INTERIOR ANGLE, an angle within any figure, formed by two straight-lined parts of the perimeter, or boundary of the figure; the exterior angle being that which is formed by producing a side of the perimeter of the figure. The exterior and the interior angle of any figure are equal to two right angles, and all the interior angles of any figure amount to twice as many right angles, with four, as the figure has sides: for the figure may be divided into as many triangles as it has sides, by drawing lines from all the angles to a point within the figure. And as the angles of every triangle are equal to two right angles, there will be as many times two right angles as the figure has sides; but as four of these right angles are round the point to which the lines were drawn, consequently all the internal angles of any straight-lined figure are equal to twice as many right angles, wanting four, as the figure has sides. This is only deduced as a corollary from the 32nd Proposition of Euclid, book I., where it is proved, that if the side of a triangle be produced, the exterior angle will be equal to the two interior and opposite angles, and the three angles of every triangle will be equal to two right angles.

Interior Angle is also applied to the two angles formed between two parallels, by a line cutting them on each side of the intersecting line.

Interior and Opposite Angles, an expression applied to the two angles formed by a line cutting two parallels.

Interior Polygon. *See* Polygon.

INTERMITTING, anything which destroys the continuity of another.

INTER-MODILLION, the space between modillions.

INTERNAL ANGLE. *See* Interior Angle.

Internal Angle of a Solid, the inclination of two planes, of which their line of concourse recedes; that is, if a point be taken in each plane, the straight line joining the two points will be without the solid.

INTERPENSIVÆ, (Latin,) in ancient architecture, are supposed to be cantalivers, formed by the ends of joists. *See* Vitruvius, book vi. chap. 3.

INTER-PILASTER, the space between two pilasters.

INTER-QUARTER, the space between two quarters.

INTER-TIES, or Interduces, horizontal pieces of timber, placed between upright posts, to tie or bind them together. They are used in roofing, partitioning, and walling, with timber frames for lath and plaster, or panelled brick-work.

INTRADOS, the under curved surface or soffit of an arch; generally cylindrical or cylindroidal.

INVENTION, (French,) the act of finding anything new, or a thing found; the discovery of a principle, or a new application of a principle already known, in performing certain kinds of motion or construction; contriving instruments or machines for the performance of some useful purpose. Design is very nearly allied to invention, but is commonly applied to a new combination, or new order of things already known.

Invention is of real use; but design is altogether fanciful, though productive of pleasing forms. In invention, we can reason why a principle or thing contrived will answer its intended purpose; not so in design, where the only power of judging of the effects of combination arises from previous experience of things of the like nature. In design, all the simple forms are already known; thus, from a few kinds of moulding, already known, an unlimited variety of cornices, capitals, and imposts, may be contrived or designed. In a building, all the simple forms exist in squares, circles, and other geometrical figures and solids, already known: but, from the combination being unlimited, an effect may be produced different from anything that has ever before existed.

INVERTED ARCHES, such as have their concavity or intrados below the centre or axis. They are useful in every part of a wall which is lower than the two adjacent parts, or where an interruption is made by an aperture near its base. *See* Foundation.

INVOLUTE. *See* Evolute.

INWARD ANGLE, the re-entrant angle of a solid: they are framed in recesses. *See* Internal Angle of a Solid.

ION, son of Xuthus, and grandson of Hellen, king of Phthiosis, in Thessaly. He led a colony of Greeks into that part of Asia Minor, which from him obtained the name of *Ionia*, where the Ionic order first originated. The account given by Vitruvius of the invention of this order will be found in the next article.

IONIC ORDER, the second order of architecture, in point of time, among the Greeks. When the novelty of the Doric order had abated, the desire of producing something new soon led the way to the invention of another species; and in erecting the temple of Diana, they sought a new order from similar traces, imitating the proportion and dress of women. The diameter of the columns was made an eighth part of their height; the base with folds, representing the shoe; the capitals with volutes, in form of the curled hair worn upon the right and left; and the cymatium, for the locks pending on the forehead from the crown. This new order they called *Ionic*, after the name of the country in which it was invented.

Such is the account given by Vitruvius, but it will scarcely obtain credit in the present day. Many other suggestions have been substituted, with more or less reason; but how the order originated must ever remain a matter of conjecture. Some maintain that the idea of the capital was suggested by the curls of a lady's hair, as Vitruvius; others, by the horns of rams slain for sacrifice; others, by the use of twigs placed upon the capital; and others, who adhere to the notion of Vitruvius respecting the model wooden hut, suppose the same idea to have arisen from the splitting and bending, or curling downwards, of the tops of the wooden props, under the weight of the roof-timbers. Others, again, suppose the order to have arisen naturally from the Doric, but these do not pretend to account for the origin of the capital, which forms the most striking and distinctive feature, and on the pre-existence of which all their theory depends. Having found a fair type of the Grecian-Doric in some of the edifices of Egypt, we may naturally look to that quarter for the origin of the Ionic, but we cannot say that we meet with anything very satisfactory in this quarter. It is true, we have some approach to the form of the Ionic capital in some Egyptian buildings; we find, for instance, the volutes arranged in a somewhat similar manner, though in larger numbers, yet we cannot say that the resemblance is so striking as to satisfy us as to their identity. Again, we have in the same country capitals composed of the heads of Isis, with the curls of the head-dress hanging down at each corner of the capital, and this ought almost to satisfy some who rest content with the Vitruvian fables, but we fear not others. The capitals which bear the greatest resemblance to the Ionic, are found amongst the ruins of Persepolis, where the volutes are introduced in a very similar manner, although there is more than two such volutes in each capital. The Greeks were well acquainted with the Persians when the

Ionic order was introduced, and we would suggest this as a not unlikely account of the origin of the order; but this, like all the other suggestions, fall far short of satisfaction.

In this order, the capital becomes the chief characteristic, which is sufficient to distinguish it from any other, although from the preceding or Doric order it is distinguishable by many other marked differences, such as the employment of a distinct base; the much-altered proportions; the increased number and different contour of the flutes, and the introduction of the fillets; the increased ornamentation of the entablature; and by many other variations.

The Ionic capital has not all its sides similar, the similar sides being arranged in pairs, of which two, which may be termed the faces, are ranged parallel to the architrave; and two others, at right angles to the face, and underneath the architrave, which may be called the sides. Spiral bands or volutes, as they are called, ornament each side of the face, and are connected together by a band passing across the upper portion of the face. The volutes, in fact, may be said to be formed by a band passing over the top of the shaft, and curled up at each extremity on either side of the shaft. The band being of the same width of the column, would naturally form a cylindrical roll on each side, and thus may be supposed to have been formed the baluster side of the capital. These balusters, however, are not perfectly cylindrical, but hollowed out both vertically and horizontally, and, if we continue our simile, we may suppose the band composed of some compressible or yielding mass, and the roll to be tied up tightly in the middle, so as to make the intermediate sections of the roll gradually to diminish both ways towards the middle. Otherwise, we may suppose the balusters to represent two tubes or horns, so placed together that the larger ends, or mouths, are at the greatest distance from each other, and abut against the back of the volutes. This arrangement gives the balusters a much lighter appearance, which is considerably enhanced by their being usually decorated with carving.

The face of the capital measured across the volutes is about a diameter and a half, or 90 minutes, equal to the diameter of the base; the whole width is divided into three parts, of which one is given to each of the volutes. The volutes are composed of spiral mouldings, which make several revolutions, and gradually approach closer to each other, as they near the centre, or what is termed the eye of the volute, where they cease.

In the capitals of the Athenian examples of the Ionic, and in that of Minerva Polias at Priene, the lower edge of the canal between the volutes is formed into a graceful curve, bending downward in the middle somewhat like a festoon, and revolving round the spirals which form the volute upon each side. In the temple of Erechtheus, and of Minerva Polias at Athens, each volute has two channels, formed by two spiral borders, and a spiral division between them. The border which forms the exterior of the volute, and that which forms the under side of the lower canal, leaves a deep recess between them, which continually diminishes in its breadth till it is entirely lost when it comes in contact with the side of the eye.

In the temple of Bacchus at Teos, the great theatre at Laodicea, and in all the Roman examples of the Ionic, the channel connecting the two volutes is not formed with a border on the lower edge, but is terminated with a horizontal line, which falls a tangent to the curve of the spiral at the commencement of the second revolution of each volute. *See* Spiral and Volute.

In the example of the temple of Erechtheus, the column is terminated with a fillet and astragal a little below the edges of the volutes, and in that of Minerva Polias in the same manner, with a single fillet; and the colorino or neck of each is charged with a beautiful succession of woodbines, alternately disposed. The upper annular moulding of the column is of a semicircular section, and embellished with a rich guilloche. The echinus, astragal, and fillet, are common to both Grecian and Roman Ionic capitals, and the echinus is uniformly cut into eggs, surrounded with angular-sectioned borders, and with tongues between every two borders. The astragal is formed into a row of beads, with two small ones between every two large ones. These mouldings are cut in a similar manner in all the Roman buildings, except the Coliseum, and what relates to the taste of the foliage.

The necking of the capital is, however, frequently omitted; and the mouldings immediately under the band that connects the volutes, are thus disposed: first, a carved convex moulding, to which succeeds the enriched echinus or ovolo, and below that a bead or some other small mouldings. The abacus is square in plan, and its profile is that of a cyma-reversa or ogee-moulding, either enriched or plain, according to the richness of the capital.

When columns are introduced in the flanks of a building as well as in the front, one of the capitals of each angular column is made to face both the contiguous sides of the building, with two volutes, one upon each side projecting the two adjacent volutes by bending them in a concave curve towards the angle; as in the temple of Bacchus at Teos, of Minerva Polias at Priene, of Erechtheus, and that on the Ilissus at Athens, as also that of Fortuna Virilis at Rome. The capitals of all the columns are sometimes made to face the four sides of the abacus alike on each side, as in the temple of Concord at Rome, from which example the Scamozzian capital was formed.

A curious and probably very ancient specimen of the angular disposition of the volutes, occurs at the temple of Apollo at Bassæ, in which the capital presents four similar faces, and so far agrees with the more modern Scamozzian capital, from which, however, it widely differs in other respects. Each face of this capital is arched vertically as well as horizontally, as it curves downwards on each side from the middle of its upper edge, as well as outwardly to form the angular volutes.

This example offers other remarkable points of difference, more especially in the construction of the base, which is of very simple form, and consists of an annular moulding above a very large one of a concave profile, which spreads out beneath to considerably more than two upper diameters of the shaft.

The base employed in the Athenian Ionics consists of two tori, and a scotia or trochilus between them, and two fillets, each separating the scotia from the torus above and below: the fillet above the torus generally projects as far as the extremity of the upper torus, and the lower fillet beyond the upper torus; the scotia is very flat, and its section an elliptic curve, joining the fillet on each side: the tori and scotia are nearly of equal heights; in the Ionic temple on the Ilissus a bead and fillet were employed above the upper torus, joining the fillet to the scape of the column; the upper torus of the basis of the same temple, and that of the basis of the temple of Erechtheus, are both fluted, preserving the lower part, that joins the upper surface of the fillet above the scotia, entire. The upper scotia of the temple of Minerva Polias is enriched with a beautiful guilloche. The lower torus of the base of the antæ of the temple of Erechtheus is reeded, and that of the base of the antæ of the temple of Minerva Polias fluted, and separated from each other by two small cylindric mouldings of a quadrantal section, having their convexities joining each other. This form of a base is, by

Vitruvius, very properly called the *Attic base*, being invented and employed by the Athenians in all their Ionics. It was also adopted by the Romans, and seems to have been their most favourite base: for it is not only employed in all the examples of this order at Rome, but most frequently in the Corinthian and Composite orders also. However, the proportions of the Attic base as employed by the Romans, are different from that employed by the Greeks, the upper torus of the former being always of a less height than the lower one, both tori plain, and the scotia containing a much deeper cavity. The proportion of the bases of the Ionic and Corinthian orders on the Coliseum, the Ionic on the theatre of Marcellus, and that on the temple of Fortuna Virilis at Rome, have nearly that assigned by Vitruvius. The Ionic bases, as employed in the temple of Minerva Polias at Priene, and in that of Apollo Didymæus, near Miletus, consist of a large torus, three pair of astragals, and two scotiæ, inverted in respect of each other. The upper pair of astragals is disposed below the torus, and the scotiæ separate each pair of astragals. In the temple of Minerva Polias, an astragal is employed above the torus, separating it from the shaft; the torus itself is formed elliptically, and the under part of it is fluted: it has also a flute cut in the upper part, near to the bead. In the temple of Apollo Didymæus, the upper torus is of a semicircular section and plan, and each bead of every pair is separated by a narrow fillet. The base of the Asiatic examples differs little from that which Vitruvius appropriates to this order. In the former, the scotiæ are inverted, which gives a greater variety in the profile than when both stand in the same position as in the Vitruvian base.

The Ionians, besides the base which they appropriated to this order, sometimes used the Attic base also, as in the temple of Bacchus at Teos. This base seems not only to have been the most favourite one among the ancients, but is likewise so among the moderns. It is not so heavy in the upper part as that denominated Ionic; its contour is pleasing, and its general appearance elegant.

The shaft is fluted as in the Doric, from which, however, it differs in this, that the number of flutes is increased to 24, and their junctions are not formed by sharp arrises, but by fillets. The channels being thus multiplied, and set apart from each other, are consequently much narrower than those of the Doric order, and are much deeper in proportion to their breadth; and their extremities terminate in the semicircle, or semi-ellipse.

The architrave of the temple by the Ilissus consists of one broad facia, and its crowning cymatium; the parts of the cornice, as seen in front, are the corona, including its cymatium and sima. The capital or cymatium of the frieze, is wrought under the cornice, and consists of a sima-reversa and bead below it. The height of the architrave is about two-fifths of the entablature; and by dividing the upper three-fifths again into five parts, the plain part of the frieze will occupy three parts, and the cornice two parts.

In the Ionic order of the temple of Erechtheus, and of the temple of Minerva Polias, the architrave consists of three faciæ and cymatium; the cymatium of the frieze is mostly wrought under the corona. If the height of the entablature from the bottom of the lower facia to the top of the cymatium of the corona be divided into nineteen parts, the architrave and the part of the frieze that is seen, will each be eight parts; and the corona, including the larmier and cymatium, the other three parts. The volutes of the capitals of these orders, both for singularity and beauty, exceed every other remain of antiquity.

The Asiatic orders differ greatly from the Attic. In most of the remains of this order, as represented in the *Ionian Antiquities*, the friezes are all wanting—except in one example, and consequently the whole height of the entablatures of those without the friezes cannot be ascertained, though the architraves and cornices belonging to each other have been accurately measured. The one which has the entire entablature belongs to the great theatre at Laodicea; the frieze is pulvinated, and is something less in height than one-fifth of that of the entablature. The architraves of the temple of Bacchus at Teos, and the temple of Minerva Polias at Priene, are each divided into three faciæ below the cymatium. In all the Asiatic examples, the crowning moulding is constantly a sima-recta of a less projection than it has height: the dentils are never omitted, and their height is nearly a mean proportion between the height of the sima-recta and that of the larmier, corona, or drip, being always greater than the height of the corona, and less than that of the sima-recta. The cymatium of the denticulated band is wrought almost entirely out of the soffit of the corona, or recessed upwards, and consequently its elevation is almost concealed. The height of the cornice from the top of the sima to the lower edge of the dentils is equal, or very nearly so, to that of the architrave. The altitude of the frieze without its cymatium, or upper mouldings, may be supposed to be about a fourth part of the whole entablature; for if higher than this, the entablature would be too great a portion of the columns for any analogy we are acquainted with. In point of beautiful proportions and elegant decorations, the entablatures of these two last examples exceed every other remain; and though their proportions are very different from those remaining at Athens, they are still pleasing.

In all the Grecian examples of the Ionic order, there seems to be a constant ratio between the upper part of the cornice from the lower edge of the corona upwards, and the height of the entablature; this is nearly as 2 to 9. If these members were regulated in any other manner, their breadths would be so variable as sometimes to be so diminutive that their forms could not be perceived, and at other times so enlarged as to overcharge the whole when viewed from a proper station. Indeed the great recess of the mouldings under the corona, makes this a very distinct division, and on this account the cornice never appears too clumsy, though the whole denticulated band and cymatium of the frieze are introduced below it, which seems to be the reason of so great an apparent difference between the Asiatic and Attic species. This order, as found in the Ionian territory, is complete; but those at Athens are deficient, from their want of the dentil band, though beautiful in many other respects.

The following account of some of the more noted specimens of Ionic building, still remaining, is extracted from a series of lectures which have been published in the *Builder*.

"The earliest specimen of which any remains are to be found is the celebrated temple of Juno at Samos, which, in the age of Herodotus, was considered as the largest and most stupendous edifice ever raised by Grecian art. This interesting ruin, although often visited, has never, until recently, received any architectural elucidation. It was built about the 60th Olympiad by Rhaechus and Theodorus, two natives of the island; and the style possessing many peculiarities is such as strongly to denote its archaic origin. The bases of the columns are remarkable from the number and complication of their parts; the shaft is not fluted, nor is there any appearance of volutes to the capitals."—(Lord Aberdeen's *Inquiry*, p. 160.)

But the purest and best known specimens are to be found at Athens, where we see at once the simplest and richest modes of employing the style. The former is to be seen in the graceful little temple on the Ilissus, and the latter in the double temple, erected in honour of the Virgin-goddess and Erechtheus. Nothing can be more simple than the design of the former beautiful little building, which is only 20 feet high to the cornice; from the fewness of the mouldings and their freedom from enrichment, it serves as a model for most of the Ionic porticos of the present day, as it is admirably adapted to domestic structures. This temple had a portico of four columns at each end, but was without any lateral columns: the columns are only 21 inches in diameter, and are eight diameters high. The architrave has only one face; and the frieze was probably also plain, although Stuart considers that it may have had an enrichment, as a fragment of sculpture representing several figures, was found at Athens, which exactly fitted the space. The cornice is composed of the fewest possible mouldings, which, throughout the building, are of the simplest character. A more enriched example is that of the temple of Minerva Polias (so called from πολις a city; thus the goddess was emphatically the protectress of the city of Athens) placed in the acropolis, at a distance of 150 feet from the Parthenon. This temple is connected with two other buildings—the Erechtheum and the Pandrosium.

We now proceed to notice this triple temple more in detail, for which purpose a plan is essential. Elevated on three steps is a portico of 6 columns, leading to what is called by Stuart the temple of Erechtheus, but which is considered by others to be the cella of the goddess. The columns are 2 feet 3 inches in diameter, 21 feet 7 inches high, including base and capital, and are 4 feet 8 inches apart. The width of the cell is 32 feet 4 inches, and its depth 23 feet 11 inches. In the rear of the cell, and divided from it by a wall, is the apartments which Stuart ascribes to Minerva, receiving its light from three openings like windows (a rare and valuable example) placed between half-columns, and having on one side a communication with the Pandroseum, and on the other with a noble portico of four columns in front, having a projection of two inter-columns. These three last-named parts are on the same level, which is, however, about 9 feet lower than that of the hexastyle portico. The columns of the tetrastyle are 2 feet 9 inches in diameter, and 25 feet in height. The little building, the Pandroseum, had six female figures, called Caryatides, instead of columns, to support the entablature, and their origin has given rise to much discussion.

There are but few examples of this order as practised by the Romans, remaining entire; amongst them are the theatre of Marcellus, the temple of Concord, and that of Fortuna Virilis. Several portions of the order have, however, been discovered in those buildings which were erected after the decline of the empire, such portions having been plundered from more ancient buildings, to enrich the new edifices. Although some of these Roman examples are of considerable merit, they would seem to fall far short of the Grecian in taste and elegance. The capital was greatly impoverished by the volutes being considerably reduced in size, and thereby losing to a great extent its importance as the chief characteristic of the capital. This fault, however, was afterwards greatly increased by the Italians. In the Greek examples the volutes were connected together by a series of mouldings or hem, hanging down over the echinus, after the manner of a festoon; but in the Roman there is merely a straight line without any moulding carried over the echinus, which is not nearly so graceful as in the former examples. In late specimens, the volute consists of fewer revolutions, and has no secondary spirals upon it; the mouldings of the spiral also, as well as the intermediate spaces between the spirals, are flat, and altogether the volute is less prominent, and less elaborately worked than in Grecian specimens. In the temple of Concord, the volutes are placed diagonally, similar to those of the capital termed Scamozzian, so as to present four similar faces. This is one amongst many varieties of the Roman-Ionic capital, of which there is no lack, some being ornamented with human figures, masks, busts, &c., as in an example given by Pyranesi. These differences are sufficient to show that the ancients did not confine themselves to one and the same treatment of this order on all occasions. The Italians in later times made very considerable alterations, first by reducing the size of the volutes, so as to make them insignificant, and afterwards, by attempting to remedy this defect, and give importance to the capital by the addition of an ornamental necking: another alteration consisted of the addition of festoons to the angular or Scamozzian capital, a festoon being suspended on each side of the capital, from the eye of one volute to that of the other on the same face; an example of this practice is to be seen in the portico to All-Souls Church, Langham-place, London. The Romans make use of the Attic base.

The Roman entablature differs also in some respects from the Grecian, and especially in the proportions of the cornice, which in the latter case is less than either of the other members, averaging at about $\frac{35}{100}$ of the entire entablature, whereas in examples of Roman practice, the cornice is by far the most important division of any, the proportions of the theatre of Marcellus giving 43 minutes to the architrave, 36 to the frieze, and 66 to the cornice, while those of the temple of Fortuna Virilis stand thus: architrave 38 minutes; frieze 29; cornice 70; which gives a great preponderance to the cornice. The projection of the cornice usually equals its height, or nearly so. The upper facia of the architrave is surmounted with a fillet and ogee often enriched, and the lower not unfrequently with a small echinus, also enriched, with a narrow fillet underneath. The frieze is mostly plain, and of little importance, but that of the temple of Fortuna Virilis has an attempt at decoration. The cornice is supported by an ogee-moulding, and dentil-band surmounted by a fillet, a bead-moulding, and a large enriched echinus; the cornice itself consisting of a corona with a small ogee and fillet, on which is placed a cymatium. In the dentil-band, the dentils are often of large size, and placed rather wide apart. The Italians have not unfrequently introduced into this order what is termed a pulvinated frieze, so called from its supposed resemblance to a cushion, its profile being convex; one of the earliest examples of the pulvinated frieze occurs in the baths of Diocletian.

The general proportions of the order, as adopted by the Grecian and Roman architects, are much alike; the principal differences existing, as we have shown, in matters of detail. Chambers gives the height of the column eighteen modules, and that of the entablature four and a half, or one-quarter the height of the column. The base is attic, and the shaft either plain or fluted, and in the latter case with twenty, or more frequently twenty-four, flutings with fillets between, which should not be broader than one-third of the width of the flutes, nor narrower than one-quarter. The ornaments of the echinus of the capital should correspond with the flutes, so as to have an egg or dart over the centre of each flute.

Modern examples of this order in London, are—

St. Pancras Church, copied from the Erectheion, and affording also a specimen of Caryatides with entablature, after the small building called the Pandrosium.

The East India House, after the Asiatic examples.

The portico of Hanover Chapel, Regent-street, after the order of Minerva Polias at Priene, which exhibits the peculiar Ionic base.

The New Post-Office.

The British Museum.

The portico of the College of Surgeons, after the small temple on the Ilissus.

The Church in Regent-square, New Road.

The Law Institution, Chancery-lane.

The subjoined table of proportions, as exhibited in various examples, may be found useful; it is extracted from Knight's Cyclopædia:—

	Height of Column.		Base of Shaft.		Upper diameter of Shaft.		Height of Entablature.	
	Ft.	In.	Ft.	In.	Ft.	In.	Ft.	In.
Temple of Apollo Epicurius, at Bassæ			2	1.9	1	9.4	3	9.31
Temple of Erechtheus, Athens	21	7.50	2	3.8	1	11.2	4	11.25
Aqueduct of Adrian	19	1.95	2	2.35	1	11.1	4	2.90
Temple on the Ilissus	14	8.300	1	9.4	1	6.2	3	7.282

Propylæa, at Eleusis			3	4.6	2	9.24		

The examples which we have selected for illustration, are as follows:—

Plate I.—Finished drawing of the order from the temple of Minerva Polias at Athens.

Plate II.—The same in outline.

Plate III.—Drawing in outline of column and entablature from the temple of Fortuna Virilis at Rome.

Plate IV.—Drawing in outline of column and entablature from the temple of Marcellus at Rome.

IRON, (from the Saxon *iren*,) a metal of a bluish-white colour; of great hardness and elasticity; very malleable; and exceedingly tenacious and ductile. The hardness of iron in some states is superior to that of any other metal; and it has the additional advantage of suffering this hardness to be increased or diminished at pleasure, by certain chemical processes, without altering its form. It is, nevertheless, easily formed into any shape, and susceptible of a high degree of polish; it is the most elastic of all the metals, and, next to platina, the most difficult of fusion. Its tenacity is also greater than that of any other metal, except gold—an iron wire, the tenth part of an inch in diameter, having been found capable of sustaining more than 500lbs. weight without breaking. Its ductility is such as to allow it to be drawn into wire as fine as a hair. It is the most abundant, the most important, and the most valuable of all the metals. Although a simple undecompounded substance, it is not naturally found in this state, except in comparatively minute quantities, but is the product of art. Some specimens of native iron, nearly pure, have been found in Siberia and South America; also many iron stones, rich in the metal, supposed to be of volcanic or meteoric origin, have been found in numerous parts of the earth; but all the iron of commerce is obtained by chemical means. Iron is so universally diffused as to form a constituent part of almost all animal, vegetable, and mineral substances. Unlike metals of inferior utility, its ores are not distributed in thin veins, or scattered in minute particles, but are thickly stratified over many thousands of square miles, chiefly in the northern regions of the earth, where nature has been less profuse of her other benefits. The use of this metal is of very great antiquity, though, on account of the difficulty of separating it from its ores, and of working it, probably not so remote as the employment of gold, silver, copper, and other comparatively soft metals, which are in many places found in a pure metallic state. It is stated by some writers, that iron is mentioned by Moses as the material of which knives and swords were fabricated; and that Herodotus mentions the presentation of a saucer or vase of iron, very curiously inlaid, by Alyattes, king of Lydia, to the Delphic oracle. Later and more erudite writers have, however, maintained, that the words of those ancient authors have been most incorrectly translated into our language; and that the working and use of iron was unknown at those periods. At what time the manufacture of iron was first attempted in Britain cannot be precisely ascertained. Some suppose (for it is in reality only a probable conjecture) that the Phœnicians, who wrought the tin-mines of Cornwall, introduced into the country men who were skilled in metallic ores, and capable of estimating their value, by applying the minerals to such purposes as their own necessities or the wants of the inhabitants might require. There is, however, much evidence to favour the belief that iron was worked in this country during the time it was in occupation by the Romans; and, that during the establishment of the Danes in England, the arts of mining and manufacturing the ores of iron were much improved.

Iron is obtained from the ore by an operation called smelting, and in this state it is called *crude-iron*, *cast-iron*, or *pig-iron*, but it is very impure. The art of smelting iron was practised in this country during the time of the Roman occupation; and in many ancient beds of cinders—the refuse of iron-works—Roman coins have been found. The principal ancient seats of the iron manufacture in this country appear to have been the Sussex and the Forest of Dean, or Arden, as it was then called. It is known that iron-works existed in that part of Gloucestershire in 1238, because there occurs, among the patent-rolls of Henry III. of that date, one entitled "De Forgeis levandis in Foresta de Dean." Remains of ancient iron-furnaces have been noticed in Lancashire, Staffordshire, and Yorkshire. The art of working in iron and steel was much practised in this island before the Norman conquest; and we are told, that not only was the army of Harold well supplied with weapons of steel and with defensive armour, but that the horses were covered with steel and iron armour; and that every officer of rank maintained a smith, who constantly attended his master to the wars, and took charge of his arms and armour, to keep them in proper repair.

The iron of commerce is usually divided into two distinct qualities, viz., pig-iron, and malleable or bar-iron—the second being the result of an extension of the processes necessary for the production of the first.

The first process is that of reducing the iron stone or ore into a metallic state by means of fusion. This operation is conducted in a blast-furnace, which is charged with certain proportions of iron-ore, of coke, and of limestone. The ore must previously have been roasted or calcined in a kiln, in order to drive out the water, sulphur, and arsenic, with which it is more or less combined in its native state; by the process, it loses one-sixth part of its weight. A furnace of the size commonly used in Wales will produce from 5 to 6 tons of pig-iron in twelve hours. For the largest quantity, the furnace must be charged progressively with 15 tons of roasted iron-ore, 22½ tons of coke, and about 6 tons of limestone. These ingredients are supplied at 50 charges, and must be intimately mixed together in the furnace. The limestone must be broken into small pieces; its use is to act as a flux to the ore, and promote its fusion. The heat that

would be produced in any furnace by merely setting fire to the fuel which is contained in it, would be altogether insufficient for the fusion of the ore, if its intenseness were not promoted by the forcing in of a current or blast of air. For this purpose it is necessary to use a strong mechanical force, and, of late years, the agency of steam has been commonly employed for this purpose. This power is applied to the working of a blowing cylinder, which may be four times the area of the cylinder of the steam-engine. If the blast thus produced were passed immediately from the blowing cylinder through the *tuyères* or tubes to the furnace, the effect would be intermitting and irregular, ceasing at the end of each stroke of the steam-piston. To remedy this inconvenience, the blast is carried into an intermediate chamber, of a spherical or cylindrical shape, called a regulator; and as the air is in a state of condensation when admitted, its effort to expand itself again to its natural volume causes the continuous and regular supply to the furnace which is necessary. The air thus forced into the furnace keeps the heat at the degree of intenseness which is indispensable for the smelting of the ore. Until the last few years, the air thus supplied was uniformly at the temperature of the atmosphere from which it was immediately taken; and the effect was, not only to produce a lower degree of heat, but also to supply a quantity of moisture which is prejudicial to the smelting process.

The blowing of heated air has, however, recently been introduced at several founderies, and likewise at the Clyde iron-works. This improvement is the invention of Mr. J. B. Nielson, of Glasgow, whose patent was enrolled in March, 1829, and is designated "an improved application of air to produce heat in fires, forges, and furnaces, where bellows or other blowing apparatus is required." He proposes, that the air supplied by any kind of machine shall, before it enters the furnace or cupola, be made to pass through an air-vessel heated to very high temperature—a red heat, if possible—by which means a current of hot air will be thrown on the fire, instead of the cold current usually employed. It is recommended that the air-vessel be surrounded with some non-conducting substance, and imbedded in masonry. The capacity of this vessel for a smith's forge he recommends to be about 1,200 cubic inches; and for a cupola or blast-furnace, about 10,000 cubic inches. It was much doubted whether the increased temperature of the fire thus blown would produce advantages equivalent to the expense of constructing the air-vessel and keeping it at the requisite heat; and, as respects the smelting of iron in particular, the theory seems opposed to the well-known fact, that a much larger quantity of iron is yielded by the blast-furnaces in the winter season, or when the air is cold, than during the summer season, when the air is warm. The experiment at the Clyde iron-works have, however, been reported most favourably of; and the saving of coal attending it is so great, that it was stated in the *Glasgow Chronicle* to be calculated to accomplish a saving in the consumption of this island to the amount of £200,000 annually. At the Clyde iron-works, the air was heated to 220° Fahrenheit before it was discharged into the furnace—an effect which was produced by the expenditure of only one-eleventh part of the cost of fuel it takes to heat it to the same temperature in the blast-furnace, which may be accounted for by the circumstance, that Mr. Nielson's air-vessel is heated by coals, while the blast-furnace is heated by coke. Further experience in this invention has fully confirmed the views of the patentee, and it must now be regarded as one of the most valuable improvements in modern metallurgic operations.

"The cost of the process of reduction by the hot-blast," observes Mr. Weale, in his 'Dictionary of Terms of Art,' "being so much less than that with the cold-blast, the ultimate value of the former is of course also partly dependent upon the quality of the produce. On this head much difference of opinion has often been manifested, and with all the earnestness usually displayed in the advocacy of self-interest. The value of each process must, no doubt, arise from the completeness of the fusion produced, and the separation effected between the iron, and the impurities combined with it in the ore. The hot-blast furnace effects the fusion more readily than the cold-blast, but admits a larger combination of cinders with the ore; and the advantage which has been taken of this facility of adulteration, in order to reduce the cost of production, has doubtless led to the introduction into the market of many qualities of hot-blast iron, which are inferior in strength to that made with the cold-blast. The results of some of the most carefully-conducted experiments which have been made upon the strength of cast-iron, and published in the sixth volume of the new series of "Memoirs of the Literary and Philosophical Society of Manchester," show that the transverse strength of the cold-blast iron tried was about 2½ per cent. greater than that of the hot-blast. The experiments here referred to were made upon rectangular bars 1 inch square, and 4 feet 6 inches long between the supports. The mean average breaking-weights, placed at the middle of these bars, were—

In 21 samples of hot-blast iron . . . 445.5714 lbs.
In 22 samples of cold-blast iron . . 456.9090 "

Cast iron, which is scarcely malleable at any temperature, is generally so hard as to resist the file, and is extremely brittle; however, it is equally permanent, in many applications, with wrought-iron, is less liable to rust, and being easily cast into various forms by melting, is much cheaper. Indeed, the labour of wrought-iron, if applied to many of the purposes to which cast-iron is used, would be incredible, and in some cases insurmountable.

The uses to which cast-iron is now applied, are so numerous, that it is quite impossible to particularize them. It is used extensively in the wheel-work of every department of machinery, in crane-work, in iron bridges, in beams, and pillars, for large buildings, and in numerous articles of manufacture. It is employed in the construction of works of the greatest magnitude, and of the most minute character. The immense iron-girders of a railway bridge are made of cast-iron, and offering a striking contrast to the delicate ornaments of the drawing-room fabricated of the same useful metal. Of late years, the perfection to which the art of moulding in iron has been brought is almost incredible, in particular, we may mention, beautiful specimens of ornamental railings, chimney-pieces, figures imitative of ancient sculptures, &c.

Cast-iron is reduced into wrought or bar-iron, or forged-iron, by divesting it of several foreign mixtures with which it is incorporated. The varieties of wrought-iron are the following: *hot-short iron* is so brittle when heated, that it will not bear the weight of a small hammer without breaking to atoms, but is malleable when cold, and very fusible in a high temperature; *cold-short iron* possesses the opposite qualities, and is with difficulty fusible in a strong heat, and though capable while hot of being beaten into any shape, is when cold very brittle, and but slightly tenacious. The iron in general use, which though, in a chemical point of view, not entirely pure, is so far perfect, that it possesses none of these defects; its principal properties are the following: 1st, When applied to the tongue, it has a styptic taste, and emits a peculiar smell when rubbed: 2nd, Its specific gravity varies from 7.6 to 7.8; a cubic foot of it weighs about 580lb. avoirdupois: 3rd, It is attracted by the magnet or loadstone, and is itself, in one of its ores, the substance which constitutes the loadstone. It is also capable of acquiring itself the attraction and polarity of the magnet in various ways; iron, however, that is perfectly pure, retains the magnetic virtue only a very short time; 4th, It is malleable in every temperature, which, as it rises, increases the malleability. It cannot, however, be hammered out so thin as gold or silver, nor even as copper. Its ductility is very great, and its tenacity such, that an iron wire something less than the twelfth of an inch in diameter is capable of supporting, without breaking, 549¼lb. avoirdupois: 5th, It melts at about 158° of Wedgewood: 6th, It combines very readily with oxygen; when exposed to the air, its surface is soon tarnished, and is gradually changed into a brown or yellow colour, usually called *rust:* this change takes place more rapidly, in proportion as it is more exposed to moisture.

"Between the cast-irons made in different parts of Great Britain, there are characteristic differences. The Staffordshire metal runs remarkably fluid, and makes fine sharp castings. The Welsh is strong, less fluent, but produces bar-iron of superior quality. The Derbyshire iron also forms excellent castings, and may be worked with care into very good bar-iron. The Scotch iron is very valuable for casting into hollow wares, as it affords a beautiful smooth skin from the moulds, so remarkable in the castings of the Carron company, in Sterlingshire, and of the Phœnix foundery at Glasgow. The Shropshire iron resembles the Staffordshire in its good qualities."—*Dr. Ure*, *Dict. of Arts.*

The following statement shows the results of some interesting experiments on the cohesive strength of bar-iron, as detailed in an American publication :—

"The mean result of numerous experiments on wrought-iron, detailed in the *Journal of the Franklin Institute*, made by a Committee of the Institute, at the request of the Treasury Department of the United States.

"The experiments were made at ordinary temperatures on bars of iron averaging ¾ inch by ¼ inch."

To preserve iron from rust, particularly when polished, various methods have been tried with more or less success: among others, the partial oxidation, known by the term *blueing*, has been adopted: the slightest coat of grease is sufficient to prevent rust.

With reference to this subject, more especially as to the effect of sea-water on cast-iron, Mr. Faraday addressed the following observations to Sir Byam Martin, chairman of the "Harbours of Refuge and Defence" commission :—

"Sir,—I hasten to reply to your note, though not, I fear, with any certain knowledge; for infirm health has prevented me from taking up the consideration of the action of sea-water on iron, as my observations will permit. I conclude that the question is of cast-iron in sea-water. Between these two bodies, there is a vigorous action. As far as I have been able to observe, it is the greatest in the water near the surface; less in deep water; and least of all when the iron is buried in sand, or earth, or building-materials (into which the water may penetrate;) for then the oxide and other results formed, are detained more or less, and form sometimes a cement to the surrounding matter, and always a partial protection. Soft cast-iron, as far as my experience goes (which is not much,) corrodes more rapidly than hard cast; soft cast-iron, as far as my experience goes, more rapidly than the brittle white iron. As to the amount of corrosion in any given time, I have not had the opportunity of observing any good and satisfactory cases of illustration.

"In estuaries and the mouths of rivers, it is very probable that great differences of corrosion will arise from the different circumstances of ariable saltness; the soil of the river, if near a town, the metallic will much affect it, thus a wharf of cast-iron might occasionally be greatly injured by making fast to it vessels that are coppered, using iron cables.

"As to the protection of iron, and first by a coating; the permanency of a coat of paint, or of tar, or bituminous matter, can only be ascertained by reference to experience. Of this I have none, except in a case where coated iron sheathed for vessels was brought to me. I was much impressed with the thorough adhesion of the coat to the iron. The process was patent, and I cannot remember whose it was. Zinc-ed iron would no doubt resist the action of the sea-water as long as the surface was covered with zinc, or even when partially crusted with that metal; but zinc dissolves rapidly in sea-water, and after it is gone, the iron would follow.

"As to voltaic protection, it has often struck me that the cast-iron piles proposed for light-houses, or beacons, might be protected by zinc, in the manner Davy proposed to protect copper by iron; but there is no doubt the corrosion of the zinc would be very rapid. If found not too expensive, the object would be to apply the zinc protectors in a place where they could be examined often, and replace them when rendered ineffective. In this manner, I have little doubt that iron could be protected in our sea-water. It is even probable that, by investigation and trial, different sorts of iron might easily be distinguished and prepared, one of which would protect the other; thus soft cast-iron would, probably, protect hard cast-iron, and then it would be easy to place the protecting masses where they could be removed when required.

"Hence, though iron be a body very subject to the action of sea-water, it does not seem unlikely that it might be used with advantage in marine constructions intended to be permanent, especially if the joint effects of preserving coats of voltaic protectors were applied. Perhaps engineers are in the possession of practical and experimental data sufficient to allow the formations of a safe judgment on this point. For my own part, I am not, and therefore am constrained to express the above opinions with much doubt and reserve."

Iron is the most useful and most plentiful of all metals. It requires a very intense heat to fuse it, on which account it can only be brought into the shape of tools and utensils by hammering: this high degree of infusibility would prevent the uniting of several masses into one, were it not from its being capable of welding, a property found in no other metal, except platina. In a white heat, iron appears as if covered with a kind of varnish; and in this state, if two pieces be applied together, they will adhere, and may be perfectly united by forging.

A very extensive manufacture of iron articles is now carried on at Birmingham, Sheffield, and other places, which, although they are cast from fluid metal, are nevertheless malleable. This property is derived from two causes; first, the pigs are prepared from the rich and pure iron ores of Cumberland; and the metal thus obtained, is combined with but a small quantity of carbon, so as nearly to resemble steel in colour, hardness, and the brilliancy of its fracture; and it has in consequence been designated by some manufacturers *run steel.* An infinite variety of articles, including nails, saddler's ironmongery, (and particularly such goods as afterwards receive another metallic coat, as those which are plated upon *steel*,) are cast from this metal. The castings thus produced are exceedingly brittle; but this property is entirely destroyed by a process termed annealing, in which the metal is deprived of the carbon to which its previous fusibility was owing, and is in consequence brought to that state of wrought iron requiring only the operations of the shingling forge and rollers to give it a laminated and fibrous texture. Nails made by this process may be drawn out longer, and bent backwards and forwards, without breaking. The metal is, however, not so strong or tough as hammered and rolled iron; the discovery of the process is nevertheless of great value, as many excellent articles are produced in consequence, which would not without it be made at double the cost. The discoverer of this mode of converting cast-iron goods into malleable, was Mr. Samuel Lucas of Sheffield.

A description of iron was introduced a short time since, under the name of corrugated iron, which has already met with great success, and promises to be very extensively used. It is called corrugated from its grooved or *wrinkly* appearance, produced by putting the sheets between rollers having grooved peripheries. Sheet-iron thus prepared, acquires a strength and stiffness much beyond its ordinary strength, and adapts it for purposes for which the common sheet-iron is found insufficient. Corrugated iron has been much used for roofs of railway stations, and works of a similar kind.

Formerly, large quantities of iron were imported from Russia and Sweden, and previously to the discovery in 1785 by Mr. Cort, of the methods of puddling and rolling or shingling iron, this country imported 70,000 tons of this metal, a vast quantity, considering the state of our manufactures at that time. So much, however, has our own wrought iron been improved in the manufacture, that it may now be considered fully equal to the Swedish. As a proof of this, the Admiralty, East India Company, and other public departments, now contract for British iron only. *See* Steel.

Mr. Jessop, of the Butterley Works, estimated the annual produce in Great Britain (exclusive of Ireland) in 1840, at 1,396,400 tons; and the quantity of coal used for smelting that quantity was 4,877,000 tons, besides 2,000,000 tons for converting into wrought iron.

At the late meeting of the British Association at Cambridge, Mr. Watt read a report on the iron trade in Scotland, from which it appears, that, at the present moment, there are extensive new iron works erecting in Scotland, especially in Ayrshire and in Renfrewshire. At several of the old works, considerable additions are being made to the number of furnaces now at work. The increase in the annual quantity of pig-iron smelted in that country in April, 1845, amounts to 37.4 per cent.; and there is every appearance that, before another year expires, a similar increase will be made in the amount of iron produced in Scotland. Sir J. Guest, of Dowlars Works, in evidence before the Import Duties Committee, 1840, stated, that the iron made at the beginning of this century amounted to 150,000 tons.—In 1806, 258,000.—In 1823, 452,000.—In 1825, 581,000.—In 1828, 703,000.—In 1835, 1,000,000.—In 1836, 1,000,000 —In 1840, 1,500,000. We may remark, that the manufacture of malleable iron is yet but in its infancy in Scotland, although making rapid strides towards an important position. There are five establishments; and the present make may be computed at about 900 tons per week, or 50,000 tons per annum. For superior finish, toughness, and uniformity, it will stand comparison with either English or Welsh iron.

IRON BRIDGE, a species of bridge constructed, as its name implies, of iron, which was first applied to this purpose in England, towards the close of the 18th century. The merit of having employed this material in bridge-building, has been generally claimed for the English, but more accurate writers state that it really belongs to the Chinese. Be this as it may, it is certain that in no country in the world have been erected so many magnificent and stupendous structures as the iron bridges in the United Kingdom.

Under the article Bridge, (p. 58, vol. i.) we gave some account of the "rise, progress, and present state" of bridge-building, reserving to each respective head the more detailed information peculiarly belonging to it. Following that course, we now proceed to describe the several forms of bridges built of iron, as cast-iron arched bridges, cast-iron girder bridges, cast-iron compound girder bridges trussed with malleable iron bars, tubular bridges of various kinds, &c.

The first iron bridge erected in this country was over the Severn, a little below Colebrook Dale, where that river is narrow and rapid. The abutments, which are of stone, are brought to about 10 feet above the surface of common low-water, where they have each a platform of squared freestone for ten feet breadth, which serves for a hauling way, and a base for the arch to spring from. Upon this platform, cast-iron plates, four inches in thickness, are laid, and formed with sockets to receive the ribs. These plates, in order to save metal, have considerable openings in them. The principal, or inner ribs, which are five in number, and which form the arch, are 9 inches by 6½. The second row behind them, and which are cut off at the top by the horizontal bearing-pieces, are 6½ by 6 inches: the third row are 6 by 6 inches: the upright standards behind the ribs are 15 inches by 6½ inches, but they have an open space in the breadth of 5¾; the back standards are 9 inches by 6½, with projections for the braces; the diagonals, and horizontal ties, are 6 inches by 4, and the cast-iron tie bolts are 2¼ inches diameter. The covering plates, which are 26 feet in length, reaching quite across the bridge, are one inch in thickness. The great ribs are each cast in two pieces, meeting at the keys, which, as the arch is circular, 100 feet 6 inches span, and 45 feet rise, are about 70 feet in length. There are circular rings of cast iron introduced into the spandrels, and there is a cast-iron railing along each side of the roadway of the bridge: the weight of the whole of the iron work is 378½ tons. Behind the iron work, at each extremity of the arch, the abutments are carried up perpendicularly of rubble masonry, faced with squared stone, and the wing-walls are also of the same materials.

The iron work was cast and put together in a very masterly manner, under the direction of Abraham Derby, of Colebrook Dale; and the whole was completed in the year 1779. The design was original and very bold, and was, as far as concerned the iron work, well executed; but being a first attempt, and placed in a situation where more skill than that of the mere iron-master was required, several defects became apparent when the bridge was completed. The banks of the Severn are here remarkably high and steep, and consist of coal measures, over the points of which vast masses of alluvial earth slide down, being impelled by springs in the upper parts of the banks, and by the rapid stream of the river, which dissolves and washes away the skirts below: the masonry of the abutments and wing-walls not being constructed to withstand this operation, was torn asunder, and forced out of the perpendicular, more particularly on the western side, where the abutment was forced forward about 3 or 4 inches, and by contracting the span, of course heaved up the iron work of the arch. This was remedied under the direction of that able mason Mr. John Simpson, of Shrewsbury, as far as the nature of the case would admit of, by removing the ground, and placing piers and counter-arches upon the natural ground behind it. Had the abutments been at first sunk down into the natural undisturbed measures, and constructed of dimensions and form capable of resisting the ground behind; and had the iron work, instead of being formed in ribs nearly semicircular, been made flat segments, pressing against the upper parts of the abutments; the whole edifice would have been much more perfect, and a great proportion of the weight of metal saved. We have already stated that one row of the principal ribs formed the arch; the two rows behind are carried concentric with the inner row, until intersected by the roadway, which passes immediately at the level of the top of the inner ribs. This has a mutilated appearance; the circular rings of the spandrels being less perfect than if the pressure had been upon straight lines; for a circle is not well calculated for resistance, unless subjected to an equal pressure all round.

The second iron bridge was built upon the same river, about three miles above the former one, at a place called Buildwas. An old stone bridge was carried away by a very high flood early in 1795, and the county of Salop was obliged to restore the communication. Mr. Telford, the celebrated engineer, was at that time surveyor for the public works of the county, and on his recommendation, the magistrates ordered the construction of a cast-iron bridge, to be of one arch 130 feet span. The Colebrook Dale Company became contractors, both for the iron work of the arch, and the masonry of the abutments. Mr. Telford had some difficulty in making that company depart from their former mode of construction: but he at last prevailed in keeping the roadway low, and adopting the suspending principle, by means of a rib on each side of the bridge, which sprung from a lower base than the bearing ribs, and rose above them to the top of the railing; thus the bearing ribs were supported by the lower parts of those before mentioned, and were suspended by their upper parts. The bearing ribs have a curve of 17 in 130, or nearly one-eighth of their span. The suspending ribs rise 34 feet, or about one-fourth of their span. There are cast-iron braces, and also horizontal ties. There are 46 covering plates, each 18 feet in length, and one inch in thickness. They have flaunches 4 inches in depth, and are screwed together at each joint; so that, by taking the curvature of the bearing ribs, and being firmly secured at the abutments, instead of a load, they compose a strong arch. There being only one rib in the middle of 18 feet breadth of bridge, on each covering plate, a cross rib or flaunch, 4 inches in depth, is cast at an equal distance between the bearing ribs. The suspending ribs are each 18 inches in depth, and $2\frac{5}{8}$ inches in thickness, exclusive of a moulding. The bearing ribs are 15 inches in depth, and $2\frac{1}{2}$ inches in thickness, and each of the ribs is cast in three pieces only, of about 50 feet each; the braces are 5 by 3 inches. The principal king-posts are $10\frac{1}{4}$ by $4\frac{1}{2}$ inches. The springing plates are each 3 feet broad, and 3 inches thick, with openings to save metal. The uprights against the abutments are $4\frac{1}{2}$ inches square. The strongest uprights in the railing are 3 inches square, and those between them 1 inch. They are placed 6 inches apart, between middle and middle. The height of the railing above the surface of the roadway, is 4 feet 9 inches. In each spandrel, there are three circular arches formed with hard-burned bricks, which preserve most of the space open, but they are concealed by iron plates, one inch in thickness, which form the outside facings. On the eastern side of the river, although the banks are not so very high or steep, the quality of the ground being similar to that of the other iron bridge, particular care was bestowed upon the abutments: the space for them was excavated down to the rock, which lay considerably under the bed of the river, and the masonry was sunk into the solid part of the rock. It was built up chiefly of square masonry, and the rest of rubble, laid very close in regular courses, and having the back part formed in the shape of a wedge, pointing to the bank. The wing-walls were curved horizontally and vertically. At the height of 10 feet above the low-water, there is a hauling path on each side of the river. This bridge, which was completed in 1796, has never shown any appearance of failure in any of its parts; nothing can be more perfect than the iron work; it is fitted as correctly as a piece of good carpentry.

It has been objected to this structure, that by connecting ribs of different lengths and curvature, they are exposed to different degrees of expansion and contraction. This appears just in theory; and that no discernible effect has hitherto been produced, is probably from the difference being small. Another objection is, an apparent heaviness in the spandrels, from concealing the circular arches with iron plates. For appearance, these spaces had certainly better not have been concealed, but they are not liable to the objections made to the former iron bridge, because the space around them is all closely filled up; and the roadway being formed with materials similar to this filling-up matter, distributes the pressure very regularly. Upon the whole, considering the strength acquired by placing the covering plates with their deep flaunches, in the form of an arch, we doubt whether a greater degree of strength can be had by any other distribution of the same quantity of cast-iron, viz., $173\frac{1}{2}$ tons: it appears to us, however, that the upright standards, braces, and king-posts, might be made of smaller dimensions.

The third iron bridge was constructed over the river Wear, near Sunderland, in the county of Durham. Its projector was Rowland Burdon, Esq., a gentleman of considerable landed property in that county, and who, for some time, represented it in parliament. The iron-work was cast at the founderies of Messrs. Walkers, of Rotherham, and erected under the inspection of Mr. Thomas Wilson. The confidence in the use of iron for arches of great extent, was by this time established. The span of the second arch, we have seen, is 30 feet more than that of the first; and, in this third instance, the span is 106 feet beyond that of the second, although its rise is only the same as that of the suspending ribs at Buildwas. The arch at Sunderland springs 60 feet above the level of the surface of low-water; the span is 236 feet; the rise, or versed sine, is 34 feet; the width of the roadway 32 feet; and there are six ribs.

In this arch the mode of construction is very different from either of the former. Instead of working with pieces of iron from about 50 to 70 feet in length, each rib is here composed of 125 small frames, each about two feet in the length or curve of the rib, and 5 deep in the direction of the radius. In each frame there are three pieces of 4 inches square, which run in the direction of the curve of the arch; and these are connected in the direction of the radius by two other pieces, 4 by 3 inches. In each side of the larger pieces is a groove, 3 inches broad, by three-quarters of an inch in depth; and opposite each cross piece there is a hole in the middle of the groove. When the abutments were brought up, and a scaffolding constructed across the river between them, six of these frames were placed against the abutments in the manner of arch-stones. Wrought-iron bars, of a length to embrace sundry frames, were then fitted into the grooves. Hollow pipes of cast-iron, 4 inches in diameter, fitted to reach between each two frames, across the soffit, were introduced. Upon the ends of these pipes are flaunches, in which there are holes, answerable to the holes in the four-inch pieces of the frames, and also to those of the wrought-iron bars. Through these holes wrought iron bolts were introduced, which brought all the before-mentioned parts together by means of fore-locks. The frames do not meet at the upright pieces, but on the three points of the four-inch pieces only. On the ends of the hollow pipes, there are small projecting pieces, which embrace the upper and lower edges of the frames opposite each joining. These operations were repeated until the whole of the frames were placed, and the arch keyed, forming six ribs between the abutments. Upon the ribs, perpendicular pillars are placed; and between them are cast-iron circles, which come in contact with the extrados, the upright pillars, and the bearers of the roadway. The bearers and covering, we suppose for cheapness, are made of timber: the railing is cast-iron. The inclinations each way upon the arch, probably to save weight, are inconveniently steep.

From its great elevation and lightness of construction this bridge is justly esteemed a bold effort of art, and a magnificent feature in the country. The wooden bridges in Switzerland, and that in America, are of greater span; but, being placed near the surface of the water, and from the difference of material, their parts being of larger dimensions, there can be no comparison as to the fineness of effect. A cast-iron bridge was also built over the river Witham, at Boston, in Lincolnshire, the design for which has been generally ascribed to Mr. Rennie. That gentleman, however, only gave the width and rise of the arch, and the abutments were founded and built under his direction. The iron arch itself was designed and executed by Mr. Thomas Wilson, of Sunderland. The span of this arch is about 85 feet; the rise about 5 feet 6 inches; the breadth is 36 feet; and there are eight ribs, each rib composed of eleven frames, 3 feet deep in the direction of the radius. At each joining there is a cast-iron grating across the arch which connects the frames, on the same principles as practised at the Pontcysylte aqueduct. Instead of three pieces in the direction of the curve, as at Sunderland, here are only two, but they are 7 inches by 4½. These are, in each frame, connected in the direction of the radius, by pieces, 4 by 3 inches. Upon the back of the ribs, pillars, 4 by three inches, are placed perpendicularly to support the roadway. The superstructure resembles that of the first iron bridge at Colebrook Dale. The arch has been kept very flat, to suit the tide below and the streets above. The frames being made about four times the length of those at Sunderland, and being connected with cast-iron gratings instead of wrought-iron, are essential improvements; but from the pieces in the frames, which are in the direction of the radius, being only 4 by 3 inches, while the main pieces in the direction of the curve are 7 by 4½, a great proportion of the former are broken. This is a defect; and the pillars which support the roadway being perpendicular, do not correspond with the radiated pieces of the frames. The ribs, in springing from the perpendicular face of the masonry of the abutment have also a crippled appearance.

In the improvements made under the direction of Mr. Jessop, at the port of Bristol, it became necessary to change the course of the river Avon, and two very handsome cast-iron bridges were built over the new channel. The span of the iron work of each arch, is 100 feet; the rise 12 feet 6 inches, or one-eighth of the span; the breadth is 30 feet. There are six ribs; each rib is composed of two pieces meeting in the middle, and they are connected crosswise by nine cast-iron ties, which are dovetailed, and wedged into the ribs; the cross sections of these ties are in the form of the letter T. The ribs stand upon abutment-plates, which are laid in the direction of the radius. These plates are 32 feet in length, 2 feet 4 inches in breadth, and 4 inches in thickness. In each plate are 5 apertures, each 5 feet long, and 20 inches in width. The ribs are 2 feet 4 inches in depth in the direction of the radius, and two inches in thickness, and have each 80 apertures, one foot square, separated by bars 3 inches broad, excepting opposite the cross ties, where the solid is 12 inches broad. Where the ribs meet in the middle they have flaunches, 8 inches broad and 2 thick, and they are connected by cast-iron screw-bolts, 3 inches in diameter. Between the ribs and the bearers of the roadway, perpendicular pillars, with cross sections formed like the letter T, are placed: the bearers are of the same form. The whole is covered with cast-iron plates, and there are railings of cast-iron.

