, that is 180—(59°+52° 15′) or 180—111° 15′ = 68.45 = angle B; make angle B 68° 45′, then A C and B C being measured by the same scale as A B, will give their respective lengths.

Case 2.—*Two sides, and an angle opposite to one of them, being given; to find the other two angles and the remaining side.*

As the side opposite the given angle
is to the side opposite the required angle
so is the given angle
to the required angle.

Example.—In the oblique-angled triangle A B C, obtuse at B, given A C 318 yards, B C 195 yards, and the angle A 32° 40′, to find the angles B and C, and the side A B.

Construction.—Draw A C = 318 from a scale of equal parts; make angle A = 32° 40′; with the distance 195 equal parts and the centre C describe an arc cutting A B at B, and join B C; the angles B and C will be found by the protractor, or line of chords, and the side A B by the same scale from which the other two sides were taken.

By Calculation.

As the side B C, 195	2.290035
is to the side A C, 318	2.502427
so is the sine' A, 32° 40′	9.732193
	12.234620
to the sine of B, 61° 40′	9.944585

But since the tables give only acute angles, and the angle required is obtuse, and the sine of any angle is the same as the sine of its supplement,
therefore 180—61° 40′ = 118° 20′ = angle B.

Note.—When the given side opposite to the given angle is greater than the other given side, the angle opposite to such other given side, or the angle to be first found, is always acute, and is found by proportion; but when the side opposite to the given angle is less than the other given side, the opposite angle may either be acute or obtuse.

To find the side A B.

As the sine of A 32° 40′	9.732193
is to the sine of C 29°	9.685571
so is B C 195	2.290035
	11.975606
to A B 175.15	2.243413

Case 3.—*Given the two sides and the included angle; to find the other two angles, and the third side.*

As the sum of the two sides
is to their difference,
so is the tangent of half the sum of the opposite angles
to the tangent of half their difference.

Having by this proportion found the difference of the angles of the base, then half of the sum added to the half difference, gives the greater angle, and half of the sum diminished by the half difference gives the lesser angle.

Example.—*For the triangle* A B C, *given the side* A C 919.95, *the side* A B 500 *feet, and the contained angle* A 36° 52′; *to find the angles* B and C, and the side B C.

Construction.—Make the angle B A C = 36° 52′; make A B = 500 from a scale of equal parts, which set from A to B; from the same scale transfer 919.95 from A to C, and join A C; then the side A C will be found upon the line of equal parts, and the angles B and C by the protractor, or line of chords.

By calculation, to find the angles.

Now 919.95 + 500 = 1419.95 the sum of the sides, and 919.95 — 500 = 419.95 their difference; the three angles are 180° from which subtract angle A 36° 52′, and there will remain 143° 8′, divided by 2, gives 71° 34′ for half the angles at the base: then

As A C + B C, 1419.95	3.152273
is to A C — B C, 419.95	2.623198
so is the tang' ½ (B — C), 71° 34′	10.477162
	13.100360
to the tangent of ½ (B — C) 41° 35′	9.948087

Then 71° 34′ + 41° 35′ = 113° 9′ = angle B
and 71° 34′ — 41° 35′ = 29° 59′ = angle C.

To find the side B C.

As the sine of C, 29° 59′	9.698751
is to the sine of A, 36° 52′	9.778119
so is A B. 500	2.698970
	12.477089
to B C, 600.26	2.778338

Case 4.—*Given the three sides of a triangle, to find the angles.*

From the angular point opposite the greater side, draw a perpendicular to that side, dividing it into two segments; then
As the base, or sum of the two segments of the base,
is to the sum of the other two sides,
so is the difference of the sides
to that of the segments of the base:
add half the sum of the segments of the base, and half their difference will give the greater segment: while the half sum subtracted from half the difference, will give the lesser segment.

Example.—*In the triangle* A B C, *given the side* A B, 562, A C 800, *and* B C 320; *to find the angles.*

Construction.—Draw the straight line A C = 800 equal parts from any scale; with a radius of 562 equal parts, and the centre A describe an arc at B, and with a radius of 320 and the centre C′ describe another arc, cutting the former at B; join A B and B C; then measure the angles by a protractor, or line of chords.

Now A B + B C =562 + 320 = 882 the sum of the sides, and A B — B C=562—320=242 their difference; then

As the base, or longest side, 800	2.903090
is to the sum, 882, of the sides	2.945469
so is the difference, 242, of the sides	2.383815
	5.329284
to A C—A D 266.81, the difference of the segments of the base	2.426194

then 133.405 is the half difference
and 400 is half the base;

therefore 533.405 is the greater segment of the base
and 266.595 is the lesser segment.

Then, to find the angle C B D.

As B C, 320	2.505150
is to C D, 266.6	2.425860
so is the sine of 90°, or radius	10000000
	12.425860
to the sine of C B D, 56° 25′	9.920710

To find the angle A B D.

As A B, 562	2.749736
is to A D, 533.405	2.727057
so is the sine of 90°	10.000000
	12.727057
to the sine A B D, 71° 39′	9.977321
then adding C B D = 56° 25′	
gives the whole angle A B C = 128° 4′	

then 90 — 71° 39′ = 18° 21′ = angle A
and 90 — 56° 25′ = 33° 35′ = angle C.

From three parts of a triangle, including at least one side as a part given, the other three remaining parts have been found upon general principles; but when the triangle is right-angled, other solutions, more simple for general practice, may be given; these are founded upon the following proportions:

Let A B C be a right-angled triangle, right-angled at B; upon A B take any radius, A D; with A as a centre, and the radius A D, describe an arc, D G, cutting A C at O; draw D E and O F parallel to B C, cutting A C at E, and A D at F; then, by the definitions given, A C or A D is the radius, E D is the tangent, G F the sine, A F the cosine, and A E the secant of the arc C D. Now the sine, cosine, tangent, &c. of an arc, being the same as the sine, cosine, tangent, &c. of an angle drawn from the centre through the extremities of the arc, the following proportions result by similar triangles, A D E and A B C.

A D : D E : : A B : B C; that is, as a radius
is to the tangent of angle, A,
so is the base, A B,
to the perpendicular, B C.

By similar triangles, A F G and A B C,
A F : F G : : A B : B C; that is,
As the cosine of angle A,
is to the sine,
so is the base, A B,
to the perpendicular, B C.

So that having the angle, A, and the side, A B, given, the side B C may be found by either of these analogies; or, having the sides or legs A B and B C, angle A can easily be found.

By similar triangles, A E D and A C B,
A E : E D : : A C : C B; that is,
As the secant
is to the tangent
so is the hypothenuse, A C,
to the perpendicular, C B;
or, by similar triangles, A G F and A C B,
A G : G F : : A C : C B; that is,
As radius
is to the sine of angle, A,
so is the hypothenuse, A C,
to the perpendicular, C B.

So that having the angle, A, and the hypothenuse given, the perpendicular, B C, may be found; or, the angle, A, may be found from having the perpendicular and the hypothenuse given.

We shall now proceed to show the use of these analogies by examples.

In making any side radius, the other sides are sines, or tangents, of their opposite angles; when either of the legs, or sides, containing the right angle, is made radius, the other leg becomes a tangent of the opposite angle, and the hypothenuse the secant of that angle, and not of an opposite angle.

When the hypothenuse is made radius, the three sides are sines of their opposite angles; in this case the hypothenuse of the sine 90° is equal to the radius, and is therefore a constant quantity, its logarithm being 10.00000.

The radius, sine, tangent, or secant, being written upon any side, or supposed to be written, is called by the name of that side. Then,
As the name of any side
is to the name of any other side,
so is the former
to the latter side.
And the same analogy obtains on the contrary.

In analogies for finding the parts of a right-angled triangle, one of the terms, or names, may always be the radius, which will lessen the labour of the operation.

To exemplify what has been said:

If radius, or r, be written upon the leg A B, the other leg, B C, will be the tangent of angle A, and A C will be the secant of angle A. Therefore upon B C write t'A, which signifies the tangent of A, which will be the name of the side B C; also upon the hypothenuse A C, write sec' A, which signifies the secant of angle A, or name of the hypothenuse A C.

Again, when the leg B C is made radius, A B becomes the tangent of the opposite angle, C, and the hypothenuse the secant of angle C. Therefore, upon B C write r, and upon A B write t' C, and upon A C write sec' C; then *radius* is the name of the side B C, *tangent of* C is the name of the side A B, and *secant of* C is the name of the hypothenuse, or side, A C.

Lastly, when the hypothenuse A C is made radius, the legs A B and B C become the sines of their opposite angles; therefore, if r be written upon A C, write s' C, signifying *sine of angle* C, upon A B, and s' A, *signifying sine of angle* A, upon A B; then *radius* is the name of A C, *sine of* C the name of A B, and *sine of* A the name of B C.

It must be remembered, that whatever be the given parts, and whatever the parts required, any side of the right-angled triangle may be made radius, except when the two legs are given to find the acute angles, and this will furnish a method of proving the result. Therefore, if two of the sides be given, radius, being always constant, must always be one of the parts concerned; whence, if the two legs be given to find the angles, one of the legs must be made radius.

To find a Side.

As the term, or name on the given side
is to that on the required side,
so is the given side
to the side required.

And to find an Angle.

As the side made radius
is to the other given side,
so is radius
to the term or name upon that side.

Note.—From this property of a plane triangle, that the three angles are together equal to two right angles, or 180°, the following very useful corollaries arise.

Corollary 1.—When two angles of a triangle are given, the third is also said to be given; for it is the supplement of the other two, and may be found by subtracting their sum from 180°.

Corollary 2.—When one angle of a triangle is given, the sum of the other two may be found, by subtracting the given angle from two right angles, or 180°.

Corollary 3.—If one angle of a triangle be right, the other two are acute, and together make another right angle; and, if one of the acute angles be given, the other is also given, being the complement of the other given one, or what it wants of 90°.

Problem I.—*Given the angles and hypothenuse of a right-angled plane triangle, to find the base and perpendicular.*

Example 1.—In the triangle A B C, right-angled at B, suppose the angle, C, 55° 30′, and the hypothenuse, A C, 121 yards; required the sides A B and B C.

Geometrically.

Draw the indefinite line B C, and from the point C, with the chord of 60°, describe an arc, upon which lay off the quantity of the angle C, 55° 30′; then place the hypothenuse 121 equal parts from C to A, and from A let fall a perpendicular to B. Measure the sides A B and B C on the scale from which A C was taken.

By Calculation.

The hypothenuse A C being radius, then A B is the sine of the angle C, and B C the sine of angle A, or cosine of angle C. Hence,

To find A B.

As radius	10.000000
is to sine of C, 55° 30′	9.915994
so is A C, 121	2.082785
to A B, 99.719	1.998779

To find B C.

As radius	10.000000
is to cosine of C, 55° 30′	9.753128
so is A C, 121	2.082785
to B C, 68.535	1.835913

The base, B C, being radius, then A B is the tangent, and A C the secant of the angle C. Hence,

To find A B.

As secant of C, 55° 30′	10.246872
is to tangent of C, 55° 30′	10.162866
so is A C, 121	2.082785
to A B, 99.719	1.998779

To find B C.

As secant of C, 55° 30′	10.246872
is to radius	10.000000
so is A C, 121	2.082785
to B C, 68.535	1.835913

The perpendicular, A B, being radius, then B C becomes the tangent of the angle A, or the cotangent of the angle C; and A C becomes the secant of angle A, or cosecant of angle C. Hence,

To find A B.

As cosecant of C, 55° 30′	10.084006
is to radius	10.000000
so is A C, 121	2.082785
to A B, 99.719	1.998779

To find B C.

As cosecant of C, 55° 30′	10.084006
is to cotangent of C, 55° 30′	9.837134
so is A C, 121	2.082785
to B C, 68.535	1.835913

General Rule for Gunter's Scale.

Extend the compasses from the first term to the second; that extent will reach from the third to the fourth term; observing to take the line marked *Num.* for feet, yards, miles, &c., the line marked S. for sines of angles, and that marked T. for tangents. The radius is 90° of sines, and 45° of tangents.

Example 2.—In the triangle A B C, right-angled at B, let the hypothenuse, A C, be 1045 feet, and the angle, A, 35° 56′; what is the length of the base and perpendicular?

Example 3.—A ship, from latitude 20° 30′ north, sailed N.W. by N. 235 leagues; what is her departure from the meridian, what her difference of latitude, and what the latitude come to?

Example 4.—Suppose one end of a rope, 350½ fathoms long, fixed at the top of an eminence, and the other end brought down to the plane below, so that its direction make with the plane an angle of 50° 40′; required the perpendicular height of the eminence, and the space of the level covered by the rope.

Problem II.—*Given the angles and one side, to find the hypothenuse and other side.*

Example 1.—In the right-angled triangle A B C, right-angled at B, let the angle at A be 35° 30′, and the side A B 294 feet; required the base, B C, and the hypothenuse, A C.

Geometrically.

Make A B = 294; at the point A make an angle of 35° 30′ from the line of chords; and from B raise the perpendicular B C. Measure B C and A C severally, by taking them in the compasses, and applying them to the scale from which A B was taken; then

By Calculation.

The hypothenuse, A C, being radius,

To find B C.

As cosine of A, 35° 30′	9.910686
is to sine of A, 35° 30′	9.763954
so is A B, 294	2.468347
to B C, 209.7	2.321615

To find A C.

As cosine of A, 35° 30′	9.910686
is to radius	10.000000
so is A B, 294	2.468347
to A C, 361.13	2.557661

The base being radius,

To find B C.

As cotangent of A, 35° 30′	10.146732
is to radius	10.000000
so is A B, 294	2.468347
to B C, 209.7	2.321615

To find A C.

As cotangent of A, 35° 30′	10.146732
is to cosecant of A, 35° 30′	10.236046
so is A B, 294	2,468347
to A C, 361.13	2.557661

The perpendicular, A B, being radius,

To find B C.

As radius	10.000000
is to tangent of A, 35° 30′	9.853268
so is A B, 294	2.468347
to B C, 209.7	2.321165

To find A C.

As radius	10.000000
is to secant of A, 35° 30′	10.089314
so is A B, 294	2.468347
to A C, 361.13	2.557661

Example 2.—In the triangle A B C, right-angled at B, suppose the base, B C, 374½ yards, and the angle, A, 52° 8′; required the other side, A B, and the hypothenuse, A C.

Example 3.—Suppose a ship sail S. W. by W. until she has made 409 miles of southing; required the distance sailed, and also how far she is west from the meridian of the place sailed from.

Example 4.—Observing the sun's altitude to be 30° 45′, and the shadow of a tree at the same time to fall 70 feet 3 inches distant from the tree, on the horizontal plane; what is the height of the tree, and what will be the length of a rope to reach from the extremity of the shadow to the top of the tree?

PROBLEM III.—*Given the hypothenuse and one side, to find the angles and the other side.*

Example 1.—In the right-angled triangle A B C, right-angled at B, let the hypothenuse, A C, be 350 feet, and the perpendicular, A B, 245 feet; required the angles, A and C, and the base, B C.

Geometrically.

Draw B C indefinitely toward C; at the point B make A B = 245, from a scale of equal parts, perpendicular to B C; and from the same scale take A C = 350; place one foot of the compasses in A, and the other, extending to the base, will cut it in C; then the angles are measured on the line of chords.

By Calculation.

The hypothenuse A C being radius,

To find angle C.

As A C, 350	2.544068
is to B A, 245	2.389166
so is radius	10.000000
to sine of C, 44° 25′ 37″	9.845098

To find B C.

As radius	10.000000
is to cosine of C, 44° 25′ 37″	9.853786
so is A C, 350	2.544068
to B C, 249.95	2.397854

The perpendicular, A B, being radius,

To find angle A.

As A B, 245	2.389166
is to A C, 350	2,544068
so is radius	10.000000
to secant of A, 45° 34′ 23″	10.154902

To find B C.

As radius	10.000000
is to tangent of A, 45° 34′ 23″	10.008688
so is A B, 245	2.389166
to B C, 249.95	2.397854

The base, B C, being radius,

To find itself.

As tangent of C, 44° 25′ 37″	9.991312
is to radius	10.000000
so is A B, 245	2.389166
to B C, 249.95	2.397854
As secant of C, 44° 25′ 37″	10.146214
is to radius	10.000000
so is A C, 350	2.544068
to B C, 249.95	2.397854

The side B C may also be found, independently of the angles, by means of the known property of a right-angled triangle; that the square of the hypothenuse is equal to the sum of the squares of the two sides.

For, since $AC^2 = AB^2 + BC^2$, it follows, that $BC^2 = AC^2 - AB^2 = (AC + AB) \cdot (AC - AB)$; and therefore $BC = \sqrt{(AC + AB) \cdot (AC - AB)}$

Or, $\text{Log. } BC = \dfrac{\text{Log. } (AC + AB) + \text{Log. } (AC - AB).}{2}$

From which B C is easily determined.

Example 2.—Suppose the hypothenuse of a right-angled triangle be 274.5 yards, and its base 196.25; what are the two acute angles?

Example 3.—Suppose a ship sailed between south and east 510 miles, and thereby made her difference of latitude, or southing, 315 miles; upon what course did she sail?

Example 4.—A ship sailed from latitude 49° 30′ north, between the south and west, 135 leagues, till, by a good observation, she is found in latitude 45° 15′; required the course on which she sailed.

PROBLEM IV.—*Given the base and perpendicular, to find the angles and hypothenuse.*

Example 1.—In the right-angled triangle A B C, right-angled at B, let the perpendicular, A B, be 650 feet, and the base, B C, 420 feet; required the acute-angles, A and C, and the hypothenuse, A C.

Geometrically.

Make B C = 420, taken from a scale of equal parts; from B raise the perpendicular A B = 650; from the same scale join A C to complete the triangle; then, with 60° taken from the line of chords, describe arches round the angles A and C; and their measures, applied to the same line of chords, will give the quantity of each angle.

By Calculation.

The base, B C, being radius,

To find angle C.

As B C, 420	2.623249
is to A B, 650	2.812913
so is radius	10.000000
to tangent of C, 57° 7′ 52″	10.189664

To find A C.

As radius	10.000000
is to secant of C, 57° 7′ 52″	10.265427
so is B C, 420	2.623249
to A C, 773.88	2.888676

The perpendicular A B being radius,

To find angle A.

As A B 650	2.812913
is to B C 420	2.623249
so is radius	10.000000
to tangent of A, 32° 52′ 8″	9.810336

To find A C.

As radius	10.000000
is to secant of A, 32° 52′ 8″	10.075763
so is A B, 650	2.822913
to A C, 773.88	2.888676

The hypothenuse, A C being radius,

To find itself.

As sine of C, 57° 7′ 52″	9.924237
is to radius	10.000000
so is A B, 650	2.812913
to A C, 773.88	2.888676

TRIGONOMETRY.

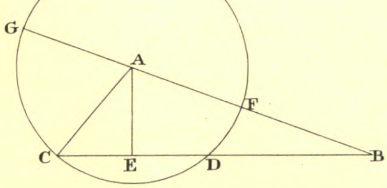
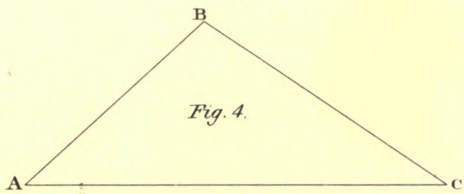
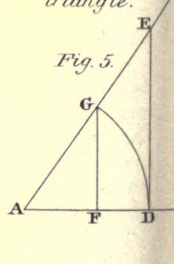
Theorem. Fig. 3.



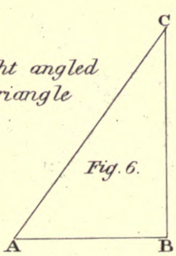
Obtuse angled triangle
Cases 1 2 3. 4.

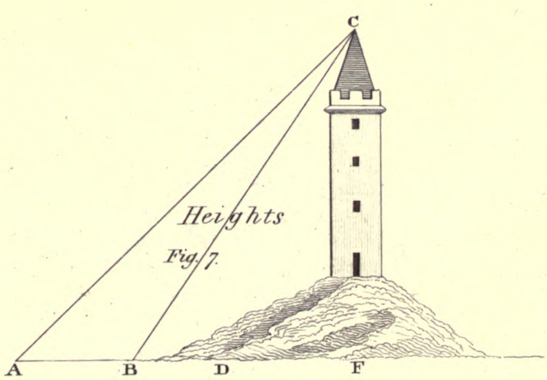


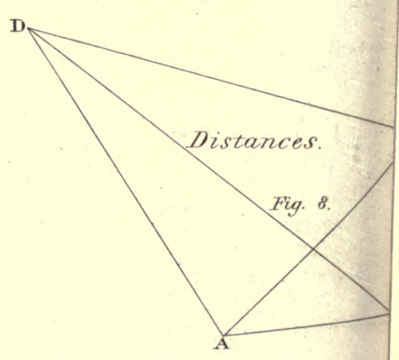
Right angled
triangle.



Right angled
triangle







As sine of A, 32° 52′ 8″	9.734573
is to radius	10.000000
so is BC, 420..............................	2.623249
to AC, 773.88..............................	2.888676

The hypothenuse may also be found, independently of the angles, for $AC = \sqrt{AB^2 + BC^2}$; from which AC is easily determined.

Example 2.—In the rectilinear triangle ABC, rectangular at B, suppose the side AB 495.45 yards, and the side BC 560.5 yards; what are the acute angles, A and C?

Example 3.—Suppose three towns so situated, that A lies $35\frac{3}{4}$ miles south from B, and C lies $50\frac{1}{4}$ miles west from B; the bearing of A from C, and of C from A are required.

Example 4.—When the sun shines, if a steeple, 196 feet high, project a shadow 237 feet 9 inches, on the horizontal plane, what is the sun's altitude at that time?

With respect to taking angles by the theodolite, when we are not obliged to cross zero, subtract the less number of degrees from the greater, which will give the angle. But if we are under that necessity, subtract the greater number from 360 and add the less to the remainder for the angle.

Thus, suppose the index to stand at 145° in looking at one point or object, and at 253° in looking at another; or, suppose first at 253°, and then at 145°, then, in either case, 253° — 145° = 108° for the angle contained between the two objects.

Again: suppose the index stands at 254°, and we are obliged to cross zero in order to come to the other object, and then the index to stand at 15°; or suppose the index stands at 15° in looking at the first object, and at 254° in looking at the second, then, in either of these cases, 360°—254° + 15° = 106° + 15° = 121°.

Figure 7.—To find the height of an inaccessible object.

Let C be the apex of a steeple, standing on the summit of a hill, and let AB be a straight line parallel to the horizon, so that the point C may be seen by a spectator from the points A and B, at a convenient distance from the eye above ground: let AB be 367 feet, the angle BAC = 44° 30′, and the angle CBD = 51° 20′; it is now required to find the height of the summit C, of the steeple above the horizon.