There is great simplicity, and much of correct principle, in this design: 1. The springing-plates being placed in the direction of the radius, and the abutments receding to produce a space behind the ribs equal to that between the upright pillars. 2. The ribs being composed of two pieces, and one joint only: and, 3. Wrought-iron being wholly excluded. But we regret still observing the varying dimensions of the parts of the ribs; and that the supporting pillars are still placed perpendicularly; and which, as the arch has more curvature, has a yet worse effect than at Boston.

In the course of his employment as engineer to the board of parliamentary commissioners for making roads and constructing bridges in the Highlands of Scotland, Mr. Telford erected a cast-iron bridge over an arm of the sea, which divides the county of Sutherland from that of Ross, at a part where several of those roads unite. In this bridge, the defects noticed in the former works of this sort appear to be avoided. The arch is 150 feet span; it rises 20 feet, it is 16 feet in width, and has 4 ribs. In the abutments, not only are the springing-plates laid in the direction of the radius, but this line is continued up to the roadway. The springing-plates are each 16 feet in length, 3 feet in breadth, and 4 inches in thickness, with sockets and shoulder-pieces to receive the ribs. In each plate are 3 apertures, 3 feet in length and 18 inches in width. Each of the ribs, for the conveniency of distant sea-carriage, is composed of 5 pieces, 3 feet in depth in the direction of the radius, and 2½ inches in thickness. There are triangular apertures in the ribs, formed by pieces in the direction of the radius, and diagonals between them; but every part is of equal dimensions. At every joining of the pieces of the ribs, a cast-iron grating passes quite across the arch; upon these are joggles or shoulderings to receive the ends of the ribs: the ribs have also flaunches, which are fixed to the gratings with cast-iron screw-bolts. Each rib is preserved in a vertical plane, by covering the whole with grated, flaunched plates, properly secured together, and to the top of the ribs, by cast-iron screws and pins. In the spandrels, instead of circles or upright pillars, lozenge, or rather triangular forms, are introduced, each cast in one frame, with a joggle at its upper and lower extremities, which pass into the sockets formed on the top of the ribs, and in the bearers of the roadway. Where the lozenges meet in the middle of their height, each has a square notch to receive a cast-iron tie, which passes from each side, and meets in the middle of the breadth of the arch, where they are secured by fore-locks. Next to the abutments, in order to suit the inclined face of the masonry, there are half-lozenges. By means of these lozenge or triangular forms, the points of pressure are preserved in the direction of the radius. The covering-plates, in order to preserve a sufficient degree of strength, and lessen the weight, are, instead of solid, made of a reticulated shape; the apertures widen below, to leave the matter between them a narrow edge; and contract upwards, so as to prevent the matter of the roadway from falling through. This disposition of the iron-work, especially in the spandrels, also greatly improves the general appearance.

The success which had attended the use of iron, as a material in bridge building, had now given such confidence to engineers, that works of the greatest magnitude were proposed by the master-minds of Telford, Rennie, and others. At this period, the practicability of constructing a bridge over the Menai Straits had been much discussed. It was deemed expedient by government to facilitate, as much as possible, the intercourse between England and Ireland. For this purpose, an investigation was made as to the most effectual mode of improving the mail-roads from Holyhead through North Wales.

The Island of Anglesea, as is well known, is separated from Carnarvonshire by the celebrated strait or arm of the sea, named the Menai, through which the tide flows with great velocity, and, from local circumstances, in a very peculiar manner. This rendered the navigation difficult, and it had always been a formidable obstacle in the before-mentioned communication. The passage between Anglesea and the opposite mainland was maintained by six ferries, the chief of which was called Bangor Ferry, from its proximity to that town; but a permanent connection, by means of a bridge, had been in contemplation, and various projects for one had been under consideration. From a report of the House of Commons, of June 1810, it appears, that Mr. Rennie, the engineer, had given plans and estimates for bridges at this place in 1802, and had been called on to revise them in 1810. His plans, which appear in the last-mentioned report, are, 1st, One arch of cast-iron, 450 feet span, over the narrowest part of the strait, at a projecting rock named Ynys-y-Moch: and, 2nd, Another upon the Swilley rocks, consisting of three cast-iron arches, each 350 feet span. The expense of that at Ynys-y-Moch is estimated at £259,140, and of that at the Swilley, £290,147. He prefers the latter, because he says, "On account of the great span of the arch at Ynys-y-Moch, and the difficulty and hazard there will be in constructing a centre to span the whole breadth of the channel at low-water, without any convenient means of supporting it in the middle, on account of the depth of water and rapidity of the tide, or of getting any assistance from vessels moored in the channel to put it up; I will not say it is impracticable, but I think it too hazardous to be recommended." And, again, in the same report: "I should be little inclined to undertake the building a bridge at Ynys-y-Moch."

But from the report of June, 1811, it appears that, in May 1810, Mr. Telford was instructed by the Lords of the Treasury to survey, and report upon the best method of improving the lines of communication between Holyhead and Shrewsbury, and also between Holyhead and Chester; and to consider, and give plans for passing the Menai. In the aforesaid report (of 1811), we have his plans and estimate. His explanations we shall give in his own words; but before doing so, it is necessary to observe that much of the following extract may, perhaps, more properly belong to the description of the Menai bridge, which will be found under the head Suspension Bridge. It is, however, given here, as it describes a mode of constructing centres applicable as well to stone as to iron arches:—

"The duty assigned me," says Mr. Telford, "being to consider, and report respecting a bridge across the Menai, I shall confine myself to this object. Admitting the importance of the communication to justify acting on a large scale, I not only consider the constructing a bridge practicable, but that two situations are remarkably favourable. It is scarcely necessary to observe, that one of these situations is at the Swilley rocks, and the other at Ynys-y-Moch. These two being so evidently the best, the only question that can arise is, to which of them the preference ought to be given.

"From the appendix to the second report to the Holyhead roads and harbour, it appears that a considerable number of small coasting vessels, viz., from 16 to 100 tons, navigate the Menai, and that there have been a few from 100 to 150 tons. By statements from the principal ship-builders in the river, made in the year 1800, to the committee for improving the port of London, it also appears that vessels of 150 tons, when they have all on end, are only 88 feet in height above the water-line; and farther, that even ships of 300 tons, with their top-gallant masts struck, are nearly the same height; these in the Menai are extreme cases, and, if provided for, ought, as to navigation, to satisfy every reasonable person; it may, indeed, rather be a question whether the height should not be limited to vessels under 100 tons, by which the expense of a bridge would be considerably diminished.

"In the plans I have formed, provision is made for admitting vessels of 150 tons to pass with all on end; that is, in one design preserving 90 feet, and in the other 100 feet, between the line of high-water and the lower side of the soffit of the arch. The first design is adapted for passing across the three rocks, named the Swilley, Benlass, and Ynys-welldog, which, by their shape and position, are singularly suitable. To embrace the situation most perfectly, I have divided the space into three openings of 260 feet, and two of 100 feet each, making piers each 30 feet in thickness. Over the three large openings, the arches are made of cast-iron; over the smaller spaces, in order to add weight and stability to the piers, semicircular arches of stone are introduced; but over these, as well as the larger openings, the spandrels, roadway, and railing, are constructed of cast-iron. In this way the navigation is not impeded, because the piers, standing near the outer edges, are guards for preventing vessels striking upon the rocks; while the whole structure presents very little obstruction to the wind. From the extremity of the abutments, after building rubble walls above the level of the tideway, I propose carrying embankments until the roadway reaches the natural ground. The annexed drawing will sufficiently explain the nature of the design. I propose the bridge to be 32 feet in breadth; and, from minute calculations made from detailed drawings, I find the expense of executing the whole in a perfect manner amounts to £158,654.

"The other design is for the narrower strait, called Ynys-y-Moch. Here the situation is particularly favourable for constructing a bridge of one arch, and making that 500 feet span, leaves the navigation as free as at present. In this I have made the height 100 feet in the clear at high water spring tides; and I propose this bridge to be 40 feet in breadth. Estimating from drawings, as already described, I find the expense to be £127,331, or £31,323 less than the former. From leaving the whole channel unimpeded, it is certainly the most perfect scheme of passing the Menai; and would, in my opinion, be attended with the least inconvenience and risk in the execution.

"In order to render this evident, I have made a drawing, to show in what manner the centering or frame, for an arch of this magnitude, may be constructed. Hitherto, the centering has been made by placing supports, and working from below; but in the case of the Menai, from the nature of the bottom of the channel, the depth at low-water, and the great rise and rapidity of the tides, this would be very difficult, if not impracticable. I therefore propose changing the mode, and working entirely from above, that is to say, instead of supporting, I mean to suspend the centering. By inspecting the drawing, the general principle of this will be readily conceived.

"I propose, in the first place, to build the masonry of the abutments as far as the lines A B, C D, and in the particular manner shown in the section. Having carried up the masonry to the level of the roadway, I propose upon the top of the abutments to construct as many frames as there are to be ribs in the centre; and of at least an equal breadth with the top of each rib. These frames to be about 50 feet high above the top of the masonry; and to be rendered perfectly firm and secure. That this can be done, is so evident, I avoid entering into details respecting the mode. These frames are for the purpose of receiving strong blocks or rollers and chains, and to be acted upon by windlasses or other powers.

"I next proceed to construct the centre itself; it is proposed to be made of deal baulk, and to consist of four separate ribs; each rib being a continuation of timber frames, 5 feet in width at the top and bottom, varying in depth from 25 feet near the abutments to 7 feet 6 inches at the middle or crown. Next to the face of the abutments, one set of frames, about 50 in length, can, by means of temporary scaffolding, and iron chain bars from the before-mentioned frames, be readily constructed, and fixed upon the offsets of the abutments, and to horizontal iron ties laid in the masonry for this purpose. A set of these frames (four in number) having been fixed against the face of each abutment; they are to be secured together by cross and diagonal braces, and there being only spaces of 6 feet 8 inches left between the ribs, (of which these frames are the commencement,) they are to be covered with planking, and the whole converted into a platform, 50 feet by 40. By the nature of the framing, and its being secured by horizontal and suspending bars, I presume every person accustomed to practical operations will admit that these platforms may be rendered perfectly firm and secure.

"The second portion of the centre frames, having been previously prepared and fitted in the carpenter's yard, are brought, in separate pieces, through passages purposely left in the masonry, to the before-mentioned platforms. They are here put together, and each frame raised by the suspending bars and other means, so that the end which is to be joined to the frame already fixed, shall rest upon a small movable carriage. It is then to be pushed forward, perhaps upon an iron railroad, until the strong iron forks, which are fixed on its edge, shall fall upon a round iron bar, which forms the outer edge of the first, or abutment frames. When this has been done, strong iron bolts are put through eyes in the forks, and the aforesaid second portion of the frame-work is suffered to descend to its intended position, by means of the suspending chain-bars, until it closes with the end of the previously fixed frame, like a rule joint. Admitting the first frames were firmly fixed, and that the hinge part of this joint is sufficiently strong, and the joint itself 20 feet deep, I conceive, that even without the aid of the suspending bars, this second portion of the centering would be supported; but we will for a moment suppose, that it is to be wholly suspended. It is known, by experiment, that a bar of good malleable iron, one inch square, will suspend 80,000 lb., and that the powers of suspension are as the sections; consequently, a bar 1½ inch square, will suspend 180,000 lb.; but the whole weight of this portion of the rib, including the weight of the suspending bar, is only about 30,000 lb., or one-sixth of the weight that might safely be suspended; and as I propose two suspending chain-bars to each portion of rib, if they had the whole to support, they would only be exerting about one-twelfth of their power; and considering the proportion of the weight which rests upon the abutments, they are equal also to support all the iron work of the bridge, and be still far within their power.

"Having thus provided for the second portion of the centering a degree of security far beyond what can be required, similar operations are carried on from each abutment until the parts are joined in the middle, and form a complete centering; and being then braced together, and covered with planking where necessary, the whole becomes one general platform or wooden bridge, to receive the iron-work.

"It is, I presume, needless to observe, that upon such a centering or platform, the iron-work, which, it is understood, has been previously fitted, can be put together with the utmost correctness and facility: the communication from the shores to the centre will be through the before-mentioned passages in the masonry. The form of the iron-work of the main ribs will be seen, by the drawing, to compose a system of triangles, preserving the principal points of bearing in the direction of the radius. It is proposed in the breadth of the bridge (*i. e.* 40 feet) to have nine ribs, each cast in twenty-three pieces, and these connected by a cross-grated plate, nearly in the same manner as in the great aqueduct of Pont-cysylte, over the valley of the Dee, near Llangollen. The fixation of the several ribs in a vertical plane, appearing (after the abutments) to be the most important object in iron bridges, I propose to accomplish this by covering the several parts or ribs, as they are progressively fixed, with grated, or reticulated and flaunched plates, across the top of the ribs. This would keep the tops of the ribs immovable, and convert the whole breadth of the bridge into one frame. Besides thus securing the top, I propose also having cross-braces near the bottom of the ribs.

"The ribs being thus fixed, covered, and connected together, the great feature of the bridge is completed. And as, from accurate experiments made and communicated to me by my friend, the late William Reynolds, of Colebrook Dale, it requires 448,000lb. to crush a cube of one quarter of an inch of cast-iron, of the quality named gun-metal, it is clear, while the ribs are kept in their true position, that the strength provided is more than ample.

"When advanced thus far, I propose, though not to remove, yet to ease the timber-centering, by having the feet of the centering ribs (which are supported by offsets in the masonry of the front of the abutment) placed upon proper wedges; the rest of the centering to be eased at the same time by means of the chain-bars. Thus the hitherto dangerous operation of striking the centering, will be rendered gradual and perfectly safe; inasmuch that this new mode of suspending centering, instead of supporting it from below, may perhaps hereafter be adopted as an improvement. Although the span of the arch is unusually great, yet by using iron as a material, the weight upon the centre, when compared with large stone arches, is very small. Taking the mere ring of arch-stones in the centre arch of Blackfriars' bridge, $156 \times 43 \times 5$, equal to 33,450 cubic feet of stone, it amounts to 2,236 tons; whereas the whole of the iron work, in the main ribs, cross-plates, and ties, and grated covering plates, that is to say, all that is lying on the centering at the time it is to be eased, weighs only 1,791 tons. It is true, that from the flatness of the iron arch, if left unguarded, a great proportion of this weight would rest upon the centering; but this is counterbalanced by the operation of the iron ties in the abutments, and wholly commanded by the suspending chain-bars.

"When the main ribs have been completed, the next step is to proceed with the iron supporters of the roadway; and these, instead of being constructed in the form of circles, or that of perpendicular pillars, as hitherto, are here a series of triangles, thus including the true line of bearing. These triangles are, of course, preserved in a vertical plane by cross ties and braces. Iron bearers are supported by these triangles, and upon the bearers are laid the covering plates under the roadway, which, instead of being solid, are (in order to lessen the weight) proposed to be reticulated.

"If I have, throughout this very succinct description, made myself understood, it will, I think, be admitted, that the constructing a single arch across the Menai, is not only a very practicable, but a very simple operation; and that it is rendered so, chiefly by adopting the mode of working from each abutment, without at all interfering with the tideway.

"In the case of the Swilley bridge, although the arches are smaller, yet being placed on piers, situated on rocks, surrounded by a rapid tide, the inconvenience of carrying materials, and working, is greatly increased; and supposing the bridge part constructed, an enormous expense is still to be incurred before the roadway can be carried over the flat ground on the Anglesea shore. Therefore whether economy, facility of performance, magnificence, or durability, be consulted, the bridge of one arch is, in my opinion, infinitely preferable; and it is no less so, if considered in what regards the navigation." *See* Suspension Bridge.

A very handsome bridge was erected over the river Trent, in the county of Stafford, from the designs and under the direction of James Potter, Esq. The specification for this structure is so ably drawn, and describes so precisely every part of the works to be contracted for, that we think we shall do good service to the student, by transcribing it *in extenso*, as a model for similar compositions.

SPECIFICATION OF WORKS.

Mason's Work.—"Specification of the mason's work of the abutments for the iron bridge intended to be erected over the river Trent, at a place commonly called High Bridge, near to Handsacre in the county of Stafford:—

"The footings to be in 3 courses, laid on level beds; the courses to be not less than 1 foot thick, and the front or outside courses to be laid header and stretcher alternately; the stretchers to be not more than 4 feet long, and to average 2 feet in width upon the beds; the headers to average 4 feet in length, and 2 feet upon the beds; the stones to be all properly worked on the beds, that is, to have a tool draught round them, and dressed off fair between with a point or pick: the joints or ends of the stretchers to be squared their whole length, and the joints of the headers squared in the width of the stretchers, and the other parts dressed or squared with a pick; all the space between the courses to be filled in with ashlar of the same thickness as the outside courses, the beds prepared as before directed, and thes ides and ends squared with a pick, and laid in proper bond to fall in with the outside courses, and when a course is finished, to be grouted; the whole surface is then to be dressed off level before another course is begun to be set.

"The front courses of these abutments, cutwaters, and wing-walls, to be not less than 1 foot thick; laid on level beds with bond, that is, the joints to overlap about 8 inches, header and stretcher alternately; the headers to average 3 feet 6 inches wide; the stretchers to be not more than 4 feet in length, and 1 foot 6 inches wide. The beds of the stones to be all worked fair, and the joints squared the width of the stretchers, and the face of them clean-tooled. The wing-walls to be built curvilinear on the plans, finishing with octangular piers, and battering in a curve line 3 feet in the whole height; the joints to be rusticated.

"The hearting of the abutments, that is, between the outside courses to be worked, to fall in with the radii of the arch, as shown on the section. The stone composing this part of the abutments, to be about 1 foot thick where they terminate at the bottom, and when they extend to require stones more than 18 inches thick, they may be in two courses if required; the stones must average not less than 2 feet upon the beds, and from 3 to 4 in length; the beds to be fair dressed by a tool draught round, and dressed off between with a pick; the headings and side joints squared and set in proper bond as before expressed; and when one course is set, it must be dressed off fair to its radii, and grouted before another course is begun.

"The springing-stones, that is, those on which the springing plates of the arch are to rest, to be 4 feet on the face on which the plates rest; the projection, or string-course, to be worked on the same stones. These stones to be not less than 3 feet on the beds.

"The cornice and plinth of the wing-walls, and piers, to be worked according to drawings, that is, to match the iron cornice. The caps of the piers and cutwaters to be each in one stone, and worked as shown on the drawings.

"To be a puddle of clay 3 feet thick put in against the back of the abutments, and wing-walls carried up with the masonry as it proceeds, and filled in behind with spoil (got out from the foundations) to the extent of the wing-walls, and well rammed down to keep the puddle in its proper place.

"The stone to be used for the works to be got from Tixall or Western quarry, or any other of as good a quality; it must be free from clay-holes or dry rents, and all to be set on its natural or quarry bed.

"The mortar to be composed of barrow lime and river or drift sand, two parts of sand to one of lime; mixed up in small quantities, as it is used, with as little water as possible, and well beat with a beater before it is used. The grout must be made with the same lime mixed up with coarse sand and small gravel, in the same proportion as above mentioned.

"The contractor must find all materials, tools and utensils, for his part of the work, and shall not let any part of the work, except quarrying the stone, and carriage of the same and other materials, to any person, but the whole to be done by men on day-wages. The excavating the earth for the foundations, to be done by the county.

"The works are to be done under the superintendence of the surveyors of the public works for the county of Stafford, or such surveyor as the justices assembled in quarter sessions shall at any time hereafter appoint; and should it at any time appear during the execution of any parts of the works to such surveyor, that the contractor is neglecting or doing any part of the work contrary to the true meaning and intent of this specification, the magistrates shall have it in their power to take the work out of his hands, and employ others to finish it; and what money may be due to the said contractor, to remain in the hands of the treasurer of the county till the whole is completed; and any loss that may be sustained by the neglect or misconduct of the said contractor, to be paid for out of it.

"*Iron work.*—Specification of the iron work for a bridge intended to be erected over the river Trent, at a place commonly called High Bridge, near to Handsacre, in the county of Stafford:—

"Upon each abutment is to be a springing plate of cast-iron, each cast in one piece, and to have shoulderings and sockets to receive the ends of the ribs. Each plate is to be of the form and dimensions as shown upon the drawings. The back of each socket, or the part against which the ends of the ribs will abut, is to be clipped, and made to have a true and even face to the exact radius of the arch.

"There is to be but one arch of 140 feet span, and rising 14 feet; the arch is to be composed of 5 ribs, each cast in 7 pieces of equal lengths. The ribs are to be 36 inches deep, in the direction of the radius, and of the exact shape and dimensions as shown upon the drawings. The parts of each rib and the ribs are to be connected by cast-iron tie or connecting plates, each cast in one piece, and passing quite across the arch; the parts composing each rib are to have flanges cast upon each of the ends which abut against the connecting or tie plates, and are to be secured to them by 3 inch square threaded wrought iron screw-pins in each flange. Each flange is to be clipped, and made true over the whole of its surface to the exact radius of the arch, so as to have a solid and true joint. The ends of the parts of the ribs which are to be fixed in the sockets of the springing-plates are to be clipped, and made true over their whole surface of section, so that they may have a sound, solid, and true abutting joint. The parts of each tie or connecting plate against which each part of the rib abuts, must, for the whole area of each flange, be made to the exact radius of the arch, and be clipped and made to have a true and even face. Joggles are also to be cast upon each tie or connecting plate, which are to fit into the joggles cast on the ends of the parts of the ribs. Both the male joggles upon the tie or connecting plates, and the female joggles at the ends of the ribs, are to be made to the radius of the arch, and clipped, and made true over their whole surface, so that each joint may be solid and true throughout.

"Upon the top of each of the ribs is to be a shouldering, running its whole length, having sockets to receive the joggles upon the bottom of the spandrils. Diagonal braces of cast-iron, of the same section, form, and dimension, and disposed in the manner as represented in the drawings, are to be used; each of the parts composing the braces are to abut against the ribs in the situations and in the manner shown upon the drawings, and secured to them by keys and cotters, or wedges, filed, and made true upon their edges; the parts of the braces which abut against the ribs, and also the face of the snugs or bed-pieces, cast upon the ribs to receive them, must be chipped so that they may have a true solid joint.

"The spandrils are to be of the same form and dimensions as shown upon the drawing. The spandrils over each rib are to be the same in every respect, excepting that upon the outside face of the outside spandrils a fillet must be cast, running round each opening, as shown upon the drawing; the fillet to be $1\frac{1}{2}$ inch wide, and projecting $\frac{3}{4}$ of an inch upon the bottom of the spandrils; at the point of each lozenge must be cast joggles to fit into sockets on the tops of the ribs. Ears also to be cast at the same place; the situations of the joggles and ears marked upon the drawings. At the central intersection of each lozenge there must be a brace running quite across the bridge; each must be done as shown upon the drawings, viz., having a wrought-iron screw bolt $1\frac{1}{2}$ inch in diameter, passing through cast-iron tubes, with washer, plates, &c., quite across the bridge. These braces are to be placed in the situations as marked upon the drawings. The spandrils may be cast in any convenient lengths, and connected by flanges of proper strength, and $1\frac{1}{2}$ inch wrought-iron screw-pins.

"The outside spandrils are also to have a flange cast on their tops, running the whole length of the bridge, to bed the cornice, &c., upon.

"The cornice is to be of the same form and dimension as shown upon the drawing, having strengthening pieces cast inside, not farther asunder than 3 feet. It must be cast in lengths not exceeding 9 feet; and each piece is to be connected to the other by internal flanges and three $1\frac{1}{4}$ inch wrought-iron screw-pins in each joint. The bottom of the cornice will lie upon a flange cast upon the top of the outside spandrils, and be secured to it, and the road-plates $1\frac{1}{4}$ inch wrought-iron screw-pins, two in each road-plate.

"The plinth is to be of the dimensions and form as shown upon the drawings; it must be cast in lengths not exceeding 8 feet 6 inches, each piece to be connected to the other by a dove-tailed joint. Ears are also to be cast on the bottom of each side, to secure it to the top of the cornice by $1\frac{1}{4}$ inch wrought-iron screw-pins, not more than two feet asunder. Sockets are to be cast in the top of the plinth, to receive.

"The palisade bars are to be $1\frac{1}{4}$ inch square, placed arris-ways, and not more than 6 inches asunder from centre to centre. The handrail is to be of the same dimensions and form as shown upon the drawings, having sockets cast on the under sides to receive the tops of the palisade bars; and it is to be screwed to the top of every sixth palisade bar, with a counter-sunk headed screw, and it must be secured or connected with the pedestals in the manner shown upon the drawings. The pedestals are to be of the same dimension and form as shown upon the drawings, having sunk panels on the front and back; internal flanges to be cast on the top to receive the handrail, and the caps are to be put on with counter-sunk headed screws. Brackets are also to be cast on each side of every sixth palisade bar, of the same form as shown upon the drawings, and secured by screw-pins to the plinth.

"The covering or road-plates are to be reticulated, and of the same dimension and form as shown upon the drawing, having flanges cast on their under sides to receive the bearers or tops of the spandrils; they are to be secured to the top of the centre spandrils, and to the flanges cast on the top of the outside spandrils, by $1\frac{1}{2}$ inch wrought-iron screw-pins, two in each joint. They are also to be connected to each other by flanges cast on their under sides, and two $1\frac{1}{2}$ inch wrought-iron screw-pins in each joint.

"None of the castings are to be run from the blast-furnace, but the whole work must be made from good No. 2 pig-iron, of a quality satisfactory to the surveyor or surveyors of the works of the county of Stafford. All the screw-pins, nuts, washers, keys, cotters, wedges, &c., are to be made of the best malleable iron. All the joints are to be made in a good workmanlike manner; and the whole of the work must be fitted and fixed at the contractor's works, and inspected by the county surveyor previous to its being sent off. All the work must be moulded, wrought, fitted, and erected, in a substantial and workmanlike manner, and to the entire satisfaction of the county surveyor or surveyors.

"The contractor must find and pay for all patterns, materials, tools, cement, tackling for fixing his work, and all other utensils or requisite things connected with the construction and fixing his part of the work. The estimates are to be given in a gross sum, and must include carriage of all materials to, and fixing the work at, the place of the intended erection.

"The county of Stafford will be at the expense of the whole of the masonry of the abutments, and cutting and letting in the iron-work into the masonry, and will also provide centering for turning the arch.

"Should any alteration be made hereafter in the dimensions or method of executing any part of the work, the extra price or deduction, whichsoever it may be, shall be agreed upon by the contractor and the county surveyor or surveyors, before such part or parts of the work are put in execution. But such alterations shall only be considered as affecting the matter or object thus specified, and not have any tendency to annul the general contract.

"The whole of the works are to be under the superintendence of the surveyor of the public works of the county of Stafford, or of such surveyor or surveyors, person or persons, as the justices assembled in quarter sessions shall at any time hereafter appoint. And should it appear, at any time during the execution of the works, that the contractor is neglecting, or doing any part contrary to the true spirit and meaning of this specification and drawings attached, then the magistrates shall have it in their power to take it out of his hands, and employ any other person or persons to complete it; and what money may remain due to him shall remain in the hands of the treasurer of the public stock of the county of Stafford till the whole work is completed; and any loss that may be sustained through the neglect or misconduct of the said contractor, to be paid for out of it.

"The whole of the work must be delivered, fixed, and completed, on or before the day of in the year

"The bridge was erected in the year 1830. The total weight of iron-work, which was executed by the Colebrook Dale Company, was 340 tons.

The whole cost of the bridge was as follows:—

Iron-work, delivered, fixed, and completed . .	£3,800 0 0
Masonry	3,193 0 0
Foundations, which were piled according to the most approved method; and the approaches, which are of considerable length and height	2,500 0 0
Total, ...	£9,493 0 0

We come now to the erection of one of the most celebrated structures in the world—the iron bridge over the river Thames—Southwark Bridge. This splendid work crosses the water between London Bridge and Blackfriars. The spot seems to have been well selected, and great improvements and alterations, particularly on the Surrey side, have taken place in consequence of its erection. Southwark Bridge was built in compliance with an act of parliament obtained by a company of proprietors in the year 1811, but not without great opposition on the part of Sir William Curtis and others. The first stone of the south pier was laid by Lord Keith, on the 25th of May, 1815, who, with the gentlemen of the committee of management, partook of a cold collation on a temporary bridge erected on the works. On the 7th June, 1817, the Right Honourable Matthew Wood, as Lord Mayor, laid the first stone of the northern abutment, and the works were then carried on with great energy. The whole was completed in something less than five years, and opened to the public at midnight, in April, 1819.

The arches of this gigantic edifice are of the largest span of any known to exist. The soffits consist of solid masses of cast-iron, of a depth similar to the voussoirs of a stone bridge, and exhibit the first instance in which such a bold plan has been carried into effect. The middle arch rises 24 feet, with a span of 248 feet, and is 4 feet wider than the famous iron bridge at Sunderland. It is composed of eight ribs, riveted to diagonal braces; each principal rib being 6 feet deep at the top of the arch, and gradually extending to 8 feet at the abutments, or parts that rest upon the stone-work. Its whole height above low-water mark is 55 feet to the roadway. The other arches are similarly formed; the span of the two side ones being 210 feet. The abutments are of solid masonry, laid in radiating courses, with large blocks of Bramley-fall and Whitby stones. Vertical bond was adopted, running through every two courses at intervals, thereby giving to the whole mass a solidity perfectly immovable. The masonry of the piers, in like manner, was carried up with horizontal and vertical courses to the springing of the arches; from which points they radiate in a wedge-like form. These piers are 60 feet high from the bed of the river to the top of the parapet, and 24 feet in breadth. The foundations of this bridge were laid in coffer-dams, which were of necessity made very strong, from the irregularities of the bed of the river at this spot. The dams were elliptical in form, and were constructed of three rows of piles of whole timber. In the spaces occupied by the base of the masonry of the piers, a row of whole timber sheeting piles were driven all round the outer edge of the offsets, making, as it were, a square internal dam. These piles, while they formed a secure barrier to the foundations of the piers, acted as a powerful auxiliary to the main dam in securing its base. The centerings on which the arches were turned were of very ingenious construction; and with such skill was the whole work designed and carried into execution, that the settling of the centre arch was only 1 inch and 7-8ths. The bridge is 718 feet long between the abutments, and 42 wide between the parapets. The width of the roadway is 28 feet, with footways 7 feet wide on each side. The weight of metal in the centre arch is 1,665 tons; in the side arches, 2,928. The total weight of iron in the whole structure is stated to be about 5,780 tons.

This noble bridge was designed and executed by the celebrated Rennie. The whole of the iron castings were made at the extensive works of Messrs. Walker and Company, at Rotherham, and there put into arches before being shipped to London. The masonry was executed by Messrs. Jolliffe and Banks. The cost of the whole, including its connecting avenues, amounted to nearly £800,000.

Iron bridges had, about this time, also attracted the attention of the French engineers; and the following description of the Pont des Arts at Paris will be interesting, not only from its being the first iron bridge erected in France, but also from its presenting much novelty of design.

The Pont des Arts was designed by M. de Cossart, the inspector-general of roads and bridges, but some variations were afterwards made from the original design by M. Dilon, to whom the execution of the work was intrusted.

The bridge is a nine-arched structure, the width between the piers measuring between 56 feet $9\frac{1}{2}$ inches, and the thickness of the piers themselves, 6 feet $4\frac{1}{2}$ inches above the footings. Each arch consists of five ribs, 7 feet $11\frac{3}{4}$ inches apart from centre to centre, each rib forming a large cast-iron arch, $6\frac{3}{8}$ inches in depth, and $3\frac{8}{16}$ inches in thickness, formed of the two beams meeting at the crown of the arch. The extremities of the arch rest on skew-backs of cast-iron, embedded in masonry at the top of the piers. The chord of the arc measures 60 feet $8\frac{3}{4}$ inches, and the versed sine 10 feet 8 inches. The smaller arches of iron are turned over the piers springing from the haunches of the adjacent principal arches, and supporting the roadway above the piers. Upright supporters are carried from the centre of the piers to the crown of the small arches, and are strengthened by struts supported on the larger arches. The ribs of each arch are bound together by tie-rods fixed to the top of the large arches. At first, the upright supports of the smaller arches were connected by only one cross-piece, and had no braces in the upper part; but owing to the visible effect produced upon the bridge by a large number of persons crossing suddenly from one side to another on the occasion of some public spectacle, it was deemed expedient to insert additional braces. The general appearance of the bridge is very good—especially for a foot bridge—for which purpose it is admirably adapted. It is of exceedingly light and elegant appearance, as also of skilful and scientific construction, and would form an excellent model for a bridge not subject to any great strain.

Iron arch-bridges of various dimensions have, since the completion of the great works we have described, become so numerous, that it is impossible, as indeed it is unnecessary, to describe or enumerate them. With the extension of railway works, however, it became apparent that some modification of the ordinary form of those bridges was desirable. It is well known by persons conversant with railway matters, how much trouble engineers have to encounter in arranging the crossings of the numerous roads, &c., by which a line of railway is intersected in its course over an extent of country. Either in passing over or under the line, there is frequently great difficulty in obtaining sufficient height, or "headway," as it is termed, for the railway trains to pass under the road-bridge, as in the former case, or for the road traffic to pass under the railway, as in the latter case. As the legislature imperatively requires a certain headway should be given, and will not permit any alterations in the levels of roads which shall increase their acclivities beyond a certain extent, immense expense has been entailed on railway companies in fulfilling all these required conditions.

The desideratum for railway-bridges then was the means of adapting iron to the construction of bridges perfectly flat, or in which might be preserved the minimum distance from the under side, or soffit of the girder, to the level of the roadway above. Bridges of this kind, it is true, had been built of timber, that is, simply of horizontal beams laid across the opening to be spanned; but the application of cast-iron girders in the construction of bridges, had as yet been made only to those of very limited span. For, the maximum length of bearing to which single cast-iron girders, liable to be loaded with heavy weights, could be safely applied, having been commonly taken at 40 feet only, it followed that the use of these girder bridges was necessarily much restricted. The convenience of this form of structure, however, was so obvious, and so desirable was it to extend its application to bridges of larger span, that attempts were continually made to combine in every variety of construction wrought-iron with cast metal, in such a manner as should impart to the compound structure the power to resist the extension of wrought-iron itself. A paper, by Mr. John Storey, describing an ingenious mode of so combining malleable iron bars or rods with cast-iron girders, and thus forming as it were a kind of metal trussing, was read at one of the meetings of the Institution of Civil Engineers.

The author states, "that his attention has been long directed to the extensive construction of the brick and stone bridges usually erected over and on the line of railways, and the apparent want of durability in the timber-bridges, which have in some instances been substituted; as well as to the cast-iron bridges, which have generally been constructed in situations where the height between the top of the rails and level of the roads which they span, were so limited, as not to admit of a stone or brick arch. In the latter case, cast-iron girders have been employed, but their great weight has rendered them expensive, and has obliged the abutment-piers for supporting them to be very substantial.

In order to obviate these objections, the author has introduced combinations of cast and wrought iron in forms which he contends may be advantageously adopted for occupation-bridges, or even for carrying the railway, and that they may be constructed at a less cost than stone, brick, or even timber bridges. These bridges consist of longitudinal and segmental girders of cast-iron, abutting against each other at the ends, secured together by bolts and nuts through the flanges, and resting on masonry abutments; a system of wrought-iron tie-trussing is then applied, and struts are placed at certain distances where they are requisite. As many of these principal trusses are used as the strength of the bridge demands, and they are connected by transverse braces, and distance-pieces of cast iron, thus preventing undue outward pressure, sockets are cast upon the girders to receive the timber joists, and the platform is covered with Dantzic deal planking spiked to the joists. The wrought-iron struts at the top, clasp the girders, to which they are also firmly bolted, and their lower extremities pass through the truss, so that on the nuts being screwed up, the truss is brought to its proper degree of tension, and being made sufficiently strong to bear the weight calculated for the bridge, independent of the segmental girders, the weight and strain are brought upon the abutments in the most favourable manner. Bridges thus constructed do not require any centering for their erection, as each side may be put together near the spot, and, by means of purchases, may be lifted entire on to the abutments, or the whole bridge may be put together before the earth is excavated from between the abutments, excepting only as much as is necessary for receiving the trussing.

The dimensions are given of occupation-bridges calculated to bear 8 tons, which is stated to be a greater weight than is required by the land-owners. The total weight of cast and wrought iron in an oblique bridge of a span of 86 feet 3 inches, and 11 feet wide, is 11 tons 7 cwt.. and that of a square bridge of 106 feet 6 inches span and 11 feet wide, is 14½ tons; their total cost, including excavating the ground, the masonry, stone penning on the sides of the excavations, the timber-work, and the painting, was for the former £280, and for the latter, £342; these sums are stated to be much less than the expense of similar bridges of stone, or even of timber.

A design is also given of a stronger kind of bridge of similar construction, for carrying two lines of railway. The span is 90 feet, and the width 22 feet between the side railings. The weight is 43 tons, and the total cost, including the masonry, is estimated not to exceed £1,200. It is calculated to bear about 50 tons, which is as much as could be brought upon it by any passing train.

Numerous railway-bridges have been erected within the last few years, in a similar manner to that suggested by Mr. Storey, and also by other engineers. Many of these designs show much ingenuity, and great variety of arrangement, and exhibit almost every form of combining wrought with cast iron. A bridge of a very novel construction, however, requires particular notice, not only from the boldness of its design, but from its being, we believe, the first application of the suspension principle to a railway-bridge.

The iron tie-bridge over the Regent's Canal at Camden Town, on the line of the London and Birmingham railway, is one of the most ingenious structures on the whole line, and was designed by Mr. Fox, one of the resident engineers, for the purpose of conveying the railway at an elevation of only 13 feet above the surface of the water, and with a span of not less than 50 feet. The structure consists of three main cast-iron ribs, each composed of two large castings, extending the whole width of the opening, and having a bearing at each end of 4 feet. These minor ribs are connected together by transverse iron bracing. The pedestals on which the ribs take their bearings, are 10 feet long, 6 feet wide, and 30 feet high, and are built of brick and stone, founded on a bed of concrete 2 feet in thickness. Eight cross girders run from either side main rib to the centre main rib, from which they are severally suspended at each end by vertical rods and keys. The girders are of fish-bellied form, and are each 28 feet in length, and 2 feet deep in the middle. The thrust of each arch is sustained by wrought iron tie-bolts running from end to end of the ribs. To the front of the ribs is bolted open ornamental work, which gives to the whole a pleasing appearance. The extreme width of this bridge is 60 feet. The rails over the bridge are set in chairs, and bolted thereto. The chairs are fixed on oak slabs running longitudinally, and resting on the tops of the girders. The side and intermediate spaces, and also the space beneath each pair of rails, are covered with iron gratings, furnished with flanges underneath to strengthen them.

A good example of cast-iron compound girder bridge trussed with malleable iron bars, was erected some years since over the river Lea, on the line of the Northern and Eastern railway. This bridge is formed with girders, each girder being 70 feet long, and made of two castings, joined at the centre by bolts passing through vertical flanges. Upon the meeting ends of the two castings, are cast dove-tailed projections, or bosses, with wrought-iron clips fixed over them.

"These bosses give additional security to the joinings of the castings. Each girder is perfectly horizontal from end to end, and the top and bottom lines parallel. The girders are 36 inches in depth, with bearings on the abutments of 2 feet at each end; the clear span between bearings being 66 feet. The sections of the castings shows a vertical rib, and projecting flanges at top and bottom. The truss bars are arranged in sets of 4 bars on each side of the girder, and pass obliquely downward from the top of the girder over the bearings at either end, to the under side of the girder, at a distance of about 11 feet short of the centre. The space between of 22 feet has horizontal truss-bars passing beneath; both horizontal and oblique bars are secured by bolts or pins 3 inches in diameter, passing through projecting saddles under the lower flange of the girders. The bars at their upper extremities pass through sockets cast upon the girders, and are keyed through them."

It would be easy to multiply examples of iron bridges, many of them possessing great merit; but the lamentable failure of some large bridges of this construction, has, within the last few years, led to the conclusion, that some radical defect existed in these compound constructions.

This defect evidently consists in the impossibility, in structures of this kind, of connecting wrought and cast iron in such a manner as to bear equally the strain of such a load as a railway train, passing over at a high velocity. This became fatally apparent in the failure of the largest bridge of this kind, erected over the river Dee, near Chester, and on the line of the Chester and Holyhead railway.

"This bridge, which crosses the Dee at an angle of 48 degrees, consists of 3 spans or bays, each 98 feet wide in the clear, the three series of girders forming the bridge being supported on two abutments of masonry, one at either end, and two intermediate piers. The width of the bridge is formed by 4 of these girders, placed parallel to each other, in 2 pairs, one roadway or railway being supported between each pair of girders, and formed of 4-inch planking laid upon transverse balks of timber, which rest upon the bottom flange of the girders. The girders are secured transversely from moving outward or away from each other by tension-bars, fitted at the ends to dove-tailed sockets, cast upon the girders. The entire bridge thus comprises 12 girders, each having a clear span of 98 feet, and a total length of 109 feet; that is, including a bearing at each end of 5 feet 6 inches in length. Each of these girders, 109 feet long, is composed of three castings, or lengths, having a uniform vertical depth of 3 feet 9 inches. The dimensions of the section are as follow:—vertical rib or web, $2\frac{1}{8}$ inches thick; top flange, $7\frac{1}{2}$ inches wide, and $1\frac{1}{2}$ inch thick; bottom flange, 2 feet wide and $2\frac{1}{2}$ inches thick. The sectional area of the top flange, including the moulding, is equal to 14 square inches; of the bottom flange, including the moulding, 66 square inches; and of the rib, 80 square inches; making a total uniform sectional area of 160 square inches. The joints of the three castings, in each girder, secured by wrought-iron bolts, passing through flanges, are strengthened by additional cast-iron joint plates, 3 feet deep at the centre, over the joint, and 13 feet in length, bolted to and scarped over the top flanges of the castings, over a length of 6 feet 6 inches upon each; dove-tailed bosses, cast upon the lower flanges, are also secured with clips of wrought-iron.

"The total depth of the girders, at each joint, is thus increased to 6 feet 9 inches. Similar plates of half the length of those over the joints, are also bolted over the ends of each compound girder; and the vertical inclination of the truss-bars, from the top of the girder at each end of the bottom of it at the joints, is thus increased to about 6 feet. The malleable iron truss-bars are arranged in sets of 4 each, 1 set on each side of the girder, each bar being 6 inches wide and $1\frac{1}{4}$ inch thick, put together in lengths or long links, similar to those used for suspension bridges, and secured by bolts at the joints of the girders, passing through the cast-iron girder and the 8 wrought-iron bars. The upper ends of the bars are secured with wrought-iron keys, driven through the bars and the casting, so as to tighten them well up in their position. By the great length of the girders, and the comparatively small depth thus afforded for the trussing, the action of the bars is reduced to nearly a horizontal direction, and their power to avert deflection in the girders is thus much diminished. Besides this, it must be remarked, that the sectional area of the bars is much less when compared with the total length of each girder, than in all smaller structures on this principle; and the relative effect of any increase of temperature in extending their length, and thus reducing the effectiveness of their assistance, is similarly augmented."—*Dempsey, Treatise on Iron Girder Bridges.*

The failure of one of these girders was ascribed to various causes, and much discussion on the subject took place at the time; but to whatever the accident in this particular case might be attributed, the inherent weakness of such combinations of wrought and cast iron became perfectly clear.

The attention of the government having been for some time past, by this and similar failures of iron girder bridges, directed to the subject, a commission was at length appointed to inquire into the whole question of the application of iron to railway structures. In the evidence given before this commission, will be found an immense mass of valuable information, obtained under all the advantages of a Board so appointed; and although in their report the commissioners do not express any very decided opinion on the merits of the various forms of construction so strongly recommended to them, there is much practical knowledge to be gained by a careful perusal of the evidence and examination of the ingenious plans attached to it. We shall now proceed to give some extracts from this report:—

"The simplest bridge," observe the commissioners, "and that which admits of the greatest possible headway at a given elevation, is, undoubtedly, the straight girder bridge.

"The length of a simple cast-iron girder appears to be limited only by the power of making sound castings, and the difficulty of moving large masses. Thus the practical length has been variously stated to us as 40, 50, and 60 feet. The form resulting from Mr. Hodgkinson's former experiments on this subject is universally admitted to be that which gives the greatest strength, but the requirements of construction compel many variations from it, especially in the ratio between the top and bottom flanges. Moreover, the convenience and the necessity of keeping the roadway for rails as low as possible, has introduced a practice of supporting the beams which sustain the rails upon one side of the bottom flange. The pressure of the roadway and of the passing loads being thus thrown wholly on one side of the central vertical web of the girder, produces torsion (which is not always taken into account in determining the proportions of the girder.) The existence of this torsion is admitted on all hands, and various schemes are employed to counteract and diminish it; but the form of a girder that will effectually resist this disturbing force without incurring other evils, still remains a desideratum.

The requisite length of girders is increased considerably by the excessive use of skew bridges, and it is much to be regretted that difficulties should often be thrown in the way of altering the course of existing roads and canals when the line of a proposed railway happens to cross them at an acute angel. Partly from these causes, and partly from a little indulgence in the pride of construction, skew bridges may be found, of which from the obliquity of the bridge, the girders are more than double the length that would be required by the direct span of the opening to be crossed.

When the span of the opening, or other circumstances, render the use of single straight girders unadvisable, straight girders built up of several separate castings bolted together, and sometimes trussed with wrought-iron tension rods, are largely employed, and necessarily with great varieties of construction. By these means the girders may be extended to spans of upwards of 120 feet.

When wrought-iron is combined with cast-iron in the manner of trussing, several difficulties arise from the different expansions of the two metals, and the difference of their two masses, which causes the wrought-iron rods to be more rapidly effected by a sudden change of temperature than the cast-iron parts. The constant strain upon the wrought-iron tends to produce a permanent elongation, and hence tension-rods may require to be occasionally screwed up. We have sought for opinions and information upon all these questions, and these show that the greatest skill and caution is necessary to insure the safe employment of such combinations. It is not admitted that the vibration of railway trains would loosen or injure the bolts or rivets of compound girders. Nevertheless, wood, felt, or other similar substances, have occasionally been introduced between surfaces, to diminish the communication of vibration.

The general opinion of engineers appears to be, that the cast-iron arch is the best form for an iron bridge, when it can be selected without regard to expense, or to the height above the river or road which is to be crossed. For low bridges the bowstring girder is also strongly recommended. Lattice bridges appear to be of doubtful merit.

We come now to the description of that new mode of construction introduced by Mr. Stephenson and his able coadjutors, and perfected in the magnificent structures to which the public attention has been so long directed, the Conway and Britannia tubular bridges :—

The application of iron in this form of bridge consists in the riveting together boiler-plates as in iron ship-building, combined in various ways with cast-iron. Hollow girders are thus formed, which are either made so large as to admit of the road and carriages passing through them, as in the bridges above described, or else these tube girders are made on a smaller scale, and employed in the same manner as the ordinary cast-iron girders, to sustain transverse joists which carry the road. The first kind is applicable to enormous spans, those of the two bridges above-mentioned being 400 and 462 feet respectively. The second kind are said to be cheaper and more elastic than other forms, for spans that exceed 40 feet. These methods appear to possess and to promise many advantages, but they are of such recent introduction, that little experience has yet been acquired of their powers to resist the various actions of sudden changes of temperature, vibrations, and other causes of deterioration. The eminent engineers examined before the commissioners, however, very generally expressed opinions favourable to the tubular form of bridge.

Before proceeding to describe the Britannia and Conway Bridges, it may be desirable to give a slight sketch of the circumstances which led to their erection :—

In the session of 1844, a Joint Stock Company proposed to parliament to undertake the construction of a railway from Chester to Holyhead, in continuation of lines already made. The bill introduced for this purpose contemplated the use of Telford's celebrated suspension bridge over the Menai straits, as the means of conveying across the railway, carriages and waggons, divested of the ponderous locomotive engine. The Commissioners of Woods and Forests, however, who had the jurisdiction of the bridge, would at first only consent to this proposal as a temporary measure, and afterwards objected to its being made use of at all. The company not being prepared with any plan for a permanent bridge, were obliged to content themselves with an act of parliament which gave them power to construct a railway from Chester to Bangor, and through the Isle of Anglesea to Holyhead, leaving an hiatus of five miles at the Menai straits. The means of filling up this break was reserved for future consideration, and for a permanent bridge to be sanctioned by the act of a subsequent session. In the following autumn, Mr. Robert Stephenson, the engineer of the company, prepared plans for a cast-iron bridge of two arches, each having a span or clear width of 350 feet. The height of each arch was to have been 100 feet at the crown, and the total cost of the bridge would have been £250,000. The Britannia rock, about a mile to the west of the suspension bridge, was selected as the most eligible point for crossing the straits ; but in consequence of the rapid current, and other circumstances of difficulty which exhibited themselves at this point, added to the necessity of interfering as little as possible with the navigation of the straits, Mr. Stephenson proposed to build the arches of this bridge, not upon supports from beneath, as is usually done, but by stringing on, as it were, a series of iron blocks or vertebræ from each pier, until they should meet in the middle, in a way somewhat similar to those which had been proposed in former years by Mr. Telford and Sir J. Brunel. The railway company made their application to parliament in the session of 1845, in order to obtain power to construct this bridge. The company, however, found themselves strongly opposed, not only by parties interested in the navigation of the straits, but by others whose interest lay in driving them to Port Dynllaen. An appeal was then made to the Lords Commissioners of the Admiralty, as conservators of the navigation, and after a lengthened inquiry, the bridge proposed by Mr. Robert Stephenson received their lordships' veto, and a form of structure was prescribed, which should leave a clear opening of not less than 450 feet over each of the two navigable channels on each side of the Britannia rock, with a height of 105 feet above high-water over 370 feet of that opening, the remaining 80 feet being allowed to have less height, so as to admit of the construction of an arch of that form, should it be desired by the company.

It was this that led to the grand and untried design of the present rigid wrought-iron tubular bridge, which Mr. Robert Stephenson, after great thought and labour, assisted by Mr. Fairbairn, Mr. Hodgkinson, of the Royal Society, Mr. Edwin Clarke, the engineer of the works—gentlemen well known for their mathematical and scientific attainments—matured. The entire length of the stupendous structure is 1,841 feet from end to end, consisting of four large sections, the two side-tubes being each of them 230 feet long, and the two middle ones 460 feet each. When originally proposed before the committee of the House of Commons, the plan was received with general incredulity. The word "tube," it may here be observed, is not one of the best epithets that could be used to describe the structure, seeing that the bridge, instead of being round, is a perfect square. Though almost a misnomer, the name arises from the circumstance of the experiments that were to decide the form of the bridge, having been made with cylindrical, elliptical, and rectangular tubes; but in reality, the structure, as it now rests on the banks of the Menai, the site of its construction, is one immense closed-in iron corridor, forming a horizontal iron gallery or passage, within which the rails for the trains are to be placed, and 450 feet in length. It is hollow from end to end, and would, if filled with shops, and lighted by sky-lights, make a Burlington Arcade.

A structure of this kind, though on a rude and miniature scale, appears to have existed for years on the Cambridge line of the Eastern Counties Railway; and Mr. Stephenson, the originator of it, amplifying upon this, designed the present tube. A long series of experiments, by engineers and mechanics fully conversant with such researches, were made, directed to the ascertaining—divested of all preconceived ideas—the strongest form for a sheet-iron tubular bridge; and the inquiry, in addition to the more immediate object it had in view, has been of immense public service in determining the strength of the materials used in the formation of railways. These experiments have been extremely laborious, and very costly. In the course of them, the remarkable fact has been disclosed, that the power of wrought-iron to resist compression is much less than its power to resist tension, or exactly the reverse of that which holds with cast-iron; and the important fact has also been arrived at, that rigidity and strength are best obtained by throwing the greatest thickness of material on the upper side. While the cylindrical tube, with a given weight, was ruptured by tearing asunder at the bottom, the elliptical showed weakness at the top: both were consequently discarded; and the rectangular tube, which indiacted strength of a higher order, and greater rigidity, was adopted. The result of every recent experiment on this species of structure, on a small scale, over the Conway, are very interesting, as confirming the accuracy of the original calculations. Measured by a cord-line in the inside of the tube, formed by the axis of a powerful telescope fixed to its side, the deflections have been made with a weight of 52 tons, 0·48 inch; 112 tons, 0·98; 173 tons, 1·30; 235 tons, 1·47; and on the removal of these loads, the tube has recovered its rigidity in ten minutes. The tube is constructed to bear, in addition to its own weight, 2,000 tons, a load ten times greater than it will ever be called upon to sustain. The deflection caused by trains and locomotives passing at full speed is very slight. A weight of 300 tons has produced a deflection of 3 inches. A very remarkable phenomenon is connected with this huge mass of iron of 1,600 tons, caused by changes of temperature in the weather, which affect it like a thermometer. A little sunshine raises the centre an inch, and produces a horizontal deflection of an inch and a half.

Its great length, and the nature of its material, so sensitive to temperature in the peculiar form that it takes, causing it to expand .0001 of its length, or ½ an inch for each increase of 50° of Fahrenheit, and contracting in the same ratio, is the assigned cause of its being such a delicate thermometer. Alternate sunshine and showers of rain cause these tubes to expand and contract; and one of them, if placed on end in St. Paul's churchyard, would be 107 feet higher than the top of the cross. It is calculated that the wind, at a velocity of 80 miles an hour—the rate of a hurricane—would only give a total pressure of 128 tons, distributed over the whole side of these tubes.

We have now to describe the means by which this gigantic structure was raised to its present lofty height, and the enormous towers by which it is supported there.

The spot selected by Mr. Stephenson for the site of the bridge, was at that part of the Menai straits where the Britannia rock rises from the bed of the stream nearly in its centre. On this rock is erected a tower of masonry; at the limit of the water-way on either side of it, similar towers; and on the land, on each shore of the strait, beyond the towers, continuous abutments of masonry. The bridge is therefore supported by the Britannia rock in the centre; at 460 feet from it, on each side, by a tower built in the same manner as that on the rock; and at 230 feet from each of these towers, by the land abutments.

The following description of these masses of masonry is taken from a very interesting little work published by Mr. Weale, "*Treatise on Tubular and other Iron Girder Bridges*," by Mr. Dempsey, C. E.

Britannia Tower.—62 feet by 52 feet 5 inches at the base, and reduced by the batter to 55 feet by 45 feet 5 inches at the height of 102 feet above high-water line, at which level the tubes pass through it. A plinth extends round the base of this and the other towers; and the height of this tower above high-water level is 200 feet, or nearly 230 feet from the bottom of the foundation on the rock. The stone used for the external parts of this, and the other towers and abutments, is a limestone of hard and durable quality, known as 'Anglesea marble.' It is quarried at Penmaen, on the shore, and near the north-eastern extremity of the island, and is 'got' in stones of great size, some of them weighing 10 to 14 tons. The interior of this, and the other masonry, is constructed of red sandstone, which is a soft stone, and therefore easily worked. It is quarried at Runcorn, in Cheshire, and is durable for inside work. The solid contents of this tower, if solid, would exceed 575,000 cubic feet, but it is constructed with hollow spaces or chambers within it, and the quantity of stone said to be actually used in it is 148,625 cubic feet of the limestone, and 144,625 cubic feet of the sandstone. The total weight of the masonry in this tower is about 20,000 tons, and about 387 tons of cast iron in beams and girders are built in it.

"The foundations were laid, and the work up to the level of high-water was constructed, during the intervals of tide, no coffer-dam being employed, and thus some months were occupied in laying the first course, which was commenced in May, 1846. The scaffolding used for this and the other parts of the work, was of whole timbers or balks, put together with iron straps and bolts where required, and braced with diagonal half-balks connecting the upright posts. Parallel timbers were laid horizontally on the tops of the posts, and rails fixed upon them, and upon these rails travelling crabs or 'jennies,' were enabled to pass in both directions, to pick up the stones from the ships, raise them to the required height, and deposit them exactly in their intended places. The stones in the whole of the masonry are left with the quarry or rough face, except at the angles, where they are dressed to a square arris, and in the recesses and top entablature, where they are dressed to a fair face all over."

"*Anglesea and Carnarvon Towers.*—The same dimensions at the base as the Britannia tower, viz., 62 feet by 52 feet 5 inches, reduced by the batter to 55 feet by 32 feet at the level of the bottom of the tubes; height from level of high-water 190 feet, or 10 feet less than the Britannia tower. In architectural design and general appearance these towers exactly resemble the Britannia tower, and they are said to contain 210 tons of cast-iron in beams and girders."

"*Anglesea and Carnarvon Abutments.*—These are also battered similar to the towers, and are 176 feet in length, and of width corresponding to the towers, viz., 55 feet at the level of the bottom of the tubes. The raised part of the abutments, in which the ends of the tubes are supported, are continuous across the railway, forming in fact complete towers, of smaller height than, but otherwise similar to, the towers already described. The remainder of the abutments are built of stone-work externally, but built up internally with longitudinal and cross walls, and intermediate arches of brick-work. Over the two parallel spaces formed between the longitudinal walls, corresponding with the two lines of railway, cast-iron girders are fixed, to support the roadway. The continuations of the abutments are surmounted with parapet-walls of solid masonry and considerable height, each of which terminates at the extremity of the bridge with a projecting pedestal, on which a couchant lion, in the Egyptian style, and of colossal dimensions, faces the approaching visitor, and seems to guard the entrance to the iron wonder behind. Each of these lions is composed of eleven pieces of limestone, and measures 25 feet in length and 12 in height, weighing about 30 tons. 'Repose and dignity' are skilfully blended in the expression, and these lions are probably, in more than one respect, among the *greatest* of the works which the talented chisel of Mr. Thomas is destined to produce.

"The four spaces between the Britannia tower and the towers, and between these towers and the abutments, are, as already described, of two dimensions, viz., two of 460 feet, and two of 230 feet. These four spaces have therefore to be spanned by the iron tubes; and as each tube serves for one line of rails only, 8 tubes are required, 4 of 460 feet net length, and 4 of 230 feet net length: the 4 longer ones being across the water, the 4 shorter ones over the land."

In the completion of the work, however, these several tubes are united together, and (with the short lengths also constructed within the towers, and joined to the other lengths,) forming two lines of tube parallel to each other, each of the length of 1,513 feet, and each line carrying its respective line of rails. The process of building and placing these tubes was conducted as follows:—

The land tubes were constructed in their proper positions, on scaffolding of enormous strength erected for that purpose. The portions of tube intended to occupy the Anglesea and Carnarvon towers, after being completed on the scaffolding at either end, were launched forward to meet the main tubes; while these again were built on the land, floated to the proper place, and then raised by hydraulic presses of immense power, to their destined situation. The method of floating these tubes from the building-stages to the base of the towers, was thus accomplished. Several large pontoons having been provided, they were placed at low-water under the tube to be floated, in such a manner that each end of the tube rested on four of these pontoons. As the tide rose lifting the pontoons, the tube borne by them was also lifted, and safely floated to its proper position, ready to be raised by the hydraulic presses.

The following graphic description, by an eye-witness, of the floating of the first tubes, is too interesting to be omitted. The operations were conducted by Captain Claxton, who, with Mr. Stephenson, and other gentlemen, was on the tube directing the proceedings. "Captain Claxton was easily distinguished by his speaking trumpet, and there were also men to hold the letters which indicated the different capstans, so that no mistake could occur as to which capstan should be worked; and flags red, blue, or white, signalled what particular movement should be made with each. About half-past seven o'clock in the evening, the first perceptible motion, which indicated that the tide was lifting the mass, was observed, and, at Mr. Stephenson's desire, the depth of water was ascertained, and the exact time noted. In a few minutes the motion was plainly visible, the tube being fairly moved forward some inches. This moment was one of intense interest; the huge bulk gliding gently and easily forwards as if she had been but a small boat. The spectators seemed spell-bound; for no shouts or exclamations were heard, as all watched silently the silent course of the heavily-freighted pontoons. The only sounds heard were the shouts from Captain Claxton; as he gave directions to 'let go ropes,' to 'haul in faster,' &c., and 'broadside on,' the tube floated majestically into the centre of the stream. I then left my station, and ran to the entrance of the works, where I got into a boat, and bade the men pull out as far as they could into the middle of the straits. This was no easy task, the tide running strong; but it afforded me several splendid views of the floating mass, and one was especially fine. The tube coming direct on down the stream,—the distant hills covered with trees,—two or three small vessels and a steamer, its smoke blending well with the scene, forming a capital back-ground; whilst on one side, in long stretching perspective, stood the three unfinished tubes, destined ere long to form, with the one then speeding on its journey, one grand and unique roadway. It was impossible to see this imposing sight, and not feel its singleness, so to speak. Anything so mighty of its kind had *never been before; again* it would assuredly be; but it was like the first voyage made by the first steam-vessel, something till then unique. At twenty-five minutes to nine o'clock, the tube was nearing the Anglesea pier, and at this moment the expectation of the spectators was greatly increased, as the tube was so near its destination; and soon all fears were dispelled, as the Anglesea end of the tube passed beyond the pier, and then the Britannia pier end neared its appointed spot, and was instantly drawn back close to the pier, so as to rest on the bearing intended for it. There was then a pause of a few minutes while waiting for the tide to turn, and when that took place the huge bulk floated gently into its place on the Anglesea pier, rested on the bearing there, and was instantly made fast, so that it could not move again. The cheering, till now subdued, was loud and hearty, and some pieces of cannon on the shore gave token, by their loud booming, that the great task of the day was done."

The preparations for performing so important and perilous an undertaking as that of hoisting the enormous fabric, to place it in its permanent position over the straits, were on a scale of immense magnitude. This will be the more readily understood, when it is stated that the total dead weight lifted 100 feet high from high-water mark, was upwards of 2,000 tons, or equivalent to the elevation to that height of upwards of 30,000 men. During the progress of this great work, a general impression appeared to prevail with the public, that when the tubular bridge was *floated*, the whole operation would be completed; but that, if it may be so termed, was a vulgar error. The floating was nothing more than the launch of the great iron ferry to the precise site, where it was to be raised by mechanical power, specially constructed for the purpose, to a height nearly equal to that of the dome of St. Paul's. The stroke of the hydraulic presses employed for the purpose, was 6 feet, that is to say, they were only capable of raising 6 feet at one lift. The tube of 2,000 tons weight was consequently to be sustained while the presses were lowered, and a fresh hold obtained. This sustentation, owing to the immense magnitude of the labour, was effected by building up successive layers of masonry at every 6-foot lift, under the tube, to support it securely in its upright ascent, during which arrangements were made for another 6-foot hoist, until the whole 100 feet were finished. Had it not been for this process of building up, the operation would have only occupied about a day, but as it was, it took a fortnight. The precaution was adopted by Mr. Stephenson and Mr. Clark, to guard against the probability of casualty, seeing that, should any accident occur, the labour of years, and the outlay of half a million of money, would have been inevitably sunk. To insure security, however, some contrivances were adopted, by which the supporting chains, as they rose, were continually followed up by wedges of wood, so that in the event of any accident having arisen to the lifting machinery, no injury, it was expected, would happen to the tube. The mechanical contrivances for the purpose were the largest in the world, and the most powerful ever constructed.

We are enabled, from a close inspection, to give a description of the vast apparatus for hoisting the huge burden. The machine used to effect this, was an enormous hydraulic press, a contrivance invented by Bramah, and used in operations where intense pressure is required. Its construction was of the most simple character, and consisted only of an exceedingly thick and very heavy iron cylinder, like a mortar. A strong piston, or plunger, also of iron, called the ram, and fitted with a leather collar at the shoulder, so as to render it water-tight, worked up and down inside this cylinder. Water was forced into the cylinder by a force-pump, through a small orifice which might be compared to the touch-hole of a gun. The whole secret of the immense power of this machine, consisted simply in the prodigious force with which the water was driven into it, and which in the present instance was so great, that it threw the water to the height of nearly 20,000 feet, which is more than five times as high as the neighbouring noble pinnacle of Snowdon, and 5,000 feet higher than the monarch of mountains, Mont Blanc. It in fact resembled the piston of a steam-engine, but instead of using steam at 30 or 40lb. pressure to the inch, water was used at a pressure of 800 or 900lb. The cylinder of course was of almost adamantine strength, to enable it to sustain and withstand that pressure. The sides of the largest of these presses used in raising the bridge, were 11 inches thick. The weight of the cylinder, which was of cast-iron, in one piece, was 16 tons alone; but the whole machine complete was 40 tons. The ram or piston within it, was 20 inches in diameter, and when worked to its utmost power, would alone be quite capable of raising one of the tubes. The marvellous thing above all was this, that in spite of its immense proportions, its stupendous action was guided and controlled with the most perfect ease and precision by one man. This hydraulic giant was constructed by Messrs. Easton and Amos, engineers of Southwark. It stood on two beams on a lofty sort of eyrie, at the top of one of the towers, whence a grand and open view is obtained of the straits seaward, while its elevation above the ravine was upwards of 200 feet. The press was composed of wrought-iron plates, riveted together at the top of the side towers, where, with its assistant machinery, it occupied a large chamber to itself, about 29 feet above the level to which the bridge had to be raised.

The sensations experienced on looking down from this lofty elevation over the rushing stream of the straits, and the great tubes and machineries strewn round about below, were of a peculiarly impressive character. In addition to this large press, there were two smaller presses, with rams 18 inches in diameter, placed side by side at a similar level on the Britannia tower, and which acted in conjunction with the large press. The chains by which the power exerted by these presses in their lofty position was communicated to the tubes lying at the base of the tower, resembled the chains of an ordinary suspension-bridge, and were similar to those of the bridge at Hungerford. They were manufactured by the patent process of Messrs. Howard and Ravenhill, of London, and consisted of flat links seven inches long, one inch thick, and six feet in length, with an eye at each end, and were bolted together in sets of eight and nine links alternately. The weight of the chains employed in lifting the 2,000 tons, was about 100 tons, far exceeding that of the well-known equestrian statue of the Duke of Wellington at Hyde Park, which has hitherto been regarded as one of the greatest "lifts" of the age. These chains were attached to the tube at two feet from the end, and in order to get sufficient purchase at the part, three strong frames of cast iron were built into each end of the tube. The innermost frame only stiffens and supports the sides, while the tube was resting on its ends. The two outer frames were the lifting frames. The chains were attached to them by three sets of massive cast-iron beams, placed across the inside of the tube, one above another, their ends fitting under deep shoulders or notches in the lifting frames, where they were secured by screw-bolts. As an additional precaution, two very strong wrought-iron straps passed over the upper pair of beams, and descended into the bottom cells beneath the frames, where they were strongly keyed. The weight of these lifting frames and cast-iron beams was 200 tons, and it was even a matter of wonder among the engineers themselves, how machinery could be made strong enough to raise the ponderous load. The way in which the chains were connected with the press, was by an exceedingly thick and heavy beam of cast-iron, strengthened by wrought-iron ties across the top. It rested like a yoke on the shoulder of the ram, and was called the cross head of the press. The two chains passed through square holes at either end of the cross head, and were securely gripped at the top of it by an apparatus called the *clams*, consisting of two strong cheeks of wrought-iron, drawn together by screws like a blacksmith's vice. The beams on which the presses stood, the cross heads, and all the parts that were subjected to a very heavy strain, were either constructed of, or strengthened by wrought-iron, which was found to be less brittle and more trustworthy than cast-iron. As the tube was 12 feet longer, allowing 6 feet at each end, than the distance between the towers in which the presses worked; recesses or grooves were left in the face of each, of 6 feet deep, in order to receive the additional length, and of sufficient width to allow the end of the tube to slide up easily within them. The recesses extended from the bottom of the towers to nearly the height of the hydraulic machines. It was in the low end of these recesses, on a soft bed of timber placed to receive it, that each great tube rested, after being floated there, until the vast mechanical equipments for ballooning it to its permanent level, 102 feet above high water mark, were completed.

The entire completion of this celebrated structure, the wonder and admiration not of a kingdom only, but of the world, perfects the communication between England and the sister country. The interchange of transit, and conveyance of correspondence between their respective capitals, may be daily within the compass of ten or twelve hours. This rapidity of locomotion in the present day may be well contrasted with the slow doings of former times. In 1685 it took the then Lord Clarendon, at that time Lord-Lieutenant of Ireland, from six o'clock in the morning to three in the afternoon, nine hours to get from Conway to Bangor, a distance of 14 miles, while a short time since the distance was accomplished by the present Lord Clarendon, Lord-Lieutenant of Ireland, in exactly twenty minutes. At the same period it took a king's messenger, "by express," six days to get over the ground now traversed between London and Chester, 188 miles, in five hours; and it is but twenty years since, that the same distance by coach took more than twenty-four hours.

These are the immediate advantages; the prospective ones consist in the completion of the great harbour of Holyhead, now being constructed for the Admiralty by Mr. Rendel the engineer, the pier at which is completed, and the breakwater for commencing the vast operations fixed. Should the Admiralty, as has been long expected, on the completion of this harbour, remove to it the West India packets, now starting from Southampton, and the Galway line of railway be finished, the voyage to the United States by this route would be shortened four or five days.

We cannot close this article, and necessarily imperfect account, of the Britannia bridge, without a passing allusion to the unfortunate *difference* that occurred during its progress, between Messrs. Stephenson and Fairbairn. It is greatly to be lamented, that men so eminent for talent should differ as to their respective claims to the conception and execution of so grand a work. It is not for us to presume to settle such claims, but surely each possesses in himself merit so surpassing ordinary minds, that he may well afford to yield a portion of honour to the many competitors who may join with him in the race for fame. A work like this might afford distinction for many minds, and varied talents; to all give honour, where honour is due. Let us then award to a Stephenson the merit justly due to him for his original conception; to a Fairbairn, the unwearied perseverance and the vast practical ability, by which that conception was realized and brought to perfection; to all associated in the undertaking, each in his peculiar walk, the merit of talent, zeal, and untiring industry.

Iron Chain, pieces of iron linked together. Iron chains are very serviceable under the roofs of circular buildings, where there is no intermediate tie, particularly at the bottom of stone domes, in order to prevent them from spreading or pushing out the walls, which, without this precaution, might be subject to separation, especially when the dome has to support an immense turret or lantern of stone. The dome of St. Paul's Cathedral, London, has two chains let into a bondage of Portland stone laid for the purpose.

Iron Girders. Girders of wrought and cast iron have now been used for some years in the construction of buildings, but more especially in the formation of railway bridges, stations, &c. The article on iron bridges will show how extensively they have been applied in that way. Various forms of girders have been recommended, and various methods suggested of combining wrought with cast iron, but these improvements have been more directed to the use of girders in the construction of railway and other bridges, than in buildings. Cast-iron beams for warehouses, and other large buildings, have been used with success.

Iron King-Posts and Queen-Posts, are in many instances preferable to those constructed of wood, and are not more expensive where both bolts and straps are used.

Iron Stone, an ore of iron composed of iron combined with oxygen, silex, carbonic acid, and water. When of a superior quality, it yields near 40 per cent. of iron. In Missouri, United States, iron stone has been found yielding 75 per cent. of metal.

Iron Wood, the popular name of some species of a genus of trees distinguished for their hardness. The *diospyrus ebenus*, or ebony, is sometimes called ironwood.

IRREGULAR, in the art of building, a term applied not only to the parts of an edifice which deviate from the proportions established by antique monuments; as when the Grecian-Doric is made more than six diameters in height, the Ionic more than nine, and the Corinthian more than ten; but also to places where the angles are unequal, and to edifices whose counterparts do not correspond in the several elevations.

A column is said to be irregular, not only when it deviates from the proportions of any of the three regular orders; but when its ornaments, whether in the shaft or capital, deviate from the established forms peculiar to the order.

Irregular Bodies, solids not terminated by equal and similar surfaces.

Irregular Figure, a figure whose sides and angles are not equal.

Irrigation, in agriculture, the art of causing water, by artificial means, to be distributed over the surface of the land, to afford moisture to the plants, &c., where insufficiently supplied with it by nature. Of late years a practice has been adopted, and with great success, of irrigating lands situated near large towns with the sewage-water diverted from the sewers, and conveyed by means of pipes to the required spot. The distribution is then effected in various ways, according to the nature of the ground to be irrigated, and other circumstances.

ISAGON, (from the Greek, *ισος*, *equal*, and *γωνια*, *an angle*,) in geometry, a figure consisting of equal angles.

ISIAC TABLE, one of the most considerable monuments of antiquity, being a plate of copper or brass, discovered at Rome, in 1525, and supposed, by the various figures in bas relief upon it, to represent the feasts of Isis, and other Egyptian deities.

With regard to the history of this monument, we may observe, that the copper or brass ground was overlaid with a black enamel, artificially intermixed with small plates of silver. When, in the year 1525, the constable of Bourbon took the city of Rome, a locksmith bought it of a soldier, and then sold it to Cardinal Bembo, after whose death it came into the hands of the Duke of Mantua, and was kept in that family till it was lost at the taking of that city by the Imperialists, in the year 1630, nor has it been ever heard of since. By good fortune it had been engraved in its full proportion, and with all possible exactness, by Æneas Vico of Parma. This tablet was divided into three horizontal compartments, in each of which were different scenes, containing different actions. These compartments are, as it were, different cartouches, distinguished sometimes by single strokes only, but oftener by a very large fascia, which is full of hieroglyphics, that is, of that mysterious writing, consecrated by the ancient Egyptians to the mysteries of religion. The four sides of the table were enclosed with a border filled up, like the ground, with several figures of the Egyptian gods, and with a great number of the hieroglyphics. There have been various opinions as to the antiquity of this monument: some have supposed that it was engraved long before the time when the Egyptians worshipped the figures of men and women. Champollion judged it to be the work of an uninitiated artist, little acquainted with the true worship of the goddess Isis, and probably of the age of Hadrian. Others, among whom is Bishop Warburton, apprehend, that it was made at Rome, by persons attached to the worship of Isis. Dr. Warburton considers it as one of the most modern of the Egyptian monuments, on account of the great mixture of hieroglyphic characters which it bears.

ISLE. *See* AISLE.

ISODOMUM, a species of walling used by the Greeks. *See* WALL.

ISOSCELES TRIANGLE, a triangle with two of its sides equal.

ISOTHERMAL LINES, curves supposed to be traced on the surface of the earth, so that each may pass through a series of points, at which the mean annual temperature is the same.

ISTHMIAN GAMES: these were one of the four great national festivals of Greece; the others being the Olympian, Pythian, and Nemean. They were celebrated under the presidency of the Corinthians, near Corinth, on the isthmus connecting Peloponnesus with the continent—hence their name,—and were performed at intervals of four years, corresponding with the recurrence of the other festivals above mentioned, so that each year had its solemnity. The Isthmian games were first established in honour of Melicertes, the son of Ino (Paus. i. 44); but were reorganized by Theseus in honour of Neptune, the presiding deity of the Isthmus. The crowns bestowed on victors were of pine leaves. See OLYMPIAN GAMES, and CIRCUS.

ISIS, one of the chief deities of the Egyptians, the sister of Osiris, was represented as the goddess of fecundity, and the cow was therefore sacred to her. She was said to have first taught men the art of cultivating corn. Heads of Isis are a frequent ornament of Egyptian capitals on the pillars of the temples. See EGYPTIAN ARCHITECTURE.

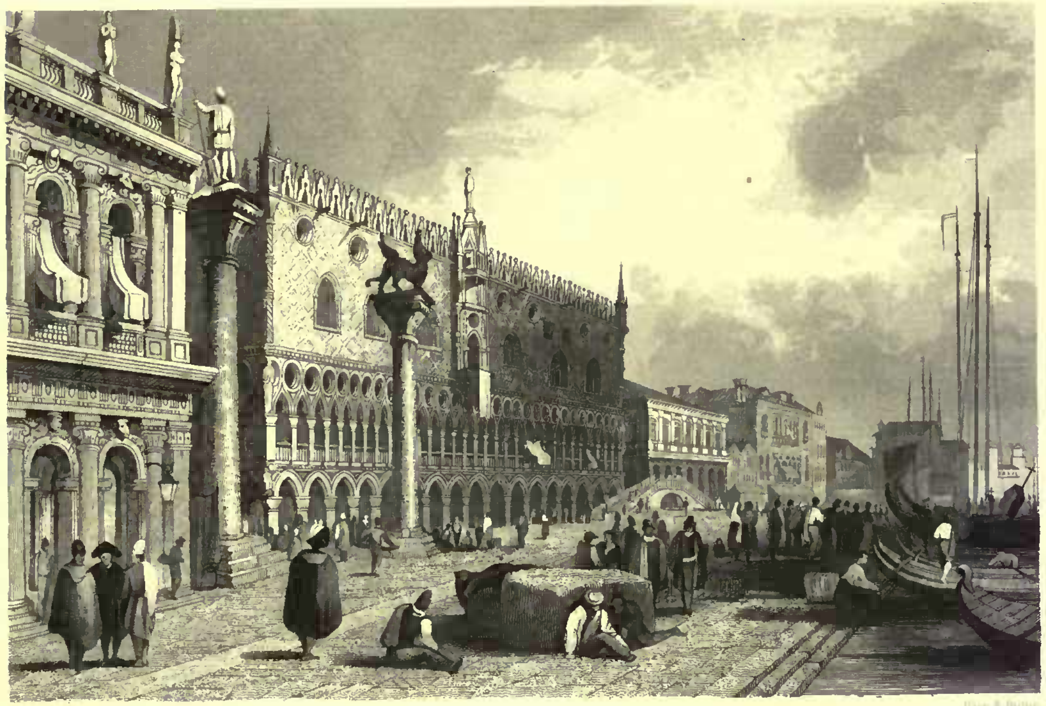
ITALIAN ARCHITECTURE.—A style of architecture prevalent in Italy during the fourteenth and two following centuries, but more especially during the fifteenth, from which circumstance it obtained another designation, being known likewise under the name of the *Cinque-cento* style. The term "Italian" does not include every style and class of building to be found in Italy, but is restricted to that style which was deduced from the ancient Roman or classical manner of building. To attempt to affix to this style anything like a precise or definite character would be perhaps impossible owing to the many varieties of design and different modes of treatment which it exhibits; all we can do is, to give some general notion of the prevailing character of the style.

After the fall of the Roman empire, its architecture declined into a state of semi-barbarism, and degenerated into what is commonly termed the Romanesque style; the cities of Italy were adorned with edifices in either the Byzantine or Lombardic manner, as their intercourse preponderated with Byzantium or Rome. Gothic architecture did not make its appearance in Italy until a comparatively late period, nor even then did it possess any decided or lasting influence; it was, however, in vogue to some extent during the thirteenth century, and, although of a mixed character, may be said to have been the prevailing style of that date. Of the buildings of the Pointed style in existence previous to the revival of the Roman method, the palace of the doge at Venice will form a fair example.

This edifice consists of three stories, the lower two of which are comprised in the lower half of the building. The first or lowermost story contains eighteen simple pointed arches springing from low stunted columns, above which, and forming the second story, is an open gallery of thirty-six small pointed ogee arches having the intrados formed in the shape of a trefoil. In the centre of the upper arcade is a large balcony with tabernacle-work above, to the right and left of which the wall is formed of masonry jointed diagonally, and containing six large pointed windows. In the centre of the building is an attic crowned by statues, and the horizontal cornice is terminated with a pierced battlement.

This style of building was not, however, destined to prevail much longer. At the close of the thirteenth century, a new cathedral was to be built at Florence, and was commenced on a grand scale in A.D. 1298, by Arnulfo di Cambio da Colle, or, as stated by other authorities, by Arnulfo di Lapo. The design of this architect was, at the outset, of an original character, and differed materially from the style then in use; this difference, however, was much increased by the alterations of succeeding architects who where engaged upon the work, amongst whom may be enumerated the names of Giotto, Taddeo Gaddi, Andrea Orgagna, and Felippo di Lorenzo. In 1408, a meeting of architects was called by the citizens, to discuss the best means for completing the cathedral, and it was at this time that Brunelleschi made his bold proposal to raise the dome, and it was he who completely effected the alteration of style. This building, which was of unusual size and magnificence, had great influence in effecting a change of style throughout Italy, and led ultimately to what is called the revival of Roman art. This, however, is not a fair designation of the mode of building prevalent in Italy in the fifteenth century; it was not a re-introduction of the old classic styles, but rather an adaptation of classical details to buildings of entirely different character, disposition, and arrangement. It is true that the artists who introduced this style adopted the classic orders, reduced them to a system, and determined their form and proportions most minutely, yet, nevertheless, applied them in a very different manner to the ancients, and to buildings of entirely different composition. Even in their delineation of the orders, they were guided rather by the writings of Vitruvius, than by existing Roman examples, and endeavoured rather to make the latter agree with the former, than the descriptions of the writer with actual examples.

It would be difficult, as we before observed, to give a definite description of Italian architecture; we can, however, attempt to give some general notion of a few of its leading characteristics. One of the main points in which it differs from purely classical art, is its partiality for fenestration or the introduction of windows, so as to form a marked feature in the design. The employment of lighting apertures had become indispensable, and in some Italian buildings was carried to great excess, so that, what with the windows and the external ornamentation, little space was left of naked walling. Now, the employment of windows, especially to such an extent, at once furnishes us with a feature of very great importance, and it is questionable whether it is not of greater importance than that of columniation: it is at least equally if not more strongly marked. The two systems of fenestration and columniation form two grand distinctions in architectural design, and are in a certain sense antagonistic in principle, nor can they readily be made to harmonize together: for fenestration either interferes with the effect aimed at by columniation, as in the case of a colonnade, where the simple and chaste effect produced by the repetition of a range of columns receding one behind the other, is marred and broken, and the unity of the composition destroyed; or otherwise is reduces columniation to an inferior and secondary position as



Venice

a mere means of decoration, to, in short, a mere accessory, as is evidenced in the use of engaged columns, and pilasters, and in the adoption of small columns, &c., for the adornment of only portions of an edifice. The latter is the method resorted to by the Italians, and though it may be said with some reason, that the columnar-fenestrated is an anonymous style, and that the terms astylar and fenestrated ought in practice to be synonymous, yet when we behold some of the beautiful structures raised in this style, we cannot yield ourselves entirely to this opinion. In our idea they may lawfully be combined when one is made clearly and distinctly an accessory to the other, and when the pre-eminence of the one is at once palpable and evident to the senses: but they may not be so employed where they hold equally important positions in the same edifice, one or the other must be ostensibly predominant. The Italians have employed the orders as ornamental accessories, and have been in many instances eminently successful, as far at least as regards the production of elegance and taste in the design; if we were to criticise too severely, and enter into the question of the unity of design and construction, we might not be so well able to vindicate the claims of this style; it will not bear such rough-handling as the Pointed.

In some instances, which are indeed the least removed from the classic in this respect, the entire edifice, or at least the principal portion of it, is comprised in one order, which is thus made to embrace two or more stories of the building, and the same number of ranges of apertures; and sometimes the main body of the building is crowned by a single pediment. This is what some would have us call classical, or at least very nearly classical; but we must confess we do not recognize the resemblance, and if there be a likeness, it is by no means a flattering one. This method would appear to us to be the first bungling attempt at adapting the ancient orders to the altered requirements of that age; such a system can be termed neither the columniated, nor the fenestrated, nor even a combination of the two, for there is no agreement or unity between the two principles so applied; you have them both together, it is true, but not in combination or unity: they are in open war, and, destroying each other's beauties, they are both spoiled—self-destroyed. The two systems are individually too prominent, they jar, and cannot blend together. Besides all this, it seems unnatural and ridiculous to comprise several distinct stories under one order; and if it seems so in theory, it has certainly no less the appearance in practice.

This system, however, was fortunately by no means universal; it was a more usual practice to give to each story its separate order, and this employment of different orders, or repetitions of the same order one above the other, in the several stories of a building, affords us another important feature of the style. This practice led to some other peculiarities worthy of especial notice, amongst which may be noticed, that of abandoning all proportion of intercolumniation, and spacing the columns according to the breadth of the piers, and the apertures between them. This again led to the abandonment of insulated columns, and the substitution of engaged columns of half or three-quarter projection; the reason for which is evident, for if insulated columns had been adopted, when placed at so great a distance from each other, they would have had an exceedingly tame and meagre effect, especially when raised tier above tier. But another alteration was still requisite, for with half or three-quarter columns, the entablature was made to project so far from the face of the wall as to produce the appearance at once of heaviness and weakness, the overhanging entablature seeming to have no support between the widely separated columns. To obviate this inconsistency, the Italians fell into a still greater, by breaking the entablature over each column, and recessing it in the intercolumn. We say a greater inconsistency, for the nature and functions of the entablature are thus entirely disregarded, but, as before observed, the designs of the Italians will not bear comparison with the requirements of constructive science. This objection, however, was somewhat lessened by the introduction of pilasters in the place of columns, which, from their slight projection, allowed the entablature to be continued without break or interruption. This was so far an improvement, but it will be noticed, that all this while, the columns and other divisions of the order were losing their natural character and office, and had at last dwindled down to nothing better than aids to decoration. Thus, by their diminution in size and projection, and by their loss of constructive propriety, columns became of little significance when compared with the windows and other apertures, which were often highly decorated with architraves and cornices, and sometimes with small columns in the jambs supporting an architrave and pedimental head, which was either triangular or segmental. This method of decorating the windows was employed where each story of the edifice was arranged as a separate order; but not unfrequently the order was entirely omitted, and columns employed only as decorations to apertures, and often were dismissed altogether, the windows having an architrave dressing only, with cornice supported by ancones on either side of the architrave. These illustrate the triumph of fenestration over the combination of the two systems; and if the former do not excel in appearance, which we are somewhat inclined to think it does, it at least surpasses in consistency. We have fair specimens in London in the Reform Club and Bridgewater House, by Mr. Barry, as also of the other system in the Carlton, Conservative, and Army and Navy Club Houses, all of which, and several other excellent examples, are in close proximity to each other, and afford ample means of judging of their comparative merits.

The walls of Italian buildings are frequently formed of rustic masonry of various descriptions, and this is more generally the case with basements, and the lower or less important stories, and in such a situation gives an appearance of great strength and massiveness, where it is most required; it adds also to the apparent strength and durability of the entire edifice; not, however, without imparting at the same time a degree of heaviness. This method of decoration, if it may be so termed, is sometimes applied to columns, but it is rather a barbarous ornamentation, as is also another practice very prevalent, of leaving projecting cubical blocks surrounding the shaft of the column at regular intervals in its height. In edifices of the astylar system, the angles are often finished with quoins.

We must not forget to allude to a feature which is common to almost all Italian buildings, and that is, the boldly projecting cornice, or cornicione, as it is termed, at the summit. It is of very unusual projection, proportioned to the entire building, and often very highly enriched; it forms a noble finish or crowning, and adds considerably to the importance of the façade. Sometimes the edifice terminates with an attic or cornice with a balustrade, which again is crowned at intervals by statues or other acroteria. Columns and pilasters in this style are frequently set upon pedestals, which is an innovation upon classic art, copied from the Roman triumphal arches, in which the practice was first resorted to. Columns also are frequently fluted in a spiral direction round the shaft, which gives them an appearance of weakness; they are also twisted and crooked, which produces an effect no less disagreeable, than the construction is unscientific and barbarous. Another innovation upon ancient precedent consisted in breaking the outline of the pediment by cutting it in the middle like a mitre; this practice was even more unsightly and unscientific than the preceding; for whereas the ancient pediment was formed for the purpose of throwing off the rain; this, on the contrary, would seem to be shaped for the very purpose of collecting and retaining it. This barbarism is frequently accompanied by another equally unauthorised and equally ugly; we allude to the practice, when the upper of two colonnades is narrower than the lower, of placing on each side of the upper story, a huge reversed console, or sort of volute, which has an exceedingly unsightly appearance. This arrangement is of common occurrence in churches, where the aisle-roofs are lower than than that of the nave, the difference of level being made up by these tasteless masses. These few last mentioned peculiarities form some of the worst features of the style; many buildings, however, are entirely free from such defects, and are of chaste and elegant design.

As we have above stated, the first attempt towards the introduction of this style was made by Arnulfo di Cambio, in his design for the duomo of Florence; but very little progress was made in this direction till the time of Brunelleschi, who may be said to be the father of the Italian style. From his time the style rapidly extended its influence throughout Italy, and was considerably varied, and in some instances improved upon, by his successors; of the life and works of the principal of them, a short account will be found in the succeeding table:—

Name of Architect.	Born.	Died.	Native of	Practised at	Erected buildings.	Wrote works.
Brunelleschi.	A. D. 1375	A. D. 1444	Florence.	Florence, Rome, and Mantua.	Dome of Cathedral, and Church of San Lorenzo, and commenced the Palace Pitti, Florence.	
Alberti.	1400		Florence.	Rome, Florence, Mantua, and Rimini.	Palazzo Rucellai, part of the church of the Annunciation, Florence; Church of St. Francis, Rimini; and St. Andrew, Mantua.	De re Ædificatoria.
Bramante bino.	1444	1514	Castel Durante, or Fermignano.	Rome.	Cloister of Convent della Pace, Cancellaria, Palazzo Giraud, part of the Vatican, commencement of St. Peter's, and the oratory of the cloister of San Pietro Montorio, Rome.	
Micheli.	1484		Verona.	Verona.	Palazzi Pompeii, Berilacqua, Canossa, Verona; and Palazzo Grimani, Venice.	
Michael Angelo, Buonarotti.	1474	1563	Florence.	Rome	St. Peter's Cathedral, finished the Farnese palace, Rome; and portions of Church of San Lorenzo, Florence.	
Sansorino.	1479	1578	Florence.	Venice.	Libreria Vecchia, Palazzi Cornaro and Delfino, La Zecca, the Public Library, and the Church of San Francesco della Vigna, Venice.	
Serlio.	1475	1552	Bologna.	Vicenza and Fontainebleau.	Theatre, Vicenza; Palace Fontainebleau.	Opere di Architettura.
Vignola	1507	1573	Vignola, Modena.	Bologna, Assisi, Perugia, Rome, &c.	Palazzo Isolani, near Bologna; Church at Massano; the Madonna degli Angeli, Assisi; St. Francesco, Perugia; Villa Giulia, Church of St. Andrea, Rome; Palace at Caprarola.	Treatise on the Five Orders.
Palladio.	1519	1580	Vicenza.	Vicenza, Venice.	Palazzi della Ragione, Tiene, Valmarana, Chieracati, Porti, Barberino, and Villa Capra, and Teatro Olimpico, Vicenza; Churches of St. Giorgio Maggiore, and Il Redentore, Venice.	
Scamozzi.	1552	1616	Vicenza.		Finished Public Library, Venice; and the Teatro Olimpico, Vicenza; Cathedral of Salzburg, the Churches of St. Nicholo di Tolentino, and SS. Simone e Giuda, and the Procuratie Nuove, Venice; Palazzi Roberto Strozzi, Florence; and Pretorio and Trissino, Vicenza.	Treatise on Perspective. Architettura Universale.
Borromini.	1599	1667	Como.	Rome.	Churches of La Sapienza, St. Agnes, and the College di Propaganda, Oratory Chiega Nuova, and the Doria Palace, Rome.	
Bernini.	1598	1680	Naples.	Rome.	Palace Barberini, Façade of the College di Propaganda, Colonnade in front of St. Peter's, and Colonnade joining the Vatican, the Church of St. Andrea à Monte Cavallo, the Palace Bracciano, &c.	

Italian architecture is usually divided into three kinds, which, with a very decided similarity in general treatment, have peculiarities sufficient to distinguish them from each other. The three classes are named after the cities in which they each prevailed, not that any one of the styles were in use at any place to the exclusion of the others, but that each style was predominant in its own locality. The cities are those of Florence, Rome, and Venice, and the classes are styled after their names—Florentine, Roman, and Venetian.

The architecture of Florence, and more especially of its palaces, is very peculiar; strong, massive, severe, and from these very qualities, grand; but at the same time gloomy and heavy, presenting the appearance of fortresses rather than the residences of merchants. Nor was this appearance a false or deceitful one, for the strength of these mansions was required for purposes of defence. The rival parties of the Guelphs and Ghibellines, and, at a later period, of the Neri and Bianchi, were the cause of ceaseless civil discord, and their quarrels kept the city in a state of continual commotion, from an early period of its history, to the time of the Medicis. It was this state of circumstances which originated the peculiar appearance of the buildings to be found in this city. Large blocks of stone were readily procurable from the quarries of Tuscany; and solidity and strength were, to some extent, demanded in residences which were not unfrequently required to answer the purpose of a stronghold. Florentine buildings excel in dignity and grandeur those of Rome and Venice, but fall far short of them in lightness and elegance; they are inferior in the refinement of detail, but surpass all others in bold and imposing masses.

Although the revival of the classic orders first took place at Florence, in the cathedral of the above city, yet the previous style, or rather many of its details, lingered there for a considerable time, and even as late as the middle of the fifteenth century, as is evident in many of the windows, some of which have the intrados of their archivolts semicircular, while the extrados is carried up in a pointed arch; others again are composed of two lights with semicircular heads, both enclosed within a larger semicircular arch, and the lights divided by a central column. The apertures on the ground floor are usually square and unimportant, and the naked of the wall of this and the other stories most frequently rusticated, a mode of decoration very much in vogue. The façades are usually continued in an unbroken line, and there is little diversity in plan. A bold cornice runs round the summit of the edifice, which is proportioned to the entire building, although smaller cornices frequently intervene between every two stories. A very important distinction between this and the other two classes of Italian architecture, is evidenced in the absence of columns from the external façades.

The court in the interior presents often a very different aspect from that of the exterior; indeed, the external distribution scarcely ever indicates that of the interior, which generally consists of a colonnaded or arcaded quadrangle.

"The buildings of Florence," says a French author, "appear to be not the work of ordinary men; we enter them with respect, expecting to find them inhabited by beings of a nature superior to ours. Whether the eye is arrested by monuments of the age of Cosmo de Medici, or of the times which preceded or followed it, all in this imposing city carries the imprint of grandeur and majesty. Frequent revolutions obliged the chief parties to consider their personal safety along with the magnificence of their dwellings. Externally, they are examples of the skilful union of grace with simplicity and massiveness, internally models of exquisite taste. After Rome, Florence is the most interesting city to every artist."

Brunelleschi may be said to have been the founder of this style, and he was succeeded by Alberti, Raffaelle, Sanzio, Ammanati, and others; the style dating from A. D. 1400 to 1600. Some of the finest examples are the cathedral, the palaces Strozzi, Pitti, Medici, Riccardi, Vecchio, Podesta, and the churches of SS. Michele, Maddelina, Pancrazio, Lorenzo, and Spirito.

Descriptions of a few of the above edifices may not be out of place.

The Cathedral of S. Maria del Fiore, or the Duomo, as it is termed, was the first building in which the Italian features were introduced; several of the peculiarities of the old style still remaining, so as to give to the edifice a kind of transition-character between the Gothic and Italian, of which it is a mixture. The edifice was commenced, A. D. 1298, by Arnolfo, and not entirely completed by Brunelleschi, who constructed the dome. The plan is that of a Latin cross, the length measuring 520 feet, and the width across the transept 313 feet. The nave is divided into three aisles by arcades resting on piers, decorated with Corinthian pilasters, the height of the central avenue being 153 feet, and that of the aisles, properly so termed, 96½ feet. The space at the intersection of the arms of the cross is octagonal, being 140 feet in width, and the terminations of the choir and transepts are semi-octagonal, covered with semi-cupolas. Above the top of these cupolas, at the intersection of the nave and transepts, rises an octagonal drum, with a circular window on each side, and terminated at the top by a horizontal cornice from which springs the octagonal dome. Above this again is a lantern, on which rests an octangular pyramid, surmounted by a ball and cross. The drum rests on four massive piers, its height is 43 feet, and the thickness of its wall 16 feet. The dome is double, consisting of two shells one within the other, with an interval of 5 feet between; the thickness of the lower shell being 4 feet 3 inches at the lower extremity, and 1.0 foot at the vertex; and of the inner one, 5 feet 6 inches at bottom, and 2 feet 1 inch at vertex. The span of the dome is 140 feet, the radius of internal curvature, 120 feet; height from drum to lantern, 116 feet; from ground to cupola, 280 feet; height of lantern, 45 feet; diameter, 24 feet.

The arcade in the nave consists of pointed arches, each segment being described with a radius equal to two-thirds of the span. From the top of the piers, or rather of the pilasters which adorn them, rises a second order, to support the ribs of a pointed vault. The aisle-windows are of two lights, divided by a central column, and having trefoil heads to each light, both of which are included under a larger pointed arch; on the exterior they are crowned by a rectilinear pediment, with a pinnacle at either end. The upper windows are circular. The external wall is almost entirely encased in coloured marbles, and is ornamented with pilasters, which at the eastern extremity are connected by semicircular arches.

Attached to the cathedral is a separate campanile, erected by Giotto and Taddeo Gaddi, A.D., 1334, which consists of five stories, ornamented on the exterior with pilasters, like the cathedral. The three lowermost stories have narrow rectangular windows, the fourth two tiers of pointed windows, of two lights each, divided by a twisted pillar, and having trefoil heads, and the uppermost one wide pointed window of three lights. At the summit is a gallery supported on brackets.

The Pitti palace was designed and partially erected by Brunelleschi, at the close of the fourteenth century. The main body or central portion of the building, is in plan a parallelogram, with a wing projecting at right angles at each extremity; behind the centre is a small cortile. In elevation, the edifice consists of three stories of equal height, each story being somewhat less in frontage than the one below it, so as to give to the whole the appearance of a pyramid, which appearance would have been increased, had the original design been carried out, in which a fourth story was contemplated. Each of the stories is of rustic masonry, and crowned by a cornice supporting a gallery with balustrade in front. The windows are placed one above another, and number alike, except in the lower story, where there is only one window under each alternate one above. They are semicircular-headed apertures, and have the voussoirs grooved at the joints. The elevations of the cortile consist of three orders, one to each story; the lowermost of which is Tuscan, with shafts fluted horizontally. The second order is Ionic, with square blocks ranged at intervals up the shaft, and between the columns are semicircular-headed recesses, containing windows, which have architraves and pilasters on the jambs, and are crowned by pediments; underneath each window is a projecting table, supported by two corbels placed under the architrave. The uppermost order is Corinthian, also with square blocks on the shafts, and between the columns are recesses with horizontal lintels, formed by voussoirs; within which again is another semicircular-headed recess, and windows crowned by a curvilinear pediment.

The Palazzo Strozzi is of rusticated masonry throughout the entire façade, in horizontal and vertical channels. The building consists of three stories; in the centre of the lowest is a doorway, with semicircular head flanked on each side by three windows having square heads. The windows in the upper story consist of two lights separated by a column, and having half-columns in the jambs. Both the lights have semicircular heads, and are included under a common semicircular arch, the spandrils of which are filled up with pateræ. Each story is separated from the adjoining one by a frieze of dentils, the entire building being crowned with a plain frieze and boldly projecting cornice, in which both dentils and modilions are employed.

The Richardi palace consists of three stories, as does the Strozzi palace, which it resembles also in many other features. The lowest story, however, is somewhat peculiar, being formed of uncoursed masonry, with some blocks projecting forward beyond the others; as in the previous example, the doorway is semicircular in the head. The second story is rusticated, and contains seventeen windows in close proximity to each other; they are of two lights, with a column in the centre, and have semicircular heads, which enclose the heads of the two lights, also semicircular. Above these windows is a large surface of naked wall, above which is a dentil band, separating this story from that above. The third story is of plain ashlar, and contains windows the same in number and description as those of the second story; the whole is crowned by a bold cornice.

The church of San Lorenzo, by Brunelleschi, is in plan a Latin cross, the length of which is considerable when compared with the width; the height of the building follows the same proportions. The body of the church is divided into a central nave with two aisles, by means of an arcade; the arches of which rest upon Corinthian columns, carrying isolated entablatures, from which the arches spring. At the intersection of the nave and transept, the building is covered by a spherical dome, which stops short ere it meets at the summit, the void so formed being covered by a hemisphere of smaller diameter; this answers to the lantern more usually applied in such positions.

"The church of Santo Spirito is a beautiful example by Brunelleschi. All the fronts are complete except the principal one, and it is certainly the finest of Brunelleschi's designs; though subsequent to the architect's death, as the works were then unfinished, they were carried on with some departure from the original design. These alterations, though not affecting the general conception, have justly excited the anger of Vasari against those who fancy themselves better qualified than artists. Oh that Vasari were alive now! The plan is a Latin cross, with aisles carried round the transepts of the choir. The intersection is surmounted by a dome ornamented with leaf-work, and rising from a low tholobate, pierced with circular openings. The clere-story and aisles have circular-headed windows. The wall being of great thickness, there is sufficient space for large niches, which occupy each intercolumn, and the wall of the lower clere-story, or that to the aisle is above the inside to the lower wall, and has circular windows similar to those of the tholobate. Thus there were three distinct levels of roof besides the dome. The interior has Corinthian columns, each supporting an entablature, from which spring semicircular arches. At the extremities of the choir and transepts there are four windows, instead of an odd number. The high altar beneath the dome is surmounted by a magnificent canopy. There is an internal dome with a lantern beneath those of the exterior. It is panelled, and perforated by the windows of the tholobate. In this church we remark the most perfect harmony of lines. Character is given to the building by the constant use of circular forms, whilst too great sameness is prevented by the occasional use of horizontals. The sacristy attached to this church, and the second cloister, are both fine works."

The edifices of Rome are of a very different character to those of Florence; they have lost the massive appearance of the latter, and assumed an air of lightness and elegance. This style forms the connecting link between the Florentine and the Venetian; for while, on the one hand, it is much less heavy and severe than the former, it is not so gay and lightsome as the latter. Columns are of frequent introduction in the façades, in which, also, the entrance becomes an important feature. The interior courts are mostly surrounded by arcades, and from them a grand staircase of imposing dimensions leads to the principal apartments. The churches consist of nave and aisles, separated by arcades, the latter being flanked by chapels. The transepts are not extended far beyond the nave, and the intersection is covered mostly by a dome. Apsides are common. The façades are generally of an inferior description, often plain; and when decorated, it is without taste; they are often only masks, having no relation to the internal distribution of the edifice. Bramante was the founder of this style; and the principal examples are St. Peter's cathedral and the Farnese palace, which we proceed to describe. Of the former, which is a subject of general interest, we shall take this opportunity of giving a full description.

The plan of St. Peter's is that of a Latin cross, with a narthex, or porch, at the west end, extending in width beyond the general line of the building. Internally, the breadth of the church is divided into three portions, central nave and aisles on either side, by means of an arcade, supported on massive piers, four of which, at the angles formed by the intersection of the nave and transept, are more massive than the rest, and serve to support the central dome. There are four arches on each side of the nave, and one in the choir, all springing from piers which are ornamented with pilasters. A chapel is formed at the extremity of each aisle, where they meet the transept, which is rectangular in plan, projecting beyond the general line of building on the exterior, and covered with a spheroidal dome. At the western extremity of the nave is a porch, as above noticed, extending in frontage from north to south beyond the main line of the building, and projecting from the extremity of the nave as much as 50 feet; this porch is separated from the nave by a wall containing five doorways, to agree with the number of doors in the outer wall of the porch itself, which forms the grand façade and entrance. The elevation of this façade is adorned with half-columns and pilasters, ten in number; leaving nine intercolumnar spaces in the whole façade; the columns are surmounted by an entablature, the height to the top of which is 125 feet, and the four central columns are included under a pediment rising above the entablature, which in consequence is broken above these columns as it is also above every column beyond the pediment. This order contains two stories in height, the lower one being occupied by the entrances, and the upper by windows. In the central compartment of the lower story is the principal doorway, with horizontal head, and in the nearest compartments on either side a smaller doorway with semicircular head, on either side of which again is one more similar to the first. In each of the extreme intercolumns which project beyond the main building is a magnificent doorway with semicircular head, and similar ones on the two other sides of each of those projections which are not contiguous to the church. In the upper story of each of the intercolumns is a window, with a segmental or triangular pediment, the two forms alternating with each other. Above the entablature is another story or attic, and above this again a balustrade.

From the four great piers at the intersection of the nave and transept, spring four large semicircular arches which support a drum or cylindrical wall 70 feet high, and perforated at intervals by windows. The windows are rectangular, surmounted alternately by triangular and segmental pedi-

ments; and between every two are a pair of coupled Corinthian columns, supporting an entablature projecting over each column. Above the entablature the wall rises 20 feet, and upon the top of this, springs the magnificent dome: it is a double dome consisting of an external and internal shell at a short distance from each other, the extreme diameter of the outer one measuring 189 feet, and that of the other on the inside, 138 feet. Both domes are of the spheroidal shape, but the inner is flatter than the outer one, the height of the former being 77 feet, while that of the latter is 100 feet; they are connected together by sixteen vertical ribs of masonry. Above the cupola is a lantern 40 feet in height, and above that a small spire supporting a ball and cross. There are three tiers of windows in the dome.

From the front of the church, and commencing at the extremities of the porch, project two corridors, one on each side, in such a manner as to approach nearer and nearer to each other as they recede from the façade of the building, and enclosing a space of ground or area in the form of a trapezoid, the length of which from east to west measures 400 feet. From the western extremity of each of these corridors, is carried a semicircular colonnade, which is surmounted by an entablature and balustrade, crowned at regular intervals by statues. The area thus enclosed is 650 feet long from north to south, and 500 feet from east to west; in its centre is a large Egyptian obelisk of black marble, and on each side of it a large fountain. The trapezoidal area contains the steps to the cathedral.

The original design for this cathedral was furnished by Bramante, but was altered by almost every architect employed upon the building, so that he cannot lay claim to the design of it as executed. Bramante commenced the erection, but did not proceed far with the work, the body of the church being erected by Peruzzi and San Gallo; the dome by Michael Angelo and Fontana; the nave and west façade by Carlo Maderno; and the colonnades by Bernini. The plan was originally designed as a Latin cross, which was changed into a Greek cross by Michael Angelo, and again into the Latin form by Carlo Maderno.

The following dimensions of the cathedral and its several parts may be found useful, especially in the comparison of this and our cathedral of St. Paul, the dimensions of which are given in a parallel column.

The Plan.—Length and Breadth.

	St. Peter's. Ft.	St. Paul's. Ft.
The whole length of the church and porch	729	500
The breadth within the doors of the porticos	510	250
The breadth of the front with the turrets	364	180
The breadth of the front without the turrets	318	110
The breadth of the church and three divisions of the nave	255	130
The breadth of the church and widest chapels	364	180
The length of the porch within	218	50
The breadth of the porch within	40	20
The length of the plateau at the upper steps	291	100
The breadth of the nave at the door	67	40
The breadth of the nave at the third pillar and tribune	73	40
The breadth of the side aisles	29	17
The distance between the pillars of the nave	44	25
The breadth of the same double pillars at St. Peter's	29	—
The breadth of the same single pillars at St. Paul's	—	10
The two right sides of the great pilasters of the cupola	65.7½	25.35
The distance between the same pilasters	72	40
The outward diameter of the cupola	189	145
The inward diameter of the same	138	100
The breadth of the square by the cupola	43	—
The length to the same	328	—
From the door within to the cupola	313	190
From the cupola to the end of the tribune	167	170
The breadth of each of the turrets	77	35
The outward diameter of the lantern	36	18
The whole space upon which one pillar stands	5,906	875
The whole space upon which all the pillars stand	23,625	7000

The Height.

	St. Peter's. Ft.	St. Paul's. Ft.
From the ground without to the top of the cross	437½	370
The turrets as they were at St. Peter's and are at St. Paul's	289½	222
To the top of the highest statues on the front	175	135

Mr. Gwilt has prepared a table of areas of the two edifices, as also of that of the Duomo, Florence; and as this table contains likewise the area occupied by piers and other means of support, it will give an idea of the comparative merits of the buildings as regards construction, and when taken in connection with the comparative sectional areas, will give a just ratio between the size or capacity of the building, and the quantity of material employed in its construction.

	St. Peter's.	St. Paul's.	St. Mary, Florence.
	Ft.	Ft.	Ft.
Area on plan	227,069	84,025	84,802
Do. of points of support	59,308	14,311	17,030
Ratio of areas . . .	1.026t	1:0170	1:0201
Sectional area at transepts	8,325:10000	6,865:10000	8,855:10000

We shall have to speak more particularly about St. Paul's presently, but must now return to examples to be found at Rome.

The great Farnese palace is probably one of the finest specimens of Italian palatial architecture in existence, and covers an area of 256 feet, by 185 feet, the height of the building measuring 177 feet. The material of the walls is brick, with the exception of the dressings, which are of Travertine stone. The edifice is three stories in height, each of which contains a range of thirteen windows, with the exception of the first, where the place of one is occupied by a doorway; those on the first story are of a rectangular form, with architrave, and horizontal cornice, supported by ancones, or corbels on either side of the window. The doorway is semicircular-headed, with prominent voussoirs. The windows in the next story are of a more ornamental character, being still of the rectangular form, but having pediments alternately triangular and segmental; the jambs, also, are decorated with columns. In the uppermost story, the windows have semicircular heads, with columns and triangular pediments. The stories are separated by impost cornices, and the entire building crowned by a boldly projecting cornice. In the interior quadrangle, the building surrounds a court 88 feet square, and presents a very different appearance to the exterior, being divided vertically into arcades. The lower arcade is of the Doric order, and is supported on piers whose sides are adorned with Doric columns, and which sustains an entablature enriched with triglyphs, &c. The upper arcade is of the Ionic order.

The Palazzo Giraud at Rome is by Bramante, and consists of a range of building enclosing a quadrangle 89 feet square, the external measurements being 249 feet by 190 feet. The front elevation contains three stories, all of which are rusticated, the lowermost by both horizontal and vertical grooves, but the upper by horizontal grooves only. In the centre is a semicircular-headed door, with horizontal cornice, and on each side of it three square windows. In the second story, the piers between the windows are ornamented with coupled pilasters, similar to those of the Corinthian order, standing on high plinths, which again rest on a podium extending all along the building, but broken under the pilasters. The pilasters support a simple entablature, and between them are seven semicircular-headed windows, with horizontal cornices, the archivolts resting on pilasters, and the spandrels filed with sculpture. Above the piers of the second story, the third story have coupled Corinthian pilasters, arranged in a similar manner on plinths and podium. Between these are two tiers of windows, the lower having rectangular, and the upper semicircular heads. Above this order is the entablature proportioned to the building, the frieze of which is occupied by blocks to support the cornice. The roof has sloping sides, and is covered by hollow tiles.

In one of the shorter sides of the building is the vestibule, which is 47 feet long, by 34 feet wide, and is divided longitudinally into three portions by two rows of columns. This gives entrance to the principal court, which is surrounded by an arcade resting on piers, ornamented with half-columns, and roofed with a groined ceiling. Opposite the entrance is a passage, the sides of which are ornamented with pilasters and niches, and which leads to a smaller court in the rear.

The Venetian style is characterized by its pre-eminent lightness and elegance, and more especially by the frequent and almost universal employment of pilasters and arcades; it bears altogether a more lively and decorative character than either of the preceding. Another feature having a similar tendency is shown in the close proximity of the windows, and the large proportion of the elevation occupied by apertures. San Michaeli, or Sansovino, may be said to have been the founder of this school, and they were followed by Palladio, Scamozzi, &c. Good examples are, the library of St. Mark, Venice, the Pompeii palace, Verona, and the chapel of St. Bernardino.

The library of St. Mark, Venice, is by Sansovino, and consists of two stories, each composed of one order, the lower one Doric, and the upper Ionic. The lower story is raised three steps above the piazza, and consists of a portico of twenty-one arches, at the back of which is a range of similar arches used as shops, and opposite the central arch is a magnificent staircase leading to the library. The piers of this story are ornamented in front by pilasters of the Doric order extending to the top of the arches, and carrying a noble entablature enriched with triglyphs, and above them with a fine cornice, with dentil-band underneath. The archivolts rest on a moulded cap or impost, and have carved key-stones which finish under the entablature. Above this is an Ionic order carried upon pedestals, ranging with which, and underneath the windows, is a balustrade, flanked by other smaller pedestals, upon which stand small Ionic columns placed in the jambs to support the archivolt, the windows having semicircular heads. As below, the order extends to the top of the arches, which have ornamented key-stones, and rest on impost mouldings; the spandrels between the archivolt and the pilasters being filled up with sculpture. The entablature to this order is very lofty, and the frieze highly decorated with sculpture; the cornice is bold, and highly enriched, being supported by modillions, and having a dentil-band underneath. The cornice is crowned by a balustrade, on every alternate pier of which is placed a statue, and at the angles of the building a pyramidal acroteral ornament.