By subtracting 51° 20′ from 180°, a remainder of 128° 40′ is left for the angle ABC; and since the three angles of a plane triangle are equal to two right angles, the third angle ACB may be found by subtracting the sum of the two angles CAB and CBA from 180°, viz. 44° 30′ + 128° 40′ = 173° 10′ from 180°, which will leave a remainder of 6° 50′; so that in the right-angled triangle all the angles and one side are given, by which to find the side BC. Now, as the sides of a plane triangle are as the sines of the opposite angles,

	Thus,	or thus.
As sine of BCA 6° 50′....log. =	10‘924520 ..	9‘075480
is to sine of BAC, 44° 30′..log. =	9‘845662 ∴	9‘845662
so is AB, 367 feet........log. =	2‘564666 ..	2‘564666
to BC, which is 2,162 feet..log. =	3‘334848 ..	12‘410328
		9‘075480
		3‘334848

In the right-angled triangle AFC, right-angled at F, we have the hypothenuse, BC, and the acute angle, CBF: therefore, making the hypothenuse radius, the sides are as the sines of their opposite angles. Wherefore,

	Thus,	or thus.
As rad. sine of 90°......log. =	10‘...... =	10‘000000
is to sine of 51° 20′......log. =	9‘892536 =	9‘892536
so is 2,162 feet..........log. =	3‘334848 =	3‘334848
to CF, which is 1688 feet..log. =	3‘227384 ..	13‘227384
		10‘000000
		3‘227384

Figure 8.—To find the distance between two inaccessible objects.

Two inaccessible objects, D and C, are both visible from each of the two places A and B, whose distance is known, and each of which is visible from the other. Required the distance CD.

Observe the $< CAD = a$, and $< DAB = \beta$ from A,
and $< DBC = a$, and $< CBA = \beta$ from B.

Let $AB = a$,

Then, if we can find DA and AC, or DB and BC, the problem is reduced to this; find the third side when the other two sides and the angle included by them are given.

$$\text{Now, in } \Delta\ CBA, \frac{CA}{AB} = \frac{\sin.\ CBA}{\sin.\ ACB} = \frac{\sin.\ \beta}{\sin.\ ACB.}$$

$$\text{But } ACB = 180\ (ADC + CAB) = 180 - (\beta + a + \beta)$$

$$\therefore \sin.\ ACB = \sin.\ (a + \beta + \beta)$$

$$\therefore CA = \frac{a \sin.\ \beta}{\sin.\ (a + \beta + \beta)}.$$

$$\text{and in } \Delta\ DBA \frac{DA}{AB} = \frac{\sin.\ ABD}{\sin.\ ADB} = \frac{\sin.\ (a + \beta)}{\sin.\ ADB}$$

$$ADB = 180 - (ABD + BAD) = 180\ (a + \beta + \beta);$$

$$\therefore \sin.\ ADB = \sin.\ (\beta + \beta + a);$$

$$\therefore AD = a \frac{\sin.\ (a + \beta)}{\sin.\ (\beta + \beta + a)}.$$

And thus knowing AC and AD, and $<$ CAD, we may, by means of a subsidiary angle compute CD.

TRILATERAL, (from the Latin *tres*, three, and *latus*, a side,) a plane figure, or solid angle, having three sides.

TRIM, (from the Saxon *trimman*, to build,) in general, signifies to fit; as, *to trim up*, is to fit up.

TRIMMED: when a piece of work is fitted between two others previously executed, it is said to be *trimmed in* between them; thus, a partition wall is said to be trimmed-up between the floor and the ceiling; a post between two beams, a trimmer between joists, &c.

TRIMMED, is also applied to the putting of anything into shape, by cutting it away by degrees until it be of the proposed form.

TRIMMED-OUT, an expression applied to the trimmers of stairs, when brought forward to receive the rough strings.

TRIMMER, a small beam, into which the ends of several joists are framed. Beams of this kind are either stair-trimmers, hearth-trimmers, or tail-trimmers.

TRIMMING JOISTS, the two joists into which each end of the trimmer is framed. The distance of the trimming-joists, when employed in fire places, must be such as to take in not only the fire place, but the flues on each side of it. Trimming-joists ought to be stronger than the other joists, on account of the support they have to give.

TRINE DIMENSIONS, the dimensions of a solid, including length, breadth, and thickness; the same as *three-fold dimensions*.

TRIPARTITION, (from the Latin *tres*, three, and *pars*, a part,) the division of a number by three.

TRIPOD, or Tripos, (from τρεῖς, *three*, and πȣς, *a foot*,) in antiquity, a three-legged seat from which the priests delivered their oracles.

TRIPTIC, or Triptych, a tablet in three divisions, of which the two outer fold over the centre one, by means of hinges, and form a cover to it. Triptics are employed to adorn the altars of churches over which they are placed; when open, they exhibit a painting, or representation, of some sacred subject.

TRISECTION, (from the Latin *tres*, three, and *seco*, to cut,) the division of anything into three equal parts; as the trisection of an angle, &c.

TROCHILUS, (from τροχος, *a wheel*,) an annular moulding, of which the section through the axis of the column is concave; more commonly denominated *scotia*. Its situation is generally between two tori. *See* Scotia, and Mouldings.

TROCHOID, (from τροχος, *a wheel*, and ειδος, *shape*,) a figure described by rolling a circle upon a straight line, with a pin or point in the circumference upon a fixed plane, in, or parallel to, the plane of the moving circle. *See* Cycloid.

TROPHY, (τροπαῖον, from τροπὴ, *to put an enemy to flight*,) in architecture, an ornament representing the trunk of a tree, charged around its circumference with military weapons, colours, and instruments of music.

TROUGH, (from the Saxon *troh*,) a vessel in the form of a rectangular prism, open on the top, having five sides enclosed for holding water.

Trough-Gutter, a gutter in the form of a trough, placed below the dripping eaves of a house, in order to convey the water from the roof to the vertical trunk, or pipe, by which it is discharged. They are only used in common buildings and out-houses. In buildings of the better class, the water-way is formed behind a blocking-course.

TROWEL. *See* Tools.

Trowel-point, a method of enrichment, applied to some mouldings of Norman and Byzantine character, such as to give them the appearance of having been indented with the point of a trowel.

TRUGG, a tray to carry mortar in.

TRUNCATED, (from the Latin *trunco*, to cut short,) signifies that quality of a solid by which the upper portion is cut off parallel to the base of the solid. Thus the frustum of a pyramid, cone, sphere, &c., is said to be truncated.

Truncated Cone, one which has the upper part cut off the frustum of a cone. *See* Cone.

Truncated Pyramid, one which has the upper part cut off; the frustum of a pyramid.

TRUNK, (from the French *trompe*, a long tube,) a vessel open at each end for the discharge of water, rain, &c.

Trunk, (from the Latin *truncus*, the body of a tree,) that part of a pilaster which is contained between the base and the capital.

TRUSS, (from the French *trousse*,) a frame of timbers so disposed, that if suspended at two given points, and charged with one or more weights in certain others, no timber would press transversely upon another, except by timbers exerting equal and opposite forces.

When one or more exterior timbers of a frame, suspended from two given points, are propped by the disposition of interior timbers at certain points in each of the exterior pieces, so as to resist the pressures of several weights, each acting upon one of the said points, without any tendency to bend or break any timber employed in the construction; the frame is called *a truss*, and each of the exterior timbers so propped in their length, are said to be *trussed*.

It is a principle in every such frame to have as few quadrangles as possible; all the interstices, or openings, should be triangles; and the intersections of the timbers should be as direct as possible, because oblique pressures exert prodigious strains, which require strong timbers of large scantlings to withstand them, and these would press upon the abutments so much as to make the truss sag by the compression of the intermediate joggles. Wherever two oblique thrusts press to the same point, no transverse timber should be interposed; for the shrinking of the transverse piece will also make the truss liable to sag. A truss of any extension may be made with a series of triangles composed of very short timbers; but then it will be necessary that every two adjoining triangles have the same common side, otherwise transverse strains will be produced. A truss may also be made of very short timbers, by making them balance each other by their position only.

Trusses are used for several purposes in building, as in partitions for supporting the floor above, to prevent it from communicating its pressure to the floor below, which may also be hung to the truss; particularly when there are neither bearing partition, nor trussed girders, which are shallow trusses, put between the ceiling and the floor, in order to stiffen the platform for walking upon. A roof of any considerable extent cannot be executed without one or more trusses; nor yet the centre of a bridge, or large vault.

Trusses employed in roofs and centerings, are placed from eight to ten feet distance in the clear, and in equidistant vertical planes. They may also be employed in the inclined sides of a roof, having their plane parallel to that of the covering, to counteract the pressure of the rafters downwards, and keep the lateral force thereby occasioned from acting upon the walls.

In all regular trusses, inclined timbers stand in pairs for mutual resistance, or counteraction. The names of the timbers which most frequently occur in trussed work are as follow: all inclined timbers are called *braces;* braces which either meet, or have ther direction to a point below their extremities, are called *struts;* hence every strut is a brace, but every brace is not a strut; those braces which form the exterior part of the truss, are called *principal rafters:* braces under the principal rafters, and parallel to them, are called *principal braces*, *discharging braces*, *auxiliary rafters*, or *cushion rafters*. Beams have various names, according as they have a higher or lower situation in the truss, or according as they perform the office of a tie or straining-piece; a beam acting as a tie, is therefore called a *tie-beam;* of which description it is always the lowest; a beam extending above the tie-beam, between a pair of principal rafters, is called a *collar-beam*, or simply a *collar*, or *straining-beam*, which name indicates its use; when a beam terminates the upper part of a truss, it is called *a camber-beam*, because it is made to slope in a small degree both ways from its middle towards each extreme on the upper edge; beams placed above the tie-beam, between a pair of posts, are called *straining-beams.* Posts when employed in trusses, stand always in pairs, except there be one in the middle: every such post is called by the general name of *truss-post:* when the head of a truss-post stands at the apex of a pair of principal rafters, it is called *the middle-post*, *crown-post*, or *king-post:* a pair of truss-posts, each of which is placed equidistant from the middle or ends of the truss, are called *side-posts:* when there is no crown-post in a truss, but one or more pairs of side-posts, the pair next the middle are called *queen-posts.* The annexed Plate shows the various parts of a truss in detail, together with various methods of connecting them together.

TRUSS.

Figure 1.—No. 1. The top of the king-post, with part of the principals, and a strap connecting the three members.

No. 2. The method of joining the king-post with the tie-beam, and of screwing it up.

No. 3. The edge of the king-post, and a section of the tie-beam.

Figure 2.—Another method of joining the principals, king-post, and tie-beams.

No. 1. Parts of the principal rafters and king-post secured together by a branched strap.

No. 2. The method of strapping the king-post and tie-beam.

No. 3. Parts of the king-post and tie-beam, showing the method of wedging them.

Figure 3.—The method of forming a joggle, when the thick part at the bottom of the king-post is not sufficient for receiving the shoulder of the struts at right angles to their directions.

Figure 4.—A similar method, with a little variation.

Figure 5.—No. 1. Another method of joining the principals and king-posts by means of an iron dovetail, which is received into a mortise in the head of each principal.

No. 2. View from the top of the principals, showing the head of the wedge.

Figure 6.—Method of securing the tie-beam and principals when the king-post is made of an iron rod.

No. 1. The principals, with a part of the iron king-rod, and the hanging up of the tie-beam.

No. 2. The struts fixed to the iron king-rod, and the hanging up of the tie-beam.

TRUSS PARTITION, a partition with a truss consisting generally of a quadrangular frame, two braces, and two queen-posts, with a straining-piece between the queen-posts, opposite the top of the braces.

TRUSS POSTS. *See* TRUSS.

TRUSSED BEAM, TRUSSED GIRDERS, or GIRDING BEAMS. *See* GIRDERS.

TRUSSED-RAFTER-ROOF, a roof which has no principal trusses, but which is composed entirely of trussed rafters. Such roofs are not uncommon in churches of the 12th or 13th centuries; they have a very pleasing perspective effect.

TRUSSELS, or TRESSELS, (from the French *tresteau*,) props for the support of anything, the under surface of which is horizontal; each trussel consists of three or four legs, attached to a horizontal part. When the trussels are high, the legs are sometimes braced. Trussels are much used in building for the support of scaffolding, and by carpenters and joiners for ripping and cross-cutting timber, and for many other purposes.

TRUSSING PIECES, those timbers in a roof that are in a state of compression.

TRY, (from the French *trier*, to bring to a test,) to plane a piece of stuff by the rule and square only.

TUBE, (from the Latin *tubus*, a pipe,) a substance perforated longitudinally, generally quite through.

TUBULAR BRIDGE. *See* IRON BRIDGE.

TUDOR ARCHITECTURE, considered in a general sense, is that style of architecture which prevailed during the Tudor dynasty. It is necessary, however, that the application of the term should be somewhat limited; for it cannot be expedient to adopt one title for so many and widely-different styles as those prevailing during that period; amongst which may be enumerated the late Perpendicular Gothic, the mixed or Elizabethan style, in which Italian details were introduced in buildings otherwise Gothic, and the Italian as practised by Inigo Jones and his cotemporaries.

As to the precise limitation of the term, there seems to be but little agreement amongst writers upon the subject; some applying it to buildings of the late Perpendicular style, in which ornamental details were profusely introduced, and which is, by other writers, designated as Florid Gothic. Under this signification, Ecclesiastical as well as Domestic and Civil structures are included; and of these, Henry VII.'s chapel, at Westminster, forms a characteristic example. The application of the term is strictly correct with respect to chronology, but is rather inconvenient as regards systematic arrangement, based upon peculiarities of style; and, besides this, there are so few important examples of this particular class, as scarcely to warrant the formation of a distinct style; they may be fairly considered as modifications of the Perpendicular.

Other writers would divide the style thus denominated into two divisions, Early and Late Tudor, the former term including the buildings just alluded to, and the latter being applied to those into which Italian details are introduced, and which are otherwise distinguished as Elizabethan. This plan we shall now adopt to a certain extent, excluding, however, the ecclesiastical buildings, which we include under the Perpendicular style, and conceding the term Tudor entirely to buildings of a domestic character. This arrangement, we must confess, is not without its objections; and we are inclined to think that the distinction between the first and second class of buildings is sufficiently great to entitle them to distinct designations, and, therefore, that the title of Elizabethan may be appropriately applied to the latter, to mark out a peculiar and separate style. We shall have before us, then, for consideration, the Early Tudor, and the Elizabethan or Late Tudor, styles.

The reign of Henry VII. introduced a new mode of living, and with it a new style of domestic architecture. With his marriage, the feuds between the houses of York and Lancaster came to an end, and a long season of internal peace seemed about to follow the troublous times of the preceding monarchs. Previous to this period, domestic architecture can scarcely be said to have had any existence; the mansions that had been erected were rather military than domestic, more like fortresses than dwellings. Now, however, with a prospect of peaceful times before them, men began to look for convenience rather than strength in their private mansions, and elegance began to be preferred to security. The halls of this and the following reign contained little of the fortified character of their predecessors beyond the battlements with which the walls were surmounted, and these, indeed, appear to have been preserved more for ornament than use: the thickness of the walls was reduced, the size of the windows enlarged, and the other arrangements influenced by the requirements for comfort and convenience rather than of security.

We know little of Henry VII.'s buildings of this class; of the palace erected by him at Shene or Richmond, not a vestige now remains, but some particulars concerning it are given in the Survey of 1649, when it was offered for sale by the Commissioners of Parliament. It abounded with bay-windows of capricious design, with rectangular and semicircular projections: and was adorned with many octagonal towers, surmounted with bulbous cupolas of the same plan, having their angles enriched with crockets.

Henry VIII. was not only a great builder himself, but encouraged his nobles to follow his example; so that there was no lack of examples in his reign. Henry, himself, is said to have built or repaired the following mansions:—

Beaulieu, or Newhall, Essex.

Hemsdon, Herts, originally built by Sir John Oldhall, temp. Edward IV.

Ampthill, Bedfordshire.

Nonsuch, Surrey.

York Place, Whitehall, Westminster.

Bridewell and Blackfriars, London, for the reception of the emperor Charles V.

St. James's, Westminster.

Kimbolton, Huntingdonshire, the jointure of the divorced Queen Catherine of Arragon.

Sheriff Hutton, Yorkshire, given for the residence of Henry, Duke of Richmond, the king's natural son.

King's Langley, Herts.

When the monarch set himself so vigorously to work in building and repairing, it is no matter of surprise to see his courtiers following in the same steps; and, accordingly, we find that many and sumptuous were the mansions erected by them. Foremost in such works stands Wolsey, amongst whose principal buildings may be enumerated Hampton Court Palace; York House, afterwards Whitehall; his episcopal residence at Esher, Surrey; the college of Christchurch, Oxford, and another at Ipswich. Edward Stafford, Duke of Buckingham, erected a magnificent palace at Thornbury, Gloucestershire; Charles Brandon, Duke of Suffolk, one at Grimsthorpe, Lincolnshire; the Duke of Norfolk, and his son, the Earl of Surrey, those of Kenninghall, Norfolk, and Mount Surrey, near Norwich. Amongst others may be mentioned Haddon Hall, Derbyshire; Coudray, Sussex, destroyed by fire in 1793; Hever Castle, Kent; Gosfield Hall, Essex, perfect; Hengreave Hall, Suffolk, perfect; Layer Marney, Essex, now in ruins; Raglan Castle, Monmouthshire, in ruins; Hunsdon House, Herts, rebuilt; South Wingfield, Derbyshire, dilapidated; Hill Hall, Essex; Wolterton, East Barsham, Norfolk, in ruins.

The plan of the larger mansions of this period was quadrangular, comprising an inner and base court, between which stood the gate-house. On the side of the inner court, facing the entrance, the principal apartments were placed, amongst which may be enumerated the hall, the chapel. the great chamber and dining-room, and were connected with a gallery for amusements running the whole length of another of the sides of the quadrangle. Several examples of this description are to be found, of which Hannaker House, near Midhurst, Sussex, will give us a good idea; this mansion was built round a court, with the entrance under an embattled gate-house, flanked by small octagonal towers on the south; a square tower stood at the south-east angle; the chapel and other apartments on the east, and the hall and principal rooms on the north. In mansions of less pretensions, the gate-house stood in advance of the building, connected with it only by mantle walls, as at East Barsham, Norfolk.

The materials of which such buildings were constructed were either brick or stone, and sometimes both combined, the main building being of brick and the dressings of free-stone; this practice was very common. Bricks of two colours, usually black and red, and sometimes highly glazed, were employed to variegate the surface, the darker-coloured bricks being disposed in the form of lozenges and other figures; and in some instances the brick-work was rendered in ornamental plaster, as at Nonsuch. Moulded brick-work and terra-cotta were also employed for decorative purposes; medallions, or busts of terra-cotta were frequently inserted in small circular and other-shaped cavities in the walls, and heraldic devices, cognizances, &c. were dispersed in various parts of the building.

The details and style of ornament adopted in those houses are, for the most part, the same as those to be found in ecclesiastical buildings of the same period, the principal difference consisting in the different composition and arrangement of the various parts. Amongst the more striking peculiarities may be reckoned the gate-houses, the numerous turrets and chimneys, the beautiful bay and oriel windows, the roof, ceilings, and panelled wainscot round the internal walls.

The gate-houses were very prominent features in these buildings, of lofty elevation, containing several apartments; they seem to have received a great deal of attention as to design, &c., and were more beautifully ornamented than almost any other part of the building. They were mostly placed in the centre of one of the sides of the court, and were usually embattled, and flanked by more lofty turrets at the angles. Stair-case turrets, rising above the general elevation, served to relieve the general outline, and of these there were frequently several in the angles and other parts of the court as occasion demanded; the gables, also, were often flanked with turrets. Grouping well with these turrets, the heavy masses of chimneys stood out in bold relief, and gave great character to the elevation. Previous to this date, chimneys had been rarely used, and, when employed, had been made of secondary importance in the general design; but now they not only began to be extensively used, but formed very prominent objects in the elevation; and received, probably, as much attention in the design as any other part of the edifice. They were of lofty proportions, circular or octagonal in plan, and usually clustered together in groups of two, four, or more. The shafts were ornamented with various devices, as roses, fleur-de-lis, &c., moulded on the surface; at other times they were carved with spiral flutings, and ornamented in an infinite variety of ways; the tops, or caps, as they may be called, were richly moulded, and, indeed, the inventive powers seem to have been exhausted in the multitude of designs for the enrichment of this member of the edifice. The projecting windows form a very characteristic feature of the style: they are of two kinds, those which rise immediately from the level of the ground being termed *bays;* and those which project out in the upper part of the building, being corbelled out so as to overhang that below, are termed *oriels*. Both kinds of windows are erected on plans of various figures, but more especially upon those of a rectangular, semi-octagonal, or semi-circular plan. Sometimes they are restricted to a single floor, while at others they are carried up through several. The bay-window is very common in large halls, where it is found at the upper end forming a recess at the side of the dais; sometimes we find a bay on either side of the dais; such windows were usually loftier than the others, being carried from about three feet from the ground to the ceiling. Oriel windows are principally confined to the buildings of Henry VII.'s and the early part of Henry VIII.'s reign, but bays were common in the reign of Elizabeth.

Many of the great halls of this period had open timber-roofs, of bold construction and beautiful design: they are mostly what are termed hammer-beam roofs. *See* Roof. The most remarkable are those erected by Cardinal Wolsey, at Hampton Court Palace, and at Christ Church Oxford, both of which are 40 feet in width: many others are to be seen in the halls of colleges at Oxford and Cambridge, and in the inns of court in London. The ceilings were usually of timber, divided into compartments by the main timbers of the floor above, and sometimes into smaller compartments by the joists, the timbers being either moulded or chamfered on the edge. Sometimes the flooring-timbers are concealed by panels with ribs of oak, which divide the surface into compartments of various forms, the ground between the ribs being either of wood or plaster. At the intersections of the ribs, bosses of foliage and devices in wood or plaster were frequently introduced.

The walls of the principal chambers were often lined with carved wainscoting in panels, which were small, and mostly of what is termed the linen pattern; sometimes they were enriched with carved work in the shape of ciphers, cognizances, chimeras, mottoes, &c.

The windows of this style are usually square-headed, divided into lights by mullions and transoms, the latter being frequently enriched with a series of small battlements on the top, and the lights arched and cusped.

The following examples will serve to afford some idea of the general character of the buildings of this period :—

Hampton Court Palace, commenced in 1514, was erected by Cardinal Wolsey; it is a very magnificent building, comprising no less than five courts. In the centre of the entrance-front is a square tower, flanked by an octagonal turret at each angle, which rises above the general elevation of the tower; in the lower story is the grand gateway, with obtuse-pointed or Tudor arch, over which in front and rear is a rich oriel window. The walls are crowned by battlements of open work, and each turret is terminated by an octagonal roof, the contour being a curve of contrary flexure.

On the right and left of the tower the buildings are partly modernized, but at each extremity is one of the old gables, the raking cornices of which are ornamented with figures of griffins. From these extremities wings project towards the front at right angles to the body of the building. The first quadrangle, which is entered by the above gateway, consists of the dwelling-house, the walls of which are crowned with embattled parapets; the windows are square-headed, and the doors covered by plain arches. In the centre of the side of this quadrangle, which is opposite to the grand entrance, is another tower similar to, but smaller than the first, and flanked by rectangular battlemented turrets; through this tower is an arched passage leading into the second quadrangle, and over it an oriel window.

The second quadrangle is smaller than the first, the left side being occupied by the grand hall, which is covered by a lofty roof; the walls are strengthened by buttresses, and the windows, which are pointed, are divided by mullions carried perpendicularly to the head. The right-hand side of the court is occupied by a colonnade designed by Sir Christopher Wren. In the third side is a tower in a line with the two previously mentioned, containing a passage leading to the third quadrangle, the ceiling of which is enriched with delicate fan-tracery. The third quadrangle is surrounded by an arcade supporting the fronts of the buildings; the walls of which are of red and dark brick set in diamond patterns, and are crowned with plain and perforated battlements. This court was modernized in the reign of William III. The windows of the ancient building are distributed without respect to symmetry; the frames are rectangular, and in general of greater width than height; they are divided vertically by one or more mullions, and some by transoms running across at about mid-height; the lights are obtusely arched at the head.

The timber-roof of the hall is of very good construction, and of beautiful design. Each frame is formed by two inclined principals, separated by a straining-piece at top, and tied together at about mid-height by a collar-beam; a hammer-beam at the bottom of each principal projects for about a quarter the entire width of the hall, and is supported at the extremity by a curved brace resting on a wall-post, which again is supported on a corbel at some distance below the top of the wall. The extremity of the hammer-beam carries a pendant, and above it springs a curved rib which meets one from the opposite side of the roof, immediately under the centre of the collar-beam, and thus forms an obtuse-pointed arch. The contour of the roof, as seen from below, will therefore present the appearance of a trefoil; it is enriched with pierced panelling, and other carved work.

Thornbury Castle, Gloucestershire, was commenced about 1511; the parts at present existing, having been built in the reign of Henry VIII., by Edward Stafford, Duke of Buckingham, who was engaged on it for ten years, but was not suffered to live to complete it. "The towers at the entrance to the inner court are bold in design; the projecting machicolations, still preserved, are very good examples. The bay-windows of the great hall are beautifully composed; the plans of the upper and lower parts vary, the one being a combination of five semi-circles of four lights in each, whilst the latter is angular, and more solid in construction."

The great oriel window is very beautiful, as are also the enriched chimney-shafts, fire-places, &c., illustrations of which will be found in *Pugin's Examples.*

The following description of a mansion of this period, at Midhurst, in Sussex, is given by Warton :—"We enter a spacious and lofty quadrangle of stone, through a lofty Gothic tower with four angular turrets. The roof of the gateway is a fine piece of old fret-work. There is a venerable old hall, with a noble oak-raftered roof, and a large high range of Gothic windows. Opposite the screen is the arched portal of the buttery. Adjoining the hall is a dining-room, the walls painted all over (as was anciently the mode soon after the beginning of the reign of Edward VI.,) chiefly with histories (out of perspective) of Henry VIII.; the roof is in flat compartments. A gallery with window-recesses, or oriels, occupies one side of the quadrangular court. A gallery on the opposite, of equal dimensions, has given way to modern convenience, and is converted into bed-chambers. In the centre of the court is a magnificent old fountain, with much imagery in brass, and a variety of devices for shooting water. On the top of the hall is the original louvre or lantern, adorned with a profusion of vanes. The chapel, running at right angles with the hall, terminates in the garden with three large Gothic windows."

Hengrave Hall, Suffolk, was built, as we learn from an inscription on the outside of the curious oriel window, in 1538. It consists of an open court surrounded on three sides by a gallery, communicating with all the apartments, and lighted by windows looking into the court: on the other side is the hall, (34 feet by 25,) which is lighted by a bay and two other windows, also looking into the court. The principal part presents a very picturesque appearance, measuring about 160 feet in length. The building is of brick and stone, and the gateway, which is in good preservation, is of peculiar design.

The manor-house at East Barsham, Norfolk, is composed almost entirely of bricks: it was commenced in the reign of Henry VII., and finished in that of his successor. The following description is given by Mr. Bury :—"The walls of the principal front are nearly on one plane, being broken only by the porch in the centre; and octagonal turrets of different sizes are so disposed as to give a variety of outline to the combination. The hall is to the left of the porch by which it is entered; the great parlour and principal apartments are beyond, or at the back of it. The windows are large, and must have given the rooms a cheerful appearance. The building consists of only two stories, except in one part, where another is added as a tower. The upper string-courses are bold in moulding, and rich in cast ornaments and panels; these are surmounted by moulded battlements with beautiful traceried panels. The stack of ten chimneys at the west end of the hall, and the turret-terminations, are fine in design and execution. "The building, which measures 140 by 58 feet, has a gate-house tower, about 40 feet in front of the porch (a paved court intervening;) on this, if possible, a still greater degree of moulding and enrichment has been bestowed; comprising figures, armorial bearings, battlements, and panelling, which are all executed in brick in a surprising manner."

Elizabethan, or Late Tudor.—During the whole of the above period, the influence of Gothic art had been disappearing throughout the continent. As early as the middle of the fifteenth century, Brunelleschi had introduced that partial revival of the classical styles which has been denominated Italian, from the name of the country where it first made its appearance, and where it afterwards chiefly flourished. This revival had been practised throughout the continent, ere it reached this country, where the Gothic maintained its position for a very long time, and even after the introduction of the Italian, gave place but slowly, and not without a severe and lengthened struggle. Our constant intercourse with the continent during the reign of Henry VIII., must have had considerable influence on the arts in this country, the effects of which are evident in the later buildings of this reign; in the hall of Hampton Court Palace are introduced details of Italian design, and in many other buildings of the same or later date. The next reign brings us a step further in this direction. John of Padua, an Italian architect, was introduced into England under the patronage of the protector Somerset; and from his designs were erected the mansions of Sion House, and Longleat, Wilts. In the reign of Elizabeth, however, the Italian style of art began to make more rapid strides, and assume a position of equality with the Gothic. Early in her reign, the treatises of Lomazzo and Philibert de Lorme were translated into English, and a work upon architecture was published by John Shute, an artist and architect who had been sent out to Italy by Dudley, Duke of Northumberland. From this and other circumstances, it is not difficult to account for the change which came over architecture during this period. This change, however, was rather in matters of detail than in general construction, although a considerable improvement would seem to have been made in the internal arrangement of houses, which were altogether more commodious. Up to this time, the mansions of the nobility were usually only one story in height, and in plan greatly deficient in the requirements incidental to the improved social condition of the country; but now we have lofty buildings, and considerable skill exhibited in the disposition of the apartments; indeed, we have ample evidence that no building was now undertaken, without the previous arrangement of a well-considered plan.

The plans of buildings of this reign were of varied character, sometimes quadrangular, having three sides surrounded with buildings, with the portico in the centre, the quadrangles being usually surrounded with an open arcade or corridor. This, however, was but one plan out of many others, some of which were exceedingly curious; for instance:—Longford Castle, Wiltshire, was in plan similar to the ecclesiastical device on which the doctrine of the Trinity was illustrated; it was a triangular court surrounded with buildings, having a circular tower of the same height as the other parts of the building, at each angle, from each of which in the interior was carried a row of buildings meeting in the centre.

A mansion, designed by John Thorpe, the architect, for his own use, was elevated on a plan which represented his own initials in monogram; and that this was designedly so arranged, we learn from the epigraph appended to his design, which is as follows:

"Thes 2 Letters I and T
"Joyned together as you see
"Is meant for a dwelling-house for mee" "John Thorpe."

The principal deviations in matters of construction from the buildings of the preceding era, consist in the multiplication of bay-windows; the addition of large projecting porticoes richly ornamented; the importance given to the halls and staircases, which became very spacious and magnificent, often occupying a large proportion of the mansion; the increased length and spaciousness of the galleries, which frequently exceeded 100 feet in length; the increase of lighting area, the windows being greatly enlarged in size, having sometimes three or four tiers of openings; the magnificence of the fire-places, which frequently reached to the ceiling, and were enriched with carving and sculpture, in the shape of heraldic devices, &c.; the beautiful and richly-moulded plaster ceilings, with deep cornices, also of plaster: the walls were either panelled or whited, and ornamented with labels containing poetry, maxims, &c. Another peculiarity is observed in the large and imposing flights of steps, and in the noble terraces in front of the mansions: these were raised one above the other, approached from one to the other by broad flights of steps, and defended on the edge with richly-perforated parapets or balconies.

The general characteristic of the style is manifested in the admixture of Italian details with Gothic features and designs. Quasi-classic columns and pilasters are frequently introduced, but they are often ill-proportioned and very inaccurately and rudely profiled; they are frequently banded at intervals in their height with circular or square blocks, which when square, are mostly ornamented with diamond or jewel-shaped projections, a species of ornament which is of frequent general application: at other times the shafts were decorated with grotesque ornaments of various kinds, flutings, &c. Arcades, with circular arches, are also common, the space from pier to pier being often of an extravagant width, their height sometimes running up into the entablature, which member, again, is rarely or never found continuous or unbroken, and it is frequently frittered away with scroll and other ornaments. The bay-windows, parapets, and gables are usually terminated by perforated crestings of scroll or geometrical pattern; this perforated work and scroll ornament in general, as also the lozenge and other ornaments, standing in relief upon the surface to be enriched, are very profusely employed, and may be considered decidedly characteristic of the style. The shell-roofed niche and caryatid columns are also frequent. The plaster ceilings were usually of very elaborate design, and very richly moulded; they form a very praiseworthy feature in buildings of this date. Heraldic devices and grotesques were not unfrequently employed in general ornamentation.

It would be superfluous to enter into a more detailed description, for the style altogether is so abnormal and intricate, that a full description would necessitate illustrations of almost every example. Very contrary opinions have been held respecting the merit of this style; for our own part, while we must condemn it as being unscientific in construction, and impure, if not barbarous, in taste, at the same time we are inclined to allow it a great deal of credit for its picturesque appearance. It certainly will not stand the test of severe criticism.

Amongst the more noted architects of this time we may mention the following:—Robert Adams, Surveyor of Works to Elizabeth; John Shute, author of a book upon architecture

Bernard Adams; Lawrence Bradshaw; and John Thorpe, who has left us a book of his designs, which are very numerous: he was engaged upon a great many works, of which the principal are—Holland House, Middlesex; Longford Castle, Wilts; Wollaton Hall, Notts; and Audley End, Essex. Gerard Christmas was engaged upon Northumberland House, as was also Moses Glover and Bernard Jansen; of whom the second was further employed in the completion of Sion House, and the latter in the erection of Audley Inn. Robert and Huntingdon Smithson, father and son, were engaged upon Wollaton House, Notts, and Bolsover, Derbyshire. Thomas Holte was architect of the Public Schools, and of the quadrangles of Newton and Wadham Colleges, Oxford.

Several mansions of this style were erected or completed during the reign of James I., and even the early works of Inigo Jones were in this style, as, for instance, the quadrangle of St. John's College, Oxford. The pure Italian, however, was rapidly gaining the ascendancy, and was destined to be permanently introduced by this same man in the early part of the 17th century.

The following is a list of some of the principal mansions belonging to this period of architecture. As a description, apart from illustrations, would be of little use, we beg to refer the reader to a beautifully-illustrated work upon the subject by Mr. Nash, entitled 'Mansions of England in the Olden Time.'

Name.	Date.	County.	Present State.
Basinghouse	1560	Hants.	In ruins.
Gorhambury	1565	Herts.	Do.
Knowle	1570	Kent	Perfect.
Penshurst	"	Kent	Do.
Kenilworth	1575	Warwick	In ruins.
Hunsdon	"	Warwick	Rebuilt.
Burleigh	1577	Lincoln	Perfect.
Longleat	1579	Wilts.	Do.
Westwood	1590	Worcester	Do.
Hardwick Hall	1597	Derby	In ruins.
Holland House	1607	Middlesex	Perfect.
Bramshill	"	Hants.	Do.
Castle Ashby	"	Northampton	Do.
Summer Hilt	"	Kent	Do.
Charlton	"	Wilts.	Restored.
Hatfield	1611	Herts.	Perfect.
Longford Castle	1612	Wilts.	Do.
Temple Newsham	"	Yorkshire	Do.
Charlton	"	Kent	Do.
Bolsover	1613	Derby	Dilapidated.
Audley Inn	1616	Essex	Perfect.
Wollaton	"	Notts.	Do.

There is one class of houses which reached its zenith during the reign of Elizabeth, and which deserve some mention in this place: we allude to the half-timbered houses. They were composed of timber frame-work, and present the appearance of brick-nogging, the spaces within the frame being plastered: the timbers are arranged sometimes vertically, with horizontal beams at intervals, and this arrangement has a very pleasing appearance; at other times the secondary timbers were ranged diagonally, or disposed so as to form geometrical figures, such as squares, triangles, diamonds, &c., and, not unfrequently, curved timbers were introduced. Such houses are peculiar in having the upper stories of larger dimensions and projecting over the lower ones, and are remarkable for their barge-boards overhanging the gables. These are frequently of very beautiful design, and delicately carved; they have a singularly pleasing appearance. Wooden corbels, in the shape of grotesque figures, are also common. The plaster-work was frequently ornamented with devices of various kinds, either in relief or recession.

The counties of Cheshire and Shropshire were peculiarly noted for country mansions of this class; and many examples are to be found in the towns of Chester, Shrewsbury, Leicester, Warwick, and Ipswich. They invariably present a very picturesque appearance. The following is a list of some of the principal examples; and, for further information respecting them, we refer the reader to a work upon the subject by Mr. Habershon:—

The Oaks, West Bromwich:	... date ...	Henry VIII.
Elmley Lodge, near Droitwich	"	Charles I.
Old House, Market Place, Preston	"	Do.
Bramall Hall, near Stockport	"	Elizabeth.
Hop-pole Inn, Bromsgrove.		
Pitchford Hall, near Shrewsbury.		
Salwarp Court, near Droitwich.		
Samlesbury Hall, near Blackburn	"	Edward VI.
Hall-i'-the-wood, near Bolton	"	Charles I.
Ince Hall, near Wigan.		
Park Hall, near Oswestry.		
Moreton Hall, near Congleton.		
Mere Hall, near Droitwich.		

For further particulars on the subject of this article, *see* House.

TUDOR FLOWER, a flat flower or leaf of a diamond shape, placed upright on its stalk, much used in the crestings of Perpendicular work.

TUFA, a calcareous earth, composed of broken and concreted shells, or the deposit from water impregnated with lime.

TUMBLING-IN, or Trimming-in: when a piece of timber is to be fitted between two others, given in position, the fitting is called *tumbling-in;* a trimmer may be tumbled-in between two joists, and the purlins of a roof between two of the rafters, when they are not bridged over them.

TUN OF TIMBER, about 40 solid feet.

TUNNEL, a subterranean passage.

TURNING PIECE, a board with a circular edge, for turning a thin brick arch upon, as the breast of a chimney.

TURRET, a small tower; frequently found attached to a larger one at its angles, or at the angles of buildings; they are sometimes built out to contain stairs.

TUSCAN ORDER, an ordinance with a column and entablature the same as the Roman Doric, divested of its triglyphs, mutules, and guttæ, the members of the entablature being continued throughout the whole length, without interruption.

It has been customary to consider this method as a separate order; but there would seem to be little reason for so doing; for indeed it is little more than a variation of the Roman Doric, which, divested of its enrichments, is to all intents and purposes Tuscan.

We find no remains of a complete Tuscan order amongst the relics of antiquity; the present delineations of the order being determined by the interpretations which different architects have put upon the passage in Vitruvius, in which it is described. As this description is somewhat obscure, it is not unnatural that we should find that different conclusions have been arrived at upon the subject: thus we have different designs by Palladio, Vignola, and Scamozzi. Although we have no remains of a perfect order, we have examples of Tuscan columns, amongst the more noted of which stands the Trajan column at Rome. Vitruvius does not speak of this as a distinct order, although he alludes to the construction of Tuscan temples. He makes the column six diameters in height, with a diminution of one quarter of a diameter; the base and capital each one module in height. He decides no height for the architrave or cornice, omits the frieze, but places mutules over the architrave, which are to project one-fourth of the total height of the column, including base and capital. He does not provide a pedestal.

Palladio makes the total height of the order nine diameters and three-quarters, of which he gives six to the column; the height of base and capital each measuring half a diameter; he provides no pedestal, but places the base on a plinth whose height is equal to one diameter.

Serlio makes the height of the architrave half a diameter, and gives an equal height to the frieze and cornice. His pedestal consists of a plinth and base, a die and cymatium, the whole being a third of the height of the column.

Scamozzi assigns as the height of the entablature one-fourth of the total height of the column, less half a diameter; and makes his pedestal of the same height. He also places a sort of triglyph in the frieze.

Plate 1.—The entablature, capital, and base of the Tuscan order finished.

Plate 2.—Outline, with the measures of the various members.

TUSK, (from the Saxon *tysos*, a fang,) a bevel shoulder made above a tenon, and let into a girder to strengthen the tenon.

TYMPAN, (from *τυμπανον*, *a timbrel*,) the hollow recessed part of a pediment, being either a plane triangle, or filled with ornaments of sculpture raised from the plane of the triangle.

Though the pediments of the ancient Greeks were very low, they were long enough to admit of the most beautiful sculpture; as that of the Temple of Minerva at Athens, now deposited in the British Museum.

Tympan also signifies the die of a pedestal, or the panel of a door.

TYPE, the canopy over a pulpit.

U.

UMBER, a fossil brown substance, used by painters, which grinds freely, and bears a good body. When burnt, it furnishes the most natural imitation of gold: with a mixture of white, it resembles the colour of new open wainscot. It dries quickly, with a considerable gloss. It has its name from the ancient province of Umbria in Italy, whence it was originally obtained; but is also found in Germany, Spain, Egypt, Cyprus, and other parts of the Turkish dominions, from which last what is brought into England mostly comes. Dr. Hill and Mr. De Costa consider it as an earth of the ochre kind, which might be found in considerable quantities in England and Ireland, if properly looked after; several large masses of it having been thrown up in digging on the Mendip hills, Somersetshire, as well as in the county of Wexford, Ireland. It is also met with occasionally in the veins of lead-ore in Derbyshire and Flintshire.

UNDECAGON, (Greek *ενδεκα*, *eleven*, and *γωνια*, *an angle*,) a figure of eleven sides.

UNDERCROFT, a crypt, or subterranean apartment.

UNDER-PINNING, the act of bringing a wall up to the ground-sill, or sometimes that part of the wall itself. The temporary support of a wall whose foundations are defective, or the formation of new foundations.

UNGULA, of a cylinder, or cone, a part of the solid comprehended by part of the curved surface, the segment of a circle, which is part of the base, and another plane.

UNIVERSITY, (from the Latin *unus*, one, and *verto versus*, to turn,) a collection of colleges for teaching the various branches of knowledge. In an architectural point of view, the term is applicable to the houses, or edifices, in which the classes are held.

UPHERS, fir poles, from 4 to 7 inches in diameter, and from 20 to 40 feet in length; they are frequently hewn on the sides, so as not to reduce the wane entirely. They are of great use in scaffolding and ladders; and are also employed in slight roofs, where they are slit.

UPRIGHT, the elevation of a building. The term is rarely used, *elevation* being more commonly employed.

URBIN, or URBINO, a name frequently given to that most sublime and excellent painter, Raphael Sanzio, from the place of his birth. He was the son of an indifferent painter, named Sanzio, and was born on Good Friday, 1482. He was employed by the popes Julian II. and Leo X., who loaded him with wealth and honours; and the cardinal De St. Bibiana held him in such high estimation that he offered him his niece in marriage: but he declined this honour, from an expectation he entertained, founded upon the promise of Leo X., of being made a cardinal himself. His pictures are to be found principally in Italy and Paris. That of the *Transfiguration*, preserved at Rome, in the church of St. Peter Monterio, is reckoned his master-piece. His person was handsome, and his manners were polite, affable, and modest, though he lived in the utmost splendour. He was not only the best painter in the world, but perhaps the best architect too; on which account he was employed by Leo X. in building St. Peter's church at Rome. This engagement prevented his acceptance of an invitation into France from Francis I., for whom he had painted a *St. Michael and the Holy Family*, and had been remunerated by that monarch with sums so far beyond his expectation, that he resolved to show his gratitude by a performance, in which he even surpassed himself: this was the *Transfiguration* above alluded to intended as a present to Francis; but he died before the picture was quite finished, and it was detained at Rome. His death happened on his birth-day, 1520, when he had completed his 38th year; the consequence of his passion for the fair sex, and the injudicious treatment of his physicians. His celebrated *Cartoons*, for which Louis XV. offered a hundred thousand pounds, were purchased by Rubens for Charles I. and brought to England, and have successively graced the palaces of Hampton Court, Buckingham House, and Windsor Castle. A considerable jealousy existed between this artist and Michael Angelo, which sometimes manifested itself in a manner not very creditable to either. Raphael frequently exercised himself in sculpture, and excelled as much in it as in painting and architecture. A *Jonas*, of the size of life, which is deemed his *chef-d'œuvre* in this line, is shown in the chapel of Madonna del Popolo, at Rome, the cupola of which he also painted.

Urbin is also a name sometimes given to Bramante, from his having been born in the province of Urbino. *See* Bramante.

URN, (from the Latin *urna*,) a vase of a circular form, used as a terminating ornament upon an acroter, or the like. Urns were not much employed in the celebrated edifices of antiquity.

V.

VAGINA, (Latin,) the lower part of a Terminus, resembling a sheath, in which the lower part of the statue is inserted.

VALLEY, (from the Latin, *vallis*, a hollow,) the internal angle of two inclined sides of a roof.

Valley-Board, a board fixed upon a valley-rafter for the leaden gutter to lie upon.

Valley-Rafter, the rafter under the valley, or that which supports the valley.

It is evident, that since the internal angle is above the roof, the external angle is under it; and, in hip-rafters, that since the external angle is outward, the internal angle is inward; therefore, the hipped angles will be stronger than the valleys, and consequently require timbers of less scantling to support them. This circumstance should be attended to in the description or particulars of a building, as the judgment of the architect will be shown in such discriminations.

Valley-Rafters, in old books, are called *sleepers;* but in this sense the term is antiquated. *See* Sleepers.

Valley-Pieces, the same as Valley-Rafters. The term is used in some parts of the country, particularly in Devonshire.

VALLUM, a rampart or raised wall or mound erected for the purpose of defence.

VALVED, anything that opens upon hinges.

VANE, a plate of metal turning on a vertical spindle, and fixed on the summit of a tower, spire, or other elevated building, to show the direction of the wind. The custom of placing vanes on church-steeples is very ancient; and as they were commonly made to represent the figure of a cock, they have been thence termed *weather-cocks.* In late Gothic buildings, they frequently present the appearance of little flags, perforated with heraldic devices, &c.

VANISHING LINE, in perspective, the intersection of the parallel of any original plane with the picture.

Vanishing Point, that point to which all parallel lines in the same plane tend in the representation.