In the same piazza is the Procuratie Vecchie, also by Sansovino. This building consists of three stories, the lowermost of which has an arcade supported on piers, and the upper ones a similar arrangement on columns, the arches of these stories, however, being so much smaller than those below, as to be admitted in pairs above the single ones on the ground-floor. The stories are divided by plain podia, and the whole crowned by an entablature, with a frieze perforated at intervals with circular apertures.

The Pompeii palace, by Michaeli, consists of two stories, the lower one of which is rusticated throughout, the apertures, with door and window, having semicircular heads, without architrave or other decoration; the doorway is in the centre, having three windows on either side. Above each of the apertures is a balustrade, and above these are the upper windows, which are of similar shape, but the piers between them are decorated with single three-quarter columns of the Doric order, which support an unbroken entablature over the windows.

Amongst the buildings of this class, we have to notice those of an architect, whose works may be said to comprise a new style, and which, for this reason, have been designated the Palladian style. Many opinions have existed, and do still exist, respecting the merit of Palladio's works, and the

school which they gave rise to, some writers extolling them above all others of the Italian style, and others decrying them with equal zeal; for ourselves, we must confess that we are no great admirers of his school.

In Palladio's designs, the ground stories are generally composed of arcades of not very ornamental design, serving as basements to the principal stories above, which are decorated with an engaged order, and most frequently with a pediment in the centre of the building above the cornice, though sometimes, when a pediment is introduced, the cornice is discontinued beneath it. His buildings frequently have vestibules consisting of three arches or rectangular openings in front. The arches of his arcades are usually of the semicircular form, but sometimes the space between the piers is subdivided into three portions by two lesser piers, the central compartment only being arched over. This form is sometimes carried out in his windows, which, however, are usually rectangular; sometimes also a semicircular shape is adopted, divided into three parts by vertical mullions.

In his churches he follows the Basilican form faced with a portico consisting of an order with entablature reaching to the height of the building, and covered by a pediment rising with the nave-roof, those of the aisles having each a kind of half-pediment to agree with the slope; so that the central pediment has the appearance of having been placed in the centre of another so as to divide it equally into two parts. Amongst Palladio's other works, those of the church of the Redeemer, and the Olympic Theatre at Vicenza, stand conspicuous.

The form of this latter building is semi-elliptical, round which the seats are extended in front of the proscenium. The entire width of the building is 109 feet, that of the proscenium 80 feet, and its depth 21½ feet. The front of the scena is composed of two tiers of Corinthian columns on pedestals, the lower tier of which is detached with pilasters behind, and the latter are half-columns attached to the walls. Between the columns stand niches with rectangular and circular pediments resting on fluted Corinthian pilasters, and above the upper tier is an attic broken by piers, the spaces between which are filled with sculpture. Three doors in the scena give admission to five passages, the sides of which are adorned with representations in relief on wood of a variety of buildings seen in perspective. The upper tier of seats is surrounded by a row of Corinthian columns, supporting an entablature, and this again surmounted by a balustrade with statues.

The church of the Redeemer at Venice was built by this architect. The form would be that of a Latin cross, were it not that the nave is flanked on either side by three chapels open to the body of the church, ranging the entire length of the nave, and receding from it to the same depth as the transepts. The division between them and the nave is effected by an arcade of semicircular arches springing from entablatures over Corinthian pilasters, which flank the piers of the nave. These piers are faced towards the nave by half-columns coupled, and extending to such a height as to carry an entablature over the arcade; above which on each side is a clere-story pierced with three semicircular windows, divided into three by vertical mullions. The choir is surrounded by isolated columns, and its extremity, as also those of the transept, is apsidal. At the intersection a cylindrical drum is supported on four large arches, and is surmounted by a cupola or dome.

The church is considerably elevated above the ground, and is approached on the exterior by a flight of steps extending the breadth of the nave, and fronting the portico, which consists of two three-quarter columns and two pilasters, covered by a pediment. On each side of this, a wing projects in the line of façade, adorned with Corinthian pilasters of less height than those of the portico, and continued round the sides of the building. The door under the portico is semicircular-headed, ornamented with half-columns, entablature, and pediment. The roofs of the aisles lean to, and in the façade present the appearance of a second pediment broken in the middle for the insertion of the portico.

After the death of Palladio, Italian architecture began to decline, under the auspices of Borromini. This architect introduced many innovations, and in his desire to produce novelties, had little care for elegance or simplicity; striving to surpass his rivals and predecessors in variety and originality, he laid aside all the common rules and restrictions, and gave form and substance to all the extravagant vagaries of his imagination. In his designs, straight lines are the exception, curvature and irregularity their ruling features. Curves, both convex and concave, appear in plan and elevation, wherever it was possible to introduce them, and that without any regard to construction; his designs are the result of an inventive and pregnant, but also a reckless and uncultivated, fancy.

The church della Sapienza, by this architect, is of a polygonal plan, of which the sides are alternately concave and convex; the exterior of the cupola, which is surrounded above by a balustrade, is of a similar plan, the convex parts being formed into steps, interrupted by buttresses. But the lantern is still more whimsical, having its vase in a zig-zag form, on which is erected a spiral staircase, sustaining a crown of metal, with a ball and cross at the top. His most extraordinary work is the church of San Carlino alle Quatro Fontaine, which abounds in his eccentricities, as does also the oratory of the Fathers della Chiesa Nuova. Here we have disorderly mixtures of all kinds of lines, straight and circular, convex, concave, and twisted; undulating coronæ which retain the rain, delicate mouldings under great weights, and strong supports without anything to sustain; breaks only in the architrave of the entablature; prominences, contortions, and every kind of absurdity. Of all his buildings, the church of St. Agnes in the Piazza Navona, is most free from his usual abuses; the façade of this, however, is in plan a curve of contrary flexure.

Bernini's buildings, though not of so bizarre a character as Borromini's, are not equal to those of his predecessors; his principal works are the colonnade in front of St. Peter's, the principal façade and staircase of the palace Berberini, the Curia Innocenziana, and some few others. Of the first of these works, a description has already been given, we pass on therefore to the second.

The palace Berberini consists of a central portion and two wings, which project at right angles to the front. In the lowest story of the central compartments, are two parallel rows of arches resting on piers, forming a vestibule, which has a groined roof. The building consists of three stories, the lower one being ornamented with a Doric order, and the upper with Corinthian columns, between which are semicircular arches springing from imposts. Each of the wings has three tiers of rectangular windows placed in recesses, which are formed by narrow projections of the wall after the manner of pilasters. Attached to this building is a Belvedere turret, with windows in each side, and having pilasters on the exterior.

The best period of Italian architecture was now over, and there are scarcely any buildings erected after this time which require comment; we shall therefore pass on to a consideration of this style as practised in England.

During the time of Palladio, Italian architecture began to be copied successfully in various parts of the Continent; and Palladio's method had become very generally popular. A mixture of Italian and Gothic architecture had been in vogue since the time of Elizabeth, after whose name the style procured the title of Elizabethan; the pure Italian, however, did not make its appearance here till the reign of James I., and Inigo Jones was the first architect to introduce it. In the early part of his practice, this architect had followed the mixed style, but on his return from a journey to Italy, he brought back with him the manner of the Palladian school, in which his principal works were, the portico of Old St. Paul's, Whitehall Palace, York-stairs, and the church of St. Paul, Covent Garden.

The first building of unmixed Italian architecture erected in England, was that of Whitehall, by Inigo Jones. This edifice was commenced during the reign of James I., A.D. 1619, but was never completed according to the original design, which contemplated the erection of an immense range of building containing seven courts, extending in one direction from the park to the river, the façade towards which would have measured 720 feet, and that towards Charing Cross, no less than 1152 feet. Only a small portion of this magnificent design was carried into execution, and this was the banqueting hall, which was completed in two years. This portion is 115 feet in length, and from its appearance we may form some idea of what the entire building would have been. The hall consists of three stories, of which the lower one is a plain rusticated basement, with simple rectangular apertures, without architrave or other decoration; the upper ones consisting of two complete orders, the lower of which is Ionic, and the upper Corinthian. Each story contains seven windows, with a column or pilaster between every two, and coupled pilasters at the angles of the building, thus making up ten columns in each story. The windows are all rectangular, and surrounded with architraves, above which are cornices supported on ancones; the lower tier, however, differs from the upper in having pediments above the cornice alternately triangular and segmental; this tier is also furnished with a balustrade which is wanting in the upper story. Both orders are surmounted by a complete entablature, which is broken over each column; the walls throughout are rusticated, and the building finished at the summit by a balustrade.

Jones's next work was the new portico to the then St. Paul's, but of this of course no remains are left. St. Paul's, Covent Garden, was another work which exhibits a chaste example of the Tuscan order; it was partially destroyed by fire in 1795, but has been restored in its original character. A beautiful, though small example of Jones's taste is exhibited in York-stairs, leading down to the river from the west end of the Strand. It consists of three arches, of which the central one is the largest, and the spaces between them are decorated with four half columns, supporting an entablature which is broken over the capitals; this again is surmounted by a segmental pediment, the tympanum of which is somewhat decorated with sculpture. The Strand front differs from that towards the river, in substituting pilasters in the place of half columns.

The great fire of 1666 gave an opportunity to the newly adopted style of architecture, which in all probability it would not otherwise have obtained; nor was it a light advantage in its favour, that it secured the services of Sir Christopher Wren; who, however we may find fault with some of his works, was undoubtedly a man of unusual attainments in his profession, and of unwonted energy and perseverance. As a proof of this assertion, we need do no more than point to the multitude of buildings erected under his superintendence. Of his twenty-five London churches, his palaces, and other public and private buildings, we can here say but little; but will endeavour to give a full account of his chef-d'œuvre, the Cathedral of St. Paul, forasmuch as it furnishes us at once with a specimen of Wren's skill, and with our most magnificent example of Italian architecture, as applied to sacred purposes. We shall commence by giving a cursory glance at the history of the structures which anciently occupied the same site.

It has been thought that, during the residence of the Romans in Britain, a temple, dedicated to Diana, had occupied the situation on which the present edifice is erected; and this opinion is said to have been confirmed by the digging up, at different times, horns and skulls of animals supposed to have been sacrificed; but Sir Christopher Wren, who found no such indications in all his researches, in the extensive excavations which he made for the foundations, gives very little credit to the common tradition. However this may be, it appears that one of the earliest Christian churches in England was erected upon this site, about the year 610, by king Ethelbert, who had been converted to Christianity by St. Augustine.

Erkenwald, the fourth bishop of London, who died in 685, expended large sums upon this church; but whether for additions, or to complete Ethelbert's plan, is not ascertained. The church was accidentally consumed by fire in the year 961, but was rebuilt immediately. In 1087, it was again destroyed by a conflagration, which also laid waste the greater part of the metropolis. At this time Maurice, or Mauritius, bishop of London, conceived the vast design of erecting the magnificent edifice which preceded the present cathedral; but the undertaking was so extensive, that neither Maurice nor his successor, De Belmeis, lived to complete it. The succeeding bishops, Gilbertus Universalis, and Robertus de Sigillo, are not known to have done anything towards the finishing of the building, till the second De Belmeis, who, following his uncle's example, contributed largely towards the work. In 1135, the edifice was again exposed to the injuries of fire, which consumed all that was combustible. The enterprise of that age, however, was not to be repressed even by such repeated disasters; for, in 1221, the central tower was finished; and, in 1229, bishop Niger undertook to rebuild the choir in a new style of architecture, and enlarged dimensions: this was completed in 1240.

The cathedral was farther enlarged by the addition of the Lady Chapel, eastward of the choir: these new works, as they are called in the records of the church, were begun in 1256, and finished about 1312; in which year we find a contract for paving this additional building with marble, at fivepence per foot.

In 1315, a great part of the timber spire being decayed, it was rebuilt, and a new cross erected at the top. In the same year, an exact measurement of the building was taken, by which the length was found to be 690 feet, the breadth 130 feet; the height of the nave, from the floor to the top of the vaulting, 102 feet, and the height of the choir 88 feet. The altitude of the tower, from the level of the ground, was 260 feet, and of the spire 274 feet; and yet, according to Dugdale, who gives these dimensions, the total height did not exceed 520 feet; this difference may be accounted for, by supposing the height of the tower to have been taken to the top of the battlements, or pinnacles, and that of the spire, to have been reckoned from its base.

This lofty spire was fired by lightning in 1444; and in 1561 the steeple suffered by a similar catastrophe; but a subscription was set on foot by Queen Elizabeth, and the damages were repaired. In the reign of James I. the church had become very ruinous throughout, owing, perhaps, to some defect in the original construction; and though large sums of money were collected, and materials provided for the reparation, it remained in the same state till the preferment of the celebrated Laud to the see of London. This prelate exerted himself zealously and successfully in favour of the neglected building, and a general subscription, supported in a munificent manner by king Charles I. was soon collected. to the amount of £101,330 4s. 8d. Having thus provided the necessary means for an entire restoration of the church. Inigo Jones was appointed to superintend the undertaking. The repairs were begun in 1633, and. in the course of nine years, a magnificent portico was erected at the west end; the whole exterior of the body of the church was new cased with stone, the roof and leaden covering were completed, and the vaulting, which was much dilapidated, and stood in need of repair, was well centred, and supported with some hundreds of tall masts.

During the time of the commonwealth, the building became exceedingly ruinous, and great part of the church was converted into stables and barracks; the choir, however, was still used for public worship.

Under the reign of Charles II. the regular government of the church being re-established, the dean and chapter proceeded immediately to remove the encroachments, and to restore the stalls and other appendages of cathedral worship; but their revenues not affording the means for a general reparation, another subscription was opened, and the repairs were commenced in 1663. Sir John Denham, the surveyor-general, had the superintendence of the works.

Dr. Wren, afterwards Sir Christopher, (as appears from the *Parentalia*) was employed to make a survey of the building, the result of which is given in an elaborate report, contained in that work. In this paper, the architect, after remarking on the general bad construction of the body of the church, and recommending a new and massy casing of stone, pronounces a final condemnation upon the tower, which, together with adjacent parts, he represents as "such a heap of deformities, that no judicious architect would think it corrigible by any expense that could be laid out upon new dressing it; but that it would still remain unworthy of the work, infirm and tottering." He therefore proposed a bold alteration of the primitive form, by cutting off the inner corners of the cross to reduce the middle part to a spacious cupola, or hemispherical roof, and upon this cupola, for the outward ornament, a lantern with a spring top, to rise proportionally; but not to the unnecessary height of the former spire. This proposal does not appear to have been much approved of by his employers, and the public opinion was expressed strongly for retaining the tower in its ancient form. The great fire of London, in 1666, at length decided the question, and this unfortunate building again became a prey to the flames, which consumed the roof; and by precipitating the vaulting, weakened, cracked, and ruined the walls and piers in such a manner, that they were judged incapable of repair. Still some years of irresolution elapsed before it was finally determined to erect a new cathedral.

Such was the fate of this venerable edifice; and, like many other monuments, it might have passed into oblivion, had not the meritorious antiquary, Dugdale, with the assistance of Hollar, preserved, in his *History of St. Paul's*, some considerable memorials of its form and decorations.

The ancient cathedral of St. Paul's must always be regarded as one of the great works of the architecture of the middle ages: in magnitude of dimension it far surpassed every other religious edifice of this country; and it is represented by historians as equally pre-eminent in magnificence and splendour of ornament.

The general form of the plan was a simple cross. with a very long choir, and a transept rather short in proportion to the extreme length of the building. The body of the church was in the Norman style of architecture; huge clustered pillars on each side divided the nave from the aisles, and supported large semicircular arches: immediately above these extended an open gallery, with arcades of the same form and width as those below, but of a much shorter proportion. From this level a different style of building prevailed, for the windows above the gallery were pointed. The vaulting, which covered the nave, was also of the pointed form, of the simplest groined construction, with soffits and diagonal ribs only, similar to Salisbury cathedral and the transept of Westminster abbey. Slender circular shafts, placed against the centre of each pier, rose from the pavement without any interruption of mouldings, and received the springing of the arches: the transept was in the style of the nave. Hence, we may conjecture that the original work of Maurice and De Belmeis comprehended the body of the church as high as the gallery; the vaulting being, undoubtedly, part of these works, which, in the preceding historical sketch, are mentioned as completed in 1221; and it thus became one of the earliest examples of the use of pointed arches in this country.

Sir Christopher Wren was of opinion, that this Norman building had been erected upon the remaining foundations of the more ancient Saxon church, for these he found to be composed of Kentish rubble-stone, cemented with mortar of extreme hardness, and both much superior to the materials used in the superstructure.

At the intersection of the nave with the transept, four massy pillars supported the tower; and, from this part, a broad flight of steps led to the choir, which was enclosed by a magnificent screen, elaborately adorned with niches and statues. The choir, which was a grand specimen of the architecture of Henry VIII.'s time, was completely in the pointed style, with a vault of a more complicated structure than that of the nave, each severy being composed of five ribs. The Lady Chapel, at the end of the choir, was a continuation of the building in the same form and style, and terminated, at the eastern extremity, by a rose window of extraordinary size and magnificence. A spacious, lofty crypt, extending beneath the eastern part of the cathedral, was appropriated to religious rites, under the designation of the church of St. Faith, and the chapel of Jesus. Three ranges of massy piers, enveloped by slender cylindrical shafts, divided the area into four equal aisles, and supported a high-pitched vault of the simplest groined construction. The exterior of the building presented a curious medley of the styles of different ages. At the western front, Inigo Jones had erected a portico of the Corinthian order, thus displaying a signal example of that bigotry in taste, which, only admitting of one mode of beauty, is insensible to the superior claims of order and congruity. This portico was, however, singly considered, a grand and beautiful composition, and not inferior to anything of the kind produced in modern times. Fourteen columns, each rising to the lofty height of 46 feet, were so disposed, that eight, with two pilasters placed in front and three in each flank, formed a square peristyle, and supported an entablature and balustrade, crowned with statues of the kings, the predecessors of Charles I. who claimed the honour of this fabric. Had the whole front been accommodated to Roman architecture, it might have deserved praise as a detached composition; but, though cased with rustic work, and decorated with regular cornices, the pediment retained the original Gothic character in its equilateral proportions, and it was flanked by barbarous obelisks and ill-designed turrets. A representation of this curious elevation is given in the works of Inigo Jones, edited by Kent. The great restorer of Roman architecture in this country, was, doubtless, pleased with having an opportunity of triumphing over the Gothic style of building, in one of its strong holds; and it must be allowed, that he only followed the example of the architects of the middle ages themselves, who have generally shown as little moderation and respect for the works of their predecessors; since we everywhere find the styles of different eras engrafted upon each other, in the most crude and undisguised contrast.

It appears that the whole body of the church had been cased and reformed in the same manner, which had obliterated every detail of antiquity, leaving only the general forms and proportions. The buttresses were converted into regular piers, and a complete cornice crowned the whole. Some of the windows were without ornament, while others were decorated in a heavy Italian manner, with architrave dressings, brackets, and cherubic heads. The transepts presented fronts of the same incongruous style as the western elevation, and without any of its beauties. At the centre of the cross, the great tower rose aloft in pre-eminent grandeur: this was in the simple style of the early Pointed architecture. In each side three remarkably pointed windows, and the same number above, but of a shorter proportion, gave an original character to the tower, with an air of great lightness and beauty. This was the foundation of an immense spire, of which, however, there are no accurate representations; for though Dugdale gives a view of the church in its entire state, yet this could not have been taken by him from personal inspection, neither does he mention any authority; and we may observe, that the style of the spire there exhibited is evidently not authentic. At each angle enormous arched buttresses, the irregular additions of various repairs, had been erected to secure the declining tower. The rest of the building, eastward of the transept, remained in its original form, a fabric of pointed arches and flying buttresses. In the east front, the most remarkable object was the rose window, which constituted the principal ornament of the Lady Chapel.

Like other ancient religious edifices, this cathedral had numerous dependencies; some of which were, the chapter-house, an octagonal building, of a rich and elegant pointed style, and surrounded by a cloister, two stories in height, of great beauty; the *clocher*, or bell-tower, standing at the east end of the church-yard, a very ancient building, to which had been added, about the time of Henry III., a spire of timber and lead; it contained four large bells, which, with the spire and an image of St. Paul, having been staked at hazard by Henry VIII., were won and taken down by Sir Miles Partridge.

It being at length determined to erect a new cathedral, Sir Christopher Wren was nominated to the superintendence. To form a just estimate of the talents of the architect employed in conducting a work of such magnitude and national importance, it is necessary to consider those preliminary steps and contemporary opinions which must ever influence or control the proceedings of an architect. We shall, therefore, condense from his posthumous collection, the *Parentalia*, an account of the formation of the design of the present church.

Before the great tax upon sea-coal, which did not commence till May, 1670, it was expected that the expenses of the building would be defrayed by voluntary contributions alone, and therefore it seemed expedient to restrict the plans to an edifice of moderate bulk. Upon these considerations, the architect prepared a design and model of a structure, with a choir, vestibule, porticos, and a lofty dome. This was applauded by some persons as containing all that was necessary for the church of a metropolis, being of a beautiful figure, and capable of erection at an expense that might reasonably have been compassed; but being designed in the Roman style, it was not so well understood and relished by others, who thought it deviated too much from the old cathedral form; while some wished for more magnificence, and were unwilling that the principal church in London should be inferior to any similar structure on the continent. The architect, enlarging his ideas, endeavoured to gratify the connoisseurs and critics with a grand colossal design, after the best style of the Greek and Roman architecture. This being much admired by some persons of distinction, a highly-finished model in wood, with all its proper ornaments, was made, which was carefully preserved, and at length deposited in a room over the morning-prayer chapel of the present edifice. Sir Christopher always appeared to set a higher value on this design than on any other he had made; but the prevailing prejudices still interfered, and the architect finally turned his thoughts to what was called a cathedral-form, but so modified as to reconcile, as nearly as possible, the Gothic to the new mode of architecture. Thus the design of the present edifice was formed; and, being approved of by king Charles II., a warrant was issued under the privy seal for beginning the work, May 1, 1675. The first stone was laid on the 21st of June following; and the works were prosecuted with so much vigour, that, within ten years from the commencement, the walls of the choir and side aisles were finished, with the circular porticos at the north and south sides, and the great pillars of the dome, were conducted to the same height. Some difficulties now occurred in procuring funds for the prosecution of this great work, but, through the operation of the coal duties, they all vanished; and, in the year 1710, the last, or highest stone, at the top of the lantern, was laid by Mr. Christopher Wren, son of the architect. Thus, by a fortune unusual to edifices of such magnitude and labour, this church was completed in thirty-five years, under the direction of one architect; and, as it has been commonly remarked as a singular coincidence, by one master-mason, Mr. Strong; and under one bishop of London, Dr. Henry Compton.

On investigating the exterior of St. Paul's cathedral, we find the general form to be that of a Latin cross, with an additional arm, or transept, at the west end, to give length to the principal point, and a semicircular projection at the east end, for the altar; there are also at the north-east, south-east, north-west, and south-west angles of the cross, square projections, which, besides containing staircases and vestries, serve as immense buttresses to the dome. This is extremely different, both in proportion and general effect, to the plan of St. Peter's at Rome, where the cross-shape is scarcely marked externally. The first object of attention is the *western front*, which is distinguished by a portico of two orders, the Corinthian supporting the Composite of grand dimensions and rich arrangement. A noble flight of steps, of black marble, forms a basement to this portico, which is terminated at the summit by a pediment. On each side of the front is a steeple; one serving as a belfry, and the other as the clock-tower: singly considered, these may be said to want repose, but yet they are picturesque; and their springing forms not only harmonize with the cupola in the distant view, but also give effect and elevation to the western front, to which they particularly belong. Nor are they without parts of considerable beauty.

The entablature of the upper order is remarkable, from the consoles of the cornice occupying the whole of the frieze. In this, as in many other instances, we see Sir Christopher sacrificing a particular, to a general, effect; for this cornice, considered as the grand termination to the body of the building, required to be treated in a bold and striking style, rather than with that delicacy appropriate to the order. The idea of this may probably have been taken from the upper entablature of the Coliseum at Rome, where the same motives of general effect have prevailed.

The ornaments of the front are well executed; and though not remarkable for elegance, are placed with judicious frugality, so as to enrich without overloading or confusing the aspect. A very large composition in basso-relievo, representing the conversion of St. Paul, occupies the tympan of the pediment. This is said to be the best work of the artist, Francis Bird. At the apex of the pediment is placed a gigantic statue of the patron saint, while St. Peter, St. James, and the four Evangelists, occupy situations at his right and left hand.

The rest of the building is a vast fabric of a wall decorated with coupled pilasters, arranged at regular distances; the intervals below being occupied with large windows, serving to light the side aisles, and those above with niches; in the pedestals of which are singularly inserted windows, belonging to galleries and rooms over the side aisles.

In the whole surface of the walling, the joints of the stones are marked by horizontal and perpendicular channels; a simple decoration, which, while it gives a vigorous expression of strength and stability, has the advantage of defining and rendering conspicuous the pilasters and entablatures.

The entrance doors of the transepts are adorned by semicircular porticos; objects equally beautiful, whether considered separately or in connection with the total mass of the building, which they adorn and diversify, by the contrast of curves and straight lines, and of insulated columns, with engaged pilasters.

At the centre, formed by the crossing of the nave and transept, rises an ample cupola, which is the most magnificent feature of the building. The basement of this part of the fabric is an octagonal wall, pierced through each side by an arcade; the two, which are in the direction of the nave, are open to the top, as are also the two in the direction of the transept: the other four have an intermediate arch, which supports the continuation of the dado or panelling above the entablature. The spandrels of the arches are spherical, and form a complete circle at the level of the summit of the arches. Upon the archivolt of the arches is placed a corbelled cornice of considerable projection, the upper side forming the floor of the whispering-gallery; from the floor of the whispering-gallery rises a cylindrical wall, called by the French, *tour du dome*, for which we have no technical expression. This is surrounded by a Corinthian peristyle, so placed as to conceal the projecting buttresses of the cupola; and thus, by a happy combination of profound skill and exquisite taste, a construction adapted to oppose, with insuperable solidity, the enormous pressure of the dome, the cone, and the lantern, is converted into a decoration of the most grand and beautiful character. The idea of this arrangement was, doubtless, taken from the interior of the Pantheon at Rome, to which it bears a striking resemblance.

On the exterior side of the building, the general disposition is divided into eight parts by piers, containing staircases, with two columns attached to the angles of each. The spaces between the piers form eight recesses, having in each two columns, which, at a distance, to a hasty observer, appear to be insulated; but they are in fact joined to the dome-tower, by walls, serving as counterforts. All these buttresses are, however, pierced with arcades, so as to leave a free communication round this part of the cupola. The columns being of a large proportion, and placed at regular intervals, are crowned with a complete entablature, which, continuing without a single break, forms an entire circle, and thus connects all the parts into one grand and harmonious whole. Above the colonnade, but not resting upon it, rises an attic story, with pilasters and windows, from which springs the exterior dome, of a bold contour, well adapted to the rising form of the lofty and elegant lantern by which it is crowned. It has been said, with some justice, that the columns of the cupola are too high in proportion to the body of the building, as they are indeed little less than those of the lower order, but higher than the columns of the upper order. This incongruity would not have existed, had circumstances allowed the architect to construct the main edifice of a single order. extending the whole height of the building; but being baffled in this his original intention, it would have been too great a sacrifice to relinquish the peristyle, the noblest feature of the building, or to materially diminish the cupola.

Comparing the cupolas of St. Peter's and St. Paul's, we shall find that, though the latter has, in a great degree. been the model of the former. there is a material difference in the decorative part, though the general idea of the construction is the same. In St. Peter's the buttresses of the dome-tower, though decorated each with two engaged columns and pilasters projecting from the cylindric wall. destroy the continuity, and render the effect disagreeable. The dome is likewise pierced with three ranges of little dormer-windows, which are suffered to spot and break the surface for the paltry consideration of lighting the interior staircases. The idea, originated in St. Paul's, has been prosecuted in the church of St. Geneviève at Paris, where the appearance of a peripteral temple is completely obtained, as the columns surrounding the tambour are all insulated; but, it is to be lamented, that the dome itself should be so deficient in grandeur of dimensions, and grace of proportions, as to destroy the effect of this beautiful decoration.

Beginning the examination of the interior of St. Paul's at the west end, we find the body of the building, as to the general form, entirely upon the plan of the ancient cathedrals; an edifice of three aisles, divided by piers and arches, and covered with vaulting.

Sir Christopher Wren has not only adopted the form of building practised by the architects of the middle ages, but he has imitated their mode of construction; for the lofty vault of the middle aisle is supported by flying buttresses concealed by an enormous screen wall. The architectural detail is in the Roman style, simple and regular.

"The Romans," says Sir Christopher, "though they sometimes used a hemisphere, as in the exhedræ of the baths, of the tribunes, of the temples, and basilicæ, yet, generally, they used a *plain cylindrical vaulting* where the walls were parallel, or cross-vaulting where the two cylinders intersected in diagonals, as in the Temple of Peace, and in all the theatres, in the passages under the steps. The moderns, whose arches are not circular, use commonly another sort, where the spandrels, resting upon the pillars, spring every way round as their arch rises in sections of circles, parallel to the horizon; that is, in four quadrants described from the angles of a square, and terminated by its sides; and, at the summit, these quadrants come in contact in the middle of the sides, the four curves forming a quadrilateral, each side being convex towards the centre; and the space thus included is filled with tracery work, which gives them great opportunity of divers variations, which I need not insist on. Another way, (which I cannot find used by the ancients, but in the latter Eastern empire, as appears at St. Sophia, and by the examples of all the mosques and cloisters of the Dervises, and everywhere at present in the East, and of all others the most geometrical,) is composed of hemispheres and their sections only; where, as a sphere may be cut in all manner of ways, and that still into circles, it may be accommodated to lie in all positions of the pillars. Let A B C D be a cupola, or hemisphere, resting upon four pillars, from whence arise the four *vertical* arches; to which the sections, being semicircles, must join on all sides, whether A B be equal to B C or not: cut the hemisphere again horizontally, the section will be an entire circle, touching in the keys of the arches, and G, H, K, L will be the spandrels, resting upon the pillars, yet still are parts of the hemisphere; and if the horizontal circle be taken away, you may build upon that circle an upright wall, which may bear a cupola again above, as is done in St. Sophia and St. Peter's, and in all the churches in Rome. I question not but those at Constantinople had it from the Greeks before them. It is so natural, and is yet found in the present seraglio, which was the episcopal palace of old; the imperial palace, whose ruins still appear, being farther eastward. Now, because I have, for just reasons, followed this way of vaulting of the church of St. Paul's, I think it proper to show that it is the lightest manner, and requires less butment than the cross-vaulting, as well as it is of an agreeable view."

We shall now proceed with the description of the other parts of this edifice.

It appears that these domes are of considerable antiquity, and, from the reasons here given from the *Parentalia*, that Sir Christopher Wren was justified in his choice in their adoption; their form is beautiful; and, when investigated, it is truly geometrical. Each wing forms a flat dome, supported by four spandrels; a rich wreath of foliage encircles the base, while the centre and the spandrels afford spaces well adapted, and probably intended, to receive ornamental paintings. The western transept is a beautiful part of the building; here insulated columns and screens of iron-railing separate from the aisles, on either side, the morning-prayer chapel, and the consistory.

In the progress of examination, we come to the intersection of the nave and the transept; and here, instead of four openings, eight are produced, which afford striking and picturesque views in various directions; and, in this respect, St. Paul's differs from every church with which we are acquainted, the cathedral of Ely only excepted. On the other hand, the junction of the aisles with the central area presented difficulties, which have caused various defects and mutilations in the architecture. The central area, as before observed, is an octagon, supported by eight piers, with as many apertures; four of which, terminating the middle aisles, are forty feet wide, while the others are only twenty-eight feet; but this disparity only exists as high as the first order of pilasters; at which height the smaller openings are expanded so as to make the main arches all equal. Spandrels between the arches form the area into a circle, which is crowned by a large cantiliver cornice, partly supporting, by its projection, the whispering-gallery. At this level commences the interior tambour of the dome, consisting of a high pedestal and an order of pilasters, the intervals of which are occupied by twenty-four windows and eight niches, corresponding with the intercolumniations and piers of the exterior. All this part is inclined forward, so as to form the frustum of a cone. From a double plinth above the cornice of the pilasters, springs the interior dome.

The choir is of the same form and architectural style as the body of the church, and is terminated by a semicircular apsis. The stalls, an enclosure, though not remarkable for elegance of design, are valuable for their ornamental carving, which is by the masterly hand of Gibbons.

In surveying the decorative parts of the interior of St. Paul's, it must be acknowledged that the general impression is that of simplicity bordering upon meanness and nudity, a defect which implies no censure on the great architect, who has left his work in that state to receive the ornament of painting and sculpture, which the frugality of following times have withheld.

The few ornaments which exist are, in general, well executed, and disposed with judgment: The soffits of the grand arches, under the cupola, are in the best style of simple and appropriate decoration. The dome is painted by Sir James Thornhill, who has deformed this beautiful vault with an absurd, heavy, and fictitious architecture, serving as a frame to eight pictures, representing so many actions of the patron saint. It is to be lamented, that instead of placing historical paintings in a situation where the spectator can distinguish nothing but the most obvious and general effect, some other system of decoration had not been adopted.

The design of the cathedral of St. Paul has been charged with various defects, the chief of which are the following: A want of proportion between the cupola and the body of the building; the divison of the exterior into two stories, of orders of columns and pilasters nearly equal; and the coupling of the columns in the western front:

In the interior, the omission of the architrave and frieze of the order, in the spaces between the great pilasters of the nave, for the purpose of raising the summits of the arches above the level of the architrave; the circumstance of the tambour of the dome being inclined forward out of the perpendicular; and, lastly, the awkward junction of the side aisles and mutilated arches.

With respect to the general division of the body of the building into two orders of architecture, we have the authority of the architect himself, as expressed in the *Parentalia* and exhibited in his favourite model, in favour of the single order; but, with regard to this, he was obliged to yield to circumstances, as the Portland quarries could not afford stones of the required dimensions; this necessity led to another, viz., the coupling of the order.

On an inspection of the ground plan of the building, it will be seen, that the exterior pilasters are placed at intervals corresponding to the interior piers, an arrangement which could not be deviated from. As to the omission of the architrave of the order, above the arches of the interior, we are informed in the *Parentalia*, that, in this respect, Sir Christopher Wren "always insisted that he had the ancients on his side; and that, in the Temple of Peace, in the great halls of the Baths, and in all the great structures of three aisles, this is done, and for this reason, that in these wide intercolumniations, the architrave is not supposed to lie from one column to another; but, from the column to the wall of the aisle, so that the end of it only will appear upon the pillar of the inside of the great navis." This is a sufficient answer to those rigorous critics, who would subject the composition of a cathedral to the strict rules which limited the Grecian temples; and it shows that the architect had studied those antique models, which, if not in the purest taste in point of ornament, were yet the most analogous, in general form, to the edifice he had to construct. But, though this was the ostensible excuse, it was not the real reason; for, upon referring to the section of St. Paul's, it will be seen, that Sir Christopher has made the pilasters of the interior a little higher than the exterior columns, which could not be much without incongruity; and, wishing to give the arches, opening to the aisles, as much elevation, and consequently lightness, as the design admitted, he chose to encroach on the entablature of the order; and thus, by a single alteration from general rules, he improved the effect of his building.

According to the large plan, published by Gwyn, the external length of the building, from east to west, exclusive of the projection of the portico, appears to be 502 feet; from north to south, excluding the two circular porticos, 244 feet; the breadth of the western front, 177; the diameter of the octagonal area, at the crossing of the nave and transept, 107; the diameter of the tambour of the dome, 112; and the diameter of the dome itself, 102. The total height, from the pavement of the church-yard, to the top of the cross, is 370 feet. The total expense of the building amounted to £747,954. 3s. which was defrayed by a duty on coals imported into London; but not less than £126,604. 6s. 5d. was furnished by voluntary contributions, chiefly from the clergy. See *The Fine Arts of the English School*, edited by John Britton, F. S. A.

Sir Christopher was architect of no less than fifty-one parish-churches in the metropolis, besides the cathedral and other public buildings, but of these we cannot speak particularly, we can only mention such as are more deserving of notice.

St. Stephen's, Walbrook, is looked upon by some as Wren's master-piece, not even excepting St. Paul's, and the interior certainly is worthy of much praise both for taste and proportion, although by no means faultless. The exterior of the church, like those of the greater number of his churches, has no pretensions to beauty, being plain even to ugliness, if we except the steeple.

The interior, which approaches a parallelogram in plan, is divided into three aisles, and a cross aisle by four rows of Corinthian columns raised on pedestals; these support the roof, which is divided into compartments. The central portion of the church is covered by a dome, which is finely proportioned and divided into small compartments, decorated with great elegance, and crowned with a lantern. On the sides, under the lower roofs, are circular windows, but those which light the upper roof are small arched ones; and at the east end are three larger arched windows. The dimensions of the building are:—length 75 feet, breadth 36 feet, height to roof 34 feet, and to lantern 58 feet.

Of the remaining churches, those most worthy of notice are St. Bride's and St. Mary-le-Bow, and these are remarkable more especially for their steeples, a feature introduced by Wren into his churches, and one on which he bestowed his principal care, many of his churches being in other respects little worthy of the praise that has been bestowed upon them.

The steeple of St. Bride's is certainly a very excellent composition. The spire is placed on a lofty tower, is octagon in plan, and consists of four similar octagonal stories placed one above another, and decreasing in dimension as they rise, so as to present a pyramidal appearance. Each tier comprises a single order, having a semicircular-headed aperture on each side of the octagon, and a pilaster at each of its angles, the two lower stories being of the Tuscan order, the third Ionic, and the fourth Composite. Above these is a smaller story, which is surmounted by a small spire. The present height of this steeple is 226 feet, but it was originally eight feet higher, the difference having been deducted after an accident by lightning in 1764.

The spire of St. Mary-le-Bow rises in a similar manner from a lofty square tower; from a stylobate, on the top of which rises a circular peristyle surmounted by entablature and balustrade. Upon this rises above each column a kind of buttress assuming in profile a curve of double curvature, and falling inwards towards the summit, so as to diminish the horizontal area. Above this is another peristyle with entablature and buttresses of a similar form above, supporting a small spire which carries the vane. This steeple is deservedly admired.

We must pass by Wren's other churches, and content ourselves with enumerating some few of his other works, amongst which the most conspicuous in this style are—Greenwich Hospital, Theatre at Oxford, College of Physicians, and Temple Bar.

Of all Wren's pupils, only one attained to any great eminence, and this was Nicholas Hawksmore, one of whose churches, that of St. Mary, Woolnoth, is of considerable merit; this church is thus described by Mr. Godwin. Speaking of the interior, he says—"It is nearly square, and on the model of a Roman atrium. Twelve well-proportioned Corinthian columns, placed three in each angle, at a distance from the outer walls, equal to about one-sixth of the whole width of the church, support an entablature and a clere-story above it, which latter presents a large semicircular window on each of the four sides. The ceiling of the square area enclosed by the clere-story walls, as well as the soffit of the aisles formed by the columns, is profusely decorated with panels and carved mouldings. A ponderous but elegantly ornamented gallery, is introduced on three sides of the church with so much skill, that it does not mar the general effect, as is often, nay, with some few exceptions, always the case.

"The general effect of the interior is rich and beautiful, and the proportions of the plan and section good; the columns are admirably arranged, and every part displays talent; the whole design is nevertheless somewhat crowded in detail, and overlaid with ornament, and, according to our view of the case, wanting fitness for its purpose, is less deserving of applause than it would be, were the building otherwise appropriated than it is." St. George's, Bloomsbury, is another church by the same architect.

The next architect of any note practising this style, was James Gibbs, the architect of St. Martin's-in-the-Fields, and St. Mary-le-Strand, both which churches present many good features; the portico to the former is much admired. Gibbs introduced a practice of placing the spire over the body of the church, so that it appears as if rising out of the roof; this is decidedly objectionable.

Passing by many architects of less note, we arrive at Sir William Chambers, who greatly excelled his cotemporaries and many of his predecessors in this style of building; his greatest work is Somerset House, which we must not pass by without a short description. "This building," says Mr. Bury, "stands on an area of 800 feet in width, by 500 feet in depth, and is disposed on the four sides of a rectangular court, the interior length of which is 319 feet from north to south, and 224 feet in breadth: the façade towards the Strand is 133 feet long, and consists of three stories: nine arches are assigned to the basement, whereof the three in the centre are open, and lead to the great court, besides having entrances to the apartments of this wing; the other rusticated arches are occupied by windows, decorated with pilasters, entablatures and pediments. Above this story are two tiers of windows of which those in the lower tier have entablatures supported by Ionic columns; the upper windows are square, and are surrounded by square architraves. Between these windows, the walls are ornamented with three-quarter columns of the Corinthian order, standing on pedestals, and extending the height of the two stories; the height of the order without the pedestals is 23 feet, and that of the entablature is 5 feet. Over the three central compartments of this façade, is an attic-story, with oval windows and statues in front: the entire height from the ground is 62 feet."

The vestibule contains a carriage-way and two foot-ways, separated by two ranges of coupled Doric columns, which with their entablature support the vaults.

The inner front of this division of the building, facing the court-yard, is similar to that in the Strand, with the exception that pilasters are employed in the place of columns.

The east and west sides of this quadrangle are similar to those already described, with the exception of those portions between the extremities and the central division, in which the windows are of a less ornamented description, being rectangular, and without architraves. The central divisions are crowned by urns surmounting the entablatures, and have each a small clock-tower above the roof. The south façade is similar to the east and west sides, but its central compartment is more highly enriched, the entablature being supported by four columns and four pilasters, both of the Corinthian order, and the windows between the columns being recessed. Above the roof is a lofty cupola, partially screened by an angular pediment.

"The front towards the river Thames, is 350 feet long, and presents a magnificent appearance. Its arrangement corresponds with that of the quadrangle, but a superior boldness of character has been adopted in its centre wings, where disengaged columns with pilasters are introduced. The centre part of this building is crowned by a cupola, as above stated. Before this façade is a terrace 50 feet wide, supported by a lofty arcade, and protected by a balustrade. In the centre is one great semicircular arch, and near each extremity is a water-gate of similar form, the piers of which are ornamented with rusticated columns."

We must now turn to a class of structures which have risen up of late, and to which this style of building is peculiarly applicable,—we allude to Club-houses. Some of these edifices are of very elegant design, and of magnificent appearance, their general treatment being borrowed from the palatial edifices of Italy: they are in our opinion the most favourable examples of Italian architecture in England, and are far preferable to the ecclesiastical edifices built in this style; a fact which arises, as we imagine, not so much from the merit of the architects employed, as from the circumstance that the style is adapted to the one class of edifice, and not to the other.

Of the clubs, all of which are of considerable merit, a full account has been given under the article Club-House, to which we beg to refer. We can here only call especial attention to the Reform, the Traveller's, the Carlton, the Army and Navy, and the Conservative. The dignified repose of the first, the simple and unpretending elegance of the second, and the lightness and magnificence of the rest, are subjects all equally worthy of the young architect's attentive study.

The same style has been applied on a somewhat less magnificent scale, yet with equal success, to many other buildings, amongst which fire and life insurance-offices stand pre-eminent. We can here only allude, in passing, to those of the Sun, Imperial, and Globe Societies. This style has also recently been adopted for private mansions, an example of which is afforded us in Bridgewater House, the mansion of the Lord Ellesmere, now erecting under the able superintendence of Mr. Barry, to whom we are indebted for some of the most beautiful and recent erections in this style, amongst which stand pre-eminent the Reform and Traveller's club-houses. We conclude this article with a description of this last, and not least, beautiful example of Mr. Barry's taste, and trust that this may be only a commencement of a new class of town residences for the nobility of this country.

The plan of this mansion is nearly square, the north front being 142 feet 6 inches from east to west, and the west front, shown in our engraving, 122 feet from north to south. The west elevation consists of three stories, separated from each other by ornamental flat-bands and cornices, and is divided into a centre and two wings, which, however, project but slightly. The lower story is rusticated with vertical and horizontal channels, and comprises seven windows, of which five, belonging to the central portion of the building, are plain rectangular apertures, with projecting key-stone, but without architrave. The two outer ones are of a similar character, but are of three lights, the central one being of the same description as the others, and the side ones a little narrower. Above the cornice of this story is a podium, pierced with balusters opposite each window, and having projecting plinths under the architraves. The same number and arrangement of windows occur in this story, but they are of a much more elaborate description, having a highly enriched architrave, and being surmounted by a segmental pediment, supported on projecting corbels, and having the tympanum enriched with sculpture. The triplets in the wings are similarly ornamented, but have a segmental pediment over the central light only, the upper mouldings being continued horizontally, with the corniee over the side lights. The upper story has the same number of square lights with moulded architraves, the spaces between them being panelled: the triple arrangement in the wings is preserved in this story. The entire building is surmounted by a bold cornice supported on consoles, the spaces between which are ornamented with roses, and the corona with dolphins' heads, one over each console. Above the cornicione is a balustrade, the dies of which are surmounted by roses. The angles of the building are finished with coins, which are enriched with reticulated rustication, and, being of considerable width, impart a very rich effect to the façade; the chimneys are brought up at the angles, and are made to form architectural features. A balustrade runs along in front of the lowermost story.

The south elevation is very similar to the west, having a series of nine windows, exactly the same as those in the central portion of the western façade, but having no projecting wings, the extreme angles only being rusticated. The entrance porch is in the centre, and is surmounted by vases similar to those above the balustrade.

IVORY, the name given to the substance composing the tusks of the elephant and the walrus, and to the horn of the narwhal, or sea unicorn. Ivory is extensively used in the arts, for making and embellishing numberless small articles of ornament and use. Tables, cabinets, &c., are frequently inlaid with ivory.

J.

JACK, Lifting Jack, in mechanics, a portable machine for raising great weights through a small space. It consists of a rack and pinion inclosed within a strong wooden case, and the power is applied by means of a winch or handle fixed upon the axis of the pinion; the upper end of the rack is formed into two horns, to take the better hold of the article to be elevated; and from the end two prongs project laterally through a longitudinal groove in the case, which are used upon occasions when there is not room to introduce the jack beneath the load. To prevent the labourers being overpowered, there is a racket wheel and pall on the axis of the pinion.

Jack Arch, an arch of only one brick in thickness.

Jack in the Box, a large wooden solid screw, turning in a hollow one, which forms the upper part of a wooden box, shaped like the frustum of a pyramid; it is used by means of levers, passing through holes in it, as a press in packing, and for other purposes.

Jack Plane, a plane about 18 inches in length, used for taking off the rough of the saw, or the irregularities of the axe, and planing off any inequalities, to prepare the stuff for the trying plane.

Jack Rafter, a short rafter, such as those which are fixed to the hips.

Jack Ribs, in a groin, or in a polygonal domic ceiling, are the ribs that are fixed upon the hips.

Jack Timber, any timber that is interrupted in its whole length, or cut short.

Jak Wood, a coarse-grained wood brought from India, sometimes used in cabinet-work and turnery.

JAMBS (French) the sides of an aperture, which connect the two sides of the wall.

Jamb Lining, the two vertical linings of a door-way or aperture, which connect the two walls.

Jamb Posts, such as are sometimes introduced on the side of a door, in order to fix the jamb linings. They are particularly used when the partition is of wood.

It having been noticed by Mr. T. N. Parker how rapidly the lower ends of door posts decayed where they were exposed to wet, he contrived a cast-iron socket for them, which is much used in Shropshire, and might be generally introduced with advantage. These sockets are cast by the Colebrook-dale company; they weigh only 7lbs. the pair, and cost about 2½d per pound.

Jamb Stones, in stone walls, such as are employed in building the sides of an aperture, in doing which, every alternate stone ought to be inserted the whole thickness of the walls.

JANTU, a machine used in Hindostan for raising water for the purpose of irrigating lands.

JAPANNING, the art of painting and varnishing, after the manner practised by the natives of Japan, in the East Indies. It is employed for the purpose of preserving and beautifying various articles, usually of wood and metal, as well as paper, leather, and cloth, when they are properly prepared for the purpose. Those articles we most commonly find japanned, are pieces of household furniture, cabinet-work, boxes of all kinds, trays, screens, &c., and, very generally, those articles made of any of the above-mentioned or similar materials, which it may be desired to preserve from moisture. This it is admirably adapted to effect, from its drying very hard, and being impervious to water at all moderate temperatures, even to boiling in some cases; but it may be employed on any dry substance that is sufficiently inflexible to prevent the japan from being cracked or forced off.

JERKIN HEAD, the end of a roof that is not hipped down to the level of the opposite adjoining walls; the gable being carried higher than the level of the said walls.

JET D'EAU, (French) a fountain, or ornamented jet, throwing up a stream of water to some height in the air. *See* Fountain.

JETTEE, Jetty, or Jutty, (French) the border made around the stilts under a pier, consisting of piles and planks, stones filling up the interstices, to secure the whole foundation.

Also the projecting portion of a building, such as the overhanging story of ancient timber houses.

JIB-DOOR, a door so constructed as to have the same continuity of surface with that of the partition in which it stands. The use of a jib-door is to preserve the symmetry of an apartment, where only one door is wanted, nearer to one end of the partition than the other. Instead of a jib-door, a real door and a false one may be used. Where jib-doors are used, it is obvious that they must be concealed as much as possible.

JOGGLE, the joint of two bodies, so constructed as to prevent them from sliding past each other, by the application of a force in a direction perpendicular to the two pressures by which they are held together. The struts of a roof are joggled into the truss-posts and into the rafters; when confined by mortise and tenon, the pressure which keeps them together is that of the rafter and the re-action of the truss-post. The same is also applied to the step and platform stones of a geometrical stair.

Joggle Piece, the truss-post in a roof, when formed to receive a brace or strut, with a joggle.

JOINER, the workman who joins wood for the finishing of buildings.

JOINERY, in civil architecture, the art of framing or joining wood together, for internal and external finishings of houses; thus the coverings and linings of rough walls, or the coverings of rough timbers, and the construction of doors, windows, and stairs, are joiners' work.

Joinery requires much more accurate and nice workmanship than carpentry; the latter consists only of rough timbers, used in supporting the various parts of an edifice: joinery is therefore used by way of decoration, and being always near to the eye, and consequently liable to inspection, requires that the joints should be fitted together with the utmost care, and the surfaces made smooth.

The wood used is called *stuff*, and is previously formed by the pit-saw into rectangular prisms, which are denominated *battens*, *boards*, or *planks*, according to their breadths. Battens run from two to seven inches wide; boards from seven to nine inches wide; and planks from nine inches to any greater breadth that can be cut out of a piece of wood.

The operations of joinery consist of forming surfaces of various kinds, also of grooving, rebating, and moulding, and of mortising and tenoning; and lastly, of joining two or several pieces together, so as to form a frame or solid mass

Surfaces, in joinery, are either plane or curved, but most frequently plane. All kinds of surfaces are first formed in the rough, and finally brought to a finish by means of appropriate tools.

Grooving consists in taking away a part of a rectangular section from a piece of wood, so as to form a channel of equal breadth throughout, with three surfaces, one parallel, and the other two perpendicular, to that of the wood; which channel is called a *groove;* and thus the piece that would fill the cavity, or which would restore it to its original form, is a square prism.

Rebating consists in taking away a part from a piece of wood of a rectangular section, so as to leave only two sides, one perpendicular, and the other parallel, to the surface of the wood; the cavity thus formed is called a *rebate.* From this definition it is manifest, that a rebate can only be formed by reducing the piece of wood to be rebated at the angle itself, and may therefore be considered as a semi-groove; and thus the piece which would restore the whole to its original form is a square prism, as in grooving.

A mortise is a cavity recessed within the surface of a piece of wood, with four sides perpendicular to the surface, and to each other. The act of making a mortise is called *mortising.*

A tenon is a projection formed on the end of a piece of wood with four plane sides, at right angles to each other, and to a plane, from which it projects, called *the shoulder of the tenon.*

In the following, all pieces of wood whatever are supposed to be rectangular prisms, and the length in the direction of the fibres; two of the sides of every mortise perpendicular, and the other two parallel, to the fibres; and the four sides of every tenon in the direction of the fibres, unless otherwise described: likewise, if two of the surfaces of a piece of wood be of greater breadth than the other two, the latter are called *the edges*, and the former *the sides;* while each line of concourse, formed by two adjacent sides, is called *an arris.*

Moulding consists in forming the surface of a piece by plane or curve surfaces, or by both, in such a manner that all parallel sections may be similar and equal figures.

The first thing to be done in joinery is to select the stuff or boards, which ought to be well seasoned for every purpose in joinery, and then line it out; and if the stuff be not already at the size, as is most frequently the case, it must be ripped out with the ripping-saw, or cross cut with the hand-saw, or both, as may be wanted. The next thing is the planing of the stuff, first upon a side, then the edge squared, and afterwards gaged to a breadth and thickness, should either or both be found necessary.

Two or more pieces of stuff may be fastened together, in various ways, by pins of wood, or by nails; but in work prepared by the joiner for building, the pieces are more frequently joined together by making their surfaces planes, and plastering them over with a hot tenacious liquid, called *glue*, then rubbing the surfaces until the glue has been almost rubbed out, and one piece brought to its situation with respect to the other. The best work is always joined by this method.

When boards are required of a greater breadth than common, several primitive boards must be fastened together edge to edge, either by nailing them to pieces extending across the breadth, or by gluing them edge to edge, or by joining pieces transversely together with small boards, tongued into grooves excavated in the edges.

Two pieces of stuff are joined together at right or oblique angles by a mortise and tenon adapted to each other, and fastened together with glue.

When a frame, consisting of several pieces, is required, the mortises and tenons are fitted together, and the joints glued all at one time, then entered to their places, and forced together by means of an instrument called a *cramp.*

A frame of wood in order to contain a panel, and surround it completely, cannot be made of less than three pieces, unless one or more of them be curved, because less than three straight lines cannot contain a space.

The operation of forming a given surface, by taking away the superfluous wood, is called *planing*, and the tools themselves *planes.*

The first tools used by joiners are *bench planes*, which generally consist of a *jack plane*, for taking away the rough of the saw and the superfluous wood, only leaving so much as is sufficient to smooth the surface; the *trying plane*, to smooth or reduce the ridges left by the jack-plane, and to straighten or regulate the surface, whether it be plane or convex; the *long plane*, when the surface is required to be very straight; and the *smoothing plane*, in smoothing, as its name implies, and giving the last finish to the work.

Besides the bench planes, there are others for forming any kind of prismatic surfaces whatever, as *rebating planes*, *grooving planes*, and *moulding planes:* but for a more particular description of these and the bench planes, we shall refer to the article PLANE.

The tools employed in boring cylindric holes are a *stock* with *bits*, of various descriptions and sizes, *gimlets*, and *bradawls* of several diameters.