VARIATION OF CURVATURE, the change made on a curve, so as to make it quicker or flatter in every succeeding part; as the curvature of the quarter of an ellipsis terminated by the two axes is continually quicker from the extremity of the greater axis to that of the lesser.

VARIETY, (from the Latin, *vario*, to change,) the agreeable disposition of the parts of an edifice.

VARNISH, a preparation used to preserve and put a glossy surface upon painted articles. It consists of different resins in a state of solution, of which the most common are mastic, sandarac, lac, copal, &c.; they are prepared with either expressed or essential oils or alcohol.

VASE, (from the Latin, *vas*, a vessel,) an ornamental termination to the wall or other parts of an edifice, or to a pillar, obelisk, or the like.

Vases are made in imitation of vessels, or urns, in the form of a solid of revolution, and are often ornamented with basso-relievos in infinite variety. Those who would form a good idea, may consult the article Oval, where they will find the mathematical outlines which give the most pleasing variety to the curvature, and to the general section of the solid through its axis; the ornaments, though essential decorations, are merely auxiliaries.

Vase of the Corinthian or Composite Capital, a solid of revolution, from the surface of which all the ornaments project: the section of the vase having its general outline of a form nearly similar to the surrounding contour of the leaves.

The situation of the vase is between the abacus and the astragal, at the top of the shaft, and the outline of the generating figure is concave, springing parallel to the axis, and receding gradually therefrom to the top, where it generally terminates in a fillet, also parallel to the axis.

Vases of a Theatre, were vessels under the seats used by the ancients, in order to produce greater harmony.

VAULT, (from the French *vaulte*, a cave,) an arched roof over an apartment, concave towards the void; the section may, therefore, be circular, elliptical, parabolical, hyperbolical, catenarian, cycloidal, &c., but, in general, the sections are either portions of a circle or of an ellipsis.

Vault, *Cylindric*, that of which the surface is any portion of a cylinder, never greater than the half when the axis is in the same plane with the springing of the arch. Also termed *barrel* or *wagon-headed* vault.

Vault in full Centre, that which is formed of the surface of a semicylinder.

Vault, *Surmounted*, or *Surhaussé*, that which is formed by the portion of any curve where the height is greater than half the span.

Vault, *Surbaisse*, that which is formed by the portion of any curve whose abscissa is less than the ordinate which forms half the base.

Vault, *Rampant*, that whose springing is not parallel to the horizon; such as those of the old staircases of the Louvre, and the descent into the cellars.

Vault, *Double*, a mode of construction, where one vault stands above another, in order to preserve the proportion between the exterior and interior of the building; as in St. Peter's at Rome.

Vault, *Conic*, that which forms the surface of a cone. Conic vaults may be of three kinds, according to the disposition of the axis, viz., parallel, perpendicular, or oblique to the horizon. They are seldom used in building houses; the only kind likely to come into use, is that with its axis parallel to the horizon.

Vault, *Spherical*, a vault forming the portion of the surface of a sphere; more usually called a Dome. *See* Dome.

Vault, *Annular*, that of which the plan is contained between two concentric circles: its generating section may either be that of a pointed arch, or of a semicircle, or indeed of any other curve.

Vault, *Simple*, that which is constructed of the surface of some regular solid, around one axis, or centre.

Vault, *Compound*, that which is compounded of more than one surface of the same solid, or of two different solids. Vaults of this kind are of the same solid as those whose surfaces have different axes, or different centres, as those formed of two cylinders, equal or unequal, or of two spheres, equal or unequal, penetrating each other.

Vault, *Cylindro-cylindric*, that which is formed of the surfaces of two unequal cylinders. When their axes cut each other, they are denominated *Welsh groins.*

Vault, *Groined*, a compound vault, which rises to the same height in its surfaces as that of two equal cylinders, or a cylinder with a cylindroid.

In the Temple of Peace, at Rome, the middle aisle is groined, all the arches are elliptic, their chord, or springing line, being that of the lesser axis : the small groins spring from mere points. The main vault of this edifice was supported by columns, which have long been removed; the entablatures, however, and the springing of the groins, still remain. The side vaulting is cylindrical, and coffered in octagons and squares. The elliptic passages of the Coliseum are groined. Groins are to be found in many Roman buildings still remaining. *See* Adams's *Ruins of Spolatro;* also the *Ruins of Balbec and Palmyra*, by Wood. The dome of the Pantheon is coffered; that of the Temple of Bacchus is plain.

The groins of Gothic edifices are numerous, and form a different class, which it would be difficult to define. The most beautiful specimens are to be found in England; and among the numerous variety, we might mention King's College, Cambridge, and King Henry the Seventh's Chapel, Westminster. *See* Gothic Architecture.

A vault is an extended arch, and therefore the theory is the same as that of the arch, which has been given under the article Stone Bridge. The four walls of a building are strong ties to every kind of vaulting; and more particularly that of groins, where the horizontal pressure is directed against the angles, and, consequently, the four walls in this case will become ties, which ought, therefore, to be firmly built or bound together with a cast-iron bar, which will be entirely concealed. Besides what has been shown under the article Stone Bridge, the reader should also consult the article Dome, and the following quotation from Hutton's *Mathematics*, vol. iii., which is necessary to be understood by every engineer.

"In the practice of engineering, with respect to the erection of powder-magazines, the exterior shape is usually made like the roof of a house, having two sloping sides, forming two inclined planes, to throw off the rain, and meeting in an angle, or ridge, at the top; while the interior represents a vault, more or less extended as the occasion may require; and the shape, or transverse section, in the form of some arch, both for strength and commodious room, for placing the powder-barrels. It has been usual to make this interior curve a semicircle. But, against this shape, for such a purpose, I must enter my decided protest; as it is an arch the farthest of any from being in equilibrium in itself, and the weakest of any, by being unavoidably much thinner in one part than in others. Besides, it is constantly found, that after the centering of semicircular arches is struck, and removed, they settle at the crown, and rise up at the flanks, even with a straight horizontal form at top, and still much more so in powder-magazines with a sloping roof; which effects are exactly what might be expected from a contemplation of the true theory of arches. Now, this shrinking of the arches must be attended with other additional bad effects, by breaking the texture of the cement, after it has been in some degree dried, and also by opening the joints of the voussoirs at one end. Instead of the circular arch, therefore, we shall in this place give an investigation, founded on the true principles of equilibrium, of the only just form of the interior which is properly adapted to the usual sloped roof.

"For this purpose, put $a =$ D K the thickness of the arch at the top, $x =$ any absciss, D P, of the required arch A D C M, $u =$ K R the corresponding absciss of the given exterior line K I, and $y =$ P C $=$ R I their equal ordinates. Then by the principles of arches, in my tracts on that subject, it is found that C I or $w = a + x - u = Q \times \frac{\dot y \ddot x - \dot x \ddot y}{\dot y^3}$, or $= Q \times \frac{\ddot x}{\dot y^2}$ suppossing $\dot y$ a constant quantity, and where Q is some certain quantity to be determined hereafter. But K R or u is $= ty$, if t be put to denote the tangent of the given angle of elevation K I R, to radius 1; and then the equation is $w = a + x - ty = \frac{Q\ddot x}{\dot y^2}$.

"Now, the fluxion of the equation $w = h + x - ty$, is $\dot w = \dot x - t\dot y$, and the second fluxion is $\ddot w = \ddot x$; therefore, the foregoing general equation becomes $w = \frac{Q\ddot w}{\dot y^2}$; and hence $w\dot w = \frac{Q\dot w\ddot w}{\dot y^2}$, the fluent of which gives $w^2 = \frac{Q\dot w^2}{\dot y^2}$: but at D the value of w is $= a$, and $\dot w = 0$, the curve at D being parallel to K I; therefore the correct fluent is $w^2 - a^2 = \frac{Q\dot w^2}{\dot y^2}$. Hence, then, $\dot y^2 = \frac{Q\dot w^2}{w^2 - a^2}$, or $\dot y = \frac{\dot w\sqrt{Q}}{\sqrt{(w^2 - a^2)}}$; the correct fluent of which gives $y = \sqrt{Q} \times$ hyp. log. of $\frac{w + \sqrt{(w^2 - a^2)}}{a}$.

"Now, to determine the value of Q, we are to consider that when the vertical line C I is in the position A L or M N, then $w =$ C I becomes $=$ A L or M N $=$ the given quantity, c suppose, and $y =$ A Q or Q M $= b$ suppose, in which position the last equation becomes $b = \sqrt{Q} \times$ hyp. log. $\frac{c + \sqrt{(c^2 - a^2)}}{a}$; and hence it is found that the value of the constant quantity $\sqrt{Q}$, is $\frac{b}{\text{h. l. } c + \sqrt{(c^2 - a^2)}}$; which being substituted for it, in the above general value of y, that value becomes

$$y = b \times \frac{\text{log. of } \frac{w + \sqrt{(w^2 - a^2)}}{a}}{\text{log. of } \frac{c + \sqrt{(c^2 - a^2)}}{a}}$$

$$= b \times \frac{\text{log. of } w + \sqrt{(w^2 - a^2)} - \text{log. } a}{\text{log. of } c + \sqrt{(c^2 - a^2)} - \text{log. } a};$$

from which equation the value of the ordinate P C may always be found, to every given value of the vertical C I.

"But if, on the other hand, P C be given, to find C I, which will be the more convenient way, it may be found in the following manner: Put A $=$ log. of a, and C $= \frac{1}{b} \times$ log. of $\frac{c + \sqrt{(c^2 - a^2}}{a}$; then the above equation gives C $y +$ A $=$ log. of $w + \sqrt{(w^2 - a^2)}$; again, put $n =$ the number whose log. is C $y +$ A; then $n = w + \sqrt{(w^2 - a^2)}$; and hence $w = \frac{a^2 + n^2}{2n} =$ C I.

"Now, for an example in numbers, in a real case of this nature, let the foregoing figure represent a transverse vertical section of a magazine arch balanced in all its parts, in which the span or width A M is 20 feet, the pitch or height D Q is 10 feet, thickness at the crown D K = 7 feet, and the angle of the ridge L K N 112° 37′, or the half of it L K D = 56° 18½′ the complement of which, or the elevation K I R, is 33° 41½′ the tangent of which is = $\frac{2}{3}$, which will therefore be the value of t in the foregoing investigation. The values of the other letters will be as follows, *viz.* D K = a = 7; A Q = b = 10; D Q = h = 10; A L = c = $10\frac{1}{3} = \frac{31}{3}$; A = log. of 7 = .8450980; c = $\frac{1}{b}$ log. × of $\frac{c + \surd (c^2 - a^2)}{a}$ = $\frac{1}{10}$ log. of $\frac{31 + \surd 520}{21}$ = $\frac{1}{10}$ log. of 2.56207 = .0408591; c y + A = .0408591 y + .8450980 = log. of n. From the general equation, then, *viz.* C I = $w = \frac{a^2 + n^2}{2n} = \frac{a^2}{2n} + \frac{1}{2}n$, by assuming y successively equal to 1, 2, 3, 4, &c., thence finding the corresponding values of c y + A or .0408591 y + .8450980, and to these, as common logs. taking out the corresponding natural numbers, which will be the values of n; then the above theorem will give the several values of w or C I, as they are here arranged in the annexed table, from which the figure of the curve is to be constructed, by thus finding so many points in it.

Value of y or C P.	Value of w or C I.
1	7.0309
2	7.1243
3	7.2806
4	7.5015
5	7.7888
6	8.1452
7	8.5737
8	9.0781
9	9.6628
10	10.3333

"Otherwise: Instead of making n the number of the log. C y + A, if we put m = the natural number of the log. C y only; them $m = \frac{w + \surd (w^2 - a^2)}{a}$, and $a m - w = \surd (w^2 - a^2)$, or by squaring, &c. $a^2 m^2 - 2 a m w + w^2 = w^2 - a^2$, and hence $w = \frac{m^2 + 1}{2m} \times a$; to which the numbers being applied, the very same conclusions result as in the foregoing calculation and table."

The following description of a method of stone-roofing in the Southern Concan, in the East Indies, was communicated to the Institution of Civil Engineers by lieutenant Outram, of the Bombay Engineers. Though hardly applicable to the climate of this country, it seems of considerable value as relating to an important part of the British Empire. The few houses which had been constructed on this plan were found to answer so well, at the time this paper was written, that government had given orders to construct, on this principle, all the public buildings, wherever suitable materials could be found.

The roofing with stone (iron-clay, or laterite) in the Southern Concan, is of a compound nature, consisting of two kinds of arches; the first being parallel to each other, from 2 to 3 feet apart, and very light, their average section being from 12 by 10 inches to 15 by 12; *i. e.* for roofs of from 25 to 35 feet span; so that when any two of these arches or ribs are complete, they are strong enough to bear slabs of stone 5 or 6 inches thick, extending a few inches over each, beginning from the wall and meeting at the top, thus forming a second complete arch, and making, with the ribs, a compound much stronger than vaulting of equal solidity over the same extent, made in the usual way.

The lateral thrust of the arches of one room are counteracted by those of the rooms on its sides, and so on for any extent; those of the end-rooms being counteracted on their outer sides by buttresses, or by the walls of baths, &c., so that the walls are required to be only sufficiently strong to support the mere weight of the masonry of the roofs, which has an average thickness of about 9 inches, excepting the plaster or tiles, and, therefore, in rooms of 400 square feet, would be about one-fifth the weight of the upper walls of a two-storied house. As the roof itself is of considerable altitude, the walls supporting it need not be of more than two-thirds the usual height.

One advantage of the lightness of these roofs is, that of whatever form the arches may be, very little *loading* will suffice; of course some arches would require no loading, but such are not the most convenient for roofs in general. The best appears to be a compound of two segments of a circle of 50° or 55°, their chords intersecting at an angle of about 100°, such compound arch requiring a little loading at the top and the haunches, which, when duly added, gives an outer surface of two inclined planes to each roof, which may be then either plastered or tiled. But instead of loading the haunches throughout with solid rubble, it is better to do so partly with hollow masonry, to the upper surface of which may be given any slopes which, by the connection of the opposite slopes of any two adjacent roofs, form a gutter of the securest kind. The average height of this gutter should be about one-third that of the roof, if to be plastered, but not so much if the roof is to be tiled.

The expense of these roofs, including the outer plaster, has been found by myself and successor, in the Concan, to be much less than that of tiled roofs over the same extent. The walls should cost no more than those of a substantial bungalow; for although the transverse walls have a greater weight to support, yet, as they need be only two-thirds the height, their total expense should not be greater than that of the walls of a substantial house. The only part of which the comparative expense remains to be considered, is the ceiling. The inner surface of the stone roofs, when finely plastered, forms an excellent ceiling; being light and cleanly, and most durable. The expense of this plastering, if not much ornamented, is below one-third that of the lath-and-plaster generally used. Hence it is plain, and has been practically found, that the total expense of stone-roofed houses in the Concan, if properly constructed, is less than that of tiled houses of the same size; but the sums saved in annual and special repairs are of far greater consideration. In the Decan, where timber is so expensive, the comparative cost of these buildings would be still less, in all those parts of it where proper stone is met with.

The principal cause of the cheapness of these stone roofs is the very little centering, &c., that is requisite. For as the ribs, or primary arches, are very light, centering of the simplest kind does for any one of them, and thus for all successively in either room. But as the centering cannot be removed from any rib till its counteracting ribs are complete, there is of course required one centering for each room, which, when one series of the primary arches is complete, may be removed with ease for the next, till a convenient number are ready for the superior arching, which of course is very quickly formed (as before described) without any centering.

The material fittest for this kind of building are the various kinds of sand-stone, including the calcareous sand-stone of Cutch. The laterite, or iron-clay, although a good material, and the only one hitherto used, is apparently not so proper as the substance generally called free-stone, which is worked with saws, &c., and would be found to answer better than the laterite, which can be shaped only with a pickaxe, and is very heavy.

This iron-clay is found to extend from Bancoate, E. N. E., to, I believe, Ceylon, lying over the trap-rock, even on the highest Ghauts, but is very unequal in thickness and quality; that of Purnalla and Pawnghur, for instance, being of the softest and most porous kind, and that near Mahabulesher of the best. This stone, when exposed to rain, &c. becomes very hard, if good; but if taken from any depth, is so soft as to be easily cut with a knife. It is hence called *soap-stone* at Belgaum and other Madras stations.

If adopted in Europe, buildings of this kind would he as remarkable for warmth as in this country for coolness. But the plastering outside would not be advisable on account of the frost; tiles, however, or slate, would protect the roof completely.

The principal advantages of these buildings in this country are, their coolness, and the little expense incurred in annual and special repairs; indeed, the latter will never be required, if the buildings be properly constructed at first. It is also very evident, that they can never take fire, nor can white ants affect them; of course they could be built of several stories, the form of the floor-ribs being merely a small segment of a circle (or ellipse) instead of a compound of two, as in the roof. The upper floor of the jailor's house at Rutnaghery is thus built, as also part of another house.

VAULT, *Reins of a*, the sides or walls which sustain the arch.

VAULTING SHAFT, the shaft which supports the ribs of a groined vault. These shafts either rise direct from the ground, or are supported upon corbels at a height above the ground; they are frequent in Romanesque and Gothic buildings.

VELLAR CUPOLA, a dome, or spherical surface, terminated by four or more walls. This kind of ceiling is frequently used over great staircases, as also over saloons, or other lofty apartments. The term is used by Alberti, vol. i. book iii., chap. 14, in the sense here defined.

VENEER, a very thin leaf of wood, of a superior quality, for covering doors, or articles of furniture, made of an inferior wood.

VENETIAN DOOR, a door lighted on each side.

VENETIAN WINDOW, a window in three separate apertures, divided by slender piers, and having the centre aperture larger than the side ones. *See* Adams's *Ruins of Spolatro*, p. 26; likewise Disgodily's *Roman Antiquities*, vol. ii. *Baths of Diocletian.*

VENT, (from the French, *fente*, a small aperture,) the tube of a chimney, for conveying the smoke from the fire. The term is mostly used in Scotland. In London it is called *flue*, and in many parts of England *funnel.*

VENTIDUCTS, (from the Latin, *ventus*, wind, and *ductus*, a passage,) subterraneous places where fresh or cool air is kept, being received by proper funnels and valves.

VENTILATION, the method of supplying buildings with fresh air. In buildings which are intended for habitation, or where large bodies of persons are at any time to be congregated, it is requisite that there should be some means of replenishing the apartment with a constant supply of pure air. This necessity arises from the fact, that air, when once passed through the human system, is unfit for re-inspiration, that portion which is emitted being not only useless, but deleterious to health. On this account it becomes necessary to remove this vitiated air, and to substitute fresh air, which should be at a temperature of about 60° to 65°. The vitiated air, on being emitted from the mouth, has a temperature between 80° and 90°, and being thereby rarified and rendered lighter, has a tendency to rise to the upper part of the apartment. The method hereby naturally suggested for its removal is the provision of some means of escape at the top of the apartment; the success of this method, however, would be nullified, if the heated air, on emerging from the top of the room into a shaft intended to conduct it away, were to meet with a current of cold air, and it is therefore found necessary to heat the air in the shaft, so as to assist the upward draft. It is further necessary to keep up a constant supply of fresh air to take the place of the foul air as it is removed; this is necessary, not only for the purposes of health, but also to preserve the upward draft. In some instances, means have been adopted of forcing fresh air in with fans or bellows; but this is scarcely necessary, for if the fresh air be only allowed admission into the apartment, it will naturally enter to fill up the vacuum caused by the dispersion of the foul air. These methods, however, are seldom adopted together; sometimes the shaft, and at others the fan, is employed. Some persons contend, that the method of heating the air in the shaft does not answer the intended object, but rather causes a downward current. In supplying fresh air, it is to be observed, that cold currents of air are to be avoided: it is sometimes customary to heat the air to a certain temperature before admitting it into the apartment, the temperature being regulated according to the season of the year.

VENTILATOR, (from the Latin, *ventilo*, to fan,) a machine made to turn with the wind, and placed in the wall or roof, in order to throw a due quantity of fresh air into a close apartment.

VERGE, a small ornamental shaft in Gothic architecture.

VERGE BOARD, same as BARGE BOARD.

VERMICULATED RUSTICS, stones worked to appear as if eaten by worms.

VERSED SINE, that part of the radius of a circle intercepted between the foot of the sine and the circumference, otherwise termed *sagitta*. *See* TRIGONOMETRY.

VERTEX, (Latin,) the top, generally applied to the termination of anything ending in a point; as the vertex of a pyramid, &c.

VERTEX OF A CONIC SECTION, the extremity of the abscissa.

VERTICAL ANGLES, the opposite angles made by two straight lines cutting each other.

VERTICAL PLANE, that position of a plane in which its surface is perpendicular to the horizon.

VESICA-PISCIS, a figure frequently used in the decorative part of Early English and Gothic architecture generally. It is formed by the intersection of two arcs of equal circles, and is somewhat similar in outline to that of a fish, whence its name. This form is commonly given to the auricola, or nimbus of glory, in which the representations of saints are enclosed.

VESTIBULE, a porch or entrance to any building.

VESTMENT, the hangings for an altar, or robes for the priests.

VESTRY, a building attached to a church, in which the sacred vestments and vessels were deposited; the same as SACRISTY.

VIADUCT, a term applied to a roadway supported on a succession of arches.

VIGNETTE, a running ornament in Gothic mouldings.

VIGNOLA, a name commonly given to JAMES BAROZZI, or BAROGGIO, from the place of his birth, a small town in the duchy of Modena. He was born in 1507, and was the son of a person of consequence, whom the political strife of the day obliged to expatriate himself. James discovered an early inclination for the arts, and was sent for education to Bologna, where, from painting, to which he was first attached, he directed his attention to architecture, and by various designs, upon the principles of Vitruvius, some of which he communicated to the historian Guicciardini, he acquired an early reputation. With a view to farther improvement, he went to Rome, and, being admitted into the Academy of Design, then newly founded, was there employed in measuring the most celebrated remains of antiquity; in the prosecution of which labour he evinced uncommon taste and precision; so that the abbé Francisco Primaticcio, an able painter and architect of Bologna, who was sent to Rome in 1537 by Francis I. of France, to procure designs of the ancient buildings and casts of statues, was induced to avail himself of the assistance of Vignola, and on his return took him with him to France, where he drew plans for several eminent structures. After two years' residence in that country, Vignola returned to Bologna, and was employed in forming a plan for the façade of the church of St. Petronius, but, through the envy of his competitors, it was not executed till some years afterwards. In and near this city he built some palaces, and constructed the canal of Naviglio, running thence to Ferrara. Unduly recompensed for this work, he went to Placentia, and planned a palace for the Duke of Parma. After his return to Rome, in 1550, he built several churches there; and, through the interest of Vasari, was appointed architect to Pope Julius III., for whom he built a villa, and near it a small church, dedicated to St. Andrew, in the form of an ancient temple; and by his command he also brought the Aqua Vergine to Rome. After the death of Julius, he was employed by Cardinal Alexander Farnese in the construction of the magnificent palace, or castle, of Caprarola; and he had likewise the charge of building the church of the Jesuits at Rome, an edifice of extraordinary beauty and grandeur; but it was raised only to the cornice before the death of Vignola, and was finished by his disciple, James della Porta. After the decease of Michael Angelo, Vignola was appointed to succeed him as architect of St. Peter's, in conjunction with Piero Ligorio, a Neapolitan; which engagement, added to his advanced age, obliged him to decline an invitation from Philip II. to the court of Spain. He was, however, consulted with regard to the different plans given in for the Escurial; and one furnished by himself was highly approved, though not adopted. His other professional labours were interrupted by a commission from Gregory XIII., to settle the limits between the territories of the Church and those of the Duke of Tuscany; which he executed to the pope's satisfaction. Upon his return from this service, he was seized with a fever, and died in 1573, aged 66. His remains were solemnly interred in the church of Santa Maria della Rotunda, the ancient Pantheon.

Vignola acquired reputation as an author no less than as a practical artist. His rules for the five orders were formed on the purest taste of antiquity, and have been always reckoned classical and original. His treatise on the subject, in three volumes quarto, has been often reprinted, and translated into almost all the European languages. The French translation, with the commentaries of Daviler, is most esteemed. Vignola also wrote a treatise on practical perspective, which has passed through many editions.

VILLA, (from the Latin.) a country-house; of which the situation ought to be agreeable, commodious, and healthy, with winter and summer apartments; and surrounded with trees, to yield a cool refreshing air and shade during the heat of summer, and break the stormy cold winds of the winter. The Roman villas were very magnificent. See the description of Pliny's villas, under the article HOUSE.

VISE, a spiral staircase winding round a central newel or perpendicular shaft.

VISUAL POINT, the point of vision from which an object is viewed. *See* POINT.

VISUAL RAY, the thread or beam of light reflected to the eye from a certain point of the object.

VITRUVIAN SCROLL a peculiar pattern of scroll-work used in classical architecture, consisting of entwined undulations.

VITRUVIUS, M. POLLIO, a very distinguished writer on architecture, is supposed to have flourished in the times of Julius Cæsar and Augustus. Of his parentage, and place of nativity, nothing certain is known: Verona and Plaisance both claim him; but the pretensions of Formiæ, now Mola de Gaëta, are more generally allowed. Of his liberal education, and his travels for information and improvement, there can be no doubt. By the exercise of his profession he had acquired some property, though perhaps not very considerable; for he says, he did not, like the generality of architects, solicit employment. Under Augustus, or perhaps one of the succeeding emperors, to whom he dedicated his works, he occupied the post of Inspector of Military Engines. But as Pliny the Elder mentions his name among other authors, in his *Natural History*, composed in the reign of Vespasian, his work must have been published before that period. Of edifices planned or constructed by him, one only is mentioned by himself, which was a basilica at Fano. His work was discovered in MS. by Poggio, in the fifteenth century, and it has ever since been held in high estimation. The ten books, into which it is distributed, not only treat on everything belonging to buildings public and private, their site, materials, forms, ornaments, conveniences, and the like; but include much of what would be termed engineering, civil and military; and even digress to geometrical problems and astronomical inventions. Besides the instruction that may be derived from it, it has afforded much important matter to the antiquary relative to the state of art and science, as well as the detail of private life, among the Romans.

Some of the most esteemed editions of Vitruvius are by Dan. Barbari, *Venet.* fol. 1567; J. de Laet, *Amst.* fol. 1649; Galiani, *Neap.* fol. 1758, with an Italian translation and notes. Claude Perrault has given a good French translation, *Paris*, fol. 1684; and we have an English one by Mr. Newton, *London*, 1791. A magnificent edition of the civil architecture of Vitruvius, in two parts, royal quarto, has been also published by W. Wilkins, Jun., A.M., F.R.S., &c. During the reign of Augustus, it does not appear that the Romans had one architect, sculptor, painter, or musician, except Vitruvius, who has given Aristoxenus's system in Latin; but he was obliged to retain the Greek *technica*, as he was the first Roman writer on the subject of music, and used Greek technical words as we do Italian. Vitruvius has described the theatrical vases used by the Greeks for the augmentation and continuation of sound, and has given a description of the organ of the ancients worked by the fall of water.

VIVO, the shaft of a column. *See* COLUMN.

VOLUTE, one of the principal ornaments in the Ionic capital composed of two or more spirals of the same species, having one common eye and centre, variously channelled, or hollowed out in the form of mouldings.

Among the remains of ancient architecture, the Ionic capitals of the temples of Erechtheus and Minerva Polias, at Athens, are the most beautiful. The spiral best adapted for this purpose, is known by the name of the *logarithmic spiral;* the method of describing which is as follows:

Draw a straight line for the cathetus; take any point in the straight line as a centre; through this point draw another straight line at right angles, and these two straight lines cutting each other, will form four right angles: bisect any two adjacent right angles, and let the bisecting lines be produced on the other side of the centre, and the whole will be divided into eight equal angles by as many lines, upon which the radii are to be placed.

In the calculation we are here about to make, that part of the cathetus above the centre is supposed to be 20 minutes at a medium, and the next radius 18.3; both these being given, the calculation is founded upon the following principle:

Let $a = 20$, and $b = 18.3$,

then $a : b :: b : \frac{b^2}{a}$, which gives the third radius.

$b : \frac{b^2}{a} :: \frac{b^2}{a} : \frac{b^3}{a^2}$, which gives the fourth radius.

$\frac{b^2}{a} : \frac{b^3}{a^2} :: \frac{b^3}{a^2} : \frac{b^4}{a^3}$, which gives the fifth radius.

Therefore, any radius may be found, independent of the rest: thus, $\frac{b^{x-1}}{a^{x-2}}$; x being a variable quantity, representing the numbers of the radius. Thus, suppose the eighth radius were required; make $x = 8$, then $\frac{b^{x-1}}{a^{x-2}} = \frac{b^7}{a^6}$.

The arithmetical operation will be best performed by logarithms: now, as $b = 18.3$, and $a = 20$, multiply the logarithm of 18.3 by 7, and the logarithm of 20 by 6, subtract the latter product from the former, and the remainder will be the logarithm of the answer.

Now the logarithm of 18.3 is 1.26245, which, multiplied by 7, gives 8.83715: and the logarithm of 20 is 1.30103; which, multiplied by 6, gives 7.80618: then 8.83715 — 7.80618 = 1.03097, which is the eighth radius.

The following method will serve to prove the result of the operations, which are all dependent on each other; and will save the trouble of frequent reference to the Logarithmic Tables.

Log. 20 = 1.301030
log. 18.3 = 1.262451
1.262451
2.524902
1.301030
1.223872, the corresponding number is 16.74, which is the third radius.

Log. 18.3 = 1.262451
log. 16.74 = 1.223872
2
2.447744
1.262451
1.185293 = log. 15.32, 4th radius.

Log. 16.74 = 1.223872
log. 15.32 = 1.185293
2
2.370586
1.223872
1.146714 = log. 14.01, 5th radius.

Log. 15.32 = 1.185293
log. 14.01 = 1.146714
2
2.293428
1.185293
1.108135 = log. 12.82, 6th radius.

Log. 14.01 = 1.146714
log. 12.82 = 1.108135
2
2.216270
1.146714
1.069556 = log. 11.73, 7th radius.

Log. 12.82 = 1.108135
log. 11.73 = 1.069556
2
2.139112
1.108135
1.030977 = log. 10.73, 8th radius.

Log. 11.73 = 1.069556
log. 10.73 = 1.030977
2
2.061954
1.069556
.992398 = log. 9.82, 9th radius.

And thus, having gone through one revolution, the radii of the remaining revolutions may be found in a similar manner.

Now to apply the number thus found:

Plate I.—The centre is marked by the point ⊙; upon the cathetus set 20 from ⊙ upwards, which will give the extremity of the first radius; upon the second radius towards the left, set 18.3 from the centre, which will give another point in the curve; then, following round in the same progression, from the centre, set 16.74, 15.32, 14.01, 12.82, 11.73, 10.73, 9.82, &c. upon each succeeding radius respectively, to 2.37, and three points will be found in each quadrant.

In the Plate here referred to, we have only retained one

VOLUTE.

Radii for Three Revolutions		
First	Second	Third
20.	9.826	4.828
18.3	8.991	4.417
16.744	8.227	4.042
15.321	7.527	3.698
14.019	6.888	3.384
12.827	6.302	3.096

decimal place, the scale not admitting of any more. And note, when the second decimal is 5, or more, the first decimal is made one more.

In the first quadrant, take the length of the middle radius, *viz.* 18.3: set one foot of the compasses in 20, then describe an arc near to the centre; with the same radius set the foot of the compasses in 16.7, and describe an arc cutting the former; then, from the point of intersection, as a centre, describe an arc through all the three points 20, 18.3, 16.7. Proceed in the same manner with every quadrant, by taking the middle radius; and from the extremity of each outer radius, describe two arcs intersecting each other; and from the point of intersection, as a centre, with the same radius describe an arc through the two extremities, until you arrive at 2.4; then with radius 2.4 describe a circle for the eye, and the whole spiral will be completed.

Should it be required to describe a spiral through any given point, so as to form a fillet, divide the distance from the centre to that point into twenty equal parts, form a new scale, and proceed in the manner already described.

The foregoing Table contains the lengths of all the radii, to three places of decimals, and will be of use for volutes upon a large scale. And instead of constructing a scale for every different spiral, the sector may be used, which is an universal scale to any distance within its reach.

But no instrument can be more easily or more accurately applied, than the proportional compasses: for if the slider be so shifted, that the two long legs may be to the two short legs in the ratio of the two first radii, then all the remaining radii may be found by extending the points of the long legs to the shortest radius, which will give the length of the next shorter radius between the points of the short legs; and by proceeding in this manner till all the points are found, the curve may be drawn as before directed.

Plate II.—A volute drawn according to the preceding principles, consisting of three spirals; the numbers affixed round the outer spiral are supposed to be minutes, and consequently no other scale will be required than that of the order itself; but in drawing the two interior spirals, two new scales must be formed; or the scale of the order might be made to answer the purpose, by setting the proportional compasses in the ratio of the two radii, then taking the length of the radii from the scale with the long legs, and transferring the distances between the short legs to the spiral, and drawing the curve; so that the whole may be completed as before.

The volute in this Plate is similar to that of the Ionic temple at Athens, the temple of Bacchus at Teos, and that of Minerva Polias at Priene in Ionia.

Plate III. *Figure* 1.—A volute in imitation of that of the temple of Erechtheus, at Athens, drawn according to the preceding principles. It consists of eleven spirals, which may be all drawn from the scale of the order by the assistance of a pair of proportional compasses. But if this useful instrument is not in the hands of the delineator, the eleven scales are here exhibited at *Figure* 2, for drawing the same number of spirals.

An universal scale may be made, as in *Figure* 3, thus: describe an equilateral triangle, C A B, upon C B, equal to the greatest radius; divide C B into twenty equal parts, and draw straight lines from the points of division to A; produce C B to *b*, and make B *b* equal to one of the equal parts; divide B *b* into ten equal parts, and draw lines to A; then make A D and A E each equal to the first radius, and draw the line E D, which produce to meet A *b* at *d;* then E D *d* will give the scale for drawing the spiral required: E D being the scale of units, and D *d* that of tenths; and thus any other radius may be divided at once.

Figure 4, is another method of obtaining an universal scale, by means of a right-angled triangle, A B C, right-angled at C, making C B and C A equal to each other: but there is no method so exact and expeditious as the proportional compasses, and one scale, which may either be that of the order or not, and consequently any scale divided into units and tenths will answer the purpose, if this instrument be used.

Plate IV. shows a design for the capital and base of an Ionic column, with the details of capital and volute.

VOUSSOIRS, the wedge-shaped stones forming the curvature or intrados of an arch.

W.

WAGGON-HEADED ceiling, a semi-cylindrical, or barrel-ceiling, not uncommon in churches of the Gothic style.

WAINSCOT, (from the Dutch *wayschot*,) in joinery, the lining of walls, constructed of wood, and most generally panelled.

The term *wainscoting*, as applied to the lining of walls, originated in a species of foreign oak of the same name, used for that purpose; and although that has long been superseded by the introduction of fir-timber, the term has been continued notwithstanding the change of the material.

Wainscoting is generally used for the lining of walls to the height of about 5 or 6 feet; and when it does not reach the whole height, it is called *dwarf wainscoting*.

To prevent the joints of panels from opening in consequence of the glue being softened or consumed by damps from the walls, the back of the wainscot ought to be primed over at the joint with white lead, or Spanish brown, and linseed oil.

The method of measuring wainscot is, to multiply the length by the breadth, and find the number of square yards; the price is adjusted according to the difficulty of the work, or the time required to perform it. *See* CARPENTRY and JOINERY.

VOUSSOIRS, the wedge-shaped stones forming the curvature or intrados of an arch.

W.

WAGGON-HEADED ceiling, a semi-cylindrical, or barrel-ceiling, not uncommon in churches of the Gothic style.

WAINSCOT, (from the Dutch *wayschot*,) in joinery, the lining of walls, constructed of wood, and most generally panelled.

The term *wainscoting*, as applied to the lining of walls, originated in a species of foreign oak of the same name, used for that purpose; and although that has long been superseded by the introduction of fir-timber, the term has been continued notwithstanding the change of the material.

Wainscoting is generally used for the lining of walls to the height of about 5 or 6 feet; and when it does not reach the whole height, it is called *dwarf wainscoting*.

To prevent the joints of panels from opening in consequence of the glue being softened or consumed by damps from the walls, the back of the wainscot ought to be primed over at the joint with white lead, or Spanish brown, and linseed oil.

The method of measuring wainscot is, to multiply the length by the breadth, and find the number of square yards; the price is adjusted according to the difficulty of the work, or the time required to perform it. *See* CARPENTRY and JOINERY.

WALL-PLATE, a piece of timber placed in or upon a wall to receive the ends of joists or rafters.

WALLS, (perhaps from the Latin *vallum*, a fence,) those masses of materials which generally have their faces in vertical or plumb-lines; or, at least are so disposed, that a plumb-line from any point in either surface will fall entirely within the surface, or within the thickness of the wall.

In walls constructed for shelter, if the materials cannot be joined without interstices, those interstices ought to be so closed as to render the work impervious to rain or drift.

The materials with which walls are generally constructed are brick or stone. Some walls may be built either of rough or squared stones. When the exterior walls of dwelling-houses are to be constructed of rough stone, the stones ought to be laid in mortar; but when they are squared and smoothed, this is not necessary. The ancients, in building their edifices with squared stones, seldom laid them in mortar; but their joints and beds were so exactly wrought, as to come nearly in contact with each other. *See* Stone Walls.

As bricks cannot be formed so regularly as stones, on account of the burning, they are usually laid in mortar. *See* Bricklaying and Brickwork.

From the definition given of a wall, founded upon the axiom, that every material which overhangs has a tendency to fall, or to break off, or to overturn the structure of which it is a part, it is evident, that as a wall rises it ought either to diminish in its thickness, or to follow the plumb-line.

Walls common to two apartments are called *partition walls*, or simply *partitions*. When a wall is divided or separated by ornaments, apertures, or projections, it is said to be *intermitted;* but if uninterrupted, it is called *a continued wall.* It is, however, generally understood, that when a wall has apertures without projections, as columns and pilasters, it is said to be *continued*, which is contradictory to the common acceptation of the term.

Walls, *Abutments in*, the beds that are prepared for the springing of an arch.

Walls, *Cased*, those that are faced up anew all round the building, in order to cover an inferior material, or old work gone to decay.

Walls, *Emplecton*, those which are built in regular courses, with the stones smoothed in the face of the work: they are of two kinds, Roman or Grecian. The difference is, that the core of the Roman emplecton is rubble; whereas in the Grecian it is built in the same manner as the face, and every alternate stone goes through the entire thickness of the wall.

Walls, *Isodomum*, those where the courses are of equal thickness, compact, and regularly built; but the stones are not smoothed on the face.

Walls, *Pseudo-isodomum*, those which have unequal courses.

For other particulars respecting walls, *see* the articles above referred to; also Building, Pise, and Mensuration.

WATER-CLOSET, an apartment so generally known as to render any definition of it unnecessary. There are no good houses without one or more of them. Their construction belongs entirely to the engineer: the chief thing which the architect has to attend to is, to place his water-closets in such a situation as to be isolated from the principal apartments, to conceal them from general observation, and to make them as accessible as possible. The number of water-closets in a house ought to be in proportion to the magnitude of the building; in large mansions, a certain number of water-closets must be appropriated to the servants, as well as to the family itself. One of the principal things which the architect must attend to is, to prevent all recoil or return of noxious effluvia.

Water Shoot, a wooden trough for discharging rain-water from a building.

Water Table, the upper surface of a coping, or projection, where the superior part of a wall recedes from the inferior or lower part.

Water tables are frequently used in edifices of the pointed style, particularly near the base of the building: as in buttresses consisting of several stages, where the sloping parts, which cover the solids below, are called *water-tables.*

WAY-WISER. *See* Perambulator.

WEATHER BOARDING, signifies the nailing up of boards lapped upon each other, so as to prevent rain or drift from passing through. For this purpose, the boards are generally made thinner on one edge than on the other; particularly when the work is intended to be permanent: the boards thus formed are called *feather-edged boards.* In using feather-edged boards, the thick edge of the upper board is laid upon the thin edge of the board below, about an inch over, or, in very secure work, an inch and a half, the nails being driven through the lap.

WEATHERING, a slight inclination given to copings or ledges of walls, for the purpose of throwing off the rain.

WEATHER MOULDING, a moulding carried over a door or window, for the purpose of diverting rain-water from the parts beneath; otherwise termed *drip-stone*, or *label.*

Weather Tiling, the covering of an upright or wall with tiles.

WEDGE, (from the Danish *wegge.*) Writers on mechanics, in treating of the wedge, have frequently drawn false conclusions respecting the proportion which exists between the impelling power applied to the head, and the resisting powers opposed to the sides; and those conclusions have resulted from false opinions concerning the directions of the resisting powers.

It is evident, that when wood or other substance is split by a wedge which does not fill the cleft, that is, when the angle of the cleft is more acute than that of the wedge, the power or action of each side of the wedge, equal and opposite to the resistance of the cleft, must be resolved into two; the one in the direction of the side of the cleft, which tends to thrust it forward; and the other perpendicular to that direction, which tends to tear it asunder. It is by not attending to the above solution, that writers on this subject have been led into mistakes; for, instead of considering the powers which act in those two directions, they have imagined a single power only as acting obliquely on each side. But if the sides of the wedge are perfectly polished, as we must here consider them, no single permanent power can be applied to impel any one of them, unless its direction be perpendicular to the plane of the side to which it is applied; therefore, two oblique powers, applied on opposite sides of the same point, are at least necessary to sustain each other and the action of the plane; and in the case of the wedge above mentioned, the directions of those two oblique powers will always be perpendicular to each other, as will appear obvious from the two following Propositions.

Proposition I. *Figure* 1.—Let A B C be a vertical section passing through the centre and at right angles to the head and sides of any isosceles wedge; also in the plane of this section, and at right angles to its sides, A B, B C, and C A, let three powers be applied, such, that their directions may all mutually intersect in the axis, and their efforts sustain the wedge in equilibrio; which three powers are as A B, B C, and C A, respectively.

Let L M, K I, E D be the directions of these three powers, which, produced, intersect each other and the axis in O. Since, by hypothesis, these three powers directed to the same point are in equilibrio, and the three sides of the triangle A B C are at right angles to their directions; therefore, by a well-known statical principle, the intensities of these two powers are as A B, B C, and C A respectively.

PROPOSITION II.—When an impelling power applied to the head of an isosceles wedge is in equilibrio with the resisting power of a cleft, the angle of which is more acute than that of the wedge inserted, then, universally,

The impelling power applied to the head,
The action of the wedge on either side of the cleft,
The part thereof which tends to thrust it forward,
And the remaining part, which tends to tear it asunder,
Are
As twice the sine of half the vertical angle of the wedge,
The radius,
The sine of the angle contained by the sides of the wedge and cleft,
And the cosine of that angle, respectively; the same radius being common.

Figure 2.—Let A B C represent a vertical section of the wedge and cleft, similar in position to that described in Proposition I.; also let the two sides of the cleft D H, D H, be equal, and in contact with the sides of the wedge A C, A C, at equal distances, D C, D C, from the vertex C, in which case the sides of the wedge make equal angles with those of the cleft. Through either point D, draw D F, at right angles, and equal to A C; also through D draw D E, at right angles to D H, and complete the parallelogram D E F G. Then, by Proposition I. the line A A represents in quantity the impelling power applied to the head, and the line D F represents in quantity and direction the whole action of the side of the wedge on that of the cleft, which, by hypothesis, is balanced by its resistance; but the power D F is resolved into two, represented in quantity and direction by D G, D E, respectively: the one, being in the direction of the cleft, tends to thrust it forward; and the other, being at right angles thereto, tends to tear it asunder,

Therefore the powers mentioned in the Proposition are as A A, D F, D G, and D E, respectively; but as A C=D F, being radius, these lines are respectively equal to
Twice the sine of half the vertical angle of the wedge,
The radius,
The sine of the angle contained by the sides of the wedge and cleft,
And the cosine of that angle. Hence the proposition is manifest.

WEIGHT, in mechanics, denotes anything to be raised, sustained, or moved, by a machine, as distinguished from the power, or that by which the machine is put in motion.

WEIGHT, in commerce, denotes a body of a known weight, appointed by law to be the standard of comparison between different quantities of merchandise of certain descriptions; the weight itself being usually of lead, iron, brass, or other metal.

The great diversity of weights and measures, in all nations, for different kinds of commodities, has always been a just subject of regret and complaint; being the cause of various disputes and deceptions, which it is almost impossible to avoid under present circumstances. And it is therefore much to be wished, though perhaps little to be expected, that one uniform system of weights should be adopted as applicable to all kinds of substances; an attempt at which was made in France during the revolution, but which was afterwards laid aside by an imperial decree, in consequence of the repeated remonstrances of people in trade; so difficult is it to overcome prejudices and customs long established, however advantageous the change may be when properly understood.

In the reign of king Richard I. it was ordained, that there should be only one weight and one measure throughout England; and in the *Phil. Trans.* No. 458, p. 457, we find an account of the analogy between English weights and measures drawn up by Mr. Barlow; in which he states, that anciently the cubic foot of water was assumed as a general standard for all liquids. This cubic foot, of 62½ lb. multiplied by 32, gives 2000 lb. the weight of a ton; and hence 8 cubic feet of water made a hogshead, and 4 hogsheads a tun, or ton, in capacity and denomination, as well as weight.

Dry measures were raised on the same model. A bushel of wheat, assumed as a general standard for all sorts of grain, also weighed 62½ lb. Eight of these bushels make a quarter; and 4 quarters, or 32 bushels, a ton. Coals were likewise sold by the chaldron, supposed to weigh a ton, or 2000 lb., though in reality it probably weighs upwards of 3000 lb.