The tools used in paring the wood obliquely, or across the fibres, and for cutting rectangular prismatic cavities, are in general denominated *chisels;* those for paring the wood across the fibres are called *firmers*, or *paring chisels*, and those for cutting mortises are called *mortise chisels.* The sides of all chisels, in a direction of their length, are straight, and the side of a chisel which contains the cutting edge at the end is of steel. The best paring chisels are made entirely of cast steel. Chisels for paring concave surfaces are denominated *gouges.*

Dividing wood, by cutting away a very thin portion of the material of equal thickness throughout, to any required extent, by means of a thin plate of steel with a toothed edge, is called *sawing*, and the instruments themselves are called *saws*, which are of several kinds; as the *ripping saw*, for dividing boards into separate pieces in the direction of the fibres; the *hand saw*, for cross cutting, or for sawing thin pieces in the direction of the grain; the *panel saw*, either for cross cutting, or cutting very thin boards longitudinally; the *tenon saw*, with a thick iron back, for making an incision of any depth below the surface of the wood, and for cutting pieces entirely through, not exceeding the breadth of that part of the plate without the iron back; likewise a *sash saw*, and a *dovetail saw*, used much in the same way as the tenon saw. From the thinness of the plates of these three last saws, it is necessary to stiffen them by a strong piece of metal, called the *back*, which is grooved to receive the upper edge of the plate that is fixed to the back, and which is thereby secured and prevented from crippling. When it is required to divide boards into curved pieces, a very narrow saw without a back, called a *compass saw*, is used; and in cutting a very small hole, a saw of a similar description, called a *key-hole saw*, is employed. All these saws have their plates longer and thinner, and their teeth finer, as they succeed each other in the order here mentioned, excepting the two last, which have thicker plates, and coarser teeth than either the sash or dovetail saws. The external and internal angles of the teeth of all saws are generally formed at an angle of 60 degrees, and the front edge teeth slope backward in a small degree, but incline or recline from the straight line drawn from the interior angle perpendicular to the edge in the plane of the plate, as the saw may be employed in ripping or in cross cutting, or cutting perpendicular to the fibres. The teeth of all saws, except turning and key-hole saws, are alternately bent on contrary sides of the plate, so that all the teeth on the same side are alike bent throughout the length of the plate, for the purpose of clearing the sides of the cut made by it in the wood.

Of all cutting tools whatever, the saw is the most useful to the joiner, as the timber or wood which he employs can be divided into slips or bars of any size, with no more waste of stuff than a slice, the breadth of which is equal to the depth of the piece to be cut through, and the thickness equal to the distance of the teeth between their extreme points on the alternate sides of the saw, measured on a line perpendicular to them: whereas, without the use of the saw, cylindrical trees could only be reduced to the intended size by means of the axe; in the use of which there would not only be an immense consumption of stuff, but also much greater labour would be required to reduce it to a straight surface.

Joiners use a small axe, called a *hatchet*, for cutting off the superfluous wood from the edge of a board, when the waste is not of sufficient consequence to be sawed.

The above are what are commonly denominated *edge tools*, but there are others required to regulate the forms. All angles whatever are formed by other reversed angles of the same number of degrees; as an exterior angle by an interior one, and the contrary. The instrument for trying right angles is called a *square*, and those for trying oblique angles are called *bevels*. The two sides which form the edge of a square are always stationary, but those of bevels are generally moveable, one leg upon the other, round a joint. In some cases, where a great number of pieces are required to be wrought to the same angle, a stationary bevel, called a *joint-hook*, is used.

When it is required to reduce a piece of stuff to a parallel breadth, an instrument called a *gauge* is used, which consists generally of a square piece, with a mortise in it, through which runs a sliding bar, at right angles, called the *stem*, furnished with a sharp point, or tooth, at one extremity, projecting a little from the surface, so that when the side of the gauge, next to the end which has the point, is applied upon the vertical surface of the wood, with the toothed side of the stem upon the horizontal surface, and pushed and drawn alternately by the workman from and towards him, the tooth will make an incision from the surface into the wood, at a parallel distance from the upper edge of the vertical side on the right hand. This line marks precisely the intersection of the plane which divides the superfluous stuff from that which is to be used.

When a mortise is required to be cut in a piece of wood, a gauge with two teeth is used. The construction of this instrument is the same as the common gauge, except that the stem has a longitudinal slider with a tooth projecting from its end, so that both teeth may be brought nearer, or removed farther from each other, at pleasure; and also to any distance, from the face of the head or guide, within the reach of the stem.

If, when a piece of wood has been planed, it is required to be sawed across the fibres; to keep it stationary during the operation, and to prevent the sides or edges from being bruised, a flat piece of wood with two projecting knobs on opposite sides, one at each end, called a *side-hook*, is used. The vertical side of the interior angle of one of the knobs is placed close to the vertical side, and the under side upon the top of the bench; then the wood is pressed against the knob which projects from the upper surface while it is cutting. But the use of two side-hooks is better, as they keep the piece more steady.

When it is required to cut a piece of wood to a mitre with one side—that is, to half a right angle—joiners use a trunk of wood with three sides, like a box without ends or a top, the sides and bottom being parallel pieces, and the sides of equal heights; through each of the opposite sides is cut a kerf, in a plane perpendicular to the bottom, at oblique angles of 45° and 135° with the planes of the sides; and another kerf is made with its plane at right angles to the two former: this trunk is called a *mitre-box*. When the wood is to be cut, the mitre-box is fixed steady against two side-hooks, and the piece, which must always be less than the interior breadth of the mitre-box, is laid in it, and pressed against its farther interior angle, with the side downwards, to which the saw-kerf is intended to be perpendicular, and in this position it is to be cut. The two kerfs in the sides of the mitre-box are requisite, in order to form the acute angle on the right or left-hand side of the piece, as may be required.

When a piece of wood is required to be made straight in one direction, joiners use a slip of wood straightened on one edge, and thence called a *straight edge*. Its use is obvious; as by its application it will be seen whether there is a coincidence between the straight edge and the surface.

When it is required to know whether the surface of a piece of wood is in the same plane, joiners use two slips, each straightened on one edge, with the opposite edge parallel, and both pieces of the same breadth between the parallel edges: each piece has therefore two straight edges, or two parallel planes. Therefore, to find whether a board is twisted, or its surface plane, the workman lays one of the slips across the one end, and the other across the other end of the board, with one of the straight edges of each upon the surface; then he looks in the longitudinal direction of the board, over the upper edges of the two slips, until his eye and the said two edges are in one plane; or otherwise, the intersection of the plane passing through the eye and the upper edge of the nearest slip, will intersect the upper edge of the farther slip. If it happen as in the former case, the ends of the wood under the slips are in the same plane; but should it happen as in the latter, they are not. In this last case, the surface is said to *wind;* and when the surface is so reduced as for every two lines to be in one plane, it is said to be *out of winding*, which implies its being an entire plane; from the use of these slips they are denominated *winding-sticks*.

Before we proceed to the method of bringing a rough surface to a plane, it is necessary to show how to make a straight edge. And here the joiner must not lose sight of the properties of a straight-line, viz., that which will always coincide with another straight line, however they may be applied together.

The operation of making the edge of a board straight is called by joiners, *shooting*, and the edge so made is said to be *shot*.

Straight edges may be formed by planing the edges of two boards, and applying them together, with their superficies or faces in the same plane; if there be no cavity in the joint, the edges will be straight; if not, the faces must be applied to each other, the edges brought together, and planed and tried as before, until they coincide.

Another mode is by having a plane surface given Plane:—the dges of a board as straight as the eye will admit of, apply the face of it to that of the plane, and draw a line by the edge of the board; turn the board over with the other side upon the plane, bring the planed edge to the line drawn before, and the extremities of the edge to their former places, and draw another line; then, if all the parts of this line coincide with the former, the edge is already straight, but if not, repeat the operation as often as may be necessary.

Another mode is to plane the edge of a board as straight as can be done by the eye, then plane the edge of another board until it coincides with the former; plane the edge of a third board in like manner, to coincide with the edge of the first, and apply their edges together; then, if they coincide, the operation is at an end, but if not repeat till they do.

By any of these methods, the superficies of the boards to be shot are supposed to be parallel planes, not very distant from each other; for if the faces be not parallel, or if the thickness be considerable, the operation will be more liable to error.

To reduce the rough surface of a body to a plane.—This will not be very difficult, when it is known that a plane will everywhere coincide with a straight line.

The most practical methods are the following:—Provide two winding-sticks, and apply them as before directed, making the ends out of winding, if they are not found to be so; then, if all the parts of the surface on which the edges of the winding-sticks were placed are straight, it is evident that the whole surface must be plane. If the surface is hollow between the said lines, one of the ends, or both, must be planed lower, until the surface acquires a small convexity in the length; and then, if straightened between the straight lines at the ends, it will be a perfect plane.

Another mode of forming a plane, supposing the surface to be of a quadrilateral form. Apply a ruler along the diagonals, then, if they are straight, they are in a plane; but if they are both hollow, or both round, the surface to be reduced is either concave or convex, and must be straightened in these directions accordingly.

Lastly, if, by trying across the diagonals with the straight edge, it be found that the one is hollow and the other round, the surface of the board winds. In this case, bring down the protuberant part of the convex diagonal, so as to be straight with the two extremities; then straighten the concave diagonal, by planing either of the two ends, or both of them, according as the thickness of the board may require. Both diagonals being now straight, traverse the wood—that is, plane it across the fibres, until all the protuberant parts between the diagonals are removed; then smooth it by working in the direction of the fibres.

To join any number of planks together, so as to form a board of a determinate breadth, the fibres of each running longitudinal to those of any other.—Shoot the two edges that are to be joined; turn the sides of the boards towards each other, so that the edges that are shot may be both uppermost; spread these edges over with strong glue of a proper consistence, made very hot; one of the boards being fixed, turn the other upon it, so that the two edges may coincide, and that the faces may be both in the same plane: rub the upper one to and fro in the direction of the fibres, till the glue is almost out of the joint; let these dry for a few hours: then proceed to make another joint; continue to join as many boards or planks in the same manner, till the whole intended breadth be made out. If the boards, or planks of which the board is to be composed, be very long, the edges that are to be united will require to be warmed before a fire; and, for rubbing and keeping the joints fair to each other, three men will be found necessary, one at each extremity, and one at the middle. Boards glued together with this kind of cement will stand as long as the substance of the deals or planks composing them, if not exposed to rain or intense heat, provided the wood has been well seasoned beforehand, and the grain be free and straight, and interrupted with few or no knots. When a board which is to be exposed to the weather is to be made of several pieces, the cement to be used for uniting them should not be of skin glue, but of white-lead ground up with linseed-oil, so thin that the colour may be sensibly changed into a whitish cast; this kind of glue will require a much greater time to dry than skin glue. Boards to be exposed to the weather, when their thickness will admit, are frequently tongued together: that is, the edges of both boards are grooved to an equal distance from the faces, and to an equal depth; and a slip of wood is made to fit the cavity made in both: this slip should be made to fill the grooves, but not so tight as to prevent the joint from being rubbed with proper cement.

To glue any two boards together forming a given angle.—This may be accomplished, either by shooting the edge of one board to the whole of the given angle, keeping the face of the other straight; and then, by applying the two surfaces together, and rubbing as before, they will form the angle required; or, if the two edges, being shot to half the given angle, be applied together, and rubbed and set as before, their faces will form the angle required. In both these methods, when only one side of the board is to be exposed to sight, which is most commonly the case, pieces of wood, called *blocks*, are fitted to the inside of the angle, and the sides glued across the joint or legs of the angle, being previously planed for that purpose.

To form wooden architraves for apertures, by giving longitudinal pieces together.—Architraves are sometimes formed of solid pieces, but a better and more economical mode is that of gluing longitudinal pieces together. See ARCHITRAVE. Architraves of the Grecian form, for doors and windows, generally consist of one or two faces in parallel planes, one of which recedes only in a small degree from the other, while the outer edge is terminated with one or several mouldings, which have a very prominent projection. In this case, make a board of sufficient thickness, and in breadth equal to the breadth of the architrave: prepare a slip of wood of a sufficient thickness and breadth for the mouldings on the outer termination of the architrave, and glue it upon the face, close to the edge of the board, with the outer edge flushed therewith. In this operation, two men, at least, will be required to rub the slip to a joint with the board; and as it often happens that the side of the slip, which is to comply with the surface of the board, is considerably bent, it must be nailed down to the board; previously to this, small square pieces of wood, called *buttons*, must be bored with holes, one in each, and a nail put through the hole to the head; then the slip is also to be bored with a bradawl, and the nails, with the pieces thus described, are entered and driven home as far as the buttons will permit. These buttons may be about three-quarters of an inch thick, and the other two dimensions each equal to, or something more than the breadth of the slip. Sometimes the slip is grooved; and the edge of the board tongued, glued, and inserted into the groove, instead of the above method. Or, the two faces may be made of different boards, tongued together at their joining, and the whole afterwards stuck into mouldings.

To form the surface of a cylinder with wood, whose fibres are in planes perpendicular to the axis of the cylinder, such as may be used in a circular dado, or the soffits of wisdom.

METHOD I.—When the dimension of the cylindric surface, parallel to the axis, is not broader than a plank or board. This may be done by bending and gluing several veneers together; the first upon a mould, or upon brackets, with their edges in the surface of the proposed cylinder, parallel to its axis.

This may be accomplished by means of two sets of brackets, fixed upon a board, with a hollow cylindric space between them, of sufficient thickness for taking in the veneers, with double wedges for confining them. If this operation be carefully done, and the glue properly dried, the wedges may be slackened, and the work will stand well; but it must be observed, that, as the wood has a natural tendency to unbend itself, the curved surface, upon which it is glued, should be somewhat sharper than that intended to be made, to allow for this tendency.

Some workmen form a hollow cradle, and bending the veneers into it, confine their ends with wedges, which compress them together; and by a very small degree of rubbing, with a hammer made for the purpose, the glue will be forced out of the joint.

METHOD II.—Form a cradle, or templet, to the intended surface, and lay a veneer upon it; then glue blocks of wood upon its back, closely fitted to its surface, and the other joints to each other, the fibres of the blocks corresponding to those of the veneer.

METHOD III.—Make a cradle, and place the veneers upon it, confining one end of them; spread the glue between the veneers with a brush, and fix a bridle across, confining its ends either by nails or by screws; open the veneers again, put glue a second time between each two, and fix another bridle across them; and in this manner proceed to the other extremity.

METHOD IV.—Run a number of equidistant grooves across the back of the board, at right angles to its edges, leaving only a small thickness towards the face; bend this round a cradle, with the grooves outwardly, and fill the grooves with slips of wood, which, after the glue is quite dry, are to be planed down to the surface of the cylindric board, which may be stiffened by gluing canvass across the back.

Instead of using a grooving-plane, workmen frequently make kerfs with the saw; but this mode is not so strong when finished, as the uncertainty of the depths of the kerfs, and the difficulty of inserting the slips, will occasion a very unequal curvature.

To bend a board, so as to form the frustum of a cone, or any segmental portion of the frustum of a cone, as the soffit of the head of an aperture.—Find the arch-form of the covering, as shown under the article ENVELOPE; cut out a board to this form, and run a number of equidistant grooves across it, tending to the centre: this being fixed to a templet made to the surface of a cone, finish it in the manner shown in the last method for a cylinder.

To bend boards so as to form a spheric surface.—Make a mould to the covering of a given portion of the sphere in plano, as shown under the article DOME; complete the number of staves by this mould; make a templet or mould to a great circle of the sphere; groove each of the staves across, at right angles to a line passing through the middle, and bend it round the templet; put slips in the grooves; shoot the edges of the staves, so as to be in planes tending to the centre of the sphere; and these staves, being glued together, will form a spheric surface.

To glue up the shaft of a column, supposing it to be the frustum of a cone.—Prepare eight or more staves, as the circumference may require, in such a manner that if the column be fluted, the joints may fall in the middle of the fillets, which disposition will be stronger than if they were to fall in the middle of the flutes.

Now, suppose eight pieces to be sufficient to constitute the shaft of a column: describe a circle to the diameter of each end; about each circle circumscribe an octagon; from the concourse of each angle draw a line to the centre; then draw an interior concentric octagon, with its sides parallel to those of the circumscribing one, the distance between any two parallel sides, on the same side of the centre, being equal to the thickness of stuff intended: and thus the sections of the staves will be formed at each end, and consequently the bevels will be obtained throughout the whole length; any two pieces when joined together having the same angle, though the staves are narrower at one end than at the other.

In order to join the column, glue two pieces together, and when quite dry, glue in blockings to strengthen them: join a third piece to the former two, and secure it also by blockings. In this manner proceed to the last piece but one.

In fixing the last, the blockings must be glued to the two adjacent staves, and their surfaces, on which the last stave is intended to rest, must be all in the same plane, that its back may rest firmly upon them. In closing up the remaining space, the part of the column that is glued together should be kept from spreading, by fixing it in a kind of a cramp, or cradle, while driving the remaining stave to close the joints.

Instead of this mode, some glue up the column in halves, and then glue them together.

When it is necessary to have an iron core, to support the roof or floor, the column must be glued up in halves; in this case, the two halves are to be dowelled together, and the joints filled with white-lead. Instead of a cramp, a rope is used, twisted by means of a lever. In the act of bringing the two halves together, the percussive force of the mallet must be applied upon the middle of the surface of one half, while an assistant holds something steady against the middle of the other, that the opposition may be equal; and by this means, the surfaces will be brought into contact, and form the joint as desired. In this operation pieces of wood ought to be inserted between the rope and column.

To glue up the Ionic and Corinthian capitals for carving.—The abacus must be glued in parts, so that their joints may be in vertical planes. The leaves and caulicoles of the Corinthian capital may be first made of rectangular blocks, and fixed to the vase.

To make a cornice round a cylindric body of the least quantity of wood, when the body is greater than a half-cylinder, and when the members will nearly touch a right line applied transversely.—Draw a section of the cylinder through its axis, and let the section of the cornice be represented upon the cylindric section. Draw a transverse line, touching the two extreme members of the cornice; and parallel to it draw another line within, at such a distance from the former, as may be necessary for thickness of stuff; produce the latter line, till it meet the line representing the axis of the cylinder, and the junction will either be above or below, according as the cornice is applied to the convex or concave sides of the cylinder. This meeting is the centre of two concentric circles, whose radii are the distances between the nearest and farthest extremes of the section of the cornice. This is evidently an application of the method of finding the covering of a cone. When mouldings are got out in this manner, viz., by a piece which does not occupy the space, when set to the place represented by the height and breadth, they are said to be sprung.

When a cornice is to have much projection, the corona, or middle part, is got out of a solid piece, and the parts above and below, or one of them, as may be found necessary, only set to the spring, and supported by brackets.

Another method is to bend veneers round the cylindric surface or surfaces; then work them to their form with moulding planes.

Raking mouldings depend principally upon the nature of a solid angle, properly called *a trihedral*. In a trihedral angle, with two of its planes at right angles to the third, let these two former make an obtuse angle; then suppose a moulding placed in the concourse of the two planes which form the obtuse angle of the solid, and another in the concourse of the two planes which form one of its right angles;

and supposing the section of the moulding which stands in the line of concourse of the obtuse angle to be given, it is required to find the section of the other, so as to mitre in a plane bisecting the remaining right angle of the solid. The trihedral will thus consist of three plane angles, two of which are right angles, and the other obtuse.

Make an angle equal to that formed by the sides of the obtuse-angled plane of the solid; let one of the legs be called the *mitre-line*, and the other the *raking-line;* draw the position of the moulding at the point of concourse in respect of the mitre-line without the angle; take any number of points in the curve of the moulding; through these points draw lines parallel to the mitre-line: also draw lines through the same points parallel to the raking-line: draw a line perpendicular to the mitre-line, cutting the other parallels at right angles; take the perpendicular, thus cut into several portions by the parallels of the mitre, and transfer it upon any part of the raking-line, marking all the points of section: through the points of section, draw lines at right angles to the raking-line, to cut its respective parallels; through the points of section of the parallels and perpendiculars of the raking-line, draw a curve which will be the section of the moulding.

The raking-mouldings in pediments depend upon this. The raking-line is the top of the tympanum; the mitre-line, the angle of the building; and the line of concourse of the obtuse angle of the solid, the level returning cornice, at right angles to the tympanum, or plane of the front of the building.

The same is also applicable to a hollow trihedral, such as the inside of a room, of which the two vertical planes are at right angles to each other, the legs of the one plane forming a right angle, and those of the other an obtuse angle; and consequently the ceiling, which is the third side of the trihedral, will be inclined to the horizon, like the exterior side of a pediment, or triangular roof, with this difference, that the surface of the former is opposed to the floor, and the latter to the sky. Open pediments are not now in use, otherwise it might be shown how the return mouldings were to be formed: if, however, the above general description is well understood, the reader cannot be at a loss to apply the principle to finding the section of such return moulding in an open pediment also. This, however, will be noticed under the article MOULDING.

In a trihedral solid, with two of its planes at right angles to the third, as in the preceding case, let the two planes make an acute angle instead of an obtuse one; then the other two angles of the solid will be both right angled, as also each of the planes forming the acute angle: now supposing one moulding to be placed in the line of concourse of the acute angle of the solid, and another in the line of concourse of one of the right angles; then if these mitre together upon a plane, passing along the line of concourse of the planes which form the remaining right angle of the solid, they will show the principle of the formation of the angle-bars of a bow-window, consisting of three or more vertical planes. As the angle-bar stands in the concourse of two of the vertical planes, suppose those two planes to be cut by a third plane at right angles to their line of concourse, and the solid thus formed again divided in halves by a plane passing along the concourse of the two vertical planes, bisecting the angle-bar, or the angle of their inclination, two equal trihedrals will be formed, each having one acute angle and two right angles: and the mouldings formed on the two legs of the front plane will be those required to mitre together. One of these mouldings will be half of the angle-bar, and the other half of the horizontal-bar.

The section of the horizontal-bar being given, to find that of the angle-bar.—Lay down the horionztal side of the trihedral, viz., that side which is contained by the acute angle; then calling one of the legs *the mitre-line*, and the other *the sash-line;* draw half the section of the horizontal bar perpendicular to the sash line, with the surface of the moulding opposed to the mitre line; take any number of points in the curve of the moulding, and draw lines through them perpendicular to the sash-line, cutting it in as many points; take the length of the intercepted line between the extreme points, and transfer it upon a line perpendicular to the mitre-line, with the several points of division from the mitre-line towards the section of the horizontal-bar; through the several points of division in the said perpendicular, draw lines parallel to the mitre-line; again, through the several points of division in the curve of the section of the horizontal-bar, draw lines parallel to the sash line, cutting the respective lines parallel to the mitre-line, and the points of intersection will give the section of half the angle-bar, by drawing a curve through them. The counter part being drawn on the other side of the mitre-line, the whole section of the angle-bar will be complete.

The reader will perceive that this principle is similar to the former, both depending upon the trihedral, or solid angle, consisting of three plane angles. The mitre passes through one of the lines of concourse, and a moulding along each of the two others. In both cases, that which is perpendicular to the other two is laid down.

A circular sash-frame in a circular wall, is a solid of double curvature; its formation, therefore, depends upon the section of a cylinder, and the covering of any portion of the cylinder.

The gluing up of the arcular bars depends upon the development of any portion of a cylindric surface.

The radial bars are portions of different elipses, which intersect each other in one common line of concourse, or conjugate axis, being the sections of a cylinder at different inclinations, all passing through a line at right angles to the axis.

Two of the sides of these bars are plane surfaces, and the other two curved surfaces are cylindrical; consequently they terminate the plane surfaces in curved lines, which are portions of elliptical figures.

The head of the sash is generally got out of the solid in halves, or in four pieces, according to the size of the window; and when put together, ought to be so formed, that one concave surface may saddle upon a cylinder of a radius equal to that of the inner circle, which forms the plan, while the outer surface is everywhere equidistant from the cylindric surface; and that the other concave surface may coincide with the convex surface of another cylinder, whose radius is equal to that required to describe the interior curve of the sash-head, while the outer surface is everywhere equally distant from the cylindric surface.

An enlarged or diminished cornice has its parts, in height and in projection, of the same proportions as those of another, already given. Here it is only necessary to suppose the height or projection given; thus, take one of them as the height to be given, and find a fourth proportional to the following three measures, placed in order, viz., the height of the given cornice, the height of the required cornice, and the projection of the given cornice; then divide the height of the required cornice in the same proportion as the height of the given one, and the projection of the one required, in the same proportion as the projection of that given.

The drawing of the flutes of a diminished pilaster, with curved sides, depends also upon the division of a line in the same proportion as one already divided: thus, a line equal to, or longer or shorter than the breadth of the pilaster, may contain the aggregate breadths of the number of flutes and fillets, in just proportion; then drawing several equidistant lines parallel to the base on the surface of the pilaster to be fluted, divide each of these equidistant lines in the same proportion; then a curve being drawn through each set of corresponding points will be the terminations of the flutes and fillets. For this purpose, an equilateral triangle, with one of its sides divided into the number of flutes and fillets, is sometimes used; for if lines be drawn to the point of concourse of the other two sides, any line parallel to the base will be divided in the same proportion as the base, which must be equal to, or greater than, the breadth of the pilaster at the bottom. The same may also be conveniently done in the following manner: divide a straight line, equal to, or shorter, than the breadth of the pilaster at top; through the points of division draw lines parallel to each other, making any angle with the divided line: then if this series of parallels be intersected by a line drawn in any direction, such line will be divided in the same proportion as the given line. Suppose, therefore, the parallels to be at right angles to the given line: to divide any line on the surface of the pilaster, take the extension of the line, and apply one end of it from any point in one of the extreme parallel lines as a centre, and describe an arc cutting the most remote of the parallel lines; then a line drawn from the centre to the intersection of the arc and the remote parallel, will be divided in the same proportion, equal to the breadth of the pilaster at the place required; then transfer the line so divided, upon the line on the surface of the pilaster. In like manner, may every other line on the surface of the pilaster be divided, and the curve drawn as before.

The method of diminishing and giving a graceful swell to the shaft of a column, depends upon the parabolic or sinical curve; both of which are easily described. The concoid of Nicomedes is also sometimes employed for this purpose; but the instrument required to describe it is very cumbersome, and the curve produced is not of a better form than that of the parabola, or figure of the sines.

Of joining boards.—A simple board, in its original state from the saw, is in one piece. A compound board is formed of several boards.

Boards may be joined together at a given angle, in various ways; by nails or pins, or by mortise and tenon, or by indenting them together; the latter mode is called *dovetailing*, from the sections of the projecting parts, and those of the hollows, being formed to that of a dovetail.

Dovetailing is of three kinds, viz., common, lap, and mitre: common dovetailing shows the form of the pins or projecting parts, as well as of the excavations made to receive them. Lap dovetailing conceals the dovetails, but shows the thickness of the lap in the return side, which appears like the edge of a thin board. Mitre dovetailing conceals the dovetails, and shows only a mitre on the edges of the planes at their surface of concourse; that is, the edges in the same plane, the seam or joint being in the concourse of the two faces, making the given angle with each other. Dovetailing is used in fixing very wide boards together, where the seam or line of junction is in the concourse of the two faces, and the fibres of the wood of each board are perpendicular to a plane passing through such line.

Concealed dovetailing is particularly useful where the faces of the boards are intended to form a saliant angle; but where the faces form a re-entrant angle, common dovetailing will best answer the purpose, as it is not only stronger and cheaper, but is entirely concealed, the dovetails only showing upon the saliant angle.

Indeed, where the faces form a re-entrant angle, and each board is to be fastened to a wall, the two boards may be fixed together by means of a groove in the one and a tongue in the other; and if well nailed previous to their being brought to their situation, so that the nails may not be seen in the faces, this will answer as good a purpose as dovetailing.

When several simple boards are glued together, to form a broad face, they are sometimes strengthened by fixing another simple board across the end, or across each end, as may be required, by means of a groove and tongue, or by mortise and tenon, and reducing the face of the whole compound board to a plane; the transverse pieces are called *clamps*, and the compound board is said to be *clamped*.

In simple and compound boards, where the faces are required to form an angle, and where the fibres of the wood are required to be parallel to the line of concourse of the two planes or faces which form the angle, the two boards are fastened together by tonguing the edge of one of them the whole of its length, and running a groove in the face of the other next to the edge to receive it, so that when the two boards are joined together, the re-entrant angle shows only a line at the concourse of the two surfaces, but the saliant angle shows a line parallel to the line of concourse, which is the intersection of the inner surface of one board produced to meet the external surface of the other; so that to form the saliant angle, the thickness of one board must be added to the breadth of the other, and thus the face of the one is lapped upon the edge of the other the whole of its thickness.

The most common way of joining boards with the fibres thus disposed, in respect of the line of concourse of their inclination, is by lapping the face of one upon the edge of the other, and fastening them together with nails, driven through the lap into the substance of the other.

Besides what has now been treated of, as principles on which the practice of joinery depends, many particulars relating to the art, the definitions of the terms, and several articles which require long description, and a reference to plates, will be found under the following alphabetical order viz.:

Gluing up of a Base refers to Base; Bridge-Board refers to Notch-Board; Curtail Step refers to the article Stair; Dog-legged Stairs refers to Staircasing; and Inlaying refers to Marquetry and Veneering. Among the foregoing articles, Boarded Floor, Floor, Boxing of a Window, and Description, are of considerable length; Hand-Railing and Hinging are complete articles, accompanied with plates.

Anything omitted in the foregoing catalogue will be explained in the subsequent part of this article.

Mouldings.—The names of moulding in joinery, according to their situation and combination, in various pieces of joiners' work.

Figure 1, edge, said to be rounded.

Figure 2, quirked bead, or bead and quirk.

Figure 3, bead and double quirk, or return bead.

Figure 4, double bead, or double bead and quirk.

Figure 5, single torus.

Figure 6, double torus. Here, it is to be observed, that the distinction between torus mouldings and beads, in joinery, is, that the outer edge of the former always terminates with a fillet, whether the torus be double or single, whereas in beads there is no fillet on the outer edge.

Figure 7, 8, 9, single, double, and triple reeded mouldings; semi-cylindric mouldings are denominated *reeds*, either when they are terminated by a straight surface equally protuberant on both sides, as in these figures, or disposed longitudinally round the circumferance of a shaft; but if only terminated on one side with a flush surface, they are then either beads or torus mouldings.

Figure 10, reeds disposed round the convex surface of a cylinder.

Figure 11, 12, 13, fluted work. When the flutes are semicircular, as in *Figure* 11, it is necessary that there should be some distance between them, as it would be impossible to bring their junction to an arris; but in flutes, whose sections are flat segments, they generally meet each other without any intermediate straight surface between them. The reason of this is, that the light and shade of the adjoining hollows are more contrasted, the angle of their meeting being more acute than if a flat space were formed between them. See *Figures* 12 and 13.

Figure 14, simple astragal, or half round bar, for sashes.

Figure 15, quirked astragal bar.

Figure 16, quirked Gothic bar.

Figure 17, another form of a Gothic bar.

Figure 18, double ogee bar. This and the preceding forms are easily kept clean.

Figure 19, quirked astragal and hollow. Bars of this structure have been long in use.

Figure 20, double reeded bar.

Figure 21, triple reeded bar.

Figure 22, base moulding of a room, with part of the skirting. When the base mouldings are very large, they ought to be sprung, as in this diagram.

A. The base moulding.

B. Part of the plinth.

In order to know of what thickness a board would be required to get out a moulding upon the spring, the best method is to draw the moulding out to the full size, then draw a line parallel to the general line of the moulding, so as to make it equally strong throughout its breadth, and also of sufficient strength for its intended purpose.

Figure 23, a cornice. The part A forming the corona, is got out of a plank.

B. A bracket.

C. The moulding on the front spring.

D. A cover board forming the upper fillet.

E. A moulding, sprung below the corona.

F. A bracket.

Shutters to be cut must first be hung the whole length, and taken down and cut: but observe that you do not cut the joint by the range of the middle bar, but at right angles to the sides of the sash-frame; for unless this be done, the ends will not all coincide when folded together. In order to hang shutters at the first trial, set off the margin from the bead on both sides, then take half the thickness of the knuckle of the hinge, and prick it on each side, from the margin so drawn towards the middle of the window, at the places of the hinges, put in brads at these pricks, then putting the shutter to its place, screw it fast, and when opened, it will turn to the place intended.

Mouldings are mitred by means of a templet, which is a small piece of wood, moulded in a reverse form to the mouldings that are to be mitred, so that the surface of the templet may coincide with that of the surface of the moulding, and to a portion of the plane surface of the framing, both on the face and on the edge adjoining: the ends of the templet are cut to an angle of 45 degrees in a plain perpendicular to the face, the one end forming a right angle with the other.

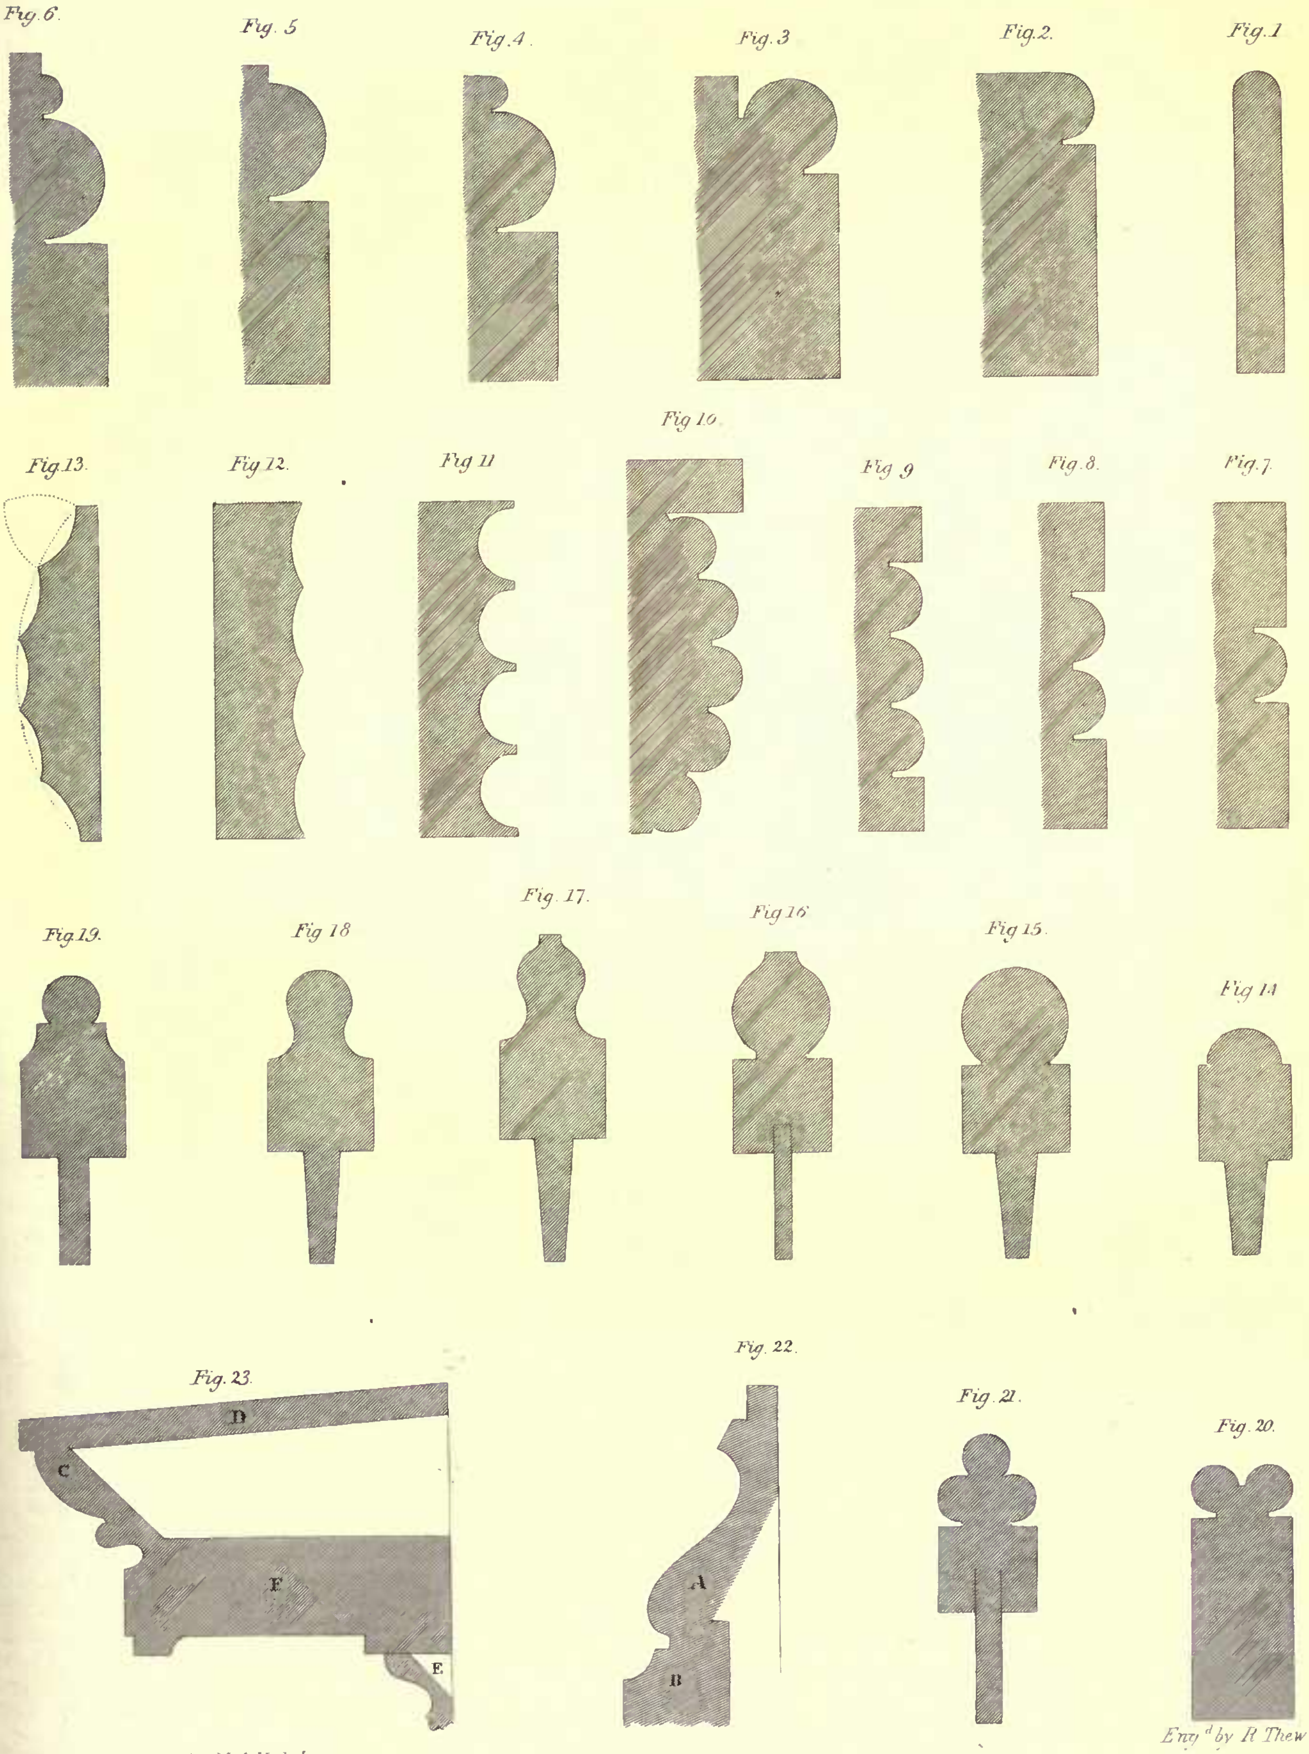
To scribe one piece of board or stuff to another.—When the edge end, or side, of one piece of stuff is fitted close to the superficies of another, it is said to be scribed to it. Thus the skirting boards of a room should be scribed to the floor. In moulded framing, the moulding upon the rails, if not quirked, are scribed to the styles, and muntins upon rails.

To scribe the edge of a board against any uneven surface.—Lay the edge of the board over its place, with the face in the position in which it is to stand, with a pair of stiff compasses opened to the widest part, keeping one leg close to the uneven surface, move or draw the compasses forward, so that the point of the other leg may mark a line on the board, and that the two points may always be in a straight line, parallel to the straight line in which the two points were at the commencement of the motion: then cut away the wood between this line and the bottom edge, and they will coincide with each other.

To rebate a piece of stuff.—When the rebate is to be made on the arris next to you, the stuff must be first tried-up on two sides: if the rebate be not very large, set the guide of the fence of the moving fillister to be within the distance of the horizontal breadth of the intended rebate; and screw the stop so that the guide may be something less than the vertical depth of the rebate from the sole of the plane; set the iron so as to be sufficiently rank, and to project equally below the sole of the plane; make the left-hand point of the cutting-edge flush with the left-hand side of the plane: the tooth should be a small matter without the right-hand side. Proceed now to gauge the horizontal and vertical dimensions of the rebate: begin your work at the fore end of the stuff; the plane being placed before you, lay your right hand partly on the top hind end of the plane, your four fingers upon the left side, and your thumb upon the right, the middle part of the palm of the hand resting upon the round of the plane between the top and the end; lay the thumb of your left hand over the top of the fore end of the plane, bending the thumb downwards upon the right-hand side of the plane, while the upper division of the fore-finger, and the one next to it, goes

JOINERY.

PLATE. I.



Drawn by M. A. Nicholson

Eng^d by R. Thew

obliquely on the left side of the plane, and then bends with the same obliquity to comply with the fore end of the plane; the two remaining fingers are turned inwards; push the plane forward, without moving your feet, and a shaving will be discharged equal to the breadth of the rebate; draw the plane towards you again to the place you pushed it from, and repeat the operation: proceed in this manner until you have gone very near the depth of the rebate, move a step backward, and proceed as before, go on by several successive steps, operating at each one as at first, until you get to the end; then you may take a shaving or two the whole length, or take down any protuberant parts.

In holding the fillister, care must be taken to keep the sides vertical, and consequently the sole level: then clean out the bottom and side of the rebate with the skew-faced rebate plane, that is, plane the bottom and side smooth, until you come close to the gauge-lines: for this purpose the iron must be set very fine, and equally prominent throughout the breadth of the sole.

If your rebate exceed in breadth the distance which the guide of the fence can be set from the right side of the plane, you may make a narrow rebate on the side next to you, and set the plough to the full breadth, and the stop of the plough to the depth: make a groove next to the gauge-line: then with the firmer chisel cut off the wood between the groove and the rebate level with the bottom; or should the rebate be very wide, you may make several intermediate grooves, leaving the wood between every two adjacent grooves of less breadth than the firmer chisel, so as to be easily cut out; having the rebate roughed out, you may make the bottom a little smoother with the paring chisel; then with a common rebate plane, about an inch broad in the sole, plane the side of the bottom next to the vertical side, and with the jack plane take off the irregularities of the wood left by the chisel: smooth the farther side of the bottom of the rebate with the skew rebate plane, as also the vertical side: with the trying plane smooth the remaining part next to you, until the rebate is at its full depth. If anything remain in the internal angle, it may be cut away with a fine-set paring chisel; but this will hardly be necessary when the tools are in good order.

When the breadth and depth of the rebate is not greater than the depth which the plough can be set to work, the most expeditious method of making a rebate, is by grooving it within the gauge-line on each side of the arris, and so taking the piece out without the use of the chisel: then proceed to work the bottom and side of the groove, as before. By these means you have the several methods of rebating when the rebate is made on the left edge of the stuff: but if the rebate be formed from the right-hand arris, it must be planed on two sides, or on one side and an edge, as before; place the stuff so that the arris of the two planed sides may be next to you. Set the sash-fillister to the whole breadth of the stuff that is to be left standing, and the stop to the depth, then you may proceed to rebate as before.

To rebate across the grain.—Nail a straight slip across the piece to be rebated, so that the straight edge may fall upon the line which the vertical side of the rebate makes with the top of the stuff, keeping the breadth of the slip entirely to one side of the rebate; then having set the stop of the dado grooving plane to the depth of the rebate, holding the plane vertically, run a groove across the wood; repeat the same operation in one or more places in the breadth of the rebate, leaving each interstice or standing-up part something less than the breadth of the firmer chisel: then with that chisel cut away these parts between every two grooves, but be careful, in doing this, that you do not tear the wood up; pare the bottom pretty smooth, or after having cut the rough away with the chisel, take a rebating plane with the iron set rather rank, and work the prominent parts down to the aforesaid grooves nearly. Lastly, with a fine-set screwed rebating plane, smooth the bottom next to the vertical side of the rebate. The other parts of the bottom may be taken completely down with a fine-set smoothing plane: in this manner you may make a tenon of any breadth.

Stairs.—Are one of the most important things to be considered in a building, not only with regard to the situation, but as to the design and execution: the convenience of the building depends on the situation, and the elegance on the design and execution of the workmanship. A staircase ought to be sufficiently lighted, and the head-way uninterrupted. The half paces and quarter paces ought to be judiciously distributed. The breadth of the steps ought never to be more than 15 inches, nor less than 10, the height not more than 7, nor less than 5; there are cases, however, which are exceptions to all rule. When you have the height of the story given in feet, and the height of the step in inches, you may throw the feet into inches, and divide the height of the story in inches by the height of the step; if there be no remainder, or if the remainder be less than the half of the divisor, the quotient will show the number of steps: but if the remainder be greater than the half of the divisor, you must take one step more than the number shown by the quotient; in the two latter cases, you must divide the height of the story by the number of steps, and the quotient will give the exact height of a step: in the first case you have the height of the steps at once, and this is the case whatever description the stairs are of. In order that people may pass freely, the length of the step ought never to be less than 4 feet, though in town-houses, for want of room, the going of the stair is frequently reduced to 2½ feet.

Stairs have several varieties of structure, which depend principally on the situation and destination of the building.

Geometrical stairs are those which are supported by one end being fixed in the wall, and every step in the ascent having an auxiliary support from that immediately below it, and the lowest step, consequently, from the floor.

Dog-legged stairs are those which have no opening or well-hole, the rail and balusters of both the progressive and returning flights fall in the same vertical planes, the steps being fixed to strings, newels, and carriages, and the ends of the steps of the inferior kind terminating only upon the side of the string, without any housing. For farther particulars, *see* Dog-Legged Stairs.

Bracket stairs are those that have an opening or well, with strings and newels, and are supported by landings and carriages, the brackets mitering to the ends of each riser, and fixed to the string-board, which is moulded below like an architrave.

The same methods must be observed as to taking the dimensions of bracket stairs, and laying down the plan and section, as in dog-legged stairs. In all stairs whatever, after having ascertained the number of steps, take a rod, the height of the story from the surface of the lower floor to the surface of the upper floor: divide the rod into as many equal parts as there are to be risers, then if you have a level surface to work upon below the stair, try each one of the risers as you go on, this will prevent any excess or defect, which even the smallest difference will occasion; for any error, however small, when multiplied, becomes of considerable magnitude, and even the difference of an inch in the last riser being too high or too low, will not only have a bad effect to the eye, but will be apt to confound persons not thinking of any such irregularity. In order to try the steps properly by the story-rod, if you have not a level surface to work from, the better way will be to lay two rods or boards, and level their top surface to that of the floor, one of these rods being placed a little within the string, and the other near or close to the wall, so as to be at right angles to the starting line of the first riser, or, which is the same thing, parallel to the plan of the string; set off the breadth of the steps upon these rods, and number the risers; you may set not only the breadth of the flyers, but that of the winders also. In order to try the story-rod exactly to its vertical situation, mark the same distances on the backs of the risers upon the top edges, as the distances of the plan of the string-board and the rods are from each other.

[The methods of describing the scroll and all ramps and knees, are described geometrically in the articles Hand-Railing and Staircasing.]

As the internal angle of the steps is open to the end, and not closed by the string, as in common dog-legged stairs, and the neatness of workmanship is as much regarded as in geometrical stairs; the balusters must be neatly dovetailed into the ends of the steps, two in every step; the face of each front baluster must be in a straight surface with the face of the riser; and as all the balusters must be equally divided, the face of the middle baluster must of course stand in the middle of the face of the riser of the preceding step and the face of the riser of the succeeding one. The risers and treads are all glued and blocked previously together; and when put up, the under side of the step nailed or screwed into the under edge of the riser, and then rough-bracketed to the rough-strings, as in dog-legged stairs, the pitching-pieces and rough-strings being similar to those. In gluing up the steps, the best method is to make a templet, so as to fit the external angle of the steps with the nosing.

Geometrical stairs.—The steps of Geometrical stairs ought to be constructed so as to have a very light and clean appearance when put up: for this purpose and to aid the principle of strength, the risers and treads, when planed up, ought not to be less than 1⅛ inch, supposing the going of the stair, or length of the step, to be 4 feet; and for every 6 inches in length you may add ⅛ part more; the risers ought to be dovetailed into the cover, and when the steps are put up, the treads are screwed up from below to the under edges of the risers: the holes for sinking the heads of the screws ought to be bored with a centre-bit, and then fitted closely in with wood, well matched, so as to conceal the screws entirely, and to appear as one uniform surface without blemish. Brackets are mitered to the riser, and the nosings are continued round: in this mode, however, there is an apparent defect, for the brackets, instead of giving support, are themselves unsupported, depending on the steps, and are of no other use, in point of strength, than merely tying the risers and treads of the internal angles of the steps together; and from the internal angles being hollow, or a re-entrant right angle, except at the ends, which terminate by the wall at one extremity, and by the brackets at the other, there is a want of regular finish. The cavetto or hollow is carried all round the front of the slip, returned at the end, returned again at the end of the bracket, thence along the inside of the same, and then along the internal angle of the back of the riser.

This is a slight imitation of the ancient mode, which was to make the steps solid all the way, so as to have everywhere throughout its length a bracket-formed section. This, though more natural in appearance, and much stronger, would be expensive and troublesome to execute, particularly when winders are used.

The best mode of constructing geometrical stairs, is to put up the strings, to mitre the brackets to the risers as usual, and finish the soffit with lath and plaster, which will form an inclined plane under each flight, and a winding surface under the winders. In elegant buildings, the soffit may be divided into panels. If the risers are got out of two-inch stuff, it will greatly add to the solidity.

In order to get a true idea of the twist of the hand-rail, the section of the rail, by a plane passing through the axis of the well-hole or cylinder, is everywhere a rectangle; that is, the plum or vertical section tending to the centre of the stair. This rectangle is everywhere of an equal breadth, but not of an equal vertical dimension in every part of the rail, unless that the risers and treads are everywhere the same from the top to the bottom: the height is greatest above the winders, because the tread is of less breadth, and less above the flyers; the tread being there the greatest. If you cut the rail, after squaring it, perpendicular to any of its curved sides, the section will not then be a rectangle, three of the sides will at least be curved. Hence two falling-moulds laid down in the usual way, will not square the rail, though in wide openings they may do it sufficiently near. Nor in squaring the rail can the square ever be applied at right angles to any one of the four arrises, for the edge of the stock will not coincide with the side of the rail, being curved; this would be easily made to appear by making a wreathed part of a rail of unusual dimensions, and cutting it in both directions. Therefore, to apply the square right, keep the stock to the plumb of the stair; and to guide the blade properly, the stock ought to be very thick, and made concave to the plan, so as to prevent the possibility of its shaking or turning from side to side; as a little matter up, or a little down, in the direction of the blade, would make a great difference in the squaring of the rail.

All this might easily be conceived from the cylinder itself, for there is no direction in which a straight line can be drawn on the surface of a cylinder but one, and this line is in a plane passing through the axis of the cylinder, and as the two vertical surfaces of the rail are portions of cylinders, there can be no straight line upon such surface but what must be vertical: all others, from this principle, are curves, or the sections of the rail are bounded by curves, or by a curve on that side.

In gluing up a rail in thicknesses, it will be sufficiently near to get out a piece of wood to the twisted form by two falling-moulds, provided the well-hole be not less than one foot diameter. The thickness of this piece, as is there stated, must be equal to the thickness, or rather the horizontal breadth of the rail, together with the thickness which the number of saw-kerfs will amount to, and also the amount of the substance taken away by planing the veneers. We are now supposing the plan of the rail to be semicircular, with two straight parts, one above and one below, a plan more frequently adopted from motives of economy, than from any property of elegance.

The first thing to be done is to make a cylinder of plank to the size of the well-hole. Draw two level lines round the surface of this cylinder at the top and bottom; upon each of these lines set off the treads of the steps at the end next the well-hole. Draw lines between every two corresponding points at the head and foot, and these lines will be all parallel to the axis of the cylinder. Upon each of the springing lines, and also upon a middle line between these two lines, set the heights of the winders, and the height of one of the flyers above and below, or as much as is intended to be taken off the straight of the rail. Take a pliable slip of wood, straight on one edge, and bend it round; keep the straight edge of it upon the three corresponding points, at the height of the last riser of the flyer; then draw the tread of the first

winding step by the straight edge, from the line where the cylindric part commences, to the first perpendicular line on the curved surface; take the next three points higher, and draw a line between the second and third perpendicular lines, proceed in like manner with the next three higher points, and draw a line between the next two adjoining cylindric lines, and the lines so drawn between each three points will be the section of the treads of the succeeding winding-steps.

Having thus gone through the cylindric part, draw a step at the top, and another at the bottom, and thus the sections of the steps will be completed; draw the hypothenusal or pitch lines of the flyer on the lower part, and that of the upper part, and whatever difference you make in the height of the rail between the flyers and the winders, you must set it up from the nosings of the steps of the winders upon two of the perpendicular lines: draw a line through the two points by bending a straight-edged slip round the cylinder, the straight edge of the slip coinciding with these points: this line will represent the top of the rail over the winders, and the hypothenusal lines at the bottom and top, that of the flyers; then curve off the angles at the top and bottom where the rail of the winding parts meets that of the flyers above and below, and a line being drawn parallel to this, will form the falling-mould. The reason of making the vertical elevation of the rail more upon the winders than the flyers, is, that the sudden elevation of the winders diminishes the height of the rail in a direction perpendicular to the raking line, and by this means persons would be liable to fall over it.

To lay the veneers upon the cylinder, if bed-screws or wedges are used, you may try the veneers first upon the cylinder, screwing them down without glue; prepare several pieces of wood, to lie from 6 to 12 inches apart, according to the diameter of the well-hole, with two holes in each, distant in the clear something more than the breadth of the rail. Then having marked the positions of the places of these pieces on the cylinder, pierce the cylinder with corresponding holes on each side, of the depth of the rail. If the cylinder be made of plank 2 inches thick, it will be sufficient for the screws: but if of thinner stuff, it will be convenient to set it on end upon stools, to get underneath, confining the top with nuts. Unscrew one half, three men being at work, one holding up all the veneers, another gluing, and the third laying them down successively one after the other, until all are glued: screw them down immediately. Unscrew the other half and proceed in like manner, and the rail will be glued up. The glue that is used for this purpose ought to be clear, and as hot as possible; the rail ought likewise to be made hot, as otherwise the glue will be liable to set before all the veneers are put down, and ready for the screws: this operation should therefore be done before a large fire, and the veneers thoroughly heated previous to the commencement, in order that the heat may be as uniformly retained as possible throughout the process. The glue in the joints of the rail will take about three weeks to harden in dry weather.

Doors.—When a board is made to fit an aperture in a wall, for the purpose of preventing ingress or egress at pleasure, it is called *a door*, or *closure.*

Doors are seldom constructed of one entire board, from the difficulty of procuring a simple board of sufficient size; neither are they often constructed of simple boards joined edge to edge, to form a compound board, without having transverse pieces fastened to one side, or being clamped at the ends; as, without such appendages, the door of this construction would be liable to break in the direction of the fibres, or be subject to crack or split, if not entirely seasoned, or when the texture is unequal in consequence of knots, or the resin not being uniformly disposed.

The most common kind of doors are constructed of several simple boards, not fixed with glue, or any tenacious substance, but by nailing transverse pieces upon the back of the boards, laid edge to edge. The transverse pieces, thus nailed, are called *ledges*, or *bars*, whence the door is said to be *ledged*, or *barred.* In this case, one of the edges, at every joint, is beaded on both sides, or at least on the face which is the outside, the ledges being placed to the inside.

Doors of this description are generally employed in the cottages of the poor, or in the out-houses of superior buildings.

Where doors are required to combine strength, beauty, and durability, a frame, joined by mortise and tenon, must be constructed, with one or more intermediate openings, each of which must be entirely surrounded by three or more parts of the frame, which have grooves ploughed in the edges, for the reception of boards to close the openings. When any parts of the framing are intended to lie in an horizontal position, after the door is hung, or fixed upon its hinges, they are called *rails;* if there are more than two rails, the extreme rail next to the floor is called *the bottom rail*, and that next to the ceiling, *the top rail.* Doors are seldom framed with less than three rails; in which case the middle one is called *the lock rail;* but most doors have two intermediate rails, of which the one next to the top rail is called *the frieze rail.* When there are more than two intermediate rails, those between the lock and frieze rails have no particular name. The extreme parts of the frame to which the rails are fixed, are called *stiles*, and the intermediate parts, *mountings*, from their vertical position. The boards by which the interstices are closed, are called *panels.* The stiles are first defined, on account of some doors being made narrower at the top than at bottom, in the manner of ancient doors.