This principle, though not sufficiently accurate in some cases, was extremely obvious, and might have been improved so as to answer all the purposes of commerce; but unfortunately, instead of rendering it more simple, it has been made infinitely more complicated by the different weights since introduced.

Modern European Weights.—1. English weights. By the twenty-seventh chapter of *Magna Charta*, the weights all over England are to be the same; but for different commodities there are two different sorts, viz.: Troy weight and Avoirdupois weight. The origin from which they are both raised is, a grain of wheat gathered in the middle of the ear.

In Troy weight, 24 of these grains make 1 pennyweight sterling; 20 pennyweights make 1 ounce; and 12 ounces 1 pound.

By this weight we weigh gold, silver, jewels, and liquors. The apothecaries also use the Troy pound, ounce, and grain: but they divide the ounce into 8 drachms, the drachm into 3 scruples, and the scruple into 20 grains.

In Avoirdupois weight, the pound contains 16 ounces, but the ounce is less by near one-twelfth than the Troy ounce; this latter containing 480 grains, and the former only 437½. The ounce contains 16 drachms; 80 ounces Avoirdupois are only equal to 73 ounces Troy; and 17 pounds Troy are equal to 14 pounds Avoirdupois.

By Avoirdupois weight are weighed meat, grocery wares, base metals, wool, tallow, hemp, drugs, bread, &c.

Comparison between Troy and Avoirdupois Weight.

175 Troy pounds are equal to 144 Avoirdupois pounds.
175 Troy ounces are equal to 192 Avoirdupois ounces.
1 Troy pound contains 5760 grains.
1 Avoirdupois pound contains 7000 grains.
1 Avoirdupois ounce contains 437½ grains.
1 Avoirdupois drachm contains 27.84375 grains.
1 Troy pound contains 13 ounces, 2.651428576 drachms Avoirdupois.
1 Avoirdupois pound contains 1 lb. 2 oz. 11 dwts. 16 gr. Troy.

Therefore the Avoirdupois lb. is to the lb. Troy as 175 to 144, and the Avoirdupois oz. is to the Troy oz. as 437½ to 480.

Goldsmiths, jewellers, &c., have a particular class of weights, viz.: for gold and precious stones, the carat and grain; and for silver, the pennyweight and grain. In the mint, they have also a peculiar subdivision of the Troy grain: thus dividing

the grain into 20 mites,
the mite into 24 droits,
the droit into 20 periots,
the periot into 54 blanks.

The dealers in wool have likewise a particular set of weights, viz.: the sack, weigh, tod, stone, and clove; the proportions of which are as follow:

the sack contains 2 weighs,
the weigh $6\frac{1}{2}$ tods,
the tod 2 stones,
the stone 2 cloves,
the clove 7 pounds.

Also 12 sacks make a last, or 4368 pounds.

Farther,

56 lb. of old hay, or 60 lb. new hay, make a truss.
40 lb. of straw make a truss.
36 trusses make a load of hay or straw.
14 lb. make a stone.
5 lb. of glass a stone.

Other nations have also certain weights peculiar to themselves: thus, Spain has its arrobas, containing 25 Spanish pounds, or one-fourth of the common quintal: its quintal macho, containing 150 pounds, or one-half of the common quintal, or 6 arrobas; its adarme, containing one-sixteenth of its ounce. And for gold, it has its castillan, or one-hundredth of a pound; and its tomin, containing 12 grains, or one-eighth of a castillan. The same are in use in the Spanish West Indies.

Portugal has its arroba, containing 32 Lisbon arratals, or pounds. Savary also mentions its faratelle, containing 2 Lisbon pounds; and its rottolis, containing about 12 pounds. And for gold, its chego, containing 4 carats. The same are used in the Portuguese East Indies.

Italy, and particularly Venice, have their migliaro, containing 4 mirres; the mirre containing 30 Venice pounds; the saggio, containing a sixth part of an ounce. Genoa has five kinds of weights, viz.: large weights, whereby all merchandizes are weighed at the custom-houses; cash weights for piasters, and other specie; the cantara, or quintal, for the coarsest commodities; the large balance for raw silks, and the small balance for the fine commodities. Sicily has its rottolo, equal to $32\frac{1}{2}$ pounds of Messina.

Germany, Flanders, Holland, the Hanse-towns, Sweden, Denmark, Poland, &c., have their schippondt, which, at Antwerp and Hamburgh, is 300 pounds; at Lubeck, 320; and at Konigsberg, 400 pounds. In Sweden the schippondt for copper is 320 pounds; and the schippondt for provisions 400 pounds. At Riga and Revel, the schippondt is 400 pounds; at Dantzic, 340 pounds; in Norway, 300 pounds; at Amsterdam, 300, containing 20 lysponts, each weighing 15 pounds. In Moscow they weigh their large commodities by the bercheroet, or berkewits, containing 400 of their pounds. They have also the poet, or poede, containing 40 pounds, or one-tenth of the bercheroet.

In order to show the proportion of the several weights used throughout Europe, we shall add a reduction of them to one standard, viz.: the London pound.

Proportion of the Weights of the principal Places in Europe.

The 100 lb. of England, Scotland, and Ireland, are equal to

lb.	oz.	
91	8	of Amsterdam, Paris, &c.
96	8	of Antwerp or Brabant.
88	0	of Rouen, the viscounty weight.
106	0	of Lyons, the city weight.
90	9	of Rochelle.
107	11	of Toulouse and Upper Languedoc.
113	0	of Marseilles or Provence.
81	7	of Geneva.
93	5	of Hamburgh.
89	7	of Frankfort, &c.
96	1	of Leipsic, &c.
137	4	of Genoa.
132	11	of Leghorn.
153	11	of Milan.
152	0	of Venice.
154	10	of Naples.
97	0	of Seville, Cadiz, &c.
104	13	of Portugal.
96	5	of Liege.
112	$0\frac{2}{3}$	of Russia.
107	$0\frac{1}{24}$	of Sweden.
89	$0\frac{1}{2}$	of Denmark.

Proportion of the Weights of several Places in Europe compared with those of Amsterdam.

The 100 lb. of Amsterdam, are equal to

lb.	
105	of Antwerp.
100	of Bayonne and Paris.
$95\frac{1}{4}$	of Bergen in Norway.
151	of Bologna.
103	of Bremen.
125	of Breslaw.
105	of Cadiz.
107	of Copenhagen.
97	of Dublin and Edinburgh.
109	of London.
114	of Madrid.
169	of Naples.
109	of Riga.
146	of Rome.
110	of Stettin.
182	of Venice.

	1 =	16 =	437.5 =	28.32
		1 =	27.975 =	1.81

German.

71 lb. or grs. English Troy = 74 lb. or grs. German apothecaries' weight.
1 oz. Nuremburg, medic. weight = 7 dr. 2 scru. 9 grains English.
1 mark Cologne = 7 oz. 2 dwt. 4 gr. English Troy.

Dutch.

1 lb. Dutch = 1 lb. 3 oz. 16 dwt. 7 gr. English Troy.
$787\frac{1}{2}$ lb. Dutch = 1038 lb. English Troy.

Swedish Weights, used by Bergman and Scheele.

The Swedish pound, which is divided like the English apothecary's, or Troy pound, weighs 6556 grains Troy.

The kanne of pure water, according to Bergman, weighs 42250 Swedish grains, and occupies 100 Swedish cubic inches. Hence the kanne of pure water weighs 48088.719444 English Troy grains, or is equal to 189.9413 English cubic inches; and the Swedish longitudinal inch is equal to 1.238435 English longitudinal inch.

From these data the following rules are deduced :—

1. To reduce Swedish longitudinal inches to English, multiply by 1.2384, or divide by 0.80747.

2. To reduce Swedish to English cubic inches, multiply by 1.9, or divide by 0.5265.

3. To reduce the Swedish pound, ounce, drachm, scruple, or grain, to the corresponding English Troy denomination, multiply by 1.1382, or divide by 0.8786.

4. To reduce the Swedish kannes to English wine pints, multiply by 0.1520207, or divide by 6.57804.

5. The lod, a weight sometimes used by Bergman, is the 32d part of the Swedish pound: therefore, to reduce it to the English Troy pound, multiply by .03557, or divide by 28.1156.

Correspondence of English Weights with those used in France before the Revolution.

The Paris pound (poids de marc of Charlemagne) contains 9216 Paris grains: it is divided into 16 ounces, each ounce into 8 gros, and each gros into 72 grains. It is equal to 7561 English Troy grains.

The English Troy pound of 12 ounces contains 5760 English Troy grains, and is equal to 7021 Paris grains.

The English Avoirdupois pound, of 16 ounces, contains 7000 English Troy grains, and is equal to 8538 Paris grains.

To reduce Paris grains to English Troy grains, divide by..........	1.2189
To reduce English Troy grains to Paris grains, multiply by..........	
To reduce Paris ounces to English Troy, divide by..........	1.015734
To reduce English Troy ounces to Paris, multiply by..........	

Or the conversion may be made by means of the following tables

I. *To reduce French to English Troy Weight.*

The Paris pound	=	7561	English Troy grains.
The ounce	=	472.5625	
The gros	=	59.0703	
The grain	=	.8204	

II. *To reduce English Troy to Paris Weight.*

The English Troy lb. of 12 oz.	=	7021.	Paris grains.
The Troy ounce	=	585.0893	
The drachm of 60 grains	=	73.1354	
The dwt. or dernier of 24 grains	=	29.2541	
The scruple of 20 grains	=	24.3784	
The grain	=	1.2189	

III. *To reduce English Avoirdupois to Paris Weight.*

The Avoirdupois lb. of 16 oz. or 7000 Troy grains	=	8538	Paris grs.
The ounce	=	533.6250	

The following is a Table of Weights, according to the new French system :

Names.	French value.		English value.
Millier......	1000 kilogrammes = 1 French ton.......	=	19.7 cwts.
Quintal	100 kilogrammes..	=	1.97 cwts.
Kilogramme...	Weight of one cubic decimeter of water of the temperature of 39° 12′ Fahrenheit		2.6803 lbs. troy. 2.5055 lbs. avoir.
Hectogramme	$\frac{1}{10}$th of kilogramme...	=	3.2 ozs. troy. 3.52 ozs. avoir.
Decagramme	$\frac{1}{100}$th of kilogramme ..	=	6.43 dwts. troy.
Gramme....	$\frac{1}{1000}$th of kilogramme..	=	15.438 grs. troy. 0.643 dwt. 0.032 ounce troy
Decigramme	$\frac{1}{10000}$ of kilogramme ..	=	1.5438 grains troy.

See also the article MEASURE.

WEIGHTS OF A SASH, two weights by which the sash is suspended, and kept steady in any situation it is put into, by means of cords passing over pulleys. The two vertical sides of the sash-frame are generally made hollow, in order to receive the weights, which by this means are entirely concealed : and thus, to keep the sash in suspension, each weight must be exactly half the weight of the sash. The cords must be of the best quality, otherwise they will soon fret to pieces.

WEIR, a dam placed across a river or stream, for the purpose of ponding back a portion of the water.

WELCH-GROINS, those formed by the intersection of two semi-cylindrical vaults, one of which is of less height then the other.

WELDING, the method of joining two pieces of metal by means of heat, by which they are brought nearly to a state of fusion.

WELL-HOLE, in building, a term differently understood by workmen and writers: by some, the whole space enclosed by the walls of a staircase is called the *well-hole;* by others, it is used only for the space left in the middle at the ends of the steps in a geometrical staircase. In strict propriety, the whole apartment in which the stairs are placed ought to be called *the well ;* and the void formed by the ends of the steps *the well-hole.*

WHEEL, (from the Saxon, *wheol,*) in mechanics, an engine consisting of a circular body turning on an axis, for enabling a given power to overcome or move a given weight or resistance. This machine may be referred entirely to the LEVER, which see.

WHEEL-WINDOW, a circular window, common in Lombardic and Gothic buildings; otherwise termed a ROSE or CATHERINE-WHEEL window.

WHETSTONE, a stone of a very fine quality, by which tools for cutting wood are brought to a fine edge, after being ground upon a grit-stone, or grinding-stone, to a rough edge.

WICKET, (from the Dutch,) a small door made in a gate.

WIND BEAM, an obsolete name for a COLLAR BEAM: *see* that article.

WINDERS, those stairs by which, in a continuous flight, the direction of ascent is changed, the risers being disposed as radii of a circle, and the treads in consequence being narrower at one end than the other; the width of the treads at the centre should be the same as that of the *flyers. See* STAIRS.

WINDING-STAIRS, those which wind round a central newel, or a circular well-hole. *See* STAIRS.

WINDLASS, or WINDLACE, a machine for raising weights, in which a cope or chain is wound about a cylindrical body, moved by several levers.

Also a handle, by which anything is turned.

WINDOWS, (from the Danish, *vindue*, or the Welsh *wynt dor*, a passage for the wind,) those apertures in walls through which light is transmitted to the interior of buildings.

Windows are generally of a rectangular form, the sides, or jambs, being vertical, and the bottom and lintel horizontal. Semicircular windows have a very elegant effect, particularly in circular buildings, as was generally the practice of the Romans; but those that are finished with segments, or semi-ellipses, are not so beautiful; and much less so are such as are constructed of entire circles or ellipses, for which, few or no precedents are to be found in the buildings of the ancients.

Windows must be proportioned in height and width to the principal rooms. The dressings of windows are the sill, and the insisting architrave, surrounding the upper part, crowned by a cornice and frieze. The breadth of the architrave may be one-sixth of that of the aperture; the frieze the same; the height of the cornice will depend upon the number of mouldings.

Windows should be so placed with respect to the principal room, or dining and drawing-rooms, as to be equally distant from each end of the apartment, and equidistantly distributed in the principal front, of one size, with their edges or sides in the same vertical lines. This adjustment will frequently be attended with difficulties; and to accommodate the principle, an alteration of the proportions, in a small degree, will sometimes be necessary. In houses of the middle class, where economy is an equal consideration with elegance or beauty, the windows frequently reach as high as the cornice, or even so high as to cut the cornice, wholly, or in part; a mutilation that destroys the beauty of the finishing. In such cases, it would be better to have more lofty stories, or lower windows. In large edifices, where proportions are considered, the spaces above the windows are more ample, and allow a more elegant finish, with a greater repose for the eye. Further particulars respecting windows will be found under APARTMENT, BUILDING, CASEMENT, HOUSE, JOINERY, SASH-FRAME, and SKYLIGHT. *See* also TRACERY, and GOTHIC ARCHITECTURE, &c.

Figure 2. The elevation of a window, where, the thickness of the wall not being sufficient to allow of boxings, the shutters are hinged upon a hanging style.

Figure 3.—The section of the foregoing.

Figure 4.—Section and plan of the sash-frame and shutters of a window, showing the same finishing, whether the shutters be folded in their boxings to admit light, or extended to their breadth upon the sashes to exclude it.

Figure 5.—Plan and section of the lower sash shutters and boxings of a common window, showing the nature of the work.

WINDOW-SHUTTERS, the wooden doors by which windows are occasionally closed, or secured. *See* BOXINGS, JOINERY, and SASH-FRAME.

WING, the outlying and returning ends of a building.

WITHS, (from the Saxon,) the partitions of flues. *See* CHIMNEY.

WOOD, (from the Saxon *wude*,) a fibrous material, of the greatest use in building, formed into shape by edge-tools. For a description of the different kinds of wood as applicable to building, see the articles TIMBER and MATERIAL; and for the method of measuring it, *see* MENSURATION, towards the end. *See* also SEASONING OF TIMBER, and STRENGTH OF MATERIALS.

WOOD BRICKS, blocks of wood cut to the form and size of bricks, inserted in the interior walls of apartments, as holds for the joinery.

WOODEN BRIDGES, are platforms constructed of carpentry, for crossing streams, rivers, roads, &c. These bridges may be looked upon as the origin of all such constructions, whether of stone, wood, or iron. In early times it may fairly be supposed, that trees, or planks made from them, would be thrown from one bank of the stream to the other, so as to serve for a footway, by which a passage might be effected. This might have been suggested in the first instance by accident, either by a tree falling in that position, or else by its growing across a stream, as sometimes happens with willows, &c. A plank placed from one bank of a stream to another, is the simplest form of a timber bridge; it is at the same time the most perfect; and the principle on which it is suspended, or kept in its proper position, is worthy of consideration, for we may learn how to construct the best and most advantageous kind of bridge, suitable for immense spans, from this unpretending, and apparently unpremeditated contrivance.

When a strong plank is thus laid upon two supports, that part of it which lies midway between them, has to sustain its own weight, together with the transit load which it has to bear, such as that of anything crossing over it, by the cohesion between its particles, for as that part of the plank has nothing to rest upon, it is therefore clear, that it has a tendency to break somewhere between the points of support when the strain becomes very great upon it; but owing to this cohesion of the particles, which attracts them to one another, such a plank cannot snap asunder, because the fibres of the timber of which it is formed, are so interwoven, that one particle or atom of the material will not readily be separated from its fellow, as long as such material remains in a sound state. This being the case, the effect of the weight upon the beam will cause it to bend, or what is technically termed, to sag, but in order to this, it will be necessary that the fibres on the under side of the beam should first be drawn out, or lengthened, that is, subjected to a tensile strain, while on the contrary, those on the upper surface will be forced to contract, or become shorter, in other words, they will be pressed upon longitudinally, and thus be subjected to a compressive force. It is also evident, that there must be some intermediate plane between the upper and lower surfaces of the beam, where the two opposite contending forces will meet, in which, of course, neither will preponderate; this, which is denominated the neutral plane, is situated lower or higher, according to the depth of the beam, the homogeneity and cohesion of the material of which it is composed, and a variety of other considerations. As a general formula for finding the weight with which it would be advisable to load such a beam, we may give the following,

$w = \dfrac{2\,b\,d^2 s}{3\,l}$ where w is the weight in lbs. with which the beam may be loaded, including that of the beam itself, b its breadth in inches, d its depth in inches, l its length in inches and s some known constant, representing the calculated strength of the kind of timber, or other material, employed. That of larch has been estimated at 280, Riga fir at 376, English oak 400, Mar Forest fir 415, red pine 447, pitch pine 544, Canadian oak 588, ash 675, teak 820. When the inertia of such a bridge is small, the deflection, or sagging, of the beam is found to depend upon a

WINDOWS.

Drawn by P. Nicholson.

Eng^d by R. Thew

certain quantity, which varies directly as the square of its length, and inversely as the product of the central statical deflection, (that is, the amount of deflection which would take place if all the load were placed at the centre of the beam,) and with the square of the velocity with which the load passes over the bridge.

In a bridge, therefore, constructed with a single beam, there are two counteracting forces, which, by mutually neutralizing each other, prevent the beam of which it consists from yielding; this constitutes what is called the rigidity of the timber, which thus opposes an obstacle to its bending, and which is increased in the direct proportion of the square of the depth and inversely as its length within certain limits, provided it is not loaded to more than a third of its calculated capability, which is taken into consideration in the above formula. This form of bridge merely rests upon its abutments, or piers, pressing vertically upon them. It exerts no force tending to overturn or push against them in an oblique direction. In this consists its superiority over bridges which are constructed solely on the principle of compression, such as arched bridges in general, or bridges formed completely on the principles of tension, as in the case of suspended bridges, in both of which it is necessary to introduce some countervailing weight or pressure, so as to resist the tendency which both those descriptions of bridges have of oversetting their supports. This adds greatly to their complicated nature, and consequently to the difficulty of their construction, involving, as it does, nice calculation, founded upon careful observation and experiment.

It may be said, if such advantages are gained by forming bridges in this simple manner, why not have adhered to their principle all along, instead of adopting difficult and intricate plans of construction, which give rise to great additional expense, besides making the subject so much more involved and uncertain? but on the other hand, it must be remarked, that independently of the short duration of timber in comparison of stone, iron, &c., where large spans have to be crossed, it cannot always be obtained of sufficient dimensions, as respects length and depth, and besides, in some localities, a supply of such timbers is not always to be obtained; and even in those where a great quantity was at one period to be found, the very fact of a large consumption leads to a deficiency in the course of time, and trees of a later growth and smaller scantling would necessarily come to be used; and further, in connexion with the application of beams to large spans, it must be borne in mind, that where the distance between the supports becomes greater, the dimensions require to be augmented, and that when the size is increased in an arithmetical proportion the weight is added in a much greater ratio. Under these circumstances, it may easily be conceived, that beam or girder bridges could only be employed within certain circumscribed limits; now, however, that the Britannia Tube has originated the system of building up hollow beams, by which their strength may be made sufficient for the work required of them, without adding so enormously to their weight, we may expect to see wooden-bridges, formed of hollow beams, taking the place of rib and arched timber bridges, and indeed, in some instances superseding both stone and iron, as being calculated for much larger spans than have hitherto been attempted, and capable of being constructed at a comparatively small cost.

But to go back to the history of wooden bridges, we will find that where rivers were broad, and their channels deep, it would be impossible to cross them by single beams of timber. In such cases, a timber framing or scaffolding would be formed in the bed of the river, by driving piles, or a pier might be formed of stones, or other materials. On these, beams of timber would be placed, with one extremity resting on the pier, and the other on the bank of the river, or on an abutment raised at the water's edge, and upon several piers in the water, as the case might be. Where the distance between the supports were too great for the dimensions of the timber forming the roadway, the main beams were propped up by struts projecting from the sides of the piers or piles, which were sometimes made to meet in the centre, or if that was not practicable on account of the distance between the supports, they could each be made to sustain the beam, and a cross-piece on which their ends should abut be placed between them, and fastened to the underside of the beam, these struts, or stays, were then multiplied and disposed in various ways, until at length a rib or arch of timber was formed to support the roadway, while the spandrels were filled up with struts and ties to resist the compression.

The ribs of bridges constructed in this manner were composed of frames, the lower portion of which form segments of circles, frequently made up of several pieces of wood placed immediately one over the other, and joggled together, so arranged, however, that their ends should break joint. To these circular arcs, or polygonal frames, upright pieces were attached either by bolts, mortises, or iron straps, by which the weight of beams supporting the roadway was sustained at intervals, and so disposed as that each part might, as far as possible, conduce to the strength of the whole.

The spandrils, or spaces between the lower rib and the roadway, were differently arranged, according to circumstances; in some there were perpendicular braces, and in others pendant pieces were made to radiate towards the centre of the circle, or polygon, of which the ribs were composed. Again; instead of forming the lower bar of the polygon, &c., by layers of timber bound closely together, it was, in some cases, constructed of two rails placed at some distance from each other, and fastened to radiating pendants, the intermediate spaces being filled up by abutting pieces placed regularly across, so as to keep all the parts of the ribs in their proper places. Besides this, *lattice*-bridges may be mentioned, which consist of two or more frames composed of top and bottom rails, either horizontal or slightly cambered, and the spaces between them filled in with diagonal pieces, crossing one another at an angle of 45°, or some other suitable angle; these pieces are bolted to one another at every crossing, as also to longitudinal walings, and the top and bottom rail; bridges of this description are easily constructed, exceedingly cheap, and have been found to answer extremely well for large spans. In addition to those enumerated, there are a large class of timber-bridges formed on the tension principle, by framing king and queen-posts to the main beam on which the roadway is supported, and bolting to them an upper rail, at the same time filling in the intermediate spaces with ties and truss-bars.