Figure 24.—A four equal-panelled door; this form is only used in common work, and frequently without mouldings.

Figure 25.—A nine-panelled door, with square panels at the top.

Figure 26.—A six equal-panel pair of folding doors, two panels in breadth and three in height.

Figure 27.—A double margin or folding-door, with three panels in height, and two in breadth; being all equal.

Figure 28.—A double margin, or pair of folding-doors, with four panels in height and two in breadth, and with two lying panels below the top rail, and two above the lock rail.

Figure 29.—A ten-panelled pair of folding-doors, five in height and two in breadth, with two lying panels under the top rail, two above the bottom rail, and two in the middle: of this form is the ancient door of the Pantheon at Rome.

Figure 30.—An ancient door, narrower at the top than at the bottom: of this form is the door of the temple of Vesta, at Rome, and that of Erechtheus, at Athens. This construction may be useful for causing the door to rise as it opens, in order to clear a carpet, or to make it shut of itself.

Figures 31 and 32.—Doors of communication, or such as shut out of the way of the floor. *Figure* 31, folds round upon the partition, by means of hanging styles: *Figure* 32, is made to shut occasionally in the partition, so as to be entirely concealed. The two middle parts open, like ordinary folding doors, upon hinges fastened to the extreme parts.

Figure 33.—A jib-door, which when shut may be as much concealed as possible. Jib-doors are used to preserve the uniformity of a room, or to save the expense of a corresponding door.

Doors ought to be made of clean good stuff, firmly put together, the mitres or scribings brought together with the greatest exactness, and the whole of their surfaces perfectly smooth, particularly those made for the best apartments of good houses; in order to effect this, the whole of the work ought to be set out and tried up with particular care; saws and all other tools must be in good order; the mortising, tenoning, ploughing, and sticking of the mouldings, ought to be correctly to the gauge lines; these being strictly attended to, the work will of necessity, when put together, close with certainty; but if otherwise, the workman must expect a great deal of trouble in paring the different parts before the work can be made to appear in any degree passable: this will also occasion a want of firmness in the work, particularly if the tenons and mortises are obliged to be pared.

In bead-and-flush doors, the best way is to mitre the work square, afterwards put in the panels, and smooth the whole off together, then marking the panels at the parts of the framing they agree to, take the door to pieces, and work the beads on the styles, rails, and mountings.

If the doors are double-margin, that is, representing a pair of folding-doors, the staff stile, which imitates the meeting stiles, must be entered to the top and bottom rails of the door, by forking the ends into notches cut in the top and bottom rails.

Of hanging doors.—Having treated fully on the various kinds of hinges under the article Hinging, we shall here make a few observations upon, and give some rules for, hanging of doors, so as to clear the ground or carpet.

First, Raise the floor under the door as much as may be necessary, according to the thickness of the carpet, &c.

Secondly, Make the knuckle of the bottom hinge to project beyond the perpendicular of the top hinge about one-eighth of an inch: this will throw the door off the floor.

Note.—The centre of the top hinge must project a little beyond the surface of the door, if the hinge is let equally into the door and into the jamb; otherwise, if the centre lie in the surface of the door, it ought to be placed at the very top, which is seldom done, except when hung with centres.

Thirdly, Fix the jamb, on which the door hangs, out of the plumb line, so that the top of the jamb may incline to the opposite jamb about one-eighth part of an inch: this will contribute to the effect of clearing the door from the floor.

Fourthly, Make the door, when shut, to project at the bottom towards the inside of the room, about one-eighth of an inch, which may be effected by giving the rebate the quantity of inclination requisite.

Note.—Although any of the above methods, properly applied, will make a door swing sufficiently clear of the floor, yet as each one separately will require to be done in so great a degree as to offend the eye, I do not recommend it in nice work, but would rather advise a combination of them all to be used, thus:

Raise the floor about one-eighth of an inch under the door; make the jamb on which the door hangs incline to the opposite jamb about one-quarter of an inch; make each rebate that stops the door project at the bottom one-eighth part of an inch to that side of the room on which the door opens. Now these several methods practised in the above small degrees, which will not be perceptible, will throw the door sufficiently out of the level when opened to a square; that is, it will be at least half an inch when the height of the door is double its width.

Fifthly, Rising hinges, which are made with a spiral groove winding round the knuckle, answer a similar end; this construction of hinge requires that the door should be beveled at the top next to the ledge or door-catch, as much as the hinge rises in one quarter of its revolution.

Sixthly, This may also be effected by adopting a door in the form of the antique doors; that is, the bottom to be wider than the top, the jambs having the same inclination.

Mouldings of Doors.—The different denominations of framed doors, according to their mouldings and panels, and framed work in general. The figures in the Plates, to which these descriptions refer, are sections of doors, through one of the stiles, taking in a small part of the panel; or they may be considered as a vertical section through the top rail, showing part of the panel.

Figure 34, the framing is without mouldings, and the panel a straight surface on both sides: this is denominated *doors square and flat panel on both sides.*

Figure 35, the framing has a quirked ovolo, and a fillet on one side, but without mouldings on the other, and the panel flat on both sides: this is denominated *doors quirked ovolo, fillet and flat panel, with square back.*

Figure 36, differs only from the last in having a bead instead of a fillet, and is therefore denominated *quirked ovolo, bead and flat panel, with square back.*

Figure 37, has an additional fillet on the framing to what there is in *Figure* 36, and is therefore denominated *quirked ovolo, bead, fillet, and flat panel, with square back.*

Note.—When the back is said to be square, as in *Figure* 35, 36, 37, the meaning is, that there are no mouldings on the framing, and the panel is a straight surface on one side of the door.

Figure 38, the framing struck with quirk ogee and quirked bead on one side, and square on the other; the surface of the panel straight on both sides; this is called *quirked ogee, quirk bead and flat panel, with square back.*

Figure 39, differs from the last only in having the bead raised above the lower part of the ogee, and a fillet. This is therefore denominated *quirked ogee, raised bead, and flat panel, with square back.*

Figure 40, is denominated *cove, raised bead, and flat panel, with square back.*

Figure 41, is denominated *quirked ovolo, bead, fillet, and raised panel on front, with square back.* The rising of the panel gives strength to the door, and on this account they are often employed in street doors, though the fashion at present is discontinued in the inside of buildings.

Figure 42, the framing is the same as the last, but the panel is raised in front, and has an ovolo on the rising. This is therefore denominated *quirked ovolo, bead, and raised panel, with ovolo on the rising on front of door, with square back.*

Figure 43, is denominated *quirked ogee, raised panel, ovolo and fillet on the rising, and astragal raised on the flat of panel and square back.*

Note.—The raised side of the panel is always turned towards the street.

Figure 44, is denominated *quirked ovolo, bead, fillet, and flat panel, on both sides.* Doors of this description are used between rooms, or between passages and rooms, where the door is equally exposed on both sides. When the panels are flat on both sides, or simply chamfered on one side and flat on the other, and the framing of the door moulded on the side which has the flat panels: such doors are employed in rooms where one side only is exposed, and the other never but when opened, being turned towards a cupboard or dark closet.

Figure 45, is denominated *bead, but, and square,* or more fully, *bead and but front, and square back.* In bead and but work, the bead is always struck on the outer arris of the panel, in the direction of the grain.

Figure 46, is denominated *bead and flush front and*

quirked ogee, raised panel, with ovolo on the rising, grooved on flat of panel, on back. Bead and flush, and bead and but work, are always used where strength is required. The mouldings on the inside are made to correspond with the other passage or hall doors.

Figure 47, is a collection or series of mouldings, the same on both sides, and project in part without the framing on each side. The mouldings are laid in after the door is framed square and put together. If bradded through the sides of the quirks, the heads will be entirely concealed; but observe, that the position of the brads must not be directed towards the panels, but into the solid of the framing. The mouldings of doors which thus project are termed *belection mouldings;* belection-moulded work is chiefly employed in superior buildings.

Geometrical Descriptions in Joinery.

To find the true bevel for hanging any door.

Figure 48.—Let *a* be the centre of the hinge; on *a b* the width of the door, describe a semicircle, *b c e d a*, cutting the other side of the door at *c* and *d*. Join *a d* and *b c*, which will be the proper edges of the door, in order to make it open freely.

Note.—The bevelling on the side *a d* is of no other consequence than to make the sides uniform.

To find the joint for a pair of folding doors.

Figure 49.—Let *h* and *g* be the centre of each hinge; bisect *h g* by a perpendicular, *a b*, cutting the thickness of the door at *a* and *b;* bisect *a b* by the perpendicular *c d* at *e;* make *e c* and *e d* each equal to half the thickness that you intend the rebate to be. Suppose you intended the flap, *g a c d f*, to open, draw a line from *d* to the centre of the hinge at *g;* on *d g* describe a semicircle *d f i g*, cutting the other side of the door at *f;* join *f d*, and through *c* draw *c k* parallel to *d f;* then *k c d f* will be the proper joint.

Note.—If you put a bead at the joint, it ought to be equally on each side of the points *a* and *b*.

To find the bevel on the edge of a door, when it is executed on a circular plan, and the door to turn towards the space on the convex side of the circle.

Figure 50.—With regard to the circular door, all that is required is to make the angle *a b c* either a right angle or greater than a right angle (for a right angle is the least that any door will admit of) formed by the edge of the door, and a line drawn from the centre of the hinge to the opposite angle.

For the folding-doors.

Figure 51.—Let *a* and *b* be the centres of the hinges; join *a b*, and bisect it by the perpendicular *c f e*, cutting the door in *c* and *e;* bisect *c e* by the perpendicular, *g f h;* make *f h* and *f g* each equal to half the thickness of the rebate: join *h b;* on it describe the semicircle *h i k b*, cutting the concave side of the door, *i;* join *i h;* through *g* draw *g l* parallel to it; then will *l g h i* be the joint required.

To find the meeting joint of folding doors when the hinges are placed on the concave side of the doors.

Figure 52.—Let *a* and *b* be the centre of the hinges; join *a b*, and bisect it by a perpendicular, *c d e*, at *c*, cutting the thickness of the door at *d* and *e;* bisect *d e* by a perpendicular, *g f h*, cutting *d e* at *f;* make *f h* and *f g* each equal to half the thickness of the rebate; join *b h;* on it describe a semicircle, *h i k b*, cutting the other side of the door contrary to the hinge at *i;* join *i h*, and through *g* draw *g l* parallel to *i h*, cutting the concave side of the door at *l;* then will *i h g l* be the joint sought.

Demonstration.—Let the door *a l g h i* remain in its place; now the angle *b i h* being a right angle, consequently the perpendicular *b i* will be the shortest line that can be drawn from the point *b* to the line *i h;* then suppose the half door to be turned round the hinge at *b;* the point *i* will then describe a circle, whose centre is the hinge at *b;* then will *i h* be a tangent to that circle at *i;* therefore the angle at *i* will touch no other part of the edge of the other door, but at *i*.

If round the centre of the door which opens as *Figure* 53, you describe circles on each side of the rebate, and the edges of each door be made circular, it is plain it will also open in this case.

The plan of the doors here shown, are two or three times thicker than those used in practice, in order to show the principle clearly.

Figure 54, a section of the jamb-post, jamb-linings, grounds, and architraves, with part of the plan of a door.

B *b*. Sections of the grounds, flush, or in the same plane with the plaster.

E *e*. Outside and inside architraves.

g g g g. Line of the plinth.

C. Jamb-lining.

H. Hanging style.

I. Door style hung to the hanging style H, by means of the hinge *m*.

Figure 55, half of the plan: showing the door folded back; the parts in this having the same references as those in Figure 54.

Figure 56, meeting styles.

Figure 57, the moulding of the door, shown to a larger size.

This method is advisable where you have no opportunity of making the doors slide into the partition, as is shown in Figure 32; but whenever that opportunity offers, it should be preferred, as no door can be seen when shut into the partition, which not only keeps them entirely out of the way, but makes the most complete appearance.

Elevation of a pair of folding-doors, to be shut quite out of the way, in order to open a communication between two rooms, or to throw both into one on any occasion.

Figure 58, plan of half the door to a small size.

A. Plan of the outside style.

B, C. Plans of the hanging styles.

D. One of the meeting styles.

G O G, *g g g*. Framed partitions, distant from each other, in the clear, the thickness of the door.

F F F. The space or cavity for the door to work in, which must be made sufficiently wide to receive one half of the door entirely within, or nearly so: doors of communication for general uses may be constructed in this larger door, in which case the middle doors may be hung to the flaps, on the flanks, so that they will open like any other common folding-door; this method, therefore, combines utility and convenience, and is a complete deception. The first leaf of the door must run in a groove at the top, to make it steady.

Figure 59, a section of the style next to the partition, to a large size, with part of the plan of the bottom rail, showing a small part of each partition.

Note. In setting out work of this kind for practice, one half of the plan ought to be completely drawn out.

To find the joint of a jib-door, so that it shall open freely at the hanging side, and the joint to be a plane surface.

Figure 60.—Let C, the centre of the hinge, be in the same plane with the dado, and placed within the substance of the lining, in order to give strength to the jamb.

C E. The thickness of the door at the joint, which produce till it cut the opposite side of the base moulding at A; make A B equal to A C; join B C, and from B draw B D perpendicular to B C; then will B D be the true line through which the surbase-moulding must be cut in a plane perpendicular to the floor. The shadowed part shows a part of the jamb-lining cut out sufficient to let the surbase-moulding move in it.

Note.—If the centre of the hinge had been placed in the plane of the side of the rebate, parallel to the jamb-lining, a deep cavity through the jamb would have been brought into view in the opening of the door, the exposure of which would have been very unsightly.

If the upper part of the door be hinged, the axis of the hinge should be in a straight line with the axis of the centre below, and both the axis of the hinge and the axis of the centre should be in the plane of the face of the door, so that the joint upon the hanging side will always be close.

Figure 61, the elevation of the surbase at the joint.

The construction of a sash-frame, and the manner of putting the several parts of it together.

Figure 62, the elevation of the sash-frame.

A B C D. The outer edge of it.

The dark perpendicular lines E F, G H, are grooves whose distances from the edges L M and K I of the sash-frame, are equal to the depth of the boxing, together with three-eighths of an inch allowed for the margin between the shutters and the bead.

Figure 63, horizontal section of the sides, showing also the plan of the sill.

Figure 64, a vertical section of the sill and top, showing the elevation of the pulley-style *m* and *n*, the pulleys let into the pulley-piece.

Figure 65, the horizontal section of the sides, showing also a plan of the head of the sash-frame.

Figure 66, the elevation of the outer side of the sash-frame: the outside lining being taken away in order to show the work within the sash-frame.

f g, the parting strip fastened by a pin: *e d*, one of the weights connected with the sash by means of a line going over the pulley *c;* the other end fixed to the edge of the sash.

Note.—The weight *d e* is equal to half the weight of the sash.

Figure 67, part of the head of the sash-frame before put together.

Figure 68, the edge of *Figure* 67.

Figure 69, the edge of the bottom, showing the manner of fixing the styles.

Figure 70, the plan of *Figure* 69.

Figure 71 and 72, sections of window-sills, with sections of the under-rail of the sash, showing the best modes of constructing them in order to prevent the weather from driving under the sash-rail.

A. Section of the bottom-rail of the sash.

B. Section of the bead tongued into the sill.

C. Section of the sill.

Figure 73, sections of the meeting-rails, with the side elevations of the upright bars.

C. Rebate for the glass.

D. A square.

E. F. An astragal and hollow moulding.

G. Fillet.

Note.—The small letters denote the same parts of the under-sash.

Figure 74, section of an upright bar, with the plans of two horizontal bars, showing the franking or manner in which they are put together, so as to keep the upright bars as strong as possible. The thickness of the tenon in general comes about one sixteenth of an inch to the edge of the hollow of the astragal, and close to the rebate on the other side.

h h. A dowel to keep the horizontal bars still firmer together.

Note.—The same parts in this have the letters of reference the same as *Figure* 73.

Note also. There is no rebate made for the glass on the inside of the meeting-bar; a groove being made to answer that purpose.

Figure 75.—*Section of common shutters and sash-frame.*

A. Section of the architrave.

B. Ground for the architrave.

F. Back lining of the boxing, tongued into the ground B, and into the inside lining G, of the sash-frame.

G. The inside lining of the sash-frame.

H. The inside bead.

I. The pulley-style.

K. The parting bead.

L. Outside lining.

M. Back lining.

C C C. The front-shutter hung to the inside lining of the sash-frame, G, by means of the hinge *a*.

D D D. Back flap or shutter hung to the front shutter by means of the hinge *b*.

E E E. Another back flap hung to D D D, by means of the hinge *c*.

As in a window, the whole of the light should be shut out, the principle of setting out the shutters is, that each boxing should contain as many shutters as will cover one half; the horizontal breadth of which is from the axis of the hinges to the central vertical line of the windows.

O P Q R. Plan of the lower sash.

O. Rebate of the glass.

P. A square.

Q. An astragal moulding

R. A small square or fillet.

Figure 76, the method of hinging two back flaps together, showing the manner of placing the hinge, when room is scanty in the boxings.

Elevation and plan of half a window, adapted, when the wall of the building is not sufficiently thick to admit of room for boxing.

Figure 77, elevation of half the window.

Figure 78, plan of the window to double the size of the elevation, in order that the parts may be more distinctly seen.

E L. The breadth of the shutter, which is hung to a hanging style G, and the hanging style G is hung to the sash-frame by the hinge at *h*.

The whole breadth of the shutter E L, together with the breadth of the hanging style at G, that is, *i h*, ought to cover exactly half the breadth of the window; viz., from the axis of the hinge at *h*, to the central vertical line of the window.

H. Architrave.

I. Back-ground.

K. Back lining.

The panel A B C D, *Figure* 77, represents the shutter, of which E F, *Figure* 78, is the breadth. The hanging style and shutter are hung together by means of a rule-joint, as before described, under the article HINGING.

Under the shutter A B C D, is a bead R, which is continued across the sash-frame to serve for a capping; P is a vertical bead continued in a line with the edge, at D, of the rule-joint.

O and N. Sub-plinth of window, flush with the bead P.

M. Plinth, or skirting-board.

The plan, front, side elevation, and section of a window proper for a building where the walls are not thick enough to admit of room for boxings, which will show the same finish as if the shutters folded into boxings.

Figure 80, front elevation of the window.

The dotted lines *a b d c*, represent a piece of framing.

The other side, A B C D, represents a sliding shutter in the wall.

The framing is supposed to be removed, in order to show the shutter.

Figure 81, the side elevation and section, supposing the shutter removed.

a. An architrave-moulding.
b. Soffit.
c. Top of the sash-frame.
d. Capping, tongued into the sash-frame sill.

Figure 82, horizontal section and plan of the window, twice the size of the elevation.

g g. Section of the framing, as shown by *a b c d*, *Figure* 80, by dotted lines.
h h. Plastering on the wall.
i i. A shutter hung to the sash-frame.
f f. Section of the sliding shutter, which runs on rollers.
k k. A flap, which is let into a rebate and hinged at the edge *p p*, so that when the flap is turned round, the hinges out of the rebate, and the shutter *i i* turned to the face of the window, there will be a clear passage for the shutter *f f* to run out.

Note.—Although there is only a stop for the back of the shutter at the bottom, yet it is quite sufficient, as it is stopped on both sides at the top, and as the edge of the shutter should never be entirely out of the boxing.

This is more clearly shown by the parts drawn larger in the next plate.

Different sections of the foregoing Plate.

Figure 83, horizontal section through the side of the window.

A. Architrave moulding.
B. Part of a piece of framing.
C. Part of the shutter.
D. Plaster or rendering upon the wall.
E. The front shutter hung to the sash-frame at *y*.
F. Back lining.
G. Inside lining of the sash-frame.
H. Inside bead of the sash-frame.
I. Pulley-piece.
K. Parting bead.
L. Back lining of the sash-frame.
M. Parting stripe.
N. Outside lining.

a. Architrave moulding.
T. Ground over the window.
C. Section of part of the shutter.

O. Soffit.
P. Top of the sash-frame.
N. Horizontal outside bead.
h, h. Inside horizontal bead.

Figure 85, vertical section through the sill of the window.

B. Edge of the framing.
C. Edge of the shutter.
Q. Capping, rebated out at S, and tongued into the sash-frame sill.
S. A flap hung to Q, by means of the hinge at *n*; then by turning the front shutter upon the window, and by turning up the small flap, S, there will be a clear passage for the shutter, C, to run in.

Plan, elevation, and section, of a window with shutters, which will show uniform and complete, whether the shutters are in the boxings, or closing the aperture of the window.

Figure 86, plan or horizontal section at *a b*.

Figure 87, elevation or front of the window.

Figure 88, vertical section at C, D, *Figure* 87, and side of the window.

E. Thickness of the pilaster or architrave.
F. A bead stuck on its edge, parting the edge of the pilaster from the shutter.
O. The breadth of the shutter.
H, I. A bead and square to correspond to the thickness of the architrave and bead, so as to show the same finish on each edge of the shutter: one edge of this finishes against the sash-frame above, and the same edge below finishes against the back of the window down to the plinth.
K. Another square, equal to the projection of the capping.
L. Bead of the sash-frame.
M. Thickness for the under sash to run in.
N. Parting bead.
O. The thickness for the upper sash to run in.
P. Outside lining and bead.
Q. The breadth of the reveal or outer brick-work. This is farther explained in another figure, where the principal sections are shown to a larger scale. *a a*. Lintels, made of strong yellow deal or oak.
b. The top of the ground.
c. The architrave fixed upon the ground *b*.
d d. The soffit tongued into the top of the sash-frame *e*, and on the other edge into the head architrave C.
f f. A hollow space between the soffit *d d*, and the lintels *a a*; the under edges of the lintels *a a*, are generally about four inches and a half above the camber of the outside of the window; but it may be less when there is any necessity for it, as, for example, when very narrow grounds are used, it may come down within a quarter of an inch of the soffit.

The face of the pulley-style of every sash-frame ought to project beyond the edge of the brick-work about three-eighths of an inch; that is, the distance between the face of each pulley-style ought to be less by three-quarters of an inch than the width of the window on the outside, so that the face of the shutters ought to be in the same plane with the brick-work on the outside.

Parts of the foregoing at large.

Figure 89. Plan of the shutters.

A. The outside lining.
B. The pulley-style.
C. Inside lining.
D. Back lining.
E, F. Weights.
G. Parting slip of weights.
H. Parting bead of sashes.
I. Inside bead.
K L M N. Plan of the sash-frame.

K L. Sill of the sash-frame.

M. Plan of the inside bead.

N. Plan of the capping.

R R. Hanging style, hung to the sash frame at *a*.

S S. A shutter, hung to the hanging style at *e*.

T T. Another shutter, hung to S S at *n*, if necessary.

P P. A door, hung to the architrave at *m*, falling upon the hanging style R R by means of a rebate.

Note. The door must fall in a rebate at top and bottom.

U. A ground to fix the architrave upon.

V. The architrave fixed upon the ground.

W. Back lining.

When the aperture is shut, the door P P must be turned round the hinge *m*, parallel to the face of the sash-frame: then the shutters R R, S S, T T, being drawn out and turned on the hinge *a*, and on the hinges *e* and *n*, will cover that part of the window for which they were intended. The door P may then be closed, and the whole will have a uniform and neat appearance.

To find the splay of the ground b c.—Draw a line from the centre of the hinge at *a* to the edge of the ground at *b*; on *a b*, as a diameter, describe a circle cutting the back lining of the boxing at *o*; join *c b*, and it will be the bevel required.

Front and two side elevations of a window, the sash-frame being out of the square, or an oblique-angled parallelogram: showing how to construct the sides of the window, so that the shutters shall make an equal margin round the edge of the sash-frame, when the window is shut: and also to fit their boxings.

Figure 90. Elevation of the window. A B C D being the edge of the sash-frame next to the bead, and E F G H the margin between the shutters and the inside beads.

The difficulty of fitting up a window of this kind may be surmounted if the following observations are attended to: the points K and I, *Figure* 91, being taken at the distance E F, *Figure* 90, and the point R, *Figure* 91, being made to correspond to K, *Figure* 90, the middle of the meeting rails; then make the angle R K L, *Figure* 91, equal to the angle K E H, *Figure* 90; through R and I draw R S and I M parallel to K L; then K I M L will be the front shutter, and R S the parting bead, in case the shutters are to be cut.

Figure 92, is constructed in the same manner as *Figure* 91; that is, by making the angle T O P equal to the angle L H E, *Figure* 90; the points O, T, N, being previously made to correspond to the points H, L, G, as on the other side.

In *Figures* 91 and 92, A and B are lintels.

C. The top of the sash frame.

D. The soffit.

G. Sash-frame sill.

F. Stone sill.

Plan and elevation of the shutters to the foregoing example; showing the manner of hanging and cutting the shutter when the sash-frame is an oblique-angled parallelogram, or out of the square, as workmen call it.

Let *Figure* 93, be the plan of the window, and let A B and D C, *Figure* 94, be the bottom and top ends of the shutters parallel to each other; now, in order that the shutters may fit close into their boxing, and also close into the window-frame, the centres of the hinges to each flap must be set in lines perpendicular to D C or A B.

To set out the shutters.—Make A *e* and D *f*, *Figure* 94, equal to the breadth of the front shutter, and draw the line *f e*; then will A D *f e* represent the front shutter, and *f e* the edge on which the flap will join to it; then if the angle D *f e* be not a right angle but obtuse, from *f* draw *f g* perpendicular to D C; then will *f g* be the line of the hinges. In the same manner, B C *q r* will represent the shutter on the other side; B *r q* being the obtuse angle, and *r s* a perpendicular to A B for the line of the hinges: the two extreme joints being made, all the other joints, *h i*, *k l*, *m n*, and *o p*, ought to be all perpendicular to the ends D C and A B of the shutters: then will the centres of the hinges be parallel to, or in the same line with, the joint.

To find the breadth of the flaps which hang to the front shutters, so that they may be as wide as possible.—From the points A and C, the obtuse angles, draw A *v* C *u* perpendicular to A B and D C, the ends of the shutters; make *v a* and A *b* equal to the breadth of the rebate; and from the point *f*, and in the line of hinges, make *f c*, *f h*, and *g d*, *g i*, respectively, equal to *f a*, *f v*, and *g b*, *g* A; then will *e f h i* be the flap required; and it is plain, from the nature of this window, that the other flap, *o q r p*, must be the same figure as the flap *e f h i*, but inverted.

The other flaps may be filled in as the width of the window will admit.

Note.—We have given this example because the method is general, and will apply to all cases; the workman ought never to trust to the sash-frame being absolutely square, for they seldom are; and if the variation be ever so small, there will be a very considerable error in the ends of the shutters when enclosed in the boxings. Such distorted examples as the above generally occur in old buildings; in such this method must be adopted: but also, for the above reason, it ought not only to be employed in old work, but even in new, where the shutters are cut, so that the ends of the shutters may not only coincide when folded, but also with the sill and top of the sash frame, and also with the meeting rail.

Customary Measures in Joiners' Work, for labour only.

Preparation of boarding by the foot super.—The different distinctions are—edges shot; edges shot, ploughed and tongued; wrought on one side and edges shot; wrought on both sides and edges shot; wrought on both sides, ploughed and tongued; boards keyed and clamped; mortise clamped; mortise and mitre clamped. The price per foot is also increased according to the thickness of the stuff. If the longitudinal joints are glued, so much more is added to the foot: and if feather-tongued still more.

Floors.—Are measured by the square, the price depending upon the surface, whether wrought or plain, and the manner of the longitudinal and heading joints, as well as upon the thickness of stuff; or whether the boards are laid one after the other, or folded; or whether the floor be laid with boards, battens, or wainscot.

Skirtings are also measured by the foot super; the price depending upon the position, whether level, raking, or ramping; or upon the manner of finishing, whether plain, torus, rebated, scribed to floor, or to steps; or upon the plan, whether straight or circular.

The price of every kind of framing depends upon the thickness, or whether the framing be plain or moulded; and if moulded, what kind of mouldings, and whether stuck on the solid, or laid in; whether mitred or scribed; and upon the number of panels in a height and breadth; also upon the nature of the plan.

The various descriptions of wainscoting, window-linings, as backs and elbows, door-linings, jambs and soffits, back-lining partitions, doors, shutters, are all measured by the foot super.

Sashes are measured by the foot super, as well as the sash-frames. The sash and frame are either measured together or separately.

Sky-lights are measured by the foot super, their price depending upon the plan and elevation.

Fig. 92.

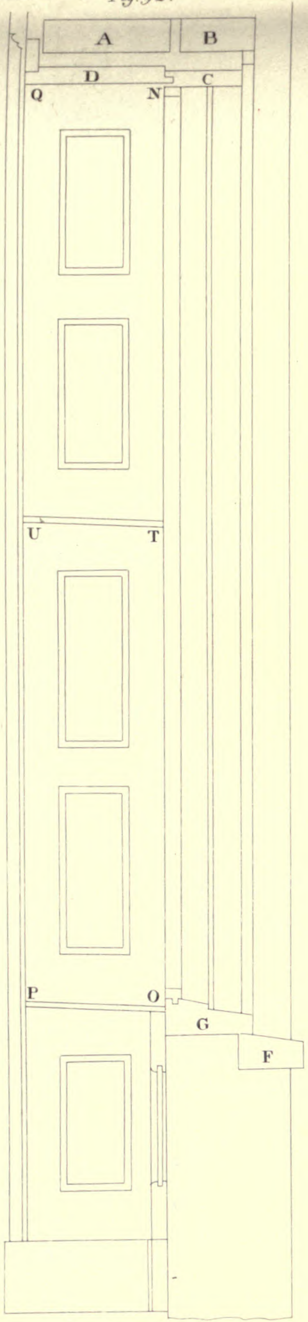

Fig. 90.

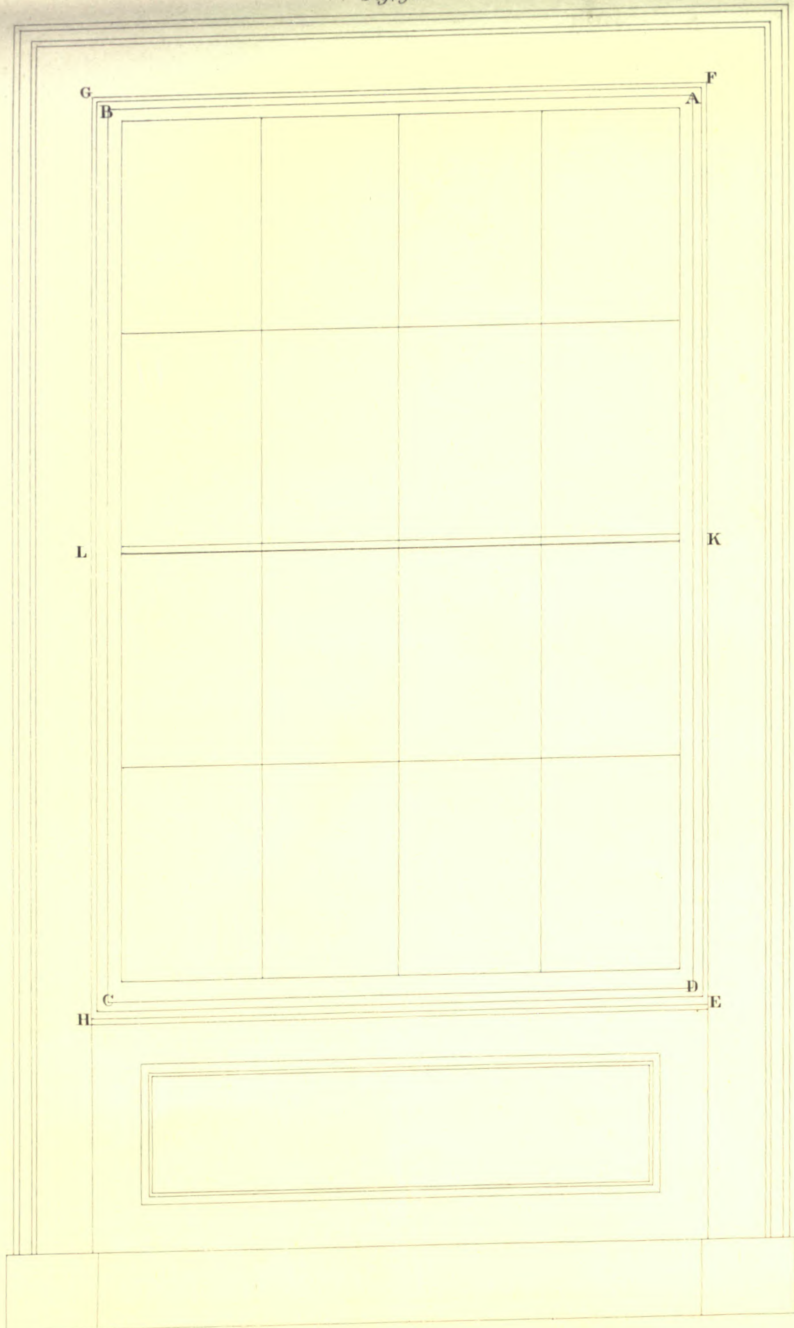

Fig. 91.

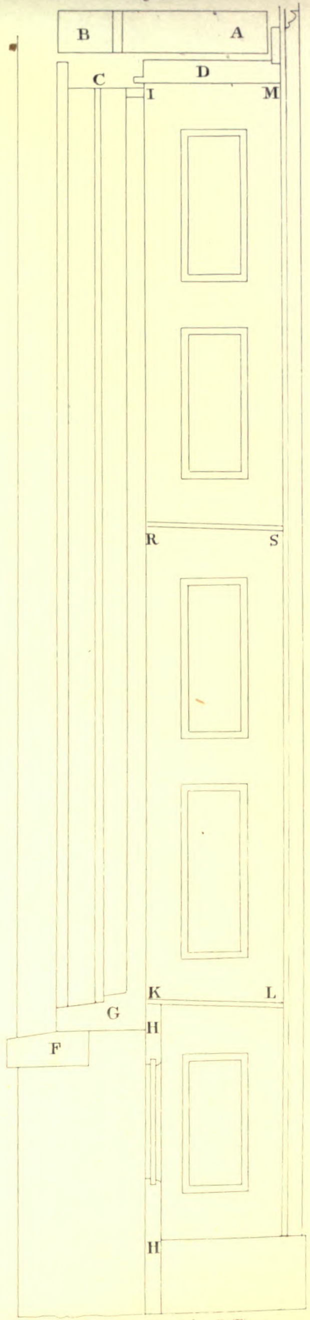

Eng^d by R. Thew.

PLATE IX.

Fig. 93.

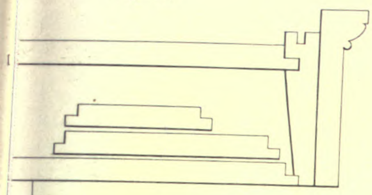

Fig. 94.

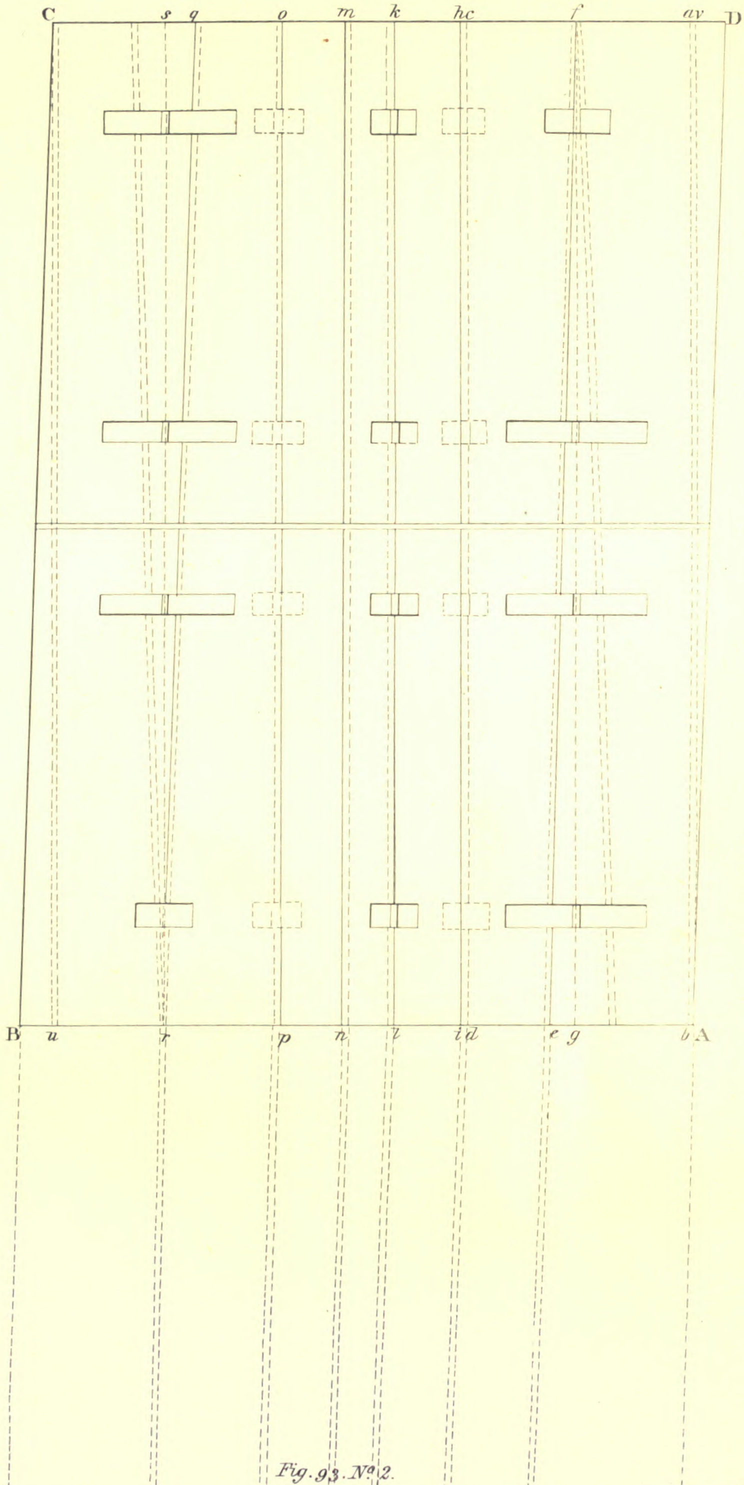

Fig. 93. No. 2.

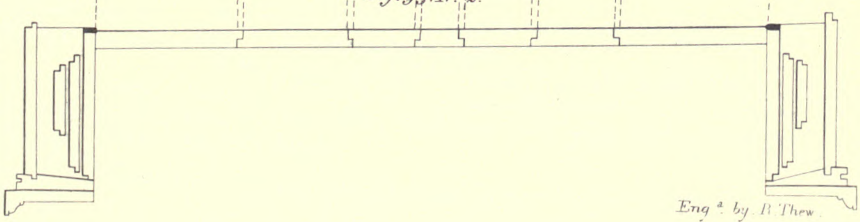

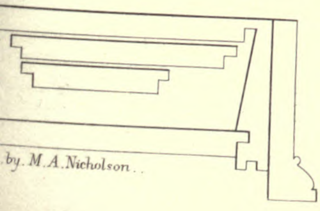

by M. A. Nicholson.

Eng^d. by R. Thew.

Framed grounds, at per foot run.

Ledged-doors by the foot super.

Dado is measured by the foot super; the price depends upon the plan being straight or circular, or upon the elevation being level or inclined as in staircases.

In staircasing, the risers, treads, carriages, and brackets, are generally classed together, and measured by the foot super; sometimes the string-board is also included. The price must be different, as the steps are flyers or winders, or as the risers are mitred into the string-board, the treads dovetailed for balusters, and the nosings returned, or whether the bottom edges of the risers are tongued into the step. The curtail-step is generally valued as a whole. Returned nosings are sometimes valued at so much each, and if circular are double the price of straight ones.

The hand-rail is measured by the foot run; the price depending upon the materials and diameter of the well-hole, or whether ramped, swan-necked, level circular, or wreathed; or whether made out of the solid, or in thicknesses. The scroll is paid at per piece; as is the making and fixing of each joint screw; three inches of the straight part at each end of the wreath are included in the measurement.

Deal balusters are prepared and fixed at so much each; as likewise, iron balusters, iron column to curtail, housings to step and riser, common cut brackets, and brackets circular upon the plan, preparing and fixing.

Extra sinking in rail for iron balusters is charged by the foot run, the price depending on the rail being straight, circular, wreathed, or ramped.

The price of the string-board is regulated by the foot super, according to the manner in which it is moulded, or whether straight or wreathed, or the manner in which the wreath string is constructed, if properly backed upon a cylinder.

The shafts of columns are measured by the foot super, the price depending upon the diameter, or whether it be straight or curved on the side, and upon its being properly glued and blocked. If the column be fluted or reeded, the flutes or reeds are measured by the foot run, and their price depends upon the size of the flute or reed. The headings of flutes and reeds are so much each. Pilasters, straight or curved in the height, are measured in the same way, and the price taken per foot super. In the caps and bases of pilasters, besides the mouldings, the mitres must be so much each, according to the size.

Mouldings, such as double-faced architraves, base and surbase, or straight mouldings stuck by hand, are valued at per foot super. Base and surbase, and straight mouldings wrought by hand, are generally fixed at the same rate per foot, being something more than double-faced architraves. The head of an architrave in a circular wall is four times the price of the perpendicular parts, not only on account of the time required to form the mouldings to the circular plan, but on account of the greater difficulty of forming the mitres. All horizontal mouldings, circular upon the plan, are three or four times the price of those on a straight plan; being charged more as the radius of the circle is less. Housings to mouldings are valued at so much each, according to the size.

The price per foot super of mouldings is regulated by the number of quirks, for each of which an addition is made to the foot.

The price of mouldings depends also upon the materials of which they are made, or upon their running figure, whether raking or curved.

The following articles are measured by the foot run. Beads, fillets, bead or ogee capping, square angle staff rebated, beaded angle staff, inch ogee, inch quirk ogee, ovolo and bead, astragals or reeds on doors, or on shutters; small reeds, each in reeded mouldings stuck by hand up to half an inch, single cornice or architrave, grooved space to let in reeds, and grooves.

Note.—In grooving, the stops are paid over and above, and so much more must be allowed for all grooves wrought by hand, particularly in the parts adjoining the concourse of an angle; and circular grooving must be paid still more. The other running articles are, narrow grounds to skirting, the same rebated, or framed to chimneys; and rule-joints, cantalivers, trusses, and cut brackets for shelves, are rated at per piece.

Water-trunks are measured by the foot run, the rate depending upon the side of their square. These ought always to be properly pitched, and put together with white-lead, and the joints ploughed and tongued; the hopper-heads and shoes are valued at so much each; moulded weather-caps at so much each; the joints at so much each. Scaffolding, &c. used in fixing, to be paid for extra.

Flooring boards are prepared, that is, planed, gauged, and rebated to a thickness, at so much each, the price depending upon the length of each board: if more than 9 inches broad, the rate to be increased according to the additional width; each board listing at so much per list. Battens in the same way, but at a different rate.

Rates of Labour in Joiners' Work from the Bench, according to the universal Method described in pages 79 *and* 80 *of the First Volume of this Dictionary.*

The column on the left hand of the table denotes the number of panels, the middle column the species of work, and the right-hand column the rate in decimals, being the rate of the part or parts of a day required to the quantity signified at the head of the column; therefore, this rate being multiplied by the wages per day, gives the real rate of the work per foot, in shillings or pence, according as multiplied by shillings or pence.

Description of One-and-a-quarter Inch Doors.

No. of Panels.		Rate per ft. super.
2.	Both sides square	.06
4.	Both sides square	.07
6.	Both sides square	.08
2.	Quirk, ovolo, and bead front, and square back	.1
4.	Quirk, ovolo, and bead front, and square back	.11
6.	Quirk, ovolo, and bead front, and square back	.12
2.	Bead and flush front, and square back	.1
4.	Bead and flush front, and square back	.11
6.	Bead and flush front, and square back	.12
2.	Bead and but front, and square back	.09
4.	Bead and but front, and square back	.10
6.	Bead and but front, and square back	.11
2.	Quirk, ovolo, and bead, on both sides	.14
4.	Quirk, ovolo, and bead, on both sides	.15
6.	Quirk, ovolo, and bead on both sides	.16
2.	Bead and but on both sides	.12
4.	Bead and but on both sides	.13
6.	Bead and but on both sides	.14
2.	Bead and flush on both sides	.14
4.	Bead and flush on both sides	.15
6.	Bead and flush on both sides	.16

For every additional quarter of an inch in thickness, add .005 to the rate per foot super.

If the panels are raised on one side, add .002; and if on both sides .004; and if an astragal or ovolo on the rising on one side, add .003; and if on both sides .006—to the rate per foot super.

If the price of a foot of a square door, and the number of pannels, are given, and the price of a foot of a door square on one side, with the same number of panels, and with extra work on the other side; then, the price of a door with the same number of panels, and the same extra work on both sides, will be found by subtracting the rate of the first from that of the second; and adding the difference to the second, will give the rate per foot extra on both sides.

Thus the rate per foot super for 1¼-inch two panel door, square on both sides, is .06; and the rate for 1¼ inch two panel door, square upon one side, with quirk, ovolo, and bead upon the other, is .1, their difference is .04, which added to .1, gives .14, for the rate per foot of 1¼-inch two panel, with ovolo and bead on both sides of the framing.

The difference of workmanship between square-framed door-linings, backs, elbows, soffits, or wainscoting and doors that are square on both sides, supposing the panels and thickness to be alike in both cases, can only arise from planing the panels and the framing on the other side of the door: therefore if the difference of the rate per foot of a door square on both sides, and one square on one side, with any extra work on the other, be added to the rate per foot of door-linings, backs, elbows, soffits, or wainscoting, framed square, will give the rate per foot for door-linings, window-linings, or wainscoting with the same extra work.

In these rates the styles or rails are supposed without rebating. Framed linings for walls or apertures, may be made of stuff ¼ of an inch thinner than doors. In common cases, the thickness of linings may be about an inch, as they are rendered sufficiently stiff by being fixed to the wall; this, however, must depend upon the distance that the panel recedes from the face of the framing, or upon the depth which the mouldings are run in the thickness of the said framing.

No. of panels.	Framed Inch Linings.	Rate per ft. super.
1.	Square, as in backs	.051
3.	Square, as in backs and elbows, measured together	.071
4.	Square, as in backs, elbows, and soffits	.061
3.	Moulded, as in backs and elbows, together	.087
4.	Moulded, as in backs, elbows, and soffits, measured together	.077
3.	Quirk moulded, as in backs and elbows, measured together	.095
4.	Quirk moulded, as in backs, elbows, and soffits, measured together	.085

Semicircular moulded soffits in two panels, seven times the straight.

For every additional quarter of an inch, add .005 to the foot super.

In the column of panels, the backs, elbows, and soffits, are numbered 3 and 4 panels, as being classed together; though this is the case, they are intended to be framed in single panels.

One-and-quarter Inch Door Linings,

Having only one panel in height.

Rebated	.051
Rebated and beaded	.058
Double rebated, not exceeding seven inches wide	.067
Double rebated, and one edge beaded	.071
Double rebated, and both edges beaded	.075

If the plan be circular, the price will vary as the diameter is less.

Semicircular heads, straight on the plan, five times the straight.

Shutters. (Rate per ft. super.)

Inch framed, uncut, shutters or flaps, two panels in height. Mouldings, when described are understood to be laid in, but if stuck on the framing to add .012 *to the rate; for every extra panel, to add* .016 *to the rate; for any extra height, to add* .012 *to the rate; if quirked moulded, add* .008 *to the rate of moulded.*

Square	.071
Bead, but, and square	.1
Bead, flush, and square	.111
Bead, flush, and bead but	.131

Inch-and-quarter uncut shutters, two panels in height, to add for extras, as above.

Moulded and square	.1
Moulded bead and but	.111
Moulded bead and flush	.135
Moulded on both sides	.111
Ovolo and bead, or quirk ogee front, and square back	.103
Ovolo and bead, or quirk ogee front, with bead and but back	.123

One-and-quarter Inch Wainscoting,

Two panels high, including square facia, framed up to ceiling.

Square	.039
Moulded	.055
Quirked moulded	.063
Bead and but	.051
Bead and flush	.059
Bead and flush, with 3 reeds	.075

If any of them are framed with raised mouldings, add .008 to the rate; or, if framed with more panels in the height, add .006 for every additional panel.

One-and-quarter Inch Dwarf Wainscoting,

With one panel, including square skirting.

Square	.047
Moulded	.063
Quirk moulded	.071
Bead and but	.059
Bead and flush	.067
Bead and flush with 3 reeds	.083

If any of the above descriptions of dwarf wainscoting are framed with two panels in height, add .016 to the rate, as in full wainscoting.

If made raking to stairs, to be paid for extra .023, and if with raised mouldings .007.

All cappings to be measured, and paid for as in running articles.

All skirting to stairs, to be paid for separate from wainscoting.

Three-quarter Inch Deal,

From the bench, called Slit Deal.

Edges shot	.004
Wrought on one side	.016
Wrought on one side, grooved, tongued, and beaded	.028
Wrought on two sides, and edges shot	.028
Wrought on two sides, grooved, tongued, and beaded	.04
If glued joints, add per foot	.004

Inch-and-quarter Deal.

	Rate per ft. super.
Wrought on one side, and edges shot	.02
Wrought on two sides, and edges shot	.032
Wrought on one side ploughed and tongued	.036
Wrought on two sides, ploughed, tongued and beaded	.052

If glued joints, add .004 to the rate.

Inch-and-half Deal.

Edges shot	.008
Ploughed and tongued	.024
Wrought on one side, with edges shot	.02
Wrought on both sides, with edges shot	.036
Wrought on both sides, ploughed and tongued	.052

If glued joints, add .012 to the rate.

Two-inch Deal,
From the bench.

Edges shot	.02
Ploughed and tongued	.036
Wrought on one side	.028
Wrought on both sides	.044
Wrought on both sides, ploughed and tongued	.056

If glued joints, add .016 to the rate.

Two-and-a-half-inch Deal,
From the bench.

Edges shot	.028
Ploughed and tongued	.048
Wrought on one side	.048
Wrought on both sides	.063
Wrought on both sides, ploughed and tongued	.083

If glued joints, add .016 to the rate.

Three-inch Deal.

Edges shot	.032
Ploughed and tongued	.056
Wrought on one side	.056
Wrought on two sides	.08
Wrought on both sides, ploughed and tongued	.103

If glued joints, add .016 to the rate.

Inch Boarding, One Side planed.

Ploughed and tongued	.024
Glued joint	.03
Clamped	.056
Mortise-clamped	.063
Laid with straight joint in floors	.02
Dado-keyed	.044
Keyed in backs and elbows	.056

Inch Boarding, wrought on Both Sides.

Ploughed and tongued	.036
Glued joints	.04
Groove-clamped flaps to shutters, in one height	.053
Clamped flaps to shutters, in two heights	.071
Inch mortise-clamped outside shutters	.063
Ledged doors with plain joint	.044
Ledged doors, ploughed, tongued, and beaded	.056

Preparing Flooring Boards.

To be gauged to a width, and rebated to a thickness not more than nine inches wide.

Inch Deal.	Rate for each board.
Ten feet long	.063
Twelve feet long	.075
Fourteen feet long	.087

1½ Inch.	Rate for each board.
Ten feet	.071
Twelve feet	.083
Fourteen feet	.1

Battens 1¼ inch.	
Ten feet	.044
Twelve feet	.056
Fourteen feet	.075

Mouldings.

	Rate per ft. super, from the bench.
Double-faced architraves	.111
Base or surbase	.127
Above four inches girt, stuck by hand	.127

If a collection of mouldings have more than two quirks, add .016 for each.

Running Articles.

	Per foot lineal.
Beads and fillets	.004
Bead or ogee capping	.016
Inch ogee	.016
Inch quirked ogee or ovolo and bead	.023
Square angle-staff rebated	.028
Angle-staff rebated and beaded	.048
Single cornice or architrave	.048
Small reeds, in reeded mouldings stuck by hand, to half an inch	.004
Reeds above half an inch, stuck by hand, including grooved space	.008
Grooves in ornamental work	.004
Narrow ground to skirting	.011
Narrow ground to skirting, rebated or grooved	.016
Narrow grounds framed to chimneys	.032
Double-beaded chair-rail	.023

Plugging included in the above rates.

Such of the above running articles as are circular on the plan, must be rated at double the straight.

Legs, rails, and runners to dressers	.055
Rule-joints to shutters	.063

Inch and Inch-and-quarter Framed Grounds to Doors.

	Rate per run from the bench.
Both edges square	.028
One edge square, and the other rebated and beaded	.032
Rebated on one edge, and both edges beaded	.036

If framed to a circular plan with a flat sweep, the head to be three times the straight, but the less the radius the greater the price.

Stairs.

1¼ *inch nailed Steps with Carriages.*	Rate per ft. super fixed.
Flyers	.08
Winders	.111
Flyers moulded and glued with close string-board	.103
Winders moulded and glued with close string-board	.135
Moulded planceer under steps	.04

Housings to flyers, .127 each.
Housings to winders, .2 each.
Common cut brackets to flyers, .143 each.
Common cut brackets to winders, .286 each.
All fancy brackets to be paid for at per value.

Hand-Rail.

2 inches deep by $2\frac{1}{4}$ inches broad	Rate per ft. run fixed.
Deal moulded	.111
Deal moulded and ramped	.495
Deal moulded, level circular	.413
Deal moulded wreathed	1.2
Mahogany moulded straight	.263
Mahogany moulded ramped	.831
Mahogany moulded swan-neck	.927
Mahogany moulded, level circular	1.08
Mahogany moulded wreath, from 12 inches and above	1.6
Mahogany moulded wreath, under 12 inches	1.8
Mahogany moulded wreath, not less than 12 inches opening	2.8
Mahogany moulded wreath, under 12 inches opening	3.4

Mahogany moulded cap, wrought by hand, .495 each.
Mahogany moulded cap, turned and mitred, .4 each.
Mahogany scroll, 1.8 each.
Making and fixing each joint with joint screw, .231.
Making model, and fixing iron balusters, each, 2.095.
Making model, and fixing iron columns to curtail, each, 2.142.
Preparing and fixing deal bar balusters, each, .04.
Preparing and fixing deal bar balusters dovetailed to steps, .056.

Extra sinking to rail, for iron rail or balusters	.032
Extra sinking in ramp or wreath	.1

Every half rail to be measured two-thirds of a whole.

All rails to be measured three inches beyond the springing of every wreath or circular part.

All cylinders used in rails glued up in thicknesses, to be paid for extra.

Articles rated at so much each.

Clamp mitres.
Cuttings to standards.
Housings in general.
Housings to steps.
Housings to mouldings.
Each scribe of skirtings to nosings of steps.
Elbow cappings.
Curtail step.
Returned moulded nosings to steps.
Caps to hand-rails.
Scroll of hand-rails.
Making and fixing joints of hand-rails with joint-screws.
Fixing iron columns in curtails of stairs and preparing mould.
Fixing iron balusters, and preparing mould.
Preparing and fixing deal balusters.
Brackets to stairs.
Mitres of pilasters according to their size.
Headings of flutes and reeds.
Hopper-heads to water-trunks.
Shoe to water-trunks.
Moulded weather caps to water-trunks.
Joints to water-trunks.
Preparing flooring-boards.
Preparing battens for floors.
Listing boards.

Articles rated at per foot lineal.

Sinking to shelves.
All raised panels on the extremity of the raising to be charged extra.
Moulded raisings of panels.
Coping to wainscoting.
Level circular string boards to stairs.
Hand-rails.
Newels to stairs.
Moulded planceer in stairs.
Sinking to rail for iron rail or balusters.
Pilasters under 4 inches wide.
Boxings to windows.
Water-trunks.
Skeleton grounds.
Flutings to columns.
Beads or fillets.
Bead or ogee capping.
Square angle-staff rebated.
Beaded angle-staff rebated.
Inch common ogee.
Inch quirk ogee.
Ovolo and bead.
Astragals on doors.
Reeds on doors.
Reeds on shutters.

Articles rated at per foot lineal.

Single cornice.
Single-faced architrave.
Ornamental grooving.
Narrow ground for skirting.
Narrow grounds for chimneys.
Legs, rails, and runners of dressers.
Rule-joints.
Framed grounds.
Skeleton grounds.