The *Pons Sublicius* was the first bridge ever built across the Tiber. It was at first constructed of timber in the reign of Ancus Martius. It was put together without either bolts or ties, so that it could readily be taken asunder; and was built for the purpose of connecting together the Aventine and Janiculum hills.

The bridge built over the Danube by Trajan is almost one of the oldest timber-bridges of which we have a detailed account. It was supported on twenty stone piers, which were 150 feet high and 6 feet broad; on these were framed timber-arches, each 170 feet span, and formed of three concentric timber-rings bound together by radiating pendants; these, together with the arches, supported the longitudinal beams on which the flooring-joists were placed across the bridge.

It had a simple parapet, formed of a top and bottom rail, supported at intervals by upright posts, with diagonal braces filling in the intermediate spaces. This bridge was unfortunately destroyed by the succeeding emperor, to prevent the possible incursions of the barbarians, by its means, into the Roman territory.

The timber-bridge of Schauffhausen, built over the Rhine, by Ulrick Grubenmann, was remarkable for its ingenious construction; it consisted of two openings, one 172 feet span, and the other about 190. Its abutments and centre-pier were of stone; on these were laid a kind of compound beam, formed of three rails or walings, each of which consisted of two longitudinal beams bolted together, and toothed into each other, so as to be perfectly united; these were supported by an infinity of struts, kept in their places by vertical binding-pieces, all tending to transfer the thrust to the supports of the bridge. It was roofed in for the ostensible purpose of protecting the timber from the bad effects of the weather; but there can be little doubt but that the roof added greatly to its strength; and it is not improbable that its ingenious architect was aware of the important advantages to be derived from its introduction. This bridge, and others designed and executed by the brothers Grubenmann, were in fact *Timber Tubular Bridges.*

The beautiful bridge of Schauffhausen was unfortunately demolished by the French, about the year 1800.

John Grubenmann, assisted by his brother Ulrick, built a splendid bridge of a similar description over the Limmat, having the enormous span of 390 feet. It was formed of two immense circular ribs, one at each side of the roadway, formed of several beams bolted together, and made to fit one into the other, in a similar manner to the Schauffhausen Bridge.

This bridge had also angular struts, longitudinal beams, perpendicular binding-pieces, and abutments of masonry; it was likewise furnished with a roof, which added considerably to the stability of the structure. It was, however, burned down shortly after the destruction of the Schauffhausen Bridge. The bridge at Ceslingen, as also that of Zurich, the one upwards of 200 feet, and the other about 130 feet span, are splendid specimens of this kind of construction, as likewise the bridges of Mellingen and Berne, by Ritter, and those over the Saone by Gauthey.

The timber-bridge of St. Clair, built over the Rhone at Lyons, has seventeen openings, the centre one having a span of 45 feet, and the others diminishing towards each bank. This bridge has a roadway of about 36 feet, which is supported upon piers each formed of 13 piles, arranged in a single row, running parallel with the banks of the river; on the top of these piles a sill was framed, and longitudinal timbers were made to bear over the head of each pile; and upon these longitudinal timbers the flooring was laid.

The bridge of Grenelle, erected over the Seine, near Paris, by M. Mallet, consists of two equal and symmetrical bridges, separated by an intermediate piece of dry ground; each of these is formed of three timber-bays of 82 feet span, supported upon two abutments and two piers of masonry. The width of this bridge is nearly 33 feet. The piers are about 11 feet wide at their foundations, and are diminished to about 9 feet at the springing. The abutments have a half-pier attached to them, on which the timber-work rests. Those at the banks of the river have, besides, two wing-walls. The ground in the centre, measuring 85 feet, the whole bridge, reckoning the entire distance from the abutments on either bank of the Seine, is 632 feet long.

All the foundations were built on piles, upon which a planking was laid. These foundations were formed by means of coffer-dams, easily constructed on account of the shallowness of the river, which, at low water, was not more than 5 feet deep; each bay is composed of seven timber frames, placed about 5 feet apart from each other. The frames consist of segmental ribs, formed of three pieces of bent timber, bolted and bound together by means of iron, which support the roadway by radiating pendants; each of these compound segmental beams is 9 inches square, and of such a length as to take in two of the spaces formed by the pendants. In cutting and placing the frames in position, they were put 5 inches higher than they should have been, in order to allow for sinking, after the flagging was put upon the bridge; and even when opened to the public, the bridge had not settled into its place, so it would seem that 2, or at most, 3 inches, would have been amply sufficient to have allowed for.

Upon the roadway, a layer of bitumen was laid about half an inch thick, in order to prevent the water from injuring the timber of the bridge; however, it must be admitted, that after very heavy rain, the moisture has been found to have percolated through this pavement, either owing to its having been badly laid, or perhaps in consequence of cracks made in this coating by the contraction and expansion of the timber roadway. It might be better, therefore, in future, to place a layer of fine sand between the flooring-boards and the bitumen. Six drain-pipes in each bay convey the water off the surface.

The pavement of the roadway consists of a flagging, 6 inches thick, laid upon sand in the ordinary manner. Each bay is loaded to the extent of about 40 tons.

There is another bridge over the Seine, at Iory, which was put up in the year 1828, and which greatly resembles the bridge of Grenelle in construction.

Besides these, which are given by way of example, there are almost an endless number of wooden-bridges erected throughout the world; among which may be mentioned the bridge at Trenton, in America, of 180 feet span; a bridge over the Tees, 150 feet span; the bridge of Neucetringen, in Bavaria, 102 feet; the bridge across the Necker, 210 feet span; the bridge of Bamberg, with an opening of 206 feet, erected by M. Wiebeking, an engineer, who has constructed an immense number of timber-bridges; the bridge of Feldrich, with a span of 65 feet; the bridge at Zete, built by M. Coffinet, with a span of 125 feet, besides several put up by the celebrated Perronet; and a number of others remarkable for their ingenious construction and variety of form.

Timber bridges are either supported upon piers and abutments of masonry built on the solid foundation of the ground, or on a platform constructed upon piles driven into the earth, or they are supported upon piers formed of one or more rows of piles driven in a line with the road or river passing under the bridge. There are an almost infinite variety of ways in which such props or piers may be made. It is, however, usual to drive the piles about a yard apart from centre to centre, and to bolt capping-pieces or walings to the top of such piles, and either filling up the spaces between with large stones laid dry, or else grouted with mortar; on this, the masonry for the supports should be placed, or a timber-framing, if desired, or else the piles may be carried up to the height of the roadway, being kept in their places by walings and diagonal pieces, bolted on each side of them; these piles should be about a foot square, and when they are driven in salt water, or in tidal rivers, their surfaces, up to high-water mark, should be sheathed with copper, or protected by scupper-nails, from the ravages of the worm. At each end of the piers in the water, in cases where several rows of piles are driven, a sort of cutwater should be formed, in order to ward off heavy bodies, such as floating trees, ice, &c., and prevent them from injuring the superstructure. This is usually done by driving one pile by itself in advance of the rest, or by forming what is called a *dolphin* at each end of the pier. The piers and abutments should be made in all cases sufficiently strong to resist the thrust of the arch. In cases of small foot-bridges, where even the distance between the supports should be as much as 20 or 30 feet, longitudinal scarfed girders may be laid upon the caps of the piles. Under such circumstances, as we have seen, there is nothing but the weight, or perpendicular pressure, to be provided for; and the same may be said of timber-bridges of greater width, for roads, and even for railways, provided the distance between the piers does not greatly exceed 10 or 15 feet; beyond that opening, however, bridges are usually sustained by struts or tension rods, or the roadway-timbers are trussed so as to exert an oblique pressure upon the supports; indeed, in all instances of the kind, where the bays are formed upon the principle of compression, or tension, the piers must be so formed as to counteract the tendency constantly exerted to force them out of their perpendicular position; this must be done either by making them of sufficient weight and strength so as to overcome, by their inertia, any force that may be exerted against them, or else to counterbalance the efforts of one bay, or arch, acting in one direction, by a similar and similarly-acting arch, or timber-frame, exerting an equal and like force in a contrary direction. The former of these methods is used in the abutments of a bridge, while the latter is invariably adopted with respect to piers.

The roadway of timber-bridges is usually a flooring of boards laid upon the joists; for, in cases where sand and stones are employed, it is found that their weight, together with the humidity they engender, causes the timbers of such bridges speedily to decay. This, however, is far from being a general rule; and many splendid erections of this description are rapidly being destroyed, owing to a want of attention to this important particular. Some have proposed to cover the surface of the roadway with lead, iron, copper, &c., but the increased expense will be a great obstacle to their frequent introduction: we would recommend the wood pavement to be laid as a covering for the roadway of all timber-bridges. The parapet or handrail of these bridges is frequently of wood, or it may be of cast and wrought iron; now, however, that it has been shown how important an addition to the strength of a bridge the sides of a beam are, and that it acts usefully in the direction of its depth, if it has only sufficient breadth to prevent its yielding laterally, we would suggest that in future it should be made available to sustain the bridge, in addition to its present purposes of ornament and protection.

Draw Bridges of timber, made after the manner of a float, to draw up or let down, as occasions serve, before the gate of a town or castle, may be made in several different ways, but the most common are made with plyers twice the length of the gate, and a foot in diameter. The inner space is traversed with a cross, which serves for a counterpoise; and the chains which hang from the extremities of the plyers to lift up or let down the bridge, are of iron or brass. Such bridges are to be seen at Stirling and Edinburgh castles, at the Tower of London, at the castle of Vincennes, and many other regularly-fortified places. In navigable rivers, it is sometimes necessary to form the middle arch of bridges with two movable platforms, to be raised occasionally, in order to let the masts and rigging of ships pass the bridge. There are two piers which support the drawbridge, one of the platforms of which is raised, and the other let down, having a beam for its plyer. To this drawbridge are suspended two movable braces, which, resting on the supports, press against the bracket and thereby strengthen it.

It is one of the first principles of statics, that if two forces are represented, both in amount and direction, by the sides of a parallelogram, then their resultant will be represented by the diagonal of such parallelogram, likewise in direction and intensity. Now, if we reduce the polygonal framing, of which many wooden bridges are formed, to their simplest form, that of two beams abutting against one another, and resting upon two solid supports at their lower ends, we shall find that, inasmuch as the forces will act in the direction of the beams, their weight or gravity tending to keep the ends of the beams against each other by preventing them from rising, will be represented by a vertical line passing through their points of contact, which will be the diagonal of the parallelogram formed by the beams and lines drawn parallel to them at such a point in each as would limit the length of the line to what would fitly represent the force acting in the direction of the beam, and it is evident that the beams being in equilibrio, their horizontal thrusts must be equal and contrary, and consequently will be neutralized by their joint action.

The fact is, in a polygonal framing of any kind, there are three forces exerted at every joint; one in the direction of each beam, and one, a vertical force, acting by gravity, which being the diagonal of the parallelogram constructed upon the beams, is the resultant of the other two, and which, by acting as a counterpoise to the others, keeps the system in equilibrio.

To construct a polygon in any particular instance, we must know the direction and amount of each of the forces, and their points of application; when these are given, we may readily construct the successive sides of a polygonal bridge. It is a well-known fact that gravity always acts vertically; we may, therefore, take a line perpendicular to the horizon, and mark upon it a number of divisions, each one representing the effect of gravity at every successive joint; having, then, found a point at such a distance from it as will represent the horizontal strains which, for a system of forces in equilibrio, are always equal, and connecting that point with the several divisions marked on the vertical line, we shall have a number of right lines which, both in direction and intensity, will respectively represent the force acting at each joint or angle of the framework. Then, by drawing lines parallel to these, placing them one after the other, we shall construct a polygonal frame which will be in equilibrio, bearing in mind that the compressions of any two sides of the polygon are reciprocally as the sines of the angles which they form with the vertical lines, or directly as the secants of their inclination to the horizon.

In order to find the resultant of two forces acting in a given angle, we must add to the sum of the squares of the forces twice their products multiplied into the co-sine of the angle, and extract the square root of the sum, and this will give the required resultant. Again; to ascertain the angle between the resultant and one of the composants, we must divide the product of the sine of the given angle and the lesser force by the product of the co-sine of that angle, and the same force to which the greater force must be added.

It has been maintained, and apparently with a great deal of truth, and several eminent men who have studied the subject deeply have coincided in the opinion, that where an arch is constructed of several key-stones or voussoirs, and remains in equilibrio, its various parts being so adjusted as to cause it to remain without change of position, that a catenary or funicular curve will be found to be wholly included somewhere between its intrados and its extrados. Now, as a wooden bridge, formed on the principle of compression, either by a polygonal frame or with a timber arch, should be made to conform as much to the principle of the arch as possible, so as to make it as strong as can be, with a uniform pressure at every point by which it may be equally sustained, without throwing an undue strain upon any of the joints or beams, it is well to make the distance between the intrados and extrados as great as can be; hence the advantage of a double arch of timbers, with the intermediate space filled in with judiciously-arranged braces and diagonal pieces, by which the ribs are kept in their proper position without materially increasing the weight.

In the construction of wooden bridges it must be constantly borne in mind that every piece of timber introduced should be placed, as far as can be, so as to bear the strain which will be thrown upon it in the direction of its length; for the more it inclines from the direction of the thrust to which it is opposed, the less resistance it will be capable of exerting, and its useful effect will decline in the ratio of the radius to the sine of the angle of its inclination. In addition to this, the tendency to fracture is much greater by a transverse strain than by a force acting longitudinally by compression through the entire length of the beam.

When it is required to join two or more pieces of timber end to end, so as to make them, together, sufficiently long for any required purpose, the joint made use of in that case is called a scarf. This is made by cutting away a portion of the thickness of the wood in both pieces, so that they may fit into each other: the scarf is then made complete by bolting them well together with iron bolts, or with trenails, and putting iron straps round the joint where necessary. A scarf may be made by cutting away half the wood at the end of each piece, that so they may partially overlie or lap upon each other, or else, in a more advantageous way, by cutting away the wood in a slanting direction, at the same time making indentations or notches in one piece which exactly coincide with similar projections cut near the end of the piece to be joined to it; such scarfs are usually from 18 inches to 3 feet long.

Tenon-and-mortise joints are used for uniting timbers at right angles to one another. The thickness is diminished on both sides at the end of a piece of wood, so as to leave an oblong projection, called a tenon, which is fitted into a space termed a mortise, hollowed out of the piece to which it is to be united, and placed at about a third of the height from the under side; a wooden pin is frequently put through the mortise and tenon so as to prevent them from getting out of their places. A combination of a tenon-and-mortise joint with a scarf is sometimes made for joining timbers longitudinally; and it is found to add greatly to its strength. Scarfs in beams likely to undergo a transverse strain must always be carefully made; they should be very long and well notched, and this tenon-and-mortise joint added, the whole strongly bolted; and it is often a good precaution to put a plate of iron on the under and upper sides of the scarf.

A dove-tail joint is made by forming a tenon increasing in width towards the extremity of the wood, and having a narrow neck near the shoulder; this is fitted to a mortise made in the same shape, on another piece of wood, into which it is admitted laterally; when the wood is hard, this is a good kind of joint, but the ends of the inverted wedges are liable to be broken off if their sides diverge too much, and if they are made in too straight a direction, they are apt to shrink and thus become useless. This joint is, however, very suitable for ties when well made, and it is used in cases where it is thought desirable to secure two horizontal pieces of wood more firmly together, which are joined to one another at an angle. In that case, a piece of wood is made to act as a tie, by being dove-tailed into both the timbers at some distance from the joint.

The ends of struts and braces are usually let into the timbers with which they are connected at the ends by mortise-and-tenon joints; these joints are generally cut at the ends perpendicularly to their direction, and in this way resist the strains which they have to bear more effectually.

A king-post is a principal vertical timber, to which the centres of bays or girders are attached, and by which means, properly speaking, they should be sustained.

Queen-posts are similar to king-posts, but do not occupy so important a position in a piece of carpentry. A number of these may be introduced with great advantage; they should be well framed into the top and bottom timbers, either by halving or by mortise-and-tenon joints; and iron straps should, in most cases, be made use of to make them secure.

The timber, &c., used in the construction of wooden bridges is, according to the position it is made to occupy, obliged to undergo four kinds of forces, which tend to overcome the cohesion exerted between the particles of which it is formed. These are, first, and principally, *transverse pressure*, or a force acting transversely upon a beam, tending thereby to destroy the cohesion and continuity of its fibre, such is the force that the platform of a bridge must be made to resist; such, also, the roof, the joists, the flooring, and many of the levers, of which it is composed. This, however, is a compound force made up of the two succeeding forces. 2nd. A *compressive or crushing* force, which acts longitudinally; this is called generally into play in the framing of the bridge, posts, struts, piles, &c. 3rd. A *tensile* force, in which there is a tendency to pull the particles of the wood from one another, and thus cause a total destruction of its parts by stretching and drawing it to pieces; this force is exerted on king-posts, tie-beams, the under parts of the roadway, and of the joists, walings, &c.; and, lastly, there is a *twisting* force, by which the particles of bolts, rivets, trenails, gudgeons, &c., are strained or wrenched from each other, or are constantly subjected to a force tending so to disunite and destroy them.

In order to prevent these forces from having the effect of injuring the bridge, great care must be taken in the selection of the proper materials; in the manner of disposing them in the bridge, by adopting such an arrangement as will make one force act as a set-off to another by neutralizing its injurious effects, and, above all, by distributing the pressures judiciously, so as never to let any portion of the structure be loaded with more than one-third of the weight which it is calculated to bear without breaking.

In the case of a beam supported at its extremities, it has been found that if it be cut on the upper side, near the middle, to about one-third of its depth, and a piece of hard wood be inserted, in the form of a wedge, so as to give the entire beam a slight camber, that its strength will be increased about a sixth of what it was previously. This plan may be practised with great advantage when the distance between the supports is small, because the rigidity of the material is so much greater in proportion to the weigth to be supported, that the deflexion is not injurious; but when the spans are great, and the props or piers far removed from each other, it becomes necessary to truss the beams to prevent their falling below the horizontal line. This deflexion is as the product of the weight and cube of the length directly, and inversely as the product of the breadth and the cube of the depth. A deflexion of about tho fiftieth part of an inch is not very injurious, but, where possible, it should be provided against. It may be well to state here, that the deflexion from a weight uniformly distributed over a bridge is to the deflexion caused by the same weight placed in the centre, as 5 is to 8.

In the event of a beam being loaded up to the point of breaking, it will bend before giving way, and the transverse strain which would produce this result is in the ratio of the breadth multiplied into the square of the depth, and inversely as the length; and the square of the secant of the angle of deflexion, immediately before giving way altogether, must also form an element of the calculation. When this is ascertained, one-third of this breaking weight must be taken for the maximum load with which it must be weighted.

The inherent qualities of timber and other materials which enable them to resist the force of compression acting in the direction of their length, is directly as the fourth power of their sides in cubic blocks, and as the square of their height inversely. The cohesion of wood, &c., by which it is able to resist the force of tension, or a drawing force, exerted in the direction of its length, varies in the proportion of its cross section. The power of resisting a tensile strain, in different kinds of wood, varies in the ratio of their different specific gravities.

All materials withstand the twisting force of tension when in the form of cylinders, in the ratio of the angle of tension, and the fourth power of the diameter directly, and in the inverse proportion of their length.

The resistance of different woods to pressure, as derived from actual experiment made with blocks of an inch cube, is found to be—for elm, 1,284 lbs.; white deal, 1,928 lbs.; oak, (English) 3,860 lbs.; and pine, (American) 1,606 lbs.

The resistance to tension for bars of an inch square of transverse section, is ascertained to be—for ash, about 11,970 lbs.; beech, 17,371 lbs.; elm, 12,231 lbs.; fir (pitch pine), about 12,917 lbs.; fir (red), 10,829 lbs.; fir (Memel), 10,662 lbs.; fir (Russian), about 9,992 lbs.; fir (American), 870 lbs.; fir (yellow deal), 8,316 lbs.; fir (white deal), 4,204 lbs.; fir (Scotch), 6,569 lbs.; larch, 10,875 lbs.; oak (English), 13,943 lbs.; oak (French), about 14,405 lbs.; oak (Baltic), 11,189 lbs.; oak (American), 10,154 lbs.; oak (Dantzic), 7,558 lbs.; and for willow, about 12,538 lbs.

Oak and fir are principally used in bridge-building, on account of their great durability and hardness, which is a point of very great importance; for the principal objection to wooden bridges in general is, that they are extremely liable to decay; still, their great cheapness, in comparison with bridges constructed of other materials, makes them very suitable in many instances.

WOODEN COLUMN, a column consisting of a trunk, base, and capital, each constructed of wood. The column is glued up in staves, the base in regular sectors, and the capital in blocks used externally. The whole ought to be painted and sanded, in order to produce the effect of a stone column; but if used internally, the painting ought to correspond with that of the apartment in which it is placed.

WORKING DRAWINGS, consist of plans, elevations, and sections of the whole, and all the parts, of an edifice, to as large a scale as may be found convenient; generally in outline, excepting the sectional parts, which are frequently shadowed, or scratched, in order to make them more obvious to the workman, for whose use the drawings are made.

The general plans, elevations, and sections, as they cannot be made to the full size of the object to be executed, should all be figured with numbers of measurement, to show the dimensions of all the parts of the edifice, without obliging the workman to refer to the scale, which is not only very troublesome, but liable to lead to many mistakes detrimental to the work.

The plans, elevations, and sections, of the parts of an edifice, ought to be made to the full size; in which case the figuring of the dimensions becomes unnecessary.

Working drawings may be divided into three classes: distinguished severally as Block Plans, General Drawings, and Detailed Drawings.

Block Plans show no more than the outline of the proposed works or buildings, and their position with reference to surrounding objects; in fact, they point out the site of the buildings, and determine the space to be occupied by them. They are drawn to a small scale, so as to embrace the entire site of the works, and so much of the neighbourhood as may be necessary. They contain every information respecting the present state of the building-ground and its vicinity, and the manner in which it will be affected by the new work; thus, in most instances, it is necessary to show the proposed method of drainage, lighting, water-supply, &c.; and as this will necessarily depend upon the existing state of things, we must mark out the old drains, gas, and water-mains, and the method of connecting them with the new works. It is well also, on such drawings, to give some idea of the comparative levels of the district.

The *General Drawings* show the whole extent of the new works, and the arrangement and distribution of the several parts. They consist of *plans* of the various stories, including those of the foundations, and roofs, and indeed of any part of the building where some peculiar treatment renders explanation necessary; *elevations* of every side of the building, or of so many sides as present a different appearance; and *sections* showing the internal structure and arrangement of the works. On each of these drawings, the dimensions of the whole, and of the various parts, should be carefully figured; the directions in which the measurement are taken, being figured in dotted lines, and the points from and to which they are measured, being clearly defined by an arrowhead, or some such contrivance. So much of the details are shown on these drawings as the scale will allow. Perspective drawings or sketches may be added, to give a more general idea of the undertaking.