Articles rated at per foot super.

Planing, ploughing, tonguing, beading, gluing, and clamping deals.
Skirtings.
Sash-frames.
Sashes.
Sashes and sash-frames.
Sky-lights.
Framed back linings.
Back elbows and soffits.
Shutters.
Door linings.
Doors.
Wainscoting.
Partitions.
Dado.
Steps to stairs, including carriages.
Cradling.
Double-faced architraves.
Mouldings wrought by hand.
Shafts of columns.

Articles done by the square.

Laying floors.

Articles at per value.

Belection mouldings.
All fancy-works.

The English writers who have treated upon joinery, are, Moxon, in his *Mechanical Exercises*, second edition, printed 1693; Halfpenny, in his *Art of Sound Building*, small folio, 1725; Oakley, in his *Magazine of Architecture*, folio, 1730; Price, in his *British Carpenter*, quarto, 1735; Hoppus, in his *Builders' Repository*, quarto, 1738; Batty Langley, in his *Builders' Complete Assistant*, royal octavo, 1738; Salmon, in his *London Art of Building*, third edition, small quarto, 1748; Mr. Abraham Swan, in his *Architect*, folio, 1750; Pain, in almost every one of his works, particularly in *The Carpenters' and Joiners' Repository*, *The British Paladio*, *The Practical Builder*, and in *The Practical House Carpenter;* and the author of the *Architectural Dictionary*, in *The New Carpenters' Guide*, published in quarto, 1792; in *The Carpenters' and Joiners' Assistant*, quarto, 1792; in Rees's *Cyclopædia;* and in the *Mechanical Exercises*, octavo, 1812.

From these authors we shall here collect such extracts as relate to mechanical principles, or to geometrical construction, in the order of the above list.

Moxon treats the subject merely as a manual art. The following is extracted from Halfpenny's *Art of Sound Building:* he seems to have been the first writer who considered joinery in a geometrical point of view; his knowledge, however, is entirely confined to hand-railing.

"*To find the raking arch, or mould, for the hand-rail to a circular pair of stairs, in such a manner that it shall stand perpendicularly over its base, or arch of the well-hole.*

Figure 95.—"First describe a circle equal to the breadth of the well-hole, whose diameter is U W; as also another from the same centre, whose diameter is A G, to represent the plan of the rail; and divide the circumference of the greater circle into the same number of equal parts as you would have steps once round the circle.

"This being done, take the back, or rake, of the bracket, equal to C F, in your compasses, and setting one foot in A, with the other strike the arch *h:* also take the height of one step, as A C, *Figure* 96, and setting one foot in B, with the other strike the arch *i;* and when this is done, take the distance from A to *h* in your compasses, and setting one foot in *h*, with the other strike the arch *k*, and take the height of two steps, and with one foot in C, draw the arch *l*, to intersect the arch *k*, and so on.

"The intersecting points of the arches *h i*, and *k l*, and *n o*, and *r s*, and *t u*, are all at the same distance from one another, and the lines B *h*, C *k*, D *n*, E *p*, F *r*, and G *t*, being the risings or heights of the steps, in *Figure* 96, B *h* being the height of one step, C *k* of two, D *n* of three, E *p* of four, F *r* of five, and G *t* of six. Now, if these lines are raised up perpendicular on the circle A D G, it is evident that the point of intersection of the arches *h* and *i*, will stand perpendicularly over the point B; of the arches *k*, *l*, over C; of the arches *n* and *o*, over D; of the arches *p*, *g*, over E; of the arches *r* and *s*, over F; and of the arches *t* and *u*, over G. Now, if nails be struck into the intersecting points of the said arches, and a thin rule be bent round them, you may describe the arch, A *h k n p r t*, by the edge thereof, being the mould to strike the arch of the rail with.

"*The arch or mould of the rail being found, as above, how to prepare the stuff of which the rail is to be made, and work the twist thereof without setting it up in its due position.*"

Figure 97. "First strike two circles, whose diameters are equal to U W and A G, in *Figure* 95, and next consider into how many pieces you glue the rail, which in the semicircle let be six, as in the example.

"Now divide the semicircle into six equal parts, as E F, F M, M S, S L, L D, and D K; from each of these points of division, draw lines to the centre A, as A E, A F, A M, A S, A L, A D, and A K. Then from F raise F G perpendicular to A F, and equal to the height of one step. Also, at the point M, raise M N perpendicular to A M, equal to the height of two steps; and in like manner at the points S, L, D, and R, raise the perpendiculars S T, L Y, D E, and R L, respectively equal in length to the height of three, four, five, and six steps. Then draw a line from G to R, parallel and equal to A F; as also another from N to *y*, parallel and equal to A M; another from T to W, parallel and equal to S A; another from Y to B, parallel and equal to L A; another from E to H, parallel and equal to D A; and another from L to P, parallel and equal to K A. From the point A draw the line A B, perpendicular to A E, and equal to the height of one step; also at the points R *y*, W, B, H, P, draw the lines R L, Y Z, W X, B C, H I, P O, all equal to the height of one step, and respectively perpendicular to R G, Y N, T W, Y B, E H, L P, and draw the hypothenuse E B, L G, Z N, T X, Y C, E I, L O.

"This being done, set off the width of the rail from E to *d*, G to *i*, N to *o*, T to *u*, Y to *a*, E to F, and L to *m*; and set the stem of a square on the line E B, till the blade touches the point *d*, and draw the line *c d*. Moreover, set a square on the line G L, and where it cuts the line R G, as in the point I, draw the line *h* I; and in like manner draw the lines *p o*, U N, Z *a*, *g* F, and *n m*. Then the angles E *d c*, G I *h*, N *p o*, &c. and the rest of the little black spaces, as you see in the Figure, do represent the twisting of each piece, and what must be taken off from the back at the lower end, to make the twist of the rails. The lines being drawn, you are next to consider after what manner they are to be applied in the working of the rail.

"Take the piece of timber, of which you design to make the first length, which is represented in *Figure* 98, and plane one side thereof straight, and cut it to its bevels *a c*, *b d*, answering to D R A and a D A, *Figure* 97, and both ends thereof being also cut to the raking-joint of the rail, proceed thus: Take that part of the raking-arch in *Figure* 95, which answers to the first length of the rail, as A *h* in the arch A *u*, and lay it on the upper side of *Figure* 98, from *l* to *h*, and strike the arch *l h*, then take E *c*, equal to G *h*, or N *p*, in *Figure* 97, and set it on the line *b d* from *h* to *m*, *Figure* 98, and strike a square stroke at pleasure from *m* to *g*; also take *d* equal to *h* I, or *p o*, &c., *Figure* 97, and set it on the line from *m* to *g*, and draw the line *h g*, which represents the back of the rail when it is worked, and is equal to E *d*, or G *i* or N *o*, &c., *Figure* 97. This being done, represent the lower end of the rail *h g k i* at right angles to *h g*; as also the upper end *l c o n* at right angles to *l c*, and baste out the inward arch *c m* square from the upper side *a b c d*, as *m g*; and take a thin lath, and bend it close to the side thereof, from *c* to *g*, whereon strike a line along the edge of the lath, and so the lines *l h* and *c g* are your guides in backing the rail; which, when done, turn the piece upside-down, and with the mould strike an arch equal to *l h*, from *a* to *k*, and baste out the side to the lines *l h* and *o k*; then you have one side and the back squared, which is the greatest difficulty in the formation of a twisted rail, because the two other sides are found by gauging from them.

"*Note.*—If the triangles in Figure 97. and lines whereon they stand, be supposed to be raised up perpendicularly, then will the lines A B, R L, Y Z, W X, B C, H I, and P O, join to each other, and produce one line perpendicularly over A, equal to seven risings or heights of the steps. But in working a rail of this kind, you have need of but one triangle, A B C E *d*, because they are all equal, and of but one effect in working, they being drawn only to satisfy the curious in the nature of the thing."

He finds the moulds for elliptical staircases in a similar manner, viz., by finding an arch line divided into equal parts, so that each of them may be equal to the hypothenuse of the pitch-board, and the distance of the points of division in succession respectively equal to the heights of the steps: this principle is to be understood in all staircases where the steps are equally divided at the well-hole, whatever be the form of the plan: but in elliptic staircases the degree of twist is different, and therefore requires a pitch-board to be made for every portion.

It is hardly possible to conceive any method so distant from principle as what is here shown: the squaring of the wreath is altogether guessed at, not to mention the great disadvantage in making the rail in so many pieces. If the rail were really executed, the above method would then be a property; but the moulds never can be obtained from any construction in plano upon the same consideration. It is rather astonishing that any attempt should be made at demonstration, for the support of a method so entirely destitute of principle as the above.

"*How to form the arch or mould to the hand-rail of a pair of stairs that sweeps two steps, so as to stand perpendicularly over its ground, and the manner of squaring the same, without setting it up in its position.*

"First: draw *Figure* 99, to represent the ground-work of the rail, whose arch, G C, consists of two different arches, one whereof is a quarter of a circle, the other a quarter of an oval. A B (equal to A C, equal to C D, equal to B D) is equal to one-third of a step: and D is the centre to the arch C B; also, B F is equal to two-thirds of a step, and F G is equal to one step and two-thirds; by means of which, and B F, is the arch G B described. G K represents the straight part of the rail to one step, and the arch H D is drawn by gauging from the arch G C; that is, it is drawn parallel to it, and the straight part I H is found by gauging from K G, or is drawn parallel to it.

Figure 100, "shows the manner of drawing the rake or arch of the rail, which is done thus: draw I L equal to G K of *Figure* 99, and represent the tread of the steps as before, by pricked lines. Then divide that part of the ground-work of the rail which belongs to each step into any number of equal parts, as A F into five, and F K into four. This being done, draw A B, B G, C D, in *Figure* 101, to represent the rising and tread of the steps, and continue out the line C B at pleasure, towards T, in which set the five divisions on the ground of the rail to the first step F E, of *Figure* 100, being equal to C *i* of *Figure* 101; also, E D equal to *i k*, D C to *k l*, C B to *l u*, and B A to *u* T. Then will the line C T, in *Figure* 101, be equal to the arch A F, of *Figure* 100; draw the line D T; then is the triangle C D T the bracket to the first step, according to the sweep of the rail: and as T C is the length of the ground to the first step, so is T D the length of the rail answering to it. Then from the points *i*, *k*, *l*, *u*, raise the perpendiculars *i* P, *k* Q, *l* Z, and *u* S, to C T; and take the four divisions on the second step, and set them in the line C T, from C to B, and draw the line B D; and then is B C the length of the ground to the second step, and B D the length of the rail answering to it. Draw lines through these divisions, as from F to *m*, G to *n*, and H to O, perpendicular to C B; and so your perpendiculars are found according to the compass brackets of each step, and may be pieced thus:—

"In *Figure* 101, take T S in your compasses, and with that distance, setting one foot in A, in *Figure* 100, strike the arch *m*; and take S *u* between your compasses, and with one foot in B strike another arch to intersect the arch *m*. Again: take S Z or S T in your compasses, and with one foot in the intersection of the arch *m* and this latter arch, describe the arch *n*; and take *l* Z in your compasses, and with one foot in C describe an arch to intersect the arch *n*; and thus proceed on, so that Z Q be equal to *n o*, Q P to *o p*, P D to *p q*, *q z* to B O, *z s* to *o n*, *s t* to *n m*, and *t u* to *m* D; as also *k* Q to D *o*, *i* P to E *p*, C D to *q* F, H *o* to G *z*, G *n* to H S, F *m* to I *t*, E D to K *u*, L *w* to three times A B. The points *n*, *o*, *p*, *q*, *r*, *s*, *t*, *u*, *v*, *w*, being found by the intersection of arches, as above, stick a nail into each point, and bend a thin rule about the nails, till it touches them all, then with a pencil describe an arch round the edge thereof, which will be the arch A *w*, being that of the rail to work by.

"*Figure* 102 shows the manner of squaring the rail, which is thus: first, describe A F, the square, or ground of the rail, being the same as that of *Figure* 99, and find the centres to answer to the different arches of the ground; from whence draw pricked lines to the places where you design to join the rail, as from G to B, from G to C, from H to E, and from H to *d*. Because the first step is to be joined in three equal pieces, you must take one-third of the rising or height of the step, and set it from B to I, perpendicular to B G, and draw the line M I, parallel and equal to G B. Now, from M to *n* draw a perpendicular to M I, to rise so much as the rail rakes over, which is one-third of the rising or height of the step, because that part of the rail is one-third of the length on the first step; and draw the line I *n*, by which means we shall have the first triangle I M *n*. Then from the point C, draw C *q* perpendicular to G C, and equal to two-thirds of the height of one step; and draw the line *q z* equal and parallel to C G; and from *z* raise a perpendicular, *z s*, to *z q*, equal to one-third of the height of one step, and draw the line *q s*, and you will have a second triangle. Again, from *d* draw *d* T perpendicular to H *d*, and equal to the height of one step, and draw the line T W equal and parallel to H *d*; and from W erect the line W X perpendicular to W T, and equal to the height of one step, because that part of the rail over the second step will be one piece, therefore the triangle must rise one height of the step; and draw the line T X, and so you will have a third triangle, W X T. This being done, from I in the line I M, set off I *k*, equal to the width of the rail; also set off the same from *q* to *o*, and T to *u*, and setting the stem of a square on the hypothenusal line, so that the blade thereof touches the point *k*, draw the line *k l*; and in like manner draw the lines *p o*, *u v*; and then the little triangles I *k l*, *q o p*, T *u v*, do represent what must be taken off from the lower end of each piece, to bring the rail to its true twist."

The form of the scroll is only a subject of fancy, but what has been quoted from this author, will show the difference of taste between the time when such were in use, and those of the present day. No elegant geometrical forms seem then to have been employed. As to the construction of the raking-mould for the scroll, it is done in a similar manner to the twist of the rail, before shown, and therefore equally destitute of principle.

Mr. Edward Oakley, in his *Magazine of Architecture*, has copied Halfpenny's descriptions and diagrams; to which we refer the reader.

The next work under review is *The British Carpenter*, by Francis Price. The article Joinery is almost confined to hand-railing, as in the preceding authors. Mr. Price proceeds as follows:

"*To find the proper kneeling and ramp of rails.*—In *Figure* 103 is represented a short flight of four steps, and part of a half-pace, on which are shown two balusters on a step; *a b* is the rise or height of one step, and *b c* is the newel, generally two feet four inches and a half high, and sometimes two feet six inches high, &c., and *c d* is the thickness of the rail; the kneeling, *o*, is in the middle of the first baluster; from *e* to *f* is also the height of the first step on the half-pace; and *f g* the height of the newel, agreeable to that of *b c*; and *g h* is the thickness of the rail; from *h* to *i* is generally the same as from *o* to *c*, which line, *h i*, continue at pleasure; for on it is the centre for the ramp. With your compasses find the centre, *k*, which touches the back of the rail, *n*, and the point of the ramp, *i*; find the point of touch, *n*; draw the line *k n*; describe the ramp, and also the turned part of the balusters, as may be seen by the pricked line.

"Over this is represented the alteration that ought to be made, if you place three balusters on a step; that is, that the kneeling ought to come to the back-side of the first and last balusters, as at *p* and *q*. If it be said, the method in *Figure* 103 is not fully expressed; to find the height of the ramp agreeable to the kneeling, let *Figure* 104 be the rail, the bottom is continued as by the pricked line appears at *u* and *w*; take the distance, *u t*, and set from *w* to *x*; from *x* set one rise, or the height of one step, as at *y*, and that gives the height of the ramp, and is the same as the method in *Figure* 103, notwithstanding they differ in appearance.

"In *Figure* 105 is shown the manner of fluting newels for stairs, and balusters; the newel having twelve flutes, and the balusters eight. If the stuff be large, the flutes may vary; thus the newels to have sixteen flutes, the balusters twelve."

We cannot comment any farther on the above, than that it shows the method of describing the ramp of a rail, and the difference of taste in the age of Price, from that now in use. The design, the quantity of work, and the massy parts, which characterized that time, when contrasted with the slightness and plainness of work executed in the present day, are really astonishing. Our hand-rails are very light, but very neat; when ornamental work is used, it is chiefly confined to iron, being rarely constructed in wood.

"Whatever may appear difficult in this method of forming scrolls proper for the plans of twisted rails, due application will make easy and expeditious.

"First, form a scroll with chalk, or a pencil, agreeable to the bigness of the place in which it is to stand; next resolve on the bigness of your stuff to be used for your rails, and also your mouldings on the side thereof, as in *Figure* 106

Fig. 114.
Fig. 115.

Let *d* be the centre of your chalked scroll in *Figure* 107; on which describe with the projection of your mouldings from *Figure* 106, the small circle *d;* take from *Figure* 106, half the bigness of the stuff, as *eg*, or *ef*, which add to the small circle, and form the circle *h i t*, which is the bigness of the eye of the scroll: this done, take the distance from *i*, to the inside of the rail, as the supposed chalked scroll, which suppose *k;* with it, make a diminishing scale, by setting that distance up, from *t* to *l;* draw the line *k l;* place one foot of your compasses in *k*, describe the part of a circle *t* 8, which divide into eight equal parts, because here your supposed chalked scroll was to come into its eye, or block, at one revolution of a circle. (Scrolls may be made to any number of revolutions desired, by the same rule, witness that above, in *Figure* 108.)

"Place one foot of your compasses in *d*, describe the large circle *w l l u*, which always divide into eight parts, because you strike one eighth part of a circle every time, till you come into the eye, or block, *i t h;* from the said divisions on the large circle, draw lines through, for on them your sections meet, which form the scroll. It is observable in drawing your sections, that they do not end in the line drawn through the great circle, only the outside scroll; for those of the inside scroll end on a line drawn to each respective centre. I suppose A and B to be two steps; the rest, I think cannot fail of being understood, by observing the letters and figures, which show each part distinctly."

Mr. Price's advice, to make a scroll first of chalk, is altogether ungeometrical, and therefore unworthy of notice. The method of forming it is of Italian invention. A similar construction is used in describing the Ionic volute in Daviler's *Cours d'Architecture*, dated Paris, 1720. He ascribes the invention to Vignola. But, in our opinion, it is far from producing that agreeable variation of curvature required. The opening next to the eye expands too rapidly towards the extremes. A much more perfect method, and not very dissimilar in construction, is that published in the *Joiner's Assistant*, by Nicholson. *See* the Articles SPIRAL and SCROLL.

"In order to make the squaring of a twisted-rail easy, see the plan, *Figure* 109, which is the same as that in the foregoing *Figure* 107, and find the point of touch, *b*. From these curves a mould must be traced out, in order to form a sweep, which when applied on the rake, is agreeable to this of *a b*, *c d*, as that of *Figure* 110. (It is first to be observed, that you will want wood extraordinary, both on the top of the rail, as in *Figure* 111, at *e*, *a;* and also under the same, as *g*, *h*.) To find which, observe where your sweep begins, in the plan *Figure* 109, as at *a c;* also observe that *o* and *n* is the end of the twisted part. Therefore, from *a* to *n*, divide into a number of equal parts, so as to transfer them on some line, as in 112, from *a* to *n;* also divide the inside of 109, as from *c* to *o*, into equal parts, so as to transfer them on some line, as in 113, from *c* to *o;* take the distance *e a*, in 109; apply it to the pitch-board, as from *g* to *e;* take the pitch-board, 114, with its place *e* to *c*, in 113; draw the line *dg*, and make the point *s;* divide from *d* to *s* into eight equal parts, also from *d* to *o* into the same number; draw the lines, which form a sweep, whose use shall be hereafter shown.

"Likewise take the pitch-board 114, and apply *e* to *a*, in 112; draw the line *ep*, and make the point *r;* from *e* to *r* divide into eight equal parts; also from *e* to *n* do likewise; draw straight lines from each division; that curve shows how much wood is wanting on the back of the rail, as *b t*, which describe in 111, from *e* to *a;* and there describe the bigness of the rail; which shows how much wood is wanting, as may be observed by what was said above. The other part of the twist is cut out of a parallel piece, as 115; which thickness extraordinary is shown in 111, at *e a*.

"To square the twisted part of the rail, having so much wood extraordinary on the top and bottom, observe in 109, from *a* to *e*, and from *c* to *f*, must be traced as was above mentioned. Take *a e* in 109, apply it to the pitch-board 114, it shows *g i*, which length place in 110, from *k* to *i;* also, take from 109 the distance *b d*, apply it to the pitch-board 114, it shows *g m*, which length place in 110; from *l* to *m*. This done, trace out the raking-mould 110, agreeable to the plan 109, which, by inspection and a little practice, will become easy, and without which nothing is known truly. I say, the wood extraordinary being accounted for in 111 both on the top and the bottom of the rail, observe to place your stroke *f* in its true place, that is, at the beginning of the twisted part; take the raking-mould 110, set *i* to *f* in 111; there strike it by; with the angle of your pitch-board describe the pricked line *f*, by the side of the rail; then apply the mould 110 to the bottom; set *i* to this pricked line, and there describe by it, with your pencil. Lastly, cut that wood away; also, cut the remaining part of the scroll out of the block; as 115; then glue these together, and bend both moulds, 112 and 113, round the rail; strike them by that, and cut the wood away; so will the back of your rail be exactly square, and fit to work."

This method of squaring the twist of the scroll is correct; the principle is that of the section of a curved prism at right angles to a given plane, and amounts to no more than tracing a common angle-bracket. The construction, however, requires a very considerable addition to the thickness of stuff; and even this thickness will be variable, according to the place of the pitch-board. This method, though much superior to that of Halfpenny, is not to be compared with that of springing the plank, introduced by Mr. Nicholson.

Mr. Price says, that his method will apply to any twist or wreath whatever: we grant that it will; but then the stuff would require to be from 4 to 8 inches in thickness, and sometimes more. In drawing the section upon the plank, in order to be cut out, the shank of the mould is always applied parallel to the arrises; this application occasions also a great waste in the breadth as well as in the thickness. In the construction of the face-mould of the scroll, he employs the pitch-board of the flyers. He gives no example of forming a wreath over winders; but if the same principle is to be applied, recourse must be had to a development of the steps. It is unnecessary to make any farther observations, as the author of the Architectural Dictionary, Mr. Nicholson, has placed these and his own before his readers, in order to compare and point out the specific differences of each, by proper diagrams, at the end of this article.

"You are always to observe this general rule, viz., to conceive each respective paragraph, as it occurs, before you begin another; the neglect of which appears by some who cannot conceive the particulars of the foregoing Figure, although I had put it in so clear a light.

"I have here described three distinct methods of squaring the twisted part of a rail, which may be known, and the rail squared, with more ease than in the foregoing Figure. But when done, they will not have that agreeable turn in their twisted part as they would have, if done by the foregoing unerring rule, as may more clearly appear by the following explanation:—

"That of *Figure* 116, is the raking-mould, taken from *Figure* 110 (whose use and application was therein clearly shown); that of 117, is the pitch-board, taken from 114; which gives the rake or declivity of the rail.

"In *Figure* 118 is shown how to square a rail, without bending a templet round the twisted part thereof; and which is by being guided by the back; first, describe the bigness of the stuff to be used, as *a b h i*, which shows how much wood will be wanted at bottom, supposing s to be the side of the rail. And because the grain of the wood should be agreeable to the falling of the twist, therefore consider how many thicknesses of stuff will make the wood required to cut the twist out of; as here three. Therefore, as in s, continue the line *a b*; place one foot of your compasses in *a*, make the section, or part of a circle, *c d;* divide it into four parts, as 1, 2, 3, 4, because the rail s must be always reckoned as one; this, by inspection, shows how the grain of the wood is to be managed, as appears by the shape of the several pieces, 119, 120, 121, which are better, if cut so by the pitch-board, before glued together.

"In 122 is shown how to square the twisted part, making the bottom your guide; the section shows how much wood is wanted on the back.

"In 123 is shown how to square the twisted part, making a middle line on the back your guide; the section shows the wood wanting on the back and at the bottom.

"That of 124 may be cut out of a parallel piece, of the thickness of the intended rail, which, when it is glued to the twisted part, will want little or no humouring.

"*N.B.*—There is a nicety in working the mitre thereof, as *k l m*."

The above method of forming the wreath by gluing different thicknesses together in parallel blocks, perhaps originated with Price, or might be in use among workmen in his time. The process is quite mechanical, and what might occur to any well-informed workman. And though the wreath might be got out of much less stuff than by the former principle, it is tedious, and much more uncertain. To apply these properly would require the workman to understand the method of orthographical elevations; and though Mr. Price seems to have had a notion of this, his representations of the wreaths are all drawn by guess, and are therefore not to be depended upon. Another method by which this might have been ascertained, is by a plan and development of the twist, where the risings of the blocks might have been ascertained according to their several thicknesses; we shall show this improvement at the end of this article, accompanied with a diagram.

"You are to observe, the foregoing Figures must be well understood; and then, in these Figures the lengths of the newel and balusters that stand under the twist or scroll are truly described; that is, their lengths and bevels may be known before the rail be put up in its place; and, that it may prove easy, observe the plan, *Figure* 125, of the twist or scroll is the same as before, and so are the two steps P and Q, and the pitch-board, 126.

"First, resolve on the bigness of your balusters, as *a*, *b*, *c*, *d*, *e*, *f*, and also the newel. Divide the said balusters truly on a line drawn in the middle of the rail; for then what is wide on one side is narrow on the other. It is for that reason I choose to divide them on a middle line. Describe the plan of the balusters, as *p q*, *r s*, *t u*, *u w*, *x y*, and *z*, for there your twisted part ends; from thence to the eye is level.

"Observe where your scroll begins, as at *l*, and on some line, as above in 127, first make a point at *l;* then from your plan take the distances *p q*, *r s*, *t v*, *u w*, *x y*, and *z*, which transfer as above, observing to have regard to place truly each distance from *l* both ways, as *p q*, *r s*, *t v*, *u w*, *x y*, and *z*. Observe also to take from the plan the distance from *l* to *m*, which apply to the pitch-board R, as from *h* to *n*, which gives the length *h o;* take this pitch board and apply it on the line above, which, by inspection, the letters will show; this gives the slope of the rail, as *h o &c*. From *o* to *h*, and from *h* to *y*, form the curve by equal divisions, and drawing straight lines, as was before shown.

"Lastly, having the lengths of your fixed balusters, as *a b*, *Figure* 127, describe the steps S and T with the pitch-board: so that by continuing perpendicular lines, from the points on the line first terminated to the said curve and to the steps, you have the accurate lengths of the balusters, as *a*, *b*, *c*, *d*, *e*, *f;* the newel *g* being the same length as *f*, because at *f* or *z* the twisted part ends.

"The curve of the first, or curtail-step, *Figure* 125, is formed by the same rule as delivered for the plan of the rail.

"It may not be amiss to observe particularly the point of the sweep or curve's beginning, and being particular also in its application, by which this and the foregoing, though represented with but two steps, is the same, in fact, as though I had described a whole flight to show its use."

To ascertain the height of the balusters is not of very great importance to workmen of the present day. The method is, however, correct; and though it might be laid down and expressed more clearly, it is as eligible as any that can be applied to the purpose. Price's remark for taking the middle line for the division of the balusters is judicious.

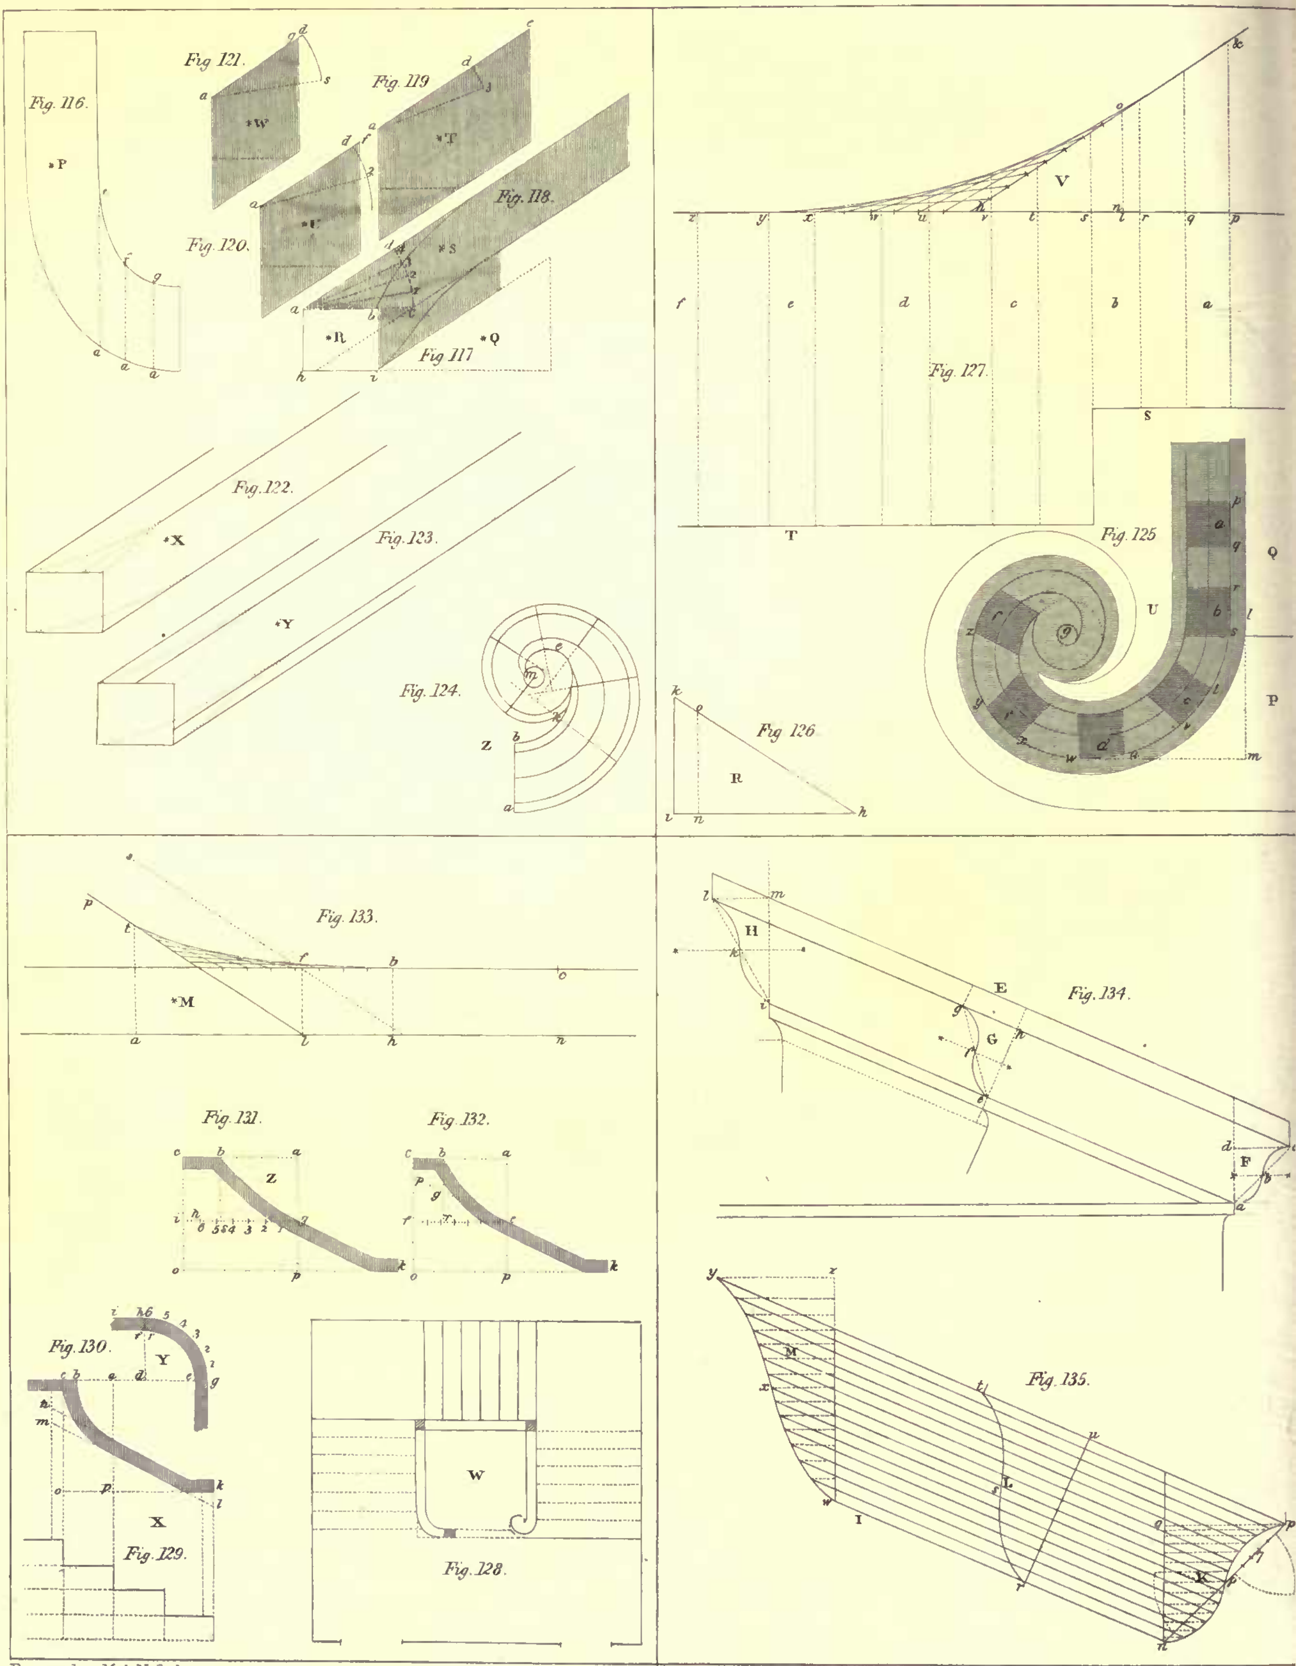
"Zealous to promote," says he, "what may be useful, I have made easy the difficulty of squaring a rail that ramps on a circular base.

"Observe, *Figure* 128 is the plan of a staircase; and at the landing is a quarter-circle: to make this easy, in 129, is three steps, described by a larger scale, and the same method as shown in 103, 104. Likewise, 109 is the plan of the rail. It was shown in 110, &c., how to trace out a mould on the rake, agreeable to this plan, or indeed any other. A considerable thickness of wood more than usual is required on the back of this rail, which will appear more plainly by inspecting 117, &c., as also the method to trace your moulds that shall bend round the said rail. Let the sides be squared, as was shown in 109, 110, 111, 112, 113, 114, 115. Observe here, in *Figure* 129, the line *k p o;* take the distance *k p*, and place it on some line at pleasure, as in 130: then divide the outer circle in 130 into a number of equal parts, as into six, as from *g* to *h*, which transfer to 131, as *g*, 1, 2, 3, 4 5, 6, *h*. The point of the ramp may be observed to fall within the fifth division, as at *s;* so that by the intersection of straight lines and equal divisions, you describe the sweep for the ramp *g b*, which makes 131, the mould, to bend round the outside of the said rail.

"Observe also in 130, from *e* to *f*, divide it into six equal parts, which transfer to 132, as from *e* to *f;* and (observe again) the ramp falls within the fifth division, as at *r*. So divide the distance from *e* to *g*, and from *g* to *b*, into equal parts, and by drawing straight lines, you have the sweep *b e*. From the point *b*, to *p*, is the thickness you want to be added extraordinary on the back of the rail 132, and which is the inner mould; so that by bending both these moulds round the rail, and by drawing them with a pencil, and cutting away the superfluous wood, you have an exact square back.

"There seems no difficulty now left unmentioned, to square twisted rails in any form whatever.

"Because I have all along strove to give variety, observe 133, in which is shown a method to have your newel under the twist, the same length as the rest; by which means also the rail twists no farther than the first quarter, and consequently the remaining part may be cut out of a plank, of the thickness of your rail, without twisting at all. There seems no explanation wanting to clear this point, but inspection. and a good conception of *Figures* 109, 110, 111, 112, 113,



Drawn by. M.A. Nicholson.

Eng.[d] by R. Th

114, 115: in this of 133, *l f* is the thickness of wood extraordinary wanting on the back of the rail."

The method which Mr. Price employs at 132, for ascertaining the thickness of stuff by a falling-mould, or development of the side of the rail, is incorrect; nor can it be found in a determinate manner without an orthographical elevation of the part of the wreath to be formed. This concludes the whole substance advanced by Price in the article Joinery, and shows improvement only in its infancy.

Mr. Price has also shown the method of forming raking-mouldings for pediments, as follows:

"And in consideration that no pediment can be performed without two kinds of cornice, (except it be knee'd at its bottom or springing, which is reckoned a kind of defect,) therefore to give each of the cymas such a shape, or curve, as shall strictly agree in their mitre, do thus: Describe the curve of the level cornice F, *Figure* 134, as *a b c*, by two such portions of circles, as that the centres for forming each may be on a horizontal or level line, drawn through the middle of the said cyma; as * *, *c d;* being the projecture thereof. Draw lines from the points of the said cyma, agreeable to the slope of the pediment, which gives or terminates the bigness of the raking cornice or cyma G; so that by drawing a line through the middle of the said member, on it are the centres * *, by which the curves *e f g* are described; the projecture, *h g*, being as before. In case a break or return be made in the pediment, then another kind of cyma must be formed, which shall agree with the two former, as H; the centres for forming each curve being on an horizontal line drawn through the middle of the cyma, as before; *i k l* is the curve, whose projecture, as before, is *l m*. These three kinds of cornice being thus formed, will agree with each other, without the trouble of tracing. But if the given curve be not described as before, then observe the method proposed in 135; by which the curve of any raking-mould whatever may be truly described. Admit the cornice given were K; *n o p* being its curve, and *p q* its projecture; by making points on the said curve, draw lines from them, agreeable to the slope of the pediment, on which place each respective projecture from K to L, so is *r s t* its curve, the projecture being *t u*, as before. And if a break or return be made, as M, then transfer the several projectures from K, observing that the points be on the lines drawn agreeable to the rake of the pediment, so will *w x y* be the curve, and *y z* the projecture, as before: which no doubt but inspection explains."

The scheme for raking-mouldings, shown at 134, is not to be depended upon. It is evident that since the figure is a prism, and since the given curve is composed of circles, the curves required must be composed of elliptic segments, unless the sections are parallel to each other, which is not the case.

The second method, shown at 135, is perfect, and is the first thing of the kind that is to be found in any English publication.

We come now to the *London Art of Building*, by William Salmon; and as it is our province to repeat only the inventions and improvements in joinery, we shall therefore omit what Mr. Salmon has said on the formation of the scroll; being, in method and substance, the same as that which we have detailed from Mr. Price, who certainly gave the first rational method of squaring the twist for the scroll part of the rail, either from his own invention, or from a practice known among workmen. And as Mr. Price has only shown the formation of the twist of a scroll, and of a rail upon a quadrantal plan in a level landing, we shall here detail the application made of the same principle by Salmon to a winding stair, where the treads of the steps are all equally divided around the circumference; but first it would be necessary to notice the candid acknowledgement which Mr. Salmon has made in respect to the principle.

"I must confess, for this method of forming twist rails, I have had my eye upon, and am obliged to, my ingenious friend, Mr. Francis Price, in his *Treatise on Carpentry*, lately published; though, on comparing them, you will not find them alike. This method of forming the raking-mould will serve for all twist rails whatsoever, with due application, as shall be shown in another example of a staircase, having a circular well-hole.

"*Figure* 136, is the plan of a circular rail having sixteen steps in the whole circumference; but here it is proposed to find the raking-mould to a fourth part thereof, or four steps, it being to a small scale. The plan being laid down, as *a c d e*, *Figure* 136, divide the outer circle into a number of equal parts, so as to transfer them on some line, as *a c*, *Figure* 137; and setting up the rise of four steps, as *a b*, gives the pitch-board, due to them all. Then taking *b c*, in *Figure* 136, applied to the pitch-board, *Figure* 137, from *c* to *d*, it gives *c e*, which transfer to *Figure* 138, from *b* to *c*. Also, from *Figure* 136, take *a d*, placed in *Figure* 137, from *c* to *g*, gives *c f*, which transfer to *Figure* 138, from *a* to *d;* and there tracing, as before taught, you will form the raking-mould required."

In such a staircase as the above, the waste of stuff is great; but when does it ever come into practice, that the steps are equally divided? In every stair there must be a landing and this would require much thicker stuff: Again, if the stair is mixed with flyers and winders, the waste stuff would in many cases be enormous, and still more so, if the joint were brought over the flyers, in order to secure the wreath and straight parts more firmly by a screw, as is the case in modern practice. The greater number of stairs now in use, are constructed upon this plan.

"Some able workmen have another method of forming this rail.

"First, they make a cylinder, equal to the whole well-hole, *f*, *e*, in *Figure* 136, or part thereof, either solid (if the well-hole be small) or (if large) by fastening boards together upright, in the exact form of the plan.

"Then they proceed to set on the said cylinder, as *Figure* 139, the height and breadth of each step, as *a*, *b*, *c*, *d*, *e*, *f*, &c., and to the extreme points, *b*, *d*, *f*, they bend round several thin pieces of the breadth of *c*, *f*, in *Figure* 137, and being glued, or otherwise fastened together, till they make the thickness of the rail, I say these when taken off from the cylinder, will be the rail, and exactly squared to the right twist.

"This is a very safe and sure method, though not very frequently made use of.

"Either of these ways will serve, should the well-hole be an ellipsis, or any other figure for its plan."

The first idea of gluing a rail in thicknesses is here shown, but the description, and the figures accompanying it, are very imperfect; nor will the rail come off squared, as Mr. Salmon asserts, without the veneers are all different in proportion to the radius of their plan, except, indeed, upon the plan which he has shown, where the rail is supposed to be continued, and therefore requires much amendment to be brought into general use.

Langley's improvements are as follow

"*To describe a twisted rail.*—Let the lines B D E, *Figure* 140, represent the edges of the two lower stairs of a staircase.

"Divide *b* 9, the tread of the second stair, into nine equal parts, continue the line D towards the left at pleasure. Draw N F, parallel to 9 *b*, at the distance of seven parts, also draw the line 14 *d* at the distance of three parts, then *d b* is the breadth of the hand-rail. Draw A *n* parallel to 9 *b*, at the distance of *b* 9, then the point *n* is the centre of the eye of the scroll. On the point *a* describe the quadrants *b c* and *d e*, which is the length of the twisted part of the rail, the remaining part, to *n*, the eye, being level. On *n* describe the circle *z x p*, whose diameter, *w p*, must be equal to *d b*, the breadth of the hand-rail. Divide the radius, *n p*, into four equal parts, and through the first part, at *o*, draw the line *r l*, cutting the line N F in *x* : on *x* describe the quadrants *c f* and *e g*, make *o t* equal unto two parts of *n p*, and draw the line *t s* parallel to A *n*. On the point *t* describe the quadrants *f h* and *g z*, make *n w* equal to three parts of *n p*, and through the point *w* draw the line *z k*, parallel to *r x* ; on *z* describe the quadrant *h v*, and on *w* the quadrant *v p*, and then is the plan completed."

This is a very anomalous attempt at the description of the scroll of a hand-rail with compasses, the first centre being at *a*, the second at *x* ; the third centre is said to be at *z*, but it proves to be at *o* ; neither *t* nor *w* answer to the remaining centres.

"*To describe the mould for the twist.*—Continue *b* 9 towards M, and F N towards *b* in *Figure* 141 ; also draw L I parallel to *b* N ; at the distance of N K, in any part of N *b*, as at *c*, draw the line *a f* at right angles to *b* N ; and on *c* describe the semicircle *a b f* : make *a d* and *f t* each equal to the rise of one stair, and draw the line *d c t*. Make *c* N equal to *c t* ; divide *b c* into any number of equal parts and draw the ordinates 15, 1 ; 16, 2 ; *k* 3, &c. ; divide *c* N into the same number of equal parts as in *b c*, and make the ordinates thereon equal to the ordinates on *b c*, and through their extremes trace the curve N *f*, which is the curve of the outside of the mould. Make *b k* equal to the breadth of the hand-rail ; and on *c*, with the radius *c k*, describe the inner semicircle. Make *c h* equal to *r t*. On *k t*, the semi diameter of the inner semicircle, make ordinates, which transfer on *c h*, as before ; and through their extremes trace the curve of the mould, which will complete the whole as required ; for as the outlines of the plan of the twisted part of the rail, *b c* and *d e*, are quadrants, therefore the outer and inner curves of the mould will be both a quarter part of two ellipses ; because the twisted rail, strictly considered, is no other than the section of a cylinder, as L M I K, whose diameter, *a f*, is equal to twice *a b*, in *Figure* 140, and its transverse diameter equal to *d t*, and conjugate diameter to *a f*.

"The twist of a rail over a circular base at a half pace, as *a b*, figure 142, is the very same thing as the preceding, as being the fourth part of an ellipsis, made by the section of a cylinder, whose diameter is equal to twice *a c*."

This method of forming the section is the same in effect as that already shown by Price. The only difference between Price and Langley is, that Price forms the face-mould of the rail from the intersection of straight lines drawn from two lines of sines placed at right angles to each other, and tracing a curve through the diagonals of the rectangles, beginning at the extremity of one of the perpendiculars, and ending at the extremity of the other. Whereas Langley divides the breadth of the plan and the length of the face-mould of each into the same number of parts, and draws lines at right angles through the points of division, and makes the respective perpendicular of the face-mould equal to those of the plan, and then traces curves through the extremities for the concave and convex sides ; and thus completes the face-mould of the twist.

Figures 143, 144.—"*To find the mould of a twisted rail to a circular or elliptical staircase.—Figure* 143. Let A B C D be the plan of a cylindrical staircase, whose base is a circle, and whose stairs wind about the cylinder *a b d*, &c. The plan of the stairs being divided, continue out the diameter *d a*, towards the right hand, as to *f*, of length at pleasure. Make *a f* equal to the girt of the semicircle *a b d*, which divide into the same number of equal parts as there are stairs in the plan of the semicircle *a b d*, as at the points 1, 2, 3, 4, &c from which erect perpendiculars, as 1 *a*, 2 *a*, 3 *a*, &c. of length at pleasure. Consider the rise of a stair, and make the perpendicular, *f g*, equal to the rise of all the twelve stairs that go round the semicircle *a b d*, and divide the perpendicular *f g* into twelve equal parts, as at the points 1, 2, 3, 4, &c. from which draw lines parallel to *f d*, continued out towards the right hand at pleasure, which will intersect the perpendiculars on the line *f a d*. in the points *ac*, *ac*, *ac*, &c. and which are the breadths and heights of the treads and risers of the twelve stairs at the side of the semi-cylinder *a b d* ; for were the whole of *Figure g f a* applied about the semi-cylinder, then the parts *a c*. *a c*, &c. would be in the respective place of each stair. Let *a e* represent the breadth of the hand-rail, and the semicircle *e* 10 *c* its base, over which its inside is to stand. Divide its diameter, *e c*, into any number of equal parts, as at 1, 2, 3, 4, &c. and draw the ordinates 1, 6 ; 2, 7 ; 3, 8 ; 4. 9, &c. which continue upwards, so as to meet the horizontal lines drawn from the perpendicular *g f*, in the points 28, 27, 26. 25, &c. through which trace the ogee curve 28, 14, *a*, which is the sectional line of the cylinder over which it stands. Make the distances, 15, 21 ; 19, 14 ; 18, 13 ; 17, 12 ; and 16, 11, equal to the ordinates 10, 5 ; 9, 4 ; 8, 3 ; 7, 2 ; and 6, 1 ; and through the points 20, 19, 18, 17, 16. to *a* on the line *f d*, trace the curve, 20, 16, *a*, which is the inside curve of the mould, and whose out-curve, 21 *a*, being made concentric thereto, will be the mould required, whose end, 21, 20, when set up in its place, will stand perpendicular over its base *b* 10.

"*Note.* This mould, though made but for one-fourth part of the cylinder, will serve for the whole, by repeating the same, or adding three or more others of the same kind to the ends of each other as often as there are revolutions in the cylinder."

It is not possible to conceive anything so void of truth as the method here shown. Over and above the absence of principle, the description is contradictory to the diagram. We are told to "divide its diameter, *e c* (into any number of equal parts) as at 1 2 3 4, &c. and draw the ordinates 1 6, 2 7, 3 8, 4 9, &c. which continue upwards so as to meet the horizontal lines drawn from the perpendicular *g f* ;" but instead of being drawn through the diameter, they pass through the divisions which divide the concave circumference of the plan into equal parts.

Langley has presumed to differ in method from Price in finding the curvature of raking-mouldings ; but in this he has been much mistaken, as may be observed in the following :—

"*To find the curvature or mould of the raking ovolo that shall mitre with the level ovolo.*—Let *n p*, *Figure* 145, be a part of the level cornice, and *a n* the points from which the raking-cornice takes its rise, also, let *f a* and *g n* represent a part of the raking-cornice. On *n* erect the perpendicular *n b*, and continue *l a* to *b* ; divide *b n* into any number of equal parts at the points 1, 2. 3, &c. and from them draw the ordinates, 1 2, 3 4, 5 6, &c. In any part of the raking ovolo, as at *c*, draw the perpendicular *c m*, and make *c d* equal to *b a*, the projection of the level ovolo. Divide *c m* into the same number of equal parts as are in *b n*, as at the points 1, 3, 5, 7, &c. from which draw ordinates equal to the ordinates in *b n*, and through the points 2, 4, 6, &c. trace the curve required. In the same manner the curvature or mould

may be found when the upper member is a cavetto, cyma-recta, or cyma-reversa, as is exhibited in *Figures* 146, 147, 148."

"*To find the curvature or mould of the returned moulding in an open or broken pediment.*—Let the point *f*, *Figure* 145, be the given point, at which the raking-moulding is to return. Continue *n p* towards *h* at pleasure, and from the point *f* let fall the perpendicular *f h;* draw *f e* parallel to *h p*, and make *f e* equal to *b a*, the projection of the level cornice. Draw *e i* parallel to *f h*, and divide *e g* into the same number of equal parts as are contained in *b n*, as at the points 1, 3, 5, 7, &c. from which draw the ordinates 2 1, 4 3, 6 5, &c. equal to the ordinates in *b n*. Through the points 2, 4, 6, 8, &c. trace the curve required. In the same manner the curvature or mould may be found when the upper member is a cavetto, cyma-recta, or cyma-reversa, as is exhibited in *Figures* 146, 147, 148."

In the treating of a subject in order to make it as perfect as possible, it ought to embrace every article hitherto known that is intimately connected with it; and no author ought to be ashamed to copy an article from another when it comes within his plan; but then he ought to acknowledge his authority, provided that it has not become common property; in this case he may either use it with or without such acknowledgment, as he pleases. There are some authors, however, who, rather than follow the principle of another, will show a different method in order to have the appearance of originality; but as this has every chance of being detected and exposed in future, it must reflect a double disgrace upon their memory. This circumstance is applicable to Langley: it would have redounded to his credit to have copied Price's second method, and to have made honourable mention of his name.

Mr. Abraham Swan has also contributed something to the practical improvement of joinery: his method of describing the scroll is that invented by Vignola; we shall therefore refer the reader to our review upon Price for the detail; but though his face-mould and its application are the same as given by Price, the manner in which he constructs his diagram in order to obtain it is more obvious to the practical joiner, as the corresponding parts of the section may be turned into the same position with regard to the plan, that the section of the solid itself has with regard to its base.

The manner of squaring twist-rails.

Figure 149, "exhibits the pitch-board, to show what part of the step the twisted part of the rail contains; the three dotted lines drawn from the rail to the pitch-board represent the width of the rail, that from the middle shows the ridge, or middle of the rail, which is to be kept level. The dotted lines *a* and *b*, show how much half the width of the rail turns up from its first beginning to 3.

Figure 150, "shows the same pitch-board, with the manner of the rails turning up. If the sides of the twisted part of the rail be shaped by the rail-mould, so that they direct down to its ground-plan; that is, the upper side of the rail being first struck by the mould, then apply the mould to the under side, as much back as the bevel of the pitch-board shows, by being struck on the side of the rail, and then *Figure* 150, being applied to the outside of the rail, from its first twisting part to 3, will show how much wood is to be taken off."

In this part Mr. Swan is so unintelligible, that his reader can only guess at his meaning; by the term *rail-mould* he may either mean the face-mould or the falling-mould; but from the application which he makes of the said *rail-mould*, a practical workman only can discover his meaning to be that of the face-mould.

Figure 151, "exhibits the square of the rail, with the raking-line of the pitch-board drawn through the middle on the upper side; then draw the depth of the side of the rail parallel to this, and the dotted lines from the diagonal of the rail; these lines show what quantity of wood will be wanting on the upper and lower sides of the rail. Set your compasses at *c*, and draw the circular stroke from the raking part of the pitch-board to *b;* take the distance *a b*, and transfer it from *a* to *b*, in *Figure* 152. The several distances thus found, may be set at any number of places, ranging with the straight part of the rail; and it then forms the width of the mould, for the twisting part of the rail.

Figure 152, "shows the sweep of the rail. The rail cannot be fixed less than one-fourth part from the nosing, or front of the step.

"The remaining part of the pitch-board may be divided into any number of parts, as here into four; from these divisions draw lines across the pitch-board to the raking-line, then take the distances from the ground-line of the pitch-board to the plan of the rail, and set them perpendicular from the raking-line of the pitch-board; so shall these divisions, when the rail is in its proper position, lie directly over the divisions on the ground-plan.

"In this Figure, *l*, *m*, and *n*, rise as much above *o*, as the dotted line in *Figure* 151, does above the width of the rail; and they sink as much below *o*, as the other dotted line in *Figure* 151, falls below the width of the rail; the same thicknesses must be glued upon *o*, though the greatest part will come off in squaring. The reason of placing the letters *l*, *m*, *n*, where you see them, is, that they might not obstruct the small divisions of the rail-mould."

This is hardly intelligible to any but Mr. Abraham Swan himself.

Figure 153, "shows how to find the rail, when it takes more than one step. The remaining part of the pitch-board is divided into four parts, as before in *Figure* 152, and it takes in two such parts of the next step. Draw lines from these divisions to the diagonal of the pitch-board, as in *Figure* 152, then take the distance, *a b*, and set it from *c* to *d*, and so proceed with the other divisions.

"Here is also shown another way to find the outside of the rail-mould. Draw all the divisions across the plan of the rail; then take the distance from the ground-line of the pitch-board to 4, transfer it from the diagonal of the pitch-board to 4 on the rail; and so proceed with the other distances. Then, when the rail is put in its proper position, *c* will be perpendicular to *b*, and all the divisions, as 1, 2, 3, 4, &c. in the rail, will be perpendicularly over 1, 2, 3, 4, &c., in the ground-plan."

This method of laying down the face mould is simple, and easily comprehended by every one who understands anything of the nature of a prismatic section.

Figure 154, "shows the plan of a rail of five steps.

"*To find the rail.*—Set five divisions, as from *e* to *h*, which is the height of the five steps; draw the diagonal from *h*, to the plan of the rail; then take the distance *e f*, and transfer it from *g* to *h*, and proceed in the same manner with the other seven distances."

"*To find the width of the rail-mould.*—Draw the lines across the plan of the rail, as at *k*, set that distance from the diagonal to *i;* and so proceed with the rest, as was shown in *Figure* 153.

"Having formed the sides of the rail, perpendicular to its ground-plan, and having squared the lower end of the rail, then take a thin lath, and bend it within the rail, as is represented by *m*, in *Figure* 155."

The general practice of forming the pitching-triangle is by the number of treads, and the rise in the same number of steps. This is not, however, to be understood of a winding-stair, but of a flight of steps.

"This is the readiest method for squaring a solid rail; but if the rail be bent in the thickness, the nosing of the steps must be drawn upon a cylinder, or some other solid body of a sufficient width to contain the width of the rail, or string-board.

"*r* represents the depth of the rail, touching the nose of each step. You are to take a sufficient number of thicknesses of this width, to make the thickness of your rail; glue them altogether upon your cylinder, or templet, confine them till they are dry, then the rail taken off is ready squared. Proceed in the same manner with the architrave marked *a*."

His method for gluing a rail in thicknesses is the same as Salmon's, but his diagram is better constructed.