The *Detailed Drawings* show such parts of the work as cannot be shown on the general drawings with sufficient clearness and accuracy; and are drawn either of full size, or to such a scale as shall make them clearly intelligible to the workman. Such drawings are required both for the decorative and constructive parts of the building; thus are included the capitals and bases of columns, entablatures, cornices, tracery, or any other enrichment; as also the sections of mouldings, string-courses, &c.; and besides these, the method of framing floors, roofs, &c., the patterns of cast-iron or trussed girders, story-posts, and such like, of everything, in short, of which a particular description is necessary. It saves much trouble, if the detailed drawings are made out on separate sheets for the different trades. These drawings, like the others, should have their dimensions clearly figured upon them, and every drawing should be provided with a scale, from which any further dimensions may be taken by the compasses.

It is usual in drawings, to tint only such parts as are in section; but it will frequently be found desirable to colour also the parts which stand back, and are in elevation; and sometimes also to project the shadows, or shade up such parts, so as to give a general idea of their distance from, and relation to each other, as also of their forms, as whether flat, concave, or convex, &c.

WREATHED COLUMNS, such columns as are twisted in the form of a screw. They are very appropriately called *contorted columns*, as being the offspring of a false taste; for as the primitive use of columns is for supporting a superincumbent weight, whatever diminishes the idea of the stability they ought to afford, is a real blemish; and the very appearance of a twisted column is indicative of weakness.

They were the production of an age when novelty was mistaken for genius, and when meretricious ornament was suffered to usurp the place of real beauty; but since science has resumed her place in the public opinion, they have been laid aside, and are justly considered as blemishes to those buildings in which they appear.

WREN, SIR CHRISTOPHER, the only son of Dr. Christopher Wren, Dean of Windsor, was born at East Knoyle, in Wiltshire, on the 20th of October, 1632. His mother was Mary, daughter and heiress of Mr. Robert Cox, of Fonthill, in the same county. His first education in classic learning was (by reason of his tender health) committed to the care of a domestic tutor, the Rev. William Shepheard, M. A., excepting that for some short time before his admission to the university, he was placed under Dr. Busby, at Westminster School. In the principles of mathematics, upon the early appearance of an uncommon genius, he was initiated by Dr. W. Holder; and he made such rapid progress, that at the age of sixteen he distinguished himself by some important discoveries in astronomy, dialing, statics, and mechanics. While at Oxford, he became acquainted with, and obtained the friendship of, Dr. Scarborough, (afterwards Sir Charles Scarborough,) an eminent physician and mathematician, under whom he performed the part of an assistant, and first introduced geometrical and mechanical sciences to the aid of anatomy. At the age of nineteen, he composed a short algebraic tract relating to the Julian Period, of great use in chronology. In 1650, he was entered Bachelor of Arts at Wadham College, Oxford; where, in 1653, he took the degree of Master of Arts; and in the same year was elected into a fellowship of All-Souls. In 1657 he was chosen Professor of Astronomy in Gresham College, upon the resignation of Dr. Seth Ward; where, in the same year, he read admirable lectures on astronomy; and in 1653 not only solved the problem proposed by the great Pascal to all the English mathematicians, but returned another to those of France, of which they could never furnish any solution. His appointment at Gresham College he resigned in 1660, on being chosen Savilian Professor of Astronomy at Oxford, where, in 1658, he had been created LL.D. as he was shortly afterwards at Cambridge. He had now attained such eminence in architecture, that he was called from Oxford by Charles II. to assist Sir John Denham as surveyor-general of his majesty's works; and in 1663 he was one of the first Fellows of the Royal Society, after the grant of their charter. In 1665 he travelled to France; and it is evident from his letters, that he surveyed every structure with the studious eye of a critic.

After that most dreadful conflagration of London, in the fatal year 1666, had laid the metropolis of England in the dust, Dr. Christopher Wren drew a noble plan for rebuilding it, which he presented to the parliament; and had his scheme been followed, London would have become the most superb metropolis in Europe, or indeed in all the world. It interfered, however, with so many interests in the landed property, that its execution was deemed impracticable. In 1668, on the decease of Sir John Denham, he was appointed surveyor-general and principal architect for rebuilding the whole city, with the cathedral church of St. Paul, and all the parochial churches, in number fifty-one. In the year 1674, the honour of knighthood was conferred upon him; in 1677, he finished the Monument, which has been compared with the celebrated columns of antiquity; in 1680, he was elected president of the Royal Society; and in 1681, he completed his most beautiful structure, the church of St. Stephen, Walbrook; in 1698, he was appointed surveyor-general and commissioner of the works and repairs of the ancient abbey church of St. Peter, Westminster; and in 1710, he finished the magnificent cathedral church of St. Paul.

During the time of his employment in the service of the public and of the crown, by virtue of letters patent, consistent with the pleasure of six crowned heads, under the great seals of King Charles II., King James II., King William and Queen Mary, Queen Anne, and King George I., (besides the ordinary duties of his office in the survey and care of the repairs and new buildings of all the royal palaces,) he began and completed the cathedral church of St. Paul; fifty-one parochial churches; the great column, called The Monument, and other public edifices, in London; the two royal palaces at Hampton Court and Winchester; the royal hospitals of Chelsea and Greenwich; the north front and repairs of Westminster Abbey; the theatre of Oxford; the theatre royal in Drury Lane; the Duke's theatre in Salisbury Court, some time since taken down; the magnificent library of Trinity College, and the elegant chapel of Emmanuel College, Cambridge; with many other fabrics of less note, as well as private seats. All these works form such a body of civil architecture, as will appear rather the production of a whole century than the life and industry of one man, of which no parallel instance can be given.

In an act of parliament of the ninth year of the reign of King William, for completing and adorning the cathedral church of St. Paul, London, a clause was inserted " to suspend a moiety of the surveyor's salary until the said church should be finished; thereby the better to encourage him to finish the same with the utmost diligence and expedition." It was at the time a common notion and misreport, that the surveyor received a large annual salary for that building, and consequently it was his interest to prolong the finishing of the fabric for the continuance of this supposed emolument, which, it would seem, occasioned that clause.

The surveyor's salary for building St. Paul's, from its foundation to its completion, (as appears from public accounts) was not more than two hundred pounds per annum. This, in truth, was his own choice; but what the rest of the commissioners on the commencement of the works judged unreasonably small, considering the extensive charge; the pains and skill in the contrivance, in preparing draughts, models, and instructions for the artificers in their several stations and allotments; in almost daily overseeing and directing in person; in making estimates and contracts; in examining and adjusting all bills and accounts, &c. : nevertheless, he was contented with this small allowance, nor coveted any additional profit, always preferring the public service to any private profit.

Upon the completing of this great fabric, a clause passed in the act of parliament of the ninth year of the reign of Queen Anne, declaring the church finished, to empower the commisioners to pay the surveyor the arrears of the moiety of his salary. His allowance for building all the parochial churches of the city of London was about one hundred pounds per annum, and the same for the repairs of Westminster Abbey.

In the act for building fifty new churches in London and its vicinity, Sir Christopher, though then at a very advanced age, was named one of the commissioners for carrying it into effect. On this occasion he wrote the following letter, for the consideration of his colleagues in office; which, as it contains many points worthy the notice of the architect, is here inserted.

" Since Providence, in great mercy, has protracted my age to the finishing the cathedral church of St. Paul, and the parochial churches of London, in lieu of those demolished by the fire; and being now constituted one of the commissioners for building, pursuant to the late act, fifty more churches in London and Westminster, I shall presume to communicate briefly my sentiments, after long experience; and without farther ceremony, exhibit to better judgment what at present occurs to me in a transient view of this whole affair; not doubting but that the debates of the worthy commissioners may hereafter give me occasion to change or add to these speculations.

"First, I conceive that the churches should be built not where vacant ground may be cheapest purchased in the extremities of the suburbs, but among the thicker inhabitants, for convenience of the better sort, although the site of them should cost more; the better inhabitants contributing most to the future repairs, and the ministers and officers of the churches, and charges of the parish.

"2. I could wish that all burials in churches might be disallowed, which is not only unwholesome, but the pavements can never be kept even, nor pews upright; and if the church-yard be close about the church, this also is inconvenient, because the ground being continually raised by the graves, occasions in time a descent by steps into the church, which renders it damp and the walls green, as appears evidently in all the old churches.

"3. It will be inquired, where then shall be the burials? I answer, in cemeteries, seated in the outskirts of the town; and since it is become the fashion of the age to solemnize funerals by a train of coaches, though the cemeteries should be half a mile or more distant from the church, the charge need be little or no more than usual; the service may be first performed in the church. But for the poor, and such as must be interred at the parish charge, a public hearse of two wheels and one horse may be kept at small expense; the usual bearers to lead the horse, and take out the corpse at the grave. A piece of ground of two acres in the fields will be purchased for much less than two roods among the buildings. This being enclosed with a strong brick wall, and having a walk round, and two cross walks, decently planted with yew trees, the four quarters may serve four parishes, where the dead need not be disturbed at the pleasure of the sexton, or piled four or five upon one another, or the bones thrown out to gain room. In these places beautiful monuments may be erected; but yet the dimensions should be regulated by an architect, and not left to the fancy of every mason, for thus the rich, with large marble tombs, would shoulder out the poor, when a pyramid, a good bust or statue on a proper pedestal, will take up little room in the quarters, and be more proper than figures lying on marble beds. The walls will contain escutcheons and memorials for the dead, and the area good air and walks for the living. It may be considered, farther, that if the cemeteries be thus thrown into the fields, they will bound the excessive growth of the city with a graceful border, which is now encircled with scavengers' dungstalls.

"4. As to the situation of the churches, I should propose, they be brought as forward as possible into the larger and more open streets, not in obscure lanes, nor where coaches will be much obstructed in the passage. Nor are we, I think, too nicely to observe east or west in the position, unless it falls out properly. Such fronts as shall happen to lie most open in view should be adorned with porticoes, both for beauty and convenience; which, together with handsome spires, or lanterns, rising in good proportions above the neighbouring houses, (of which I have given several examples in the city, of different forms,) may be of sufficient ornament to the town, without a great expense for enriching the outward walls of the churches, in which plainness and duration ought principally, if not wholly, to be studied. When a parish is divided, I suppose it may be thought sufficient if the mother-church has a tower large enough for a good ring of bells, and the other churches smaller towers, for two and three bells; because great towers and lofty steeples are sometimes more than half the charge of the church.

"5. I shall mention something of the materials for public fabrics. The earth about London, rightly managed, will yield as good bricks as were the Roman bricks, and will endure in our air beyond any stone our island affords; which, unless the quarries be near the sea, are too dear for general use; the best is Portland or Roch Abbey stone; but these are not without their faults. The next material is the lime. Chalk lime is the constant practice; which, well mixed with good sand, is not amiss, though much worse than hard stone lime. The vaulting of St. Paul's is becoming as hard as stone; it is composed of cockle-shell lime, well beaten with sand: the more labour in the beating, the better and stronger the mortar. I shall say nothing of marble, for this will prove too costly for our purpose, unless for altar-pieces. In windows and doors, Portland-stone may be used, and with good bricks and stone quoins. As to roofs, good oak is certainly the best, because it will bear some negligence. The churchwardens' care may be defective in speedily mending drips; they usually whitewash the church, and set up their names, but neglect to preserve the roof over their heads. It must be allowed, that the roof being more out of sight, is still more unminded. Next to oak is yellow deal, which is a timber of length, and light, and makes excellent work at first, but if neglected, will speedily perish; especially if gutters (which is a general fault in builders) be made to run upon the principal rafters, the ruin may be sudden. Our tiles are ill made, and our slate not good; lead is certainly the best and lightest covering; and being of our own growth and manufacture, and lasting, if properly laid, for many hundred years, is, without question, the most preferable.

"6. The capacity and dimensions of the new churches may be determined by a calculation. They must be large, but must be fitted for auditories. I can hardly think it practicable to make a single room so capacious, with pews and galleries, as to hold above 2000 persons, and all to hear the service, and both to hear distinctly and see the preacher. I endeavoured to effect this in building the parish church of St. James, Westminster, which, I presume, is the most capacious, with these qualifications, that hath yet been built; and yet, at a solemn sime, when the church was much crowded, I could not discern from a gallery that 2,000 were present. In this church I mention, though very broad, and the middle nave arched up, yet there are no walls of a second order, nor lanterns, nor buttresses, but the whole roof rests upon the pillars, as do also the galleries. I think it may be found beautiful and convenient, and as such, the cheapest of any form I could invent.

"7. Concerning the placing of the pulpit, I shall observe, a moderate voice may be heard 50 feet distant before the preacher, and 20 behind the pulpit; and not this, unless the pronunciation be distinct and equal, without losing the voice at the last word of the sentence, which is commonly emphatical, and if obscured spoils the whole sense. A Frenchman is heard farther than an English preacher, because he raises his voice instead of sinking it at his last words. I mention this as an insufferable fault in the pronunciation of some of our otherwise excellent preachers, which schoolmasters might correct in the young, as a vicious pronunciation; and not as the Roman orators spoke, for the principal verb is, in Latin, usually the last word; if that be lost, what becomes of the sentence?

"8. By what I have said, it may be thought reasonable, that the new church should be at least 60 feet broad, and 90 feet long, besides a chancel at one end, and the belfry and portico at the other. The proportions may be varied; but to build more room than that every person may conveniently hear and see, is to create noise and confusion. A church should not be so filled with pews, but that the poor may have room enough to stand and sit in the alleys, for to them equally is the gospel preached.

"9 I cannot pass over mentioning the difficulties that may be found in obtaining the ground proper for the sites of the churches among the buildings, and the cemeteries in the borders without the town; and therefore I shall recite the method that was taken for purchasing in ground at the north side of St. Paul's cathedral, where, in some places, the houses were but 11 feet distant from the fabric, exposing it to the continual danger of fires. The houses were 17, and contiguous, all in leasehold of the dean, or bishop, or the petty canons, with divers under-tenants. First, we treated with the superior landlords, who, being perpetual bodies, were to be recompensed in kind, with rents of the like value for them and their successors; but the tenants in possession, for a valuable consideration, which, to find what it amounted to, we learned, by diligent inquiry, what the inheritance of houses in that quarter were usually held at. This we found was fifteen years' purchase at the most, and proportionally to this the value of each lease was easily determined in a scheme referring to a map. These rates, which we resolved not to stir from, were offered to each; and to cut off much debate, they were assured that we went by one uniform method, which could not be receded from. The whole at last was cleared, and all concerned were satisfied, and their writings given up. The greatest debate was about their charges for fitting up their new houses to their particular trades; for this we allowed one year's purchase, and gave leave to remove all their wainscot, reserving the materials of the fabric only. This was happily finished without a judicatory, or jury.

"Christopher Wren."

In the year 1685, Sir Christopher Wren was elected and returned a burgess for the borough of Plympton, in the county of Devon, and served in that parliament which began at Westminster on the 29th of May, 1685 in the first year of James II. In the parliament which met at Westminster on the 22nd of June, 1689, he was returned a burgess for the borough of New Windsor, in the county of Berks. In the year 1700, he was returned a burgess for the borough of Weymouth and Melcomb Regis, in the county of Dorset, and served in that parliament which began at Westminster on the 10th of February, in the 12th year of William III.

In 1718, Sir Christopher Wren's patent for the office of surveyor of the royal works was superseded, in the four-score-and-sixth year of his age, and after more than fifty years spent in a continued, active, and laborious service to the crown and public, at which time his merit and labours were not remembered by some. He then betook himself to a country retirement at Hampton Court; where, free from worldly affairs, he passed the greatest part of the five following and last years of his life in contemplation and study, principally of the Holy Scriptures; though he partially turned his thoughts to the discovery of the longitude at sea, and a review of his former tracts on astronomy and mathematics. Time had now greatly enfeebled his limbs, but it had little impaired the vigour of his mind, which continued, with a vivacity rarely found at his age, till within a few days of his dissolution, which happened on the 25th of February, 1723, in the ninety-first year of his age. He was buried in the vault under St. Paul's cathedral, a privilege accorded to him and his family exclusively. A plain stone covers his grave, bearing the appropriate inscription, *Si Monumentum quæris, circumspice:* "If thou seekest my monument, look around thee."

As an architect, his learning was great, and his invention fertile: his discoveries in mathematics and natural philosophy were numerous, and are only eclipsed by his performances in his master-science. He contrived an instrument for measuring the quantity of rain that falls on any space of land for a year: he invented many ways of making astronomical observations more accurately and easily; and was the author of the anatomical experiment of injecting liquors into the veins of animals. He translated into Latin Mr. Oughtred's *Horologiographia Geometrica;* and wrote a *Survey of the Cathedral Church of Salisbury*, and other places. He never printed any of his works, though some have been published by his friends. This excellent artist does not, therefore, derive his glory from his publications, but from the numerous edifices which adorn the British metropolis, and which hourly attract the regard even of the most inattentive.

His private character was extremely amiable, continuing to the last an example of benevolence, free from all moroseness in behaviour or aspect. He left a son, named after himself, who published in 1708, an elaborate treatise on ancient medals, intitled *Numismatum Antiquorum Sylloge*, and died in 1747, aged seventy-two.

X.

XENODOCHIUM, a room in a monastery of religious houses, for the reception and entertainment of strangers.

XYSTOS, or Xystus, (from ξυω, *to make smooth,*) among the ancient Greeks, a portico of unusual length, open or covered, where the athletæ practised wrestling and running, The word is derived from the custom of the athletæ of anointing their bodies with oil before the encounter, to render them smooth, so as to prevent their antagonists from taking hold of them: hence they were called *xystici*, and the place of their exercise *xystos.*

The Romans also had their xystos, which, was a long aisle, or portico, sometimes roofed over, and sometimes open, with trees on each side, forming an agreeable shade to walk under.

Y.

YARD, (from the Saxon, *gerd*), a well-known measure, 3 feet in length; the square yard will, therefore, contain 9 square feet, and the cubic yard 27 solid or cubic feet.

The square yard is used by artificers in measuring their work, and the cubic yard in finding the capacities of cavities dug in the earth. The solid yard is also used in measuring great masses of brick or stone work; of which a few examples, for practice, are here given.

Example 1.—Suppose a room 28 feet 6 inches long, and 14 feet 9 inches wide; how many square yards are contained in the ceiling, or floor?

```
     28   6
     14   9
    ---------
    119   0
    28
     21   4   6
    -----------
 9) 420   4   6
    -----------
     46   6
```

Therefore, the superficial contents are 46 square yards, 6 feet superficial, 4-twelfths of a foot superficial, and 6-twelfths of the twelfth part of a foot superficial, which is the contents of the floor, or ceiling, of the room.

Example 2.—Suppose a pit dug in the earth 58 feet long, 39 feet broad, and 19 feet deep; how many solid yards have been excavated?

```
          58
          39
         ----
         522
        174
        ----
        2262
          19
       -----
       20358
       2262
      ------
  27) 42978 (1591
      27
      ---
      159
      135
      ---
       247
       243
       ---
        48
        27
        --
        21
```

So that the contents is 1591 solid yards, and 21 solid feet.

Example 3.—Suppose a mound of earth, whose section is everywhere a given segment of a circle, the breadth of the mound 27 feet, the height 9 feet, and the length 3837 feet; what will be the expense of raising it, at 15d. per yard?

The easiest method of finding the area of the segment is the following, taken from the article MENSURATION, viz., Multiply the chord and versed sine together, to two-thirds of the product add the cube of the altitude, divided by twice the chord, and the sum will be the area of the section, which, being multiplied by the length of the mound, will give the solidity in feet: see the operation.

```
           27
            9
          ---
       3) 243
          ---
           81
            2
          ---
          162
Again,
            9
            9
          ---
           81
            9
          ---
     54) 729 (13
         54
         ---
         189
         162
         ---
          27
```

So that 162 + 13 = 175 feet, the area of the segment.

```
Then,      3837
            175
          -----
          19185
         26859
         3837
        ------
   27) 671475 (24869
       54
       ---
       131
       108
       ---
        234
        216
        ---
         187
         162
         ---
          255
          243
          ---
           12
```

Now 24869 at first is 24869 shillings
at $\frac{1}{4}$ is . . . 6217 3

2,0) 3108.6 3

1554 6 3
and $\frac{12}{27}$ or $\frac{4}{9}$ of a yard is 0 $6\frac{1}{2}$

1554 6 $9\frac{1}{2}$

Therefore the whole expense will be £1554 6s. $9\frac{1}{2}$d. *See* Brickwork and Mensuration, where yard-measure is employed.

Yard, an enclosed court or area.

YELLOW, (from the Saxon, *yealewe*,) a colour like that of gold. Yellows are of considerable variety, as yellow ochre, orpiment, gamboge, and many others, too well known to require description.

Z.

ZACCO, or Zaccho, (Italian,) the lowest part of a column, or pedestal.

ZAX, an instrument used for cutting slates.

ZETA, or Zeticula, (from the Greek,) a small withdrawing chamber, with pipes conveyed along in the walls to receive from below either the cool air or the heat of warm water; also a stove-room. The term is sometimes extended to signify a parlour, or even a dining-room.

ZIGZAG MOULDING, a moulding common in Norman buildings. *See* Norman Architecture.

ZINC, a bluish-white metal, which tarnishes but slowly when exposed to the air; and on this account is much used in external works, such as roofs, fences, &c.

ZOCCO, or Zocle, a low square member, serving to support a column instead of a pedestal.

A *continued zocle* is that on which an edifice is raised.

ZOPHORUS, (from ζωος, *living*, or ζωον, *an animal*, and φερω, *to bring*,) the frieze, or broad member which separates the cornice and architrave. It was so called by the Greeks, because they adorned it with representations of animals.

The ancients had no fixed proportion of the order for the height of the zophorus. However, in the same order, though the friezes are to be found of different heights in different examples, the variation is not very great.

When the zophorus was required to be ornamented, its height was generally enlarged in order to make room for the ornaments. This, however, was not the case with the Grecian Doric, as this extension would have necessarily destroyed the proportion of the triglyphs, and consequently that of the metopes, or spaces between them. The Tuscan order did not admit of any ornaments, and therefore the zophorus, or frieze, was always plain. The Doric, though grand, was extremely elegant, and the metopes were generally ornamented with sculpture, as in the Parthenon and temple of Theseus at Athens. The zophorus of the Ionic and Corinthian orders was not interrupted by any member of the order, as in the Doric, but the ornaments were frequently continued throughout the whole extent, in one or more processions. In the Doric order also, within the pronaos, the triglyphs were always omitted, and in this case the frieze, or zophorus, was adorned, equally with the Ionic and Corinthian, as may be seen within the pronaos of the Parthenon, and that of the temple of Theseus, already referred to. *See* Frieze.

ZOPHORIC COLUMN, any pillar supporting the figure of an animal.

ZOTHECA, a small room or alcove, which might be added to, or separated from, the room to which it adjoined.

ANALYSIS OF CONTENTS.

The CAPITAL letters denote the titles of each article.
The *Italics* " " words referred to under each article.
The Roman " " contents of each article.
The Numeral Letters " " volume.
The Figures " " page.