Mr. Abraham Swan has also applied the development of a conic frustum to the formation of mouldings upon the spring, round a cylinder, as follows:

Figure 156, "shows the method of bending a cornice round any circular body. When you have found the spring of your cornice, which is shown at the right hand, let the dotted lines be drawn parallel to the spring, and where they intersect the centre, or middle of this body, as in *c*, you will have the radius to strike the curve of your cornice. This principle is as correct as the nature of wood will admit of, and the thinner the wood is, the more exactly will it apply. Besides this, there is another method of forming an annular moulding on a cylinder by thicknesses.

Mr. William Pain has also contributed to the practice of joinery; and though he has not invented any new methods, the plates of his books exhibit the various elevations of stairs, or sections, as they are called, in greater perfection than is to be found in any prior publication: by this means he ascertains the lengths of the rough strings, and the framing of the carriages. He has also shown the stretch-out or development of the rail, and its connection with the string-board, in a more obvious manner to the student, than any of his predecessors. In his *Builder's Pocket Treasury and Practical Builder*, he describes the scroll in the same manner as is to be found in the *British Carpenter*, by Price; his text is, however, very unintelligible. In *Plate* 93, of his *Golden Rule*, third edition, is the following description, engraved on the plate, for finding the face-mould of a hand-rail upon a circular or elliptic plan:—"The method for tracing the raking-moulds for stairs, or any kind of moulding on a cylinder, (see *Figure* 157).—The mould *a* on an ellipsis, and the mould *b* on a circle. Stretch the rise and tread of one quarter, as *a b*, or *c d*, and trace the moulds *a* and *b*, from the plan, as 1, 2, 3, 4, 5, 6, 7, 8, &c. which is plain to inspection." It is not so very plain, nor is there any connection by which its evidence appears. He does not even show how the outer edge of the face-mould is to be obtained: in the diagram it is quite erroneous, its breadth being equal throughout the length of the curve. He tells us to stretch out the rise and tread of one quarter, as *a b*, or *c d*; but on inspecting the diagram, we find that "*a b*, or *c d*," is the hypothenuse of a right-angled triangle, whose base is the tread, and its height the rise of the steps in one quarter: this method is not regulated by principle, but by whim or trial, and is therefore erroneous. In *Plate* 67, of his *Practical House Carpenter*, sixth edition, is a semicircular stair, with winders in the semicircle, and flyers adjoining to the winders, where they begin and end, (see *Figure* 158.) As is usual with Mr. Pain, there is no description of letter-press, and the explanation is contained on the plate, as follows:

"A staircase on a circular plan, drawn half an inch to a foot, with falling moulds and face-mould stretched out, with all the parts figured for practice, the ramps may be traced by the intersection of lines.

"A. Depth of the block for the circular part.

"B. The thickness of ditto."

Figure 159, shows the rail stretched out for the outside falling-moulds, showing the thickness of stuff.

Figure 160, the rail stretched out for the inside falling-mould; and *Figure* 161, the method of getting out the face-mould. In the construction of the face-mould, instead of the rise and tread of the steps, as he writes, on the lines of the figure, we find, by the said diagram, that the diameter and rise of the steps in the semi-circumference are used. Such contradictions entirely confound his readers; and though the latter is nearer to the truth than the rise and treads of the steps, as he writes, the face-mould is far from the pitch, except the wreath were formed for a whole semicircle, as we shall hereafter show; nor can the thickness of stuff be obtained from the stretch-out of the outside falling-mould, as exhibited in *Figure* 159. In the said figure, the reader may also notice the inconsistency of showing the scroll in perspective, while the rail itself is stretched out.

In *Plate* 68, of the said *Practical House Carpenter*, is shown the plan of the rail of a semicircular stair, upon a level landing. *See Figure* 162. He writes thus upon the Plate: "Face-mould for a continued rail on a landing, without winders." In this diagram he uses the diameter and height of one step, which is quite analogous to the method used in the preceding example.

In *Plate* 70, of the said "*Practical House Carpenter*," he shows another stair, upon the same plan as in the first example, (*see Figure* 163;) above is shown an elevation of the rail at *e*, in order to get the thickness of stuff. This diagram certainly shows some idea of the principle, but he has failed in not giving the true delineation with regard to the thickness and depth, and in drawing the two lines which ought to contain the thickness of stuff, to touch the sections at each end, without cutting into them; but to be correct, they should touch the extreme parts. The method of tracing the face-mould is shown in *Figure* 164. It is quite analogous to the two preceding examples. He shows the face-mould in all these examples for the wreath of a whole semi-circumference, which is twice the extent that it ought to be: for though it is not impossible to execute the whole wreath for a semicircle, yet such execution is attended with a prodigious waste of stuff and time; besides the impossibility of matching the grain of the wood. He writes thus upon the plate:

"B. The string-board stretched out for the circular part, (*Figure* 165.)

"*d f*. The hand-rail stretched out.

"*e*. The section of the circular rail, showing the thickness of stuff.

"*c*. The face-mould traced from the plan A, for a solid rail.

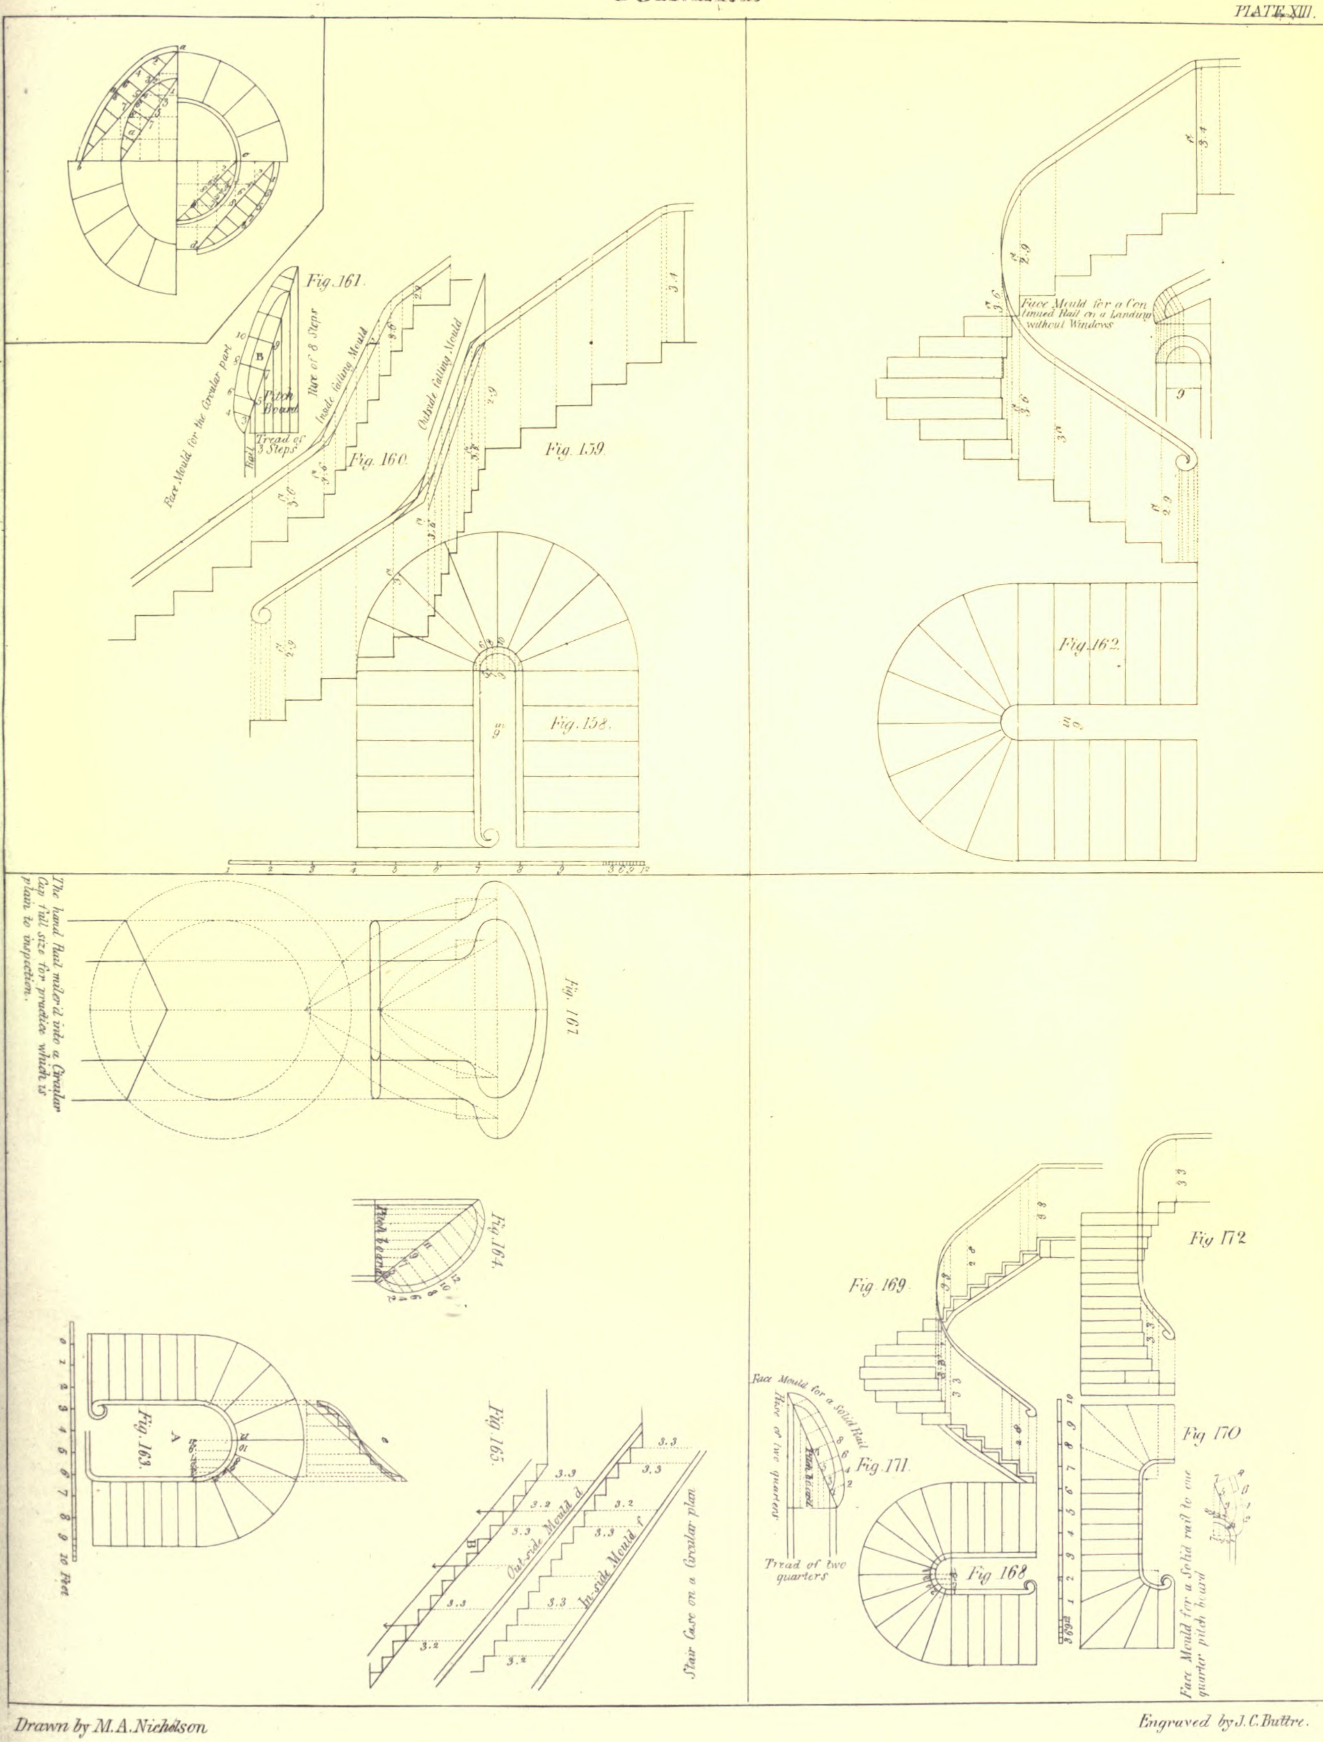
"If the rail is bent in thicknesses, *d* and *f*, *Figures* 165, 166, represent the mould drawn a quarter of an inch to a foot."

In *Figure* 167, is his erroneous method of drawing the circular cap with compasses, which has no relation to any principle.

In *Plate* 76, of the said *Practical House Carpenter*, see *Figure* 168, is also shown a stair upon the same plan as in the first example: the method of finding the face-mould is analogous to the first, viz., the diameter of the plan of the rail, and the rise of the steps round the semi-circumference, he forms a mould for the whole semi-circumfer-

JOINERY.

PLATE XIII.



Drawn by M.A. Nicholson

Engraved by J.C. Buttre.

ence as before. The elevation of the rail is shown above. See *Figure* 169.

In *Figure* 170, also in the said *Plate* 76, is shown a stair with winders in the quadrantal turnings, and flyers joining the winders. In finding the face-mould, *Figure* 171, the radius of the rail, and the height of the steps in the quadrantal are used, and the face-mould is traced, as in the former examples, and is exactly one-half. Besides the waste of stuff attending this method, it is impossible to match the grain; for if the fibres match the straight rail at one end, they will stand at right angles to those of the straight rail at the other end, in such a stair as the present; and in semicircular turnings the fibres of the wreathed piece would be at right angles to both of the straight parts of the rail. These are not the only disadvantages which accompany this method: as it is evident, that a rail thus got out must be much weaker than one where the fibres run parallel with the chord of the face-mould, neither can it be well secured by bolts at the joints. In Mr. Pain's works, he does not show the application of the face to the plank. However, upon the whole, though he has little or no invention in respect of hand-railing, he has as much originality to claim as any of his predecessors, Price excepted. His orthographical elevations of stairs, though very useful, are very ill projected. In his display of dog-legged staircases, his elevations are tolerably well drawn, see *Figure* 172. He has also been useful in showing the constructions of carriages for geometrical stairs, as they were produced in his time. Though his plates abound in contradictions and false schemes, they show his intention more clearly than some of the preceding authors.

Although the principles of cylindric soffits in an oblique straight wall, where the axis of the cylinder is parallel to the horizon, may be gathered from Price; Pain has exhibited the first example: but the constructions which he gives in his *British Palladio*, and in his *Practical House Carpenter*, are wrong, as we shall show under the article SOFFIT; and yet, in the *British Palladio*, in a similar case, in the covering of polygonal domes, *Plate* 39, *Figures* A, B, C, D, he is right. It is something singular, that the construction which he gives for a circular wall is correct, as shown in his *Golden Rule*, in his *Practical Builder*, in his *British Palladio*, and in his *Practical House Carpenter*.

The method of constructing and gluing up columns is shown in *Plate* 18, of the *Practical House Carpenter*. He shows the methods for gluing on the blocks for carving the leaves in the Ionic and Corinthian capitals, *Plates* 34 and 35, *Practical House Carpenter*.

In *Plate* 63, of the same work, he attempts the construction of raking-mouldings, but fails, as Langley had done before. He also shows, in the same work, how the proportions of the heights of the members of cornices upon a diminished scale are obtained, but neglects to show the projections in the same ratio.

In summing up the whole, we shall omit the several schemes which have failed; and the various authors, with their inventions and improvements, will stand as follow: Price first showed a method for constructing hand-rails, and applied the same to the wreath part of a scroll and to the quadrantal rail on a landing: he also spoke of its application to continued winding stairs, but gave no example. We shall afterwards notice the disadvantages attending his method. This author also gave the first construction of raking-mouldings, in the *Art of Hand-railing*, and Salmon, following Price's principle, gave an example of a continued winding-stair. Langley, in his first example, varied this construction, by applying ordinates dividing the plan and the section into a like number of equal parts, and making the ordinates of the section equal to the corresponding ordinates of the plan; and in this Langley gave the first introduction to ordinates in hand-railing, though ordinates were used by Price in other prismatic constructions.

Swan connected the face-mould with the plan, by placing the pitch-board between them, and so drew ordinates perpendicular to the base of the pitch-board, which he carried up to the hypothenusal line, used as a base to the prismatic section, and then drawing ordinates to such base, made the corresponding ordinates of the section equal to those of the plan, and thus completed the face-mould. This was certainly an improvement upon Langley's first method, as by this means it became more evident to the reader. The methods, however, shown by Langley and Swan, were in effect the same as Price's; that is, they would give the same moulds, under the same data or circumstances, and consequently would partake of the same advantages or disadvantages, as we shall exemplify at the end of this article.

The application of the surface of the frustum of a cone was first applied by Swan, to mouldings bent to the spring round a cylindric body. Pain followed the scheme of ordinates laid down by Swan, and constructed his falling-moulds in a more eligible manner than any of the preceding authors; but he is very inconsistent in a disagreement between his text and his diagrams, as well as in showing his moulds for the formation of rails, answering to a complete semicircular plan.

There are several particulars with respect to hand-railing to be observed on the whole; in all the wreaths hitherto constructed, the joints are always made at the spring, viz., at the dividing surface, between the straight and circular parts, and the fibres of the wood will always run perpendicular to those of the straight rail, at one end at least; by this means the fibres, or grain, as they are called, are ill-matched, and the wreath becomes extremely weak at the joint. In none of these methods shown by Langley and Swan, which in effect are Price's, will the section coincide in any more than any one point on the top of the lower extremity of the wreath, and this circumstance, therefore, occasions a vast waste of stuff, as we shall presently prove. Pain also showed the method of constructing columns; forming and gluing up capitals, in order to be carved; with the formation of a cylindro-cylindric soffit, when the axis of the cylindric opening was in a plane perpendicular to the axis of the cylindric wall. The construction of a pediment in a circular wall was also tried by this author, and so far as he proceeded he was correct, but was deficient in not giving the whole of the requisite moulds and instructions, which rendered what he had done of no value.

We have now noticed all the methods that may be considered either as inventions or improvements in the art of joinery, and we trust that the account is impartial, and what every one inclined to do justice will find to be the case; and if anything has been mistaken, it is occasioned by the disagreement between their text and diagrams, and not from any intention to lessen their merit, or the value of their works.

Mr. Nicholson has invented the method for the development of a conic soffit in a circular wall, or of a conic surface terminated by a plane, or by a cylindric surface. And though the cuneoidal surface is not capable of development, he has shown how it may be unfolded, so as to terminate upon a plane or cylindric surface, by a method which comes very near to the truth.

He has discovered an entire new principle of squaring the wreath of a hand-rail, by which the face-mould may touch the tops of two vertical sections at each end, either in one of its angular points or in its whole breadth, supposing both the wreath and the mould to be set up in the true pitch.

He has invented a method of tracing the mitre-cap for the hand-rail, as used in dog-legged staircases, from a given section of the rail.

He has invented a method of gradating the steps, so as to form a regular surface upon the soffit at the junction of the flyers and winders; this not only gives an easy turn to the skirting, but permits the rail to be kept at a uniform distance from the nosings of the steps.

He was the first that showed a development of the plank, in order to apply the face-mould, and to range the two sides in the cylindric or prismatic surfaces according to the plan of the rail.

In the article Hand-Railing, he has shown a more regular method of lescribing the spiral lines of the scroll, by finding the centres in a fret or right-angled guilloche; so that the difference of any two adjoining sides of the fret will be always the same. In order to describe the scroll with compasses, he also invented the method of regulating the difference of radii of a scroll by a line of sines; as had formerly been done by a line of tangents, in order to trace the scroll by hand.

He was the inventor, and the first that showed the method of getting the scroll out of the solid, without gluing any part.

The method of apping an iron rail was never practised with certainty until his invention appeared in the *Carpenter's Guide.*

He was the inventor of the method of springing the plank, by making its plane of inclination to rest upon three vertical sections of the wreath, viz., one at each end and one in the middle, being obtained by three heights taken from the falling-mould. By this means the thickness of the rail is ascertained with certainty, and will never exceed 2½ inches where the rail is intended to be 2 inches deep, and 2¼ inches broad; whereas, by former methods, the plank would require to be 6 or 8, or even 10 inches thick.

No author before him ever regulated the pitch of the plank by the falling-mould, but by the height of the steps only; by this he obtained an immense saving of stuff.

He also invented the method of cutting the veneers in thickness, so that the rail may come off squared from the cylinder.

He was the first author that showed the method of scribing down the skirting upon stairs, however irregular the steps might be in respect of each other.

He also invented a method for squaring the bars for the head of a sash in a circular wall; no method had been ever shown before by which such work might be executed.

He invented, and was the first to show, a method for the formation of a circular architrave in a circular wall.

Besides Price's method of raking mouldings, he added that for the angle-bars of a polygonal window, such as are used in shop fronts.

He improved the method of proportioning mouldings, by showing how the projections were to be found in the same ratio with the heights, which had been neglected by other writers.

He was the first that treated upon hinging, and the hanging of doors and shutters, and the various kinds of folding joints.

In *Figure* 176, No. 1, A B C D E F G H I is half the ground-plan of a continued rail, viz., where the risers are equal to each other, as are likewise the heads.

Figure 177 shows the falling-mould, and the development below it, to the quadrant E F G H I; and because the risers and treads are all equal, the edges of the falling-mould will be straight lines parallel to each other: *e f g h i*, No. 2, is an orthographic projection of the quarter of the rail, corresponding to E F G H I, No. 1; in No. 2, draw L V parallel to A I, No. 1; make the angle V L M, No. 2, equal to the angle which the edge of the falling-mould makes with the base of the development in *Figure* 177; through *i* draw K N parallel to L M; through N draw N M perpendicular to L M; through L draw L K parallel to M N; then M N or L K will be the thickness of stuff necessary, according to the method given by Price and Swan.

a b c d e f g h i, No. 3, is a projection of the rail to the whole semi-circumference. We shall now show the thickness of stuff according to Pain. It will be recollected that he finds the pitch of the rail by the diameter or semi-diameter, and the rise of the steps in the semi-circumference or quarter accordingly: suppose, then, there are eight steps in the semi-circle, now *w y* is the diameter, and *y x* the rise of eight steps; therefore join *w x* and you have the line of section of the cutting-plane: through *a* draw R S parallel to *w x*, and through *i* draw Q T, also parallel to *w x:* draw T S and Q R perpendicular to *w x;* then the breadth Q R or T S, and the length Q T or R S of the rectangle Q R S T, will be respectively the thickness and length of the stuff.

The projection of the upper half of No. 3 is equal and similar, and similarly situated to No. 2; the lower half of No. 3 is equal and similar to the upper part when reversed, the lower part at *a b c d* showing the soffit, and the upper, *f g h i*, the back or top of the rail.

Figure 178 shows the projection for a quarter of the rail, upon a plane parallel to one of the radii: this shows an equal thickness to that shown at No. 3, *Figure* 176, the pitch being obtained from the radius, and the height of the steps in a quarter of the circumference.

Figure 179 shows the method of finding the face-mould, according to the first invention of Nicholson, shown in the *Carpenter's New Guide*, where the cutting plane of the cylinder is perpendicular to the plane of the chord of the rail, and passes through the upper corners of the sections at each end. *Figure* 180 shows the projection upon a plane parallel to the chord of the plan, agreeable to the face-mould, *Figure* 179. All these projections are made agreeable to one pitch-board, *Figure* 177.

We shall now show the quantity of stuff according to each method. *Figure* 181 is a development of the plank, showing the application of the face-mould according to Price, together with the thickness, the length, and breadth of the plank. The particular measures are to be taken from the subjoined scale.

	Ft.	In.	
The length measures	1	5	which reduced to inches, gives 17.
The breadth	0	8½	
The thickness	0	6	

By these measures we obtain 867 solid inches in the quantity of stuff required by Price's method.

Figure 182 is a development of the plank according to the pitch and face-mould required by Pain's method, for a whole semi-circumference.

	Ft.	In.	
The length measures	2	10	which reduced to inches, gives 34.
The breadth	0	8½	as in Price's.
The thickness	0	4½	

By these measures we obtain 1,300½ solid inches in the quantity of stuff for a whole semi-circumference, as required by Pain's method.

Figure 183 is a development of the plank for a quarter of the circumference, as required by Pain's method.

	Ft.	In.	
The length measures	1	8	which reduced to inches, gives 20.
The breadth	0	8½	as before.
The thickness	0	4½	

By these measures we obtain 765 solid inches required by Pain for one quarter of the circumference.

Figure 184 is a development of the plank, showing the quantity of stuff according to the method used by Nicholson.

	Ft.	In.	
The length measures	1	8½	which reduced to inches, gives 20½.
The breadth	0	4	
The thickness	0	3	

By these measures we obtain 246 solid inches for the quantity of stuff, by the method invented by Nicholson.

From these calculations, it appears that if the quantity of stuff which Nicholson's method requires, be called *unity*, or *one*, Pain's method will require three times as much, and that invented, or first presented by Price, three and a half times as much. In these we have only compared the numbers answering to the solidity of one quarter of the circumference, as the formation of a rail for the whole semi-circumference would be ridiculous, not only on account of the quantity of stuff, but the impossibility of being able to match the fibres at the joint, as has been before observed.

It may, however, be observed, in Pain's method, that though the quantity of stuff required for one quarter of the circumference be much greater than the necessary quantity, yet the thickness and breadth for a whole semi-circumference does not appear extra for such a large portion of the rail.

It may also be observed, that none of the preceding authors ever followed a falling-mould, nor has only one of them brought the solid of the wreath into the straight of the rail. If these had been done, the thickness of stuff required would have been much greater than that required for the quadrantal part of the circumference only.

It is remarkable that they should have made the sections of the prism for the face-mould upon a plane perpendicular to one of the radii, and consequently parallel to the other radius of the quadrantal plan, as the rail requires much thicker stuff in this position than any other they could have chosen.

Figure 185 shows the several inclinations according to the plane of section: A B C is the inclination according to Price and his followers; A B E is that according to Pain; and A B D that practised by Nicholson; which indeed is the only inclination founded upon principle, and is nearly an arithmetical mean between the other two; that used by Pain being too high, and that by Price too low.

It has already been observed that the method of preparing the scroll, by gluing blocks side by side, was very incorrect, being founded only in whim: and though gluing up scrolls in parallel blocks is not an approved method, nor ought to be so, yet it may not be amiss to show the true principle. Let *Figure* 185 be the plan of the scroll, the shank being formed by the parallel blocks K B, E C, F D, glued to the block or central part, which forms the eye. *Figure* 186, the falling-mould, the heights k l, a m, b n, c o, d p, i q, are those upon the points A, B, C, D, on the plan, and the height h r that upon F or H. *Figure* 187 is an elevation or projection of the blocks, showing the method of gluing them together; the heights *k l*, *a m*, *b n*, *c o*, *d p*, are respectively equal to the corresponding heights in *Figure* 186. This *Figure*, viz., 187, shows how the blocks are to be formed before they are put together.

In addition to the copious treatise given on this article, the following general description will be found very useful.

Plate XVI.—*Figures* 1, 2, 3, 4. *The method of hinging folding-doors.*—Suppose the bead to be drawn on both sides of the door; so that a plane parallel to, and equidistant from, either jamb, may bisect each of the beads, and the joint to be formed alike on both sides of this plane: Let C be the centre of the hinge, and B the arris on the plane side of the quirk next to the bead; join C B; draw B D at right angles, cutting the concentric circle, G E, which bisects the thickness of the door in G; also let F be the arris on the plane side of the quirk of the opposite bead on the alternate side: draw F E parallel to B D; then B G E F will be the joint required.

Figure 5.—*To make a door swing either way, supposing the jamb formed alike on both sides.* Let A and B be the points where the faces of the door intersect the jambs; join A B, and bisect it in C; draw C D perpendicular to A B, and make C D equal to A C or C B; on D, as a centre, with the radius D A or D B, describe the arc A B; and A B will be the joint required.

Figure 6.—*To make the joints correspond to a rebate on the opposite jamb or lintel.*—Let A and C be the points where the faces of the door intersect the jamb; produce D C, the face of the door, to B, and draw A B perpendicular to B D; make B D equal to A B; join A D and A C; bisect A C in E; draw E F perpendicular to A C, cutting A D at F; from F, as a centre, with the distance F A, or F C, describe the arc A C, which will be the joint required.

Figure 7.—*The method of concealing the revolving joint of doors or shutters.*—Make the angle F A E half a right angle; place the centre of the hinge at B, in the line A E, and let the hinge be so constructed that the two sides of the cavity, or hollow, may form a right angle.

JOINT, the surface of separation of two bodies brought into contact, and held firmly together either by a glutinous liquid, or by opposite pressures, or by the weight of one body lying upon the other. A joint is, however, not the mere contact of surfaces, but the nearer they approach the more perfect is the joint. Perhaps two pieces of wood adhering together by means of glue, or other such tenacious liquid, between two plane surfaces, is the most perfect. In masonry, the distances of the planes intended to form a joint are very considerable, owing to the coarseness of the particles which enter the composition of the cement.

JOINTER, in joinery, the largest plane used by the joiner to straighten the face or edge of the stuff which he is preparing.

JOINTER, in bricklaying, a crooked piece of iron, forming two curves of contrary flexure by its edges on each side, used for drawing the coursing and vertical joints by the edge of the jointing-rule.

JOINTING RULE, a straight edge used by bricklayers for regulating the direction or course of the jointer, in the horizontal and vertical joints of the brickwork.

JOISTS, one or more horizontal rows of parallel equidistant timbers in a floor, on which the flooring is laid. There are three kinds of joists, viz., binding-joists, bridging-joists, and ceiling-joists.

JONES, INIGO, a celebrated architect, born in London about 1572. He was bred a joiner, but his skill in drawing recommended him to the notice of the earl of Pembroke; who sent him to Italy, where he acquired a complete knowledge of architecture. James I. made him surveyor-general of his works, which office he discharged with great fidelity. He continued in the same post under Charles I., and had the superintendence of the building of St. Paul's, Covent-garden; with the management of the masques and interludes for the entertainment of the court. This brought him into a squabble with Ben Jonson, his coadjutor, who ridiculed him in his comedy of *Bartholomew-fair*, under the name of *Lantern Leatherhead.* He suffered considerably during the time of Cromwell, so that grief, misfortunes, and age, brought him to his grave in July, 1651. In 1655, appeared his *Discourse on Stonehenge*, in which he attempts to prove it to have been a Roman temple. As an architect, Inigo generally, but not always, shines to great advantage. He designed the palace of Whitehall and the Banqueting-house, the church and piazza of Covent-garden, Coleshill in Berkshire, Cobham-hall in Kent, and various other buildings, public and private. The principal of his designs were published in folio, in 1727, and some in 1744.

JUFFERS, stuff about four or five inches square, of any length. This term is not now in use, though frequently found in old books.

JUMP, in masonry, one among the very numerous appellations given to the dislocations of the strata, by practical miners of different districts.

JUMPER, a long iron tool, with a steel chisel-like point, used in quarries and mines for drilling or boring shot-holes in rocks which require to be blasted with gunpowder. *Drill*, *neger*, and *gad*, are other terms by which this tool is called.

K.

KAABA. *See* Caaba.

KALEIDOSCOPE, an optical instrument, the invention of Sir David Brewster. It creates and exhibits, by reflections, a variety of beautiful colours and symmetrical forms; so that such as may be deemed appropriate, may be made use of for patterns, as in carpets, and for other purposes of ornamental design.

KAOLIN, a species of clay, one of the two ingredients in Chinese porcelain.

KEEP TOWER, the middle, or principal tower in a castle. *See* Castle.

KEEPING, to be in keeping with, or harmonize with,—a technical term used in painting, and signifying the peculiar management of those parts of the art, colouring and chiaroscuro, which produces the proper degree of relievo in objects admitted into a composition; according to their relative positions in the imagined scene, and the degree of importance the artist attaches to them.

KENILWORTH CASTLE, is famed in the annals of Warwickshire for its antiquity. "This ancient castle," says Dugdale, "was the glory of all these parts, and for many respects may be ranked, in a third place at the least, with the most stately castles of England." This fortress was built by Geoffry de Clinton, in the time of Henry I. He was chamberlain and treasurer to that monarch. By subsequent kings and occupiers it was greatly enlarged and strengthened at different times: and in the various civil and domestic wars of England, it was frequently the object of contention with different monarchs and nobles. Edward II. was confined for a time in Kenilworth Castle, shortly before his murder in Berkley Castle, (A.D. 1327). In the following reign, John of Gaunt became owner of the castle, which he much augmented by new and magnificent buildings. Henry IV., son of John of Gaunt, united the castle, which he inherited, to the domains of the crown, of which it formed part till the time of Elizabeth, who granted it to Robert Dudley, Earl of Leicester. The magnificent entertainment given here by Leicester to Elizabeth, has been made familiar to the general reader by Sir Walter Scott's historical romance of "Kenilworth." After the civil war of Charles I., the castle was dismantled, but extensive and picturesque ruins remain. What remains of the buildings shows that the whole was an immense and spacious pile; consisting of an outer wall with bastion towers, a tilt-yard, with towers at each end; and several buildings within the ballium, or base-court. The area within the walls consists of seven acres. There were four gatehouses, and the walls were from ten to fifteen feet in thickness. At a short distance from the castle was a priory for Black Canons; of which buildings, parts of the gateway and chapel remain. Near these is the parish church, the western door-way of which is a curious specimen of ancient architecture.

KERF, the way made by a saw through a piece of timber, by displacing the wood with the teeth of the saw.

KEY, in a general sense, a fastener; that which fastens, as a piece of wood in the frame of a building, &c.

KEY or COTTAR, in engineering, a wedge-shaped or tapering piece of iron or wood; which is driven firmly into a mortise prepared to receive the same, to tighten and secure the several parts of any framing or contrivance together, as a rail to a chair, &c., forming a fastening. When a key is passed through a timber-beam, or two or more thicknesses of metal or other material, placed side by side, it is customary to clasp them together by *gibbs*, previous to inserting the key.

Key, now more commonly spelt Quay, a long wharf by the side of a harbour, river, or canal, furnished with posts, and rings, whereby ships and boats may be secured; also with cranes, capstans, and other convenient mechanism for loading and unloading.

Key, an instrument for locking and unlocking doors, *See* Lock.

Key, of a floor, the last board that is laid.

KEYED DADO, that which is secured from warping by bars grooved into the back; see the following article.

KEY-HOLE, a hole or aperture in a door or lock, for receiving a key.

KEY-PILE, the centre pile plank of one of the divisions of sheeting-piles contained between two gauge piles of a coffer-dam or similar work. It is made of a wedge-form, narrowest at the bottom, and, when driven, keys or wedges the whole together.

KEYS, in naked flooring, pieces of timber framed in between every two joists, by mortise and tenon; and when driven fast between each pair, with their ends butting against the grain of the joists, are called *strutting pieces*.

Keys, in joinery, pieces of timber let into the back of a board, transverse to the fibres, and made of one or several breadths of timber, either by a dovetailing, or by first making a groove equal to the width of the keys, and then cutting narrow grooves in the sides of the first-made groove close to the bottom, preserving a sufficient substance at the top of each.

Keys are used for the purpose of preventing boards from warping.

Dado, when made of broad boards, glued together, should always be keyed. *See* Dado.

KEY-STONE, of an arch or vault, the last stone placed on the top thereof; which, being wider and fuller at the top than at the bottom, wedges, as it were, and binds in all the rest.

M. Belidor makes the thickness of the arch-stones of a bridge, one twenty-fourth part of the width of the arch; but Mr. Gautier, another experienced engineer, makes their length, in an arch 24 feet wide, 2 feet; in arches, 45, 60, 75, 90 wide, 3, 4, 5, 6 feet respectively; and it is observed by Mr. Muller, that the thickness allowed by Belidor is not sufficient to prevent the weight of the arches from crushing the key-stones to pieces by their pressure against one another.

The name *key-stones*, or *arch-stones*, is sometimes also given to all the stones which form the sweep of an arch, or vault, answering to what the French more distinctly call *voussoirs.*

KILDERKIN, a liquid measure, which contains two firkins, or eighteen gallons. Two kilderkins make a barrel, and four a hogshead.

KILN, a kind of oven, or stove, for admitting heat, in order to dry substances of various kinds, as corn, malt, hops, &c. It also signifies a fabric or building constructed for the purpose of burning limestone, chalk, and other calcareous stones, into lime. Kilns are of different kinds, and formed in different ways, according to the purposes for which they are designed.

Kiln, *Brick*. *See* Brick.

Kiln, *Hop*, a stove or kiln for the purpose of drying or stoving hops.

Kiln, *Lime*, a sort of kiln constructed for the purpose of burning lime. The operation called burning lime, consists in exposing marble, limestone, chalk, oyster-shells, or any other carbonate of lime, for some time to a white heat, by which means the carbonic acid and water contained in these substances are expelled; and the earth, which has the peculiar characters assigned to lime, is left behind in a mass which has little coherence, and is therefore easily reduced to powder. It is usually called quick-lime after calcination. Newly prepared, it absorbs water with great avidity; it will absorb one-fourth of its weight of that fluid, and still remain perfectly dry. If a sufficient quantity of water be poured upon it, the lime falls into powder; some of the water is converted into vapour by the disengaged caloric of that part which unites with the lime; this is called the slacking of lime; if the quantity slacked be considerable, and performed in a dark place, light will be observed as well as heat. Kilns are built of different forms or shapes, according to the manner in which they are to be wrought, and the kinds of fuel to be employed. It may be remarked, that, in places where materials are dear, from their being fetched from a distance, and where the fuel is coals, and also expensive, the form of a kiln is mostly that of an inverted cone, a form which has its inconveniences; but in districts where the art of burning lime is practised with superior attention and correctness, the form has of late years been gradually changing from conical to elliptical. Some writers are of opinion, that the best form of a lime-furnace, in the established practice of the present day, is that of an egg placed upon its narrower end, having part of its broader end struck off, and its sides somewhat compressed, especially towards the lower extremity; the ground-plot or bottom of the kiln being nearly an oval, with an eye, or draft-hole, toward each end of it. It is supposed that two advantages are gained by this form, over that of the cone. By the upper part of the kiln being contracted, the heat does not fly off so freely as it does out of a spreading cone. On the contrary, it thereby receives a degree of reverberation, which adds to its intensity. But the other, and still more valuable effect, is this: when the cooled lime is drawn out at the bottom of the furnace, the ignited mass, in the upper parts of it, settles down, freely and evenly, into the central parts of the kiln; whereas, in a conical surface, the regular contraction of its width, in the upper as well as the lower parts of it, prevents the burning materials from settling uniformly and levelling downward. They *hang* upon the sides of the kiln, and either form a dome at the bottom of the burning mass, with a void space beneath it, thereby endangering the structure, if not the workmen, employed; or, breaking down in the centre, form a funnel, down which the underburnt stones find their way to the draft-holes. And the contraction of the lower part of the kiln has not the same effect; for, after the fuel is exhausted, the adhesion ceases, the mass loosens, and, as the lime cools, the less room it requires. It therefore runs down freely to the draft-holes, notwithstanding the quick contraction of the bottom of the kiln or surface.

Lastly, with respect to the lime-furnace, the fire requires to be furnished with a regular supply of air. When a kiln is first lighted, the draft-holes afford the required supply. But after the fire becomes stationary in the middle, or towards the upper part of the kiln, (especially of a tall kiln,) while the space below is occupied by burnt lime, the supply from ordinary draft-holes becomes insufficient. If the walls of the kiln have been carried up dry or without mortar, the air finds its way through them to the fire. In large deep kilns that are built with air-tight walls, it is common to form air-holes in their sides, especially in front, over the draft-holes. But these convey the air, in partial currents, to one side of the kiln only, whereas that which is admitted at the draft-holes passes regularly upward to the centre, as well as to every side of the burning mass; and, moreover, tends to cool the burnt lime in its passage downward, thereby contributing to the ease and health of the workmen. Hence, it is to be observed, the size of the draft-holes ought to be proportionate to that of the kiln and the size of the stones taken jointly, (air passing more freely among large than among small stones,) and the required supply of air should be wholly admitted at the draft-holes. By a sliding or a shifting valve, the supply may be regulated, and the degree of heat be increased or diminished, according to circumstances.

The most ancient kind of lime-kiln is probably that which is made by excavating the earth in the form of a cone, of such a size as may be necessary; and afterwards building up the sides, or not, according to the circumstances of the case; the materials being then laid in, in alternate layers of fuel and stone, properly broken, until the whole is filled up. The top is then covered with sods, in order that the heat may be prevented from escaping: and the fire lighted at the bottom, and the whole of the contents burnt, in a greater or less space of time, in proportion to the nature of the stone, and the quantity that is contained in the kiln. From the circumstance, of the top parts of these kilns, in some districts, being covered over and the sides sometimes built up with sods, they are termed *sod-kilns*, in order to distinguish them from the other sorts. When the whole of the contents of such kilns are grown cold, they are drawn or taken out from the bottom; and the kiln again filled, if necessary. These kilns are obviously intended for burning only one kiln-full at a time. But as the burning of lime in this way is tedious and uneconomical, other methods and forms of kilns have been had recourse to. Where lime is much wanted, either for building or other purposes, they use perpetual kilns, or what are more generally known by the name of *draw-kilns*. These, as all lime-kilns ought to be, are situated by the side of a rising bank, or sheltered by an artificial mound of earth. They are generally built either of stone or brick; but the latter, as being better adapted to stand excessive degrees of heat, is considered as preferable. The outside form of such kilns is sometimes cylindrical, but more generally square. The inside should be formed in the shape of a hogshead, or an egg, opened a little at both ends, and set on the smallest; being small in circumference at the bottom, gradually wider towards the middle, and then contracting again towards the top. In kilns constructed in this way, it is observed, fewer coals are necessary, in consequence of the great degree of reverberation which is created, above that which takes place in kilns formed in the shape of a sugar-loaf reversed. Near the bottom, in large kilns, two or more apertures are made: these are small at the inside of the kiln, but are sloped wider, both at the sides and the top, as they extend towards the outside of the building. The uses of these apertures are for admitting the air necessary for supplying the fire, and also for permitting the labourers to approach with a drag and shovel, to draw out the calcined lime. From the bottom of the kiln within, in some cases, a small building, called *a horse*, is raised in the form of a wedge, and so constructed as to accelerate the operation of drawing out the burned limestone, by forcing it to fall into the apertures which have been mentioned above. In other kilns of this kind, in place of this building, there is an iron grate near the bottom, which comes close to the inside wall, except at the apertures, where the lime is drawn out. When the kiln is to be filled, a parcel of furze or faggots is laid at the bottom; over this a layer of coals; then a layer of limestone, which is previously broken into pieces, about the size of a man's fist; and so on alternately; ending with a layer of coals, which is sometimes, though seldom, covered with sods or turf, in order to keep the heat as intense as possible. The fire is then lighted in the apertures; and when the limestone towards the bottom is completely calcined, the fuel being considerably exhausted, the limestone at the top subsides. The labourers then put in an addition of limestone and coal at top, and draw out at bottom as much as they find thoroughly burned; and thus go on, till any quantity required be calcined. When limestone is burned with coals, from two-and-a-half to three-and-a-half bushels, on a medium, three bushels of calcined limestone are produced for every bushel of coals used in the process.

A lime-kiln of this sort is described in Count Rumford's *Essays*, in the possession of the Dublin Society, as well as the principal objects that ought to be had in view in constructing the kiln pointed out: the first of which is, to cause the fuel to burn in such a manner as to consume the smoke, which has here been done by obliging the smoke to descend and pass through the fire, in order that as much heat as possible might be generated. Secondly, to cause the flame and hot vapour which rise from the fire to come in contact with the lime-stone by a very large surface, in order to economize the heat, and prevent its going off into the atmosphere; which was done by making the body of the kiln in the form of a hollow truncated cone, and very high in proportion to its diameter; and by filling it quite up to the top with lime-stone, the fire being made to enter near the bottom of the cone.

"Thirdly, to make the process of burning lime perpetual, in order to prevent the waste of heat which unavoidably attends the cooling of the kiln, in emptying and filling it, when, to perform that operation, it is necessary to put out the fire.

"And fourthly, to contrive matters so that the lime in which the process of burning is just finished, and which, of course, is still intensely hot, may, in cooling, be made to give off its heat in such a manner as to assist in heating the fresh quantity of cold limestone with which the kiln is replenished, as often as a portion of lime is taken out of it.

"To effectuate these purposes, the fuel is not mixed with the limestone, but is burned in a close fire-place, which opens into one side of the kiln, some distance above the bottom of it. For large lime-kilns on these principles, there may be several fire-places all opening into the same cone, and situated on different sides of it: which fire-places may be constructed and regulated like the fire-places of the furnaces used for burning porcelain.

"At the bottom of the kiln there is a door, which is occasionally opened to take out the lime.

"When, in consequence of a portion of lime being drawn out of the kiln, its contents settle down or subside, the empty space in the upper part of the kiln, which is occasioned by this subtraction of the burned lime, is immediately filled up with fresh limestone.

"As soon as a portion of the lime is taken away, the door by which it is removed must be immediately shut, and the joinings well closed with moist clay, to prevent a draught of cold air through the kiln. A small opening, however, must be left, for reasons which are explained below.

"As the fire enters the kiln at some distance from the bottom of it, and as the flame rises as soon as it comes into this cavity, the lower part of the kiln (that below the level of the bottom of the fire-place) is occupied by lime already burned; and as this lime is intensely hot, when, on a portion of lime from below being removed, it descends into this part of the kiln; and as the air in the kiln, to which it communicates its heat, must arise upwards in consequence of its being heated, and pass off through the top of the kiln, this lime, in cooling, is by this contrivance made to assist in heating the fresh portion of cold limestone with which the kiln is charged. To facilitate this communication of heat from the red-hot lime just burned, to the limestone above in the upper part of the kiln, a gentle draft of air through the kiln, from the bottom to the top of it, must be established, by leaving an opening in the door below, by which the cold air from without may be suffered to enter the kiln. This opening (which should be furnished with some kind of a register) must be very small, otherwise it will occasion too strong a draft of cold air into the kiln, and do more harm than good; and it will probably be found best to close it entirely, after the lime in the lower part of the kiln has parted with a certain proportion of its heat."

It is a common practice in some places to burn limestone with furze. The kilns which are made use of in these cases are commonly known by the denomination of *flame-kilns*, and are built of brick; the walls from 4 to 5 feet thick, when they are not supported by a bank or mound of earth. The inside is nearly square, being 12 feet by 13, and 11 or 15 feet high. In the front wall there are three arches, each about 1 foot 10 inches wide, by 3 feet 9 inches in height. When the kiln is to be filled, three arches are formed of the largest pieces of limestone, the whole breadth of the kiln, and opposite to the arches in the front wall. When these arches are formed, the limestone is thrown promiscuously into the kiln to the height of 7 or 8 feet, over which are frequently laid fifteen or twenty thousand bricks, which are burned at the same time with the limestone. When the filling of the kiln is completed, the three arches in the front wall are filled up with bricks almost to the top, room being left in each sufficient only for putting in the furze, which is done in small quantities, the object being to keep up a constant and regular flame. In the space of thirty-six or forty hours, the whole limestone, about 120 or 130 quarters, together with 15,000 or 20,000 bricks, are thoroughly calcined. Kilns constructed in this way may be seen near Wellingborough, in Northamptonshire, and other places in the northern parts of the kingdom. In many of the northern counties of Scotland, which are situated at a great distance from coal, it is also a common practice to burn limestone with peat; and, considering the rude ill-constructed kilns which are used for the purpose, it is astonishing with what success the operations are performed. In some of these districts, it is stated that limestone is sufficiently calcined with peats, laid *stratum super stratum*, in kilns formed of turf; but owing to the quantity of ashes which fall from the peat, the quality of the lime is considerably injured; and, from the open and exposed situation of many of these kilns, the waste of fuel is immense. But the most common method of burning limestone with peat, is in kilns constructed somewhat similar to those in the districts where furze is used as the only fuel. In kilns of this description there are, in general, only two arches, or fire-places, and the peats are thrown into the bottom of these arches, the fronts of which are seldom closed up, by which means the wind has often great influence in retarding the operation, and frequently prevents the complete calcination of the limestone. An improvement might, it is supposed, be made on these kilns at a very trifling expense: if an iron grate were laid across the bottom of the arch, with a place below for the ashes to fall down, and the front of the arch closed up by a door made of cast-metal, one-third of the fuel might be saved, and the operation performed in a shorter time, and with a much greater certainty, than by the method now practised in such kilns.

In a communication to the Board of Agriculture, Mr. Rawson described a method of constructing a lime-kiln, by which a considerable saving of fuel was effected.

This kiln was made 20 feet in height; at the bottom was placed a metal plate, one foot in height, intended to give air to the fire; the sloped sides were 6 feet in height, the breadth at the top of the slope 8 feet; the sides carried up perpendicular 14 feet; so that every part of the inside, from 14 feet to the mouth, was exactly of the same dimensions. On the mouth of the kiln was placed a cap, built of long stones, and rather sharply contracted, about 7 or 8 feet high. In the building of this cap, on one side of the slope, the mason being over the centre of the kiln, anything dropping down would fall perpendicularly to the eye beneath. Here was placed an iron door 18 inches square, and then the remainder of the building of the cap was carried up until the whole of the top was contracted to 14 inches. The kiln was fed through the iron door, and, when filled, the door was close shut. The outside wall was 3 feet at the bottom battering up to 2 feet at top, and built at such a distance from the inside wall of the kiln, that 2 feet of yellow clay might be well packed in between the walls; without this precaution kilns are almost certain to split. At 8 feet high from the eye of the kiln, two flues were carried through the front wall, through the packed clay to the opposite side of the kiln, to give power to the fire. It is asserted, that, with this kiln, one-third more lime has been produced from a given quantity of fuel, and also that stones of bad quality might be put into the kiln without the necessity of being broken so small as usual. As many situations will not admit of building a kiln 20 feet high, while other situations may allow of its being built 30, or even 40 feet, (for it cannot be made too high,) the diameter of the kiln should be proportioned to the height to which it is carried up.

In the same communication, Mr. Rawson also described another and rather curious application of this sort of contrivance. He states that, "for several years, he has made use of a small kiln in an outside kitchen, the height 9 feet, the diameter 3½ feet. In the side of the kiln next the fire, he had 3 square boilers placed, one of them large, containing half a barrel, with a cock, which supplied the family with constant boiling water; for the two others, he had tin vessels made to fit the inside with close covers, in which meat and vegetables with water were placed, and put into the two smaller boilers, which never had any water, but had close covers. The tin boilers were heated sooner than on the strongest fire, and when the meat, &c., were sufficiently dressed, the whole was taken out of the metal boilers. At one side he had an oven placed for roasting and boiling meat; the bottom was metal of 26 inches diameter, and 1½ inch thick, a flue from the fire went underneath. Even with the bottom of the oven, a grating 9 inches square was placed, which opened a communication between the oven and the hot fire of the kiln. The height of the oven was 14 inches, shut close by a metal door of 18 inches square, and the top, level with the mouth of the kiln, was covered by another metal plate of half an inch thick, on which was placed a second oven; the heat which escaped through the half-inch plate, though not near the fire, was sufficient to do all small puddings, pies, breakfast-cakes, &c. &c. The meat in the large oven was placed on an iron frame, which turned on a pivot, and stood on a dripping-pan, and was turned by the cook every half hour. And over the kiln he had a tiled stage for drying corn, and a chimney at one side, with a caul on the top, which carried off all steam and sulphur: a large granary was attached to the building." It is added, that the lime, if sold, would more than pay for fuel and attendance; and he has frequently had dinner dressed for fifty men, without interfering with his family business in any great degree.

An admirable combination of a lime-kiln, with a coke-oven, was the subject of a patent granted to Mr. Charles Heathorn some years ago, since which time it has been in successful operation at Maidstone and other places. The object of this invention, as expressed in the specification of the patent, is the preparation of quick-lime and coke in the same kiln at one operation. The economy of this process must be evident from the circumstance, that the inflammable part of the coal, which is separated to form it into coke, is the only fuel employed to burn the lime; and as the coke is in many places as valuable as the coal from which it is prepared, the cost, if any, of making lime, must be reduced to the most trifling amount.

In burning lime, some burners prefer peat to coal for the fuel; but that preference has probably arisen from an injudicious management of coal. Mr. Dobson asserts peat to be more economical than coal; that coal, by its excessive heat, causes the limestone to run into solid lumps, which it never does with peat, as it keeps them in an open state, and admits the air freely; that the process of burning goes on more slowly with coal, and does not produce half the quantity of lime.

This inconsistency requires no comment; nevertheless, peat is a very useful fuel for the purpose, and an excellent substitute for coal, where the latter is scarcer or dearer. All kinds of lime exposed to the air recover nearly their original weight, except chalk-lime, which, although long exposed, never recovers more than seven-eighths of its original weight. Some limestones, as Portland-stone, yield a very white lime; others, as chalk and roe-stone, a lime with a yellowish cast; the latter is best adapted for mixing with tarras, puzzolana, or Parker's cement, for buildings under water. It has long been said by lime-burners, that if limestone be imperfectly burned in the first instance, no further exposure of it to the fire will produce quick-lime. This assertion, which it was supposed was the offspring of ignorance, has been confirmed by M. Vicat, in a valuable treatise lately published by him on mortar and cements. Such lime, which is technically termed dead lime, does not slake with water, but upon being ground and made into a paste with water, differs from common mortar by setting under water.

KILOMETRE, a thousand metres. In the French system of measures, the metre is the unit, and is equivalent to 3.2808992 English feet. The kilometre is about five-eighths of our statute mile.

KING-POST, or Crown-Post. *See* Crown-Post.

KIOSK, a word applied in Turkey to a kind of open pavilion, or summer-house, supported by pillars.

KIRB-PLATE. *See* Curb-Plate.

KIRB-ROOF. *See* Curb-Roof.

KITCHEN (Welsh, *kegin*) the cooking-room, an apartment used for the preparation of food, and furnished with suitable accommodations and utensils for that purpose, of which the following are some of the principal.

A range of grating; a smoke-jack in the chimney, to turn the spits for roasting; a large screen to stand before the fire, to keep off the cold air from the articles roasting, by which means the operation is considerably accelerated. An oven, and also a copper boiler, should be constructed on one side of the fire-place, and on the other side, a large cast-iron plate, fixed horizontally, on which to keep sauce and stew-pans continually boiling with a uniform degree of heat. Several preserving stoves should be fitted up, according to the number of the family; and a table as large as the kitchen will admit of. It would be impossible to enumerate the whole of the articles for culinary purposes; but, besides the above, the kitchen should also be furnished with dressers, having drawers or cupboards under them, put up in every vacant part; it should also have shelves fitted up round the sides, in order to set stew-pans, sauce-pans, &c. out of the way. Adjoining to the kitchen, ought to be a large coal-cellar, for the convenient supply of the fire. The water ought to be conducted to the kitchen by means of pipes, to be drawn off by one or more cocks, as may be wanted. The screen should be made of wood, and lined with tin, and fitted up with shelves, so as to hold the dishes and plates to be made hot for dinner. The copper-boiler is sometimes made double, or divided, and both parts heated by the same fire; each part should be furnished with a water-cock. The kitchen table should not be less than three inches thick. If the windows do not afford a very good light, a sky-light should be placed over the table, with a moveable cap, so as to admit any quantity of air at pleasure.

Modern science has introduced so many improvements in this part of a large establishment, that it would be impossible to describe them. For the perfection of the department comprehended under the simple word *kitchen*, we would recommend our readers to inspect that of the Reform Club, or any similar *cuisine*. It is to be regretted that similar improvements, as far as may be deemed advisable, are not more generally introduced into establishments of a humbler description.

KNEE, a piece of timber cut at an angle, or having grooves to an angle.

Knee, in hand-railing, a part of the back with a convex curvature; it is the reverse of a *ramp*, which is hollow on the back.

KNIFE, *Drawing*. *See* Drawing Knife.

KNOTTING, a process in painting, for preventing the knots from appearing in the finish.

Knotting is a composition of strong size, mixed with red lead, for the first knotting, which prevents the gum from coming through. The second knotting is a composition of white-lead, red-lead, and oil; but in principal rooms, where the knots happen to be very bad, they are often silvered: which is done by laying on a coat of gold size, and, when properly dry, a silver leaf is placed on them, which is sure to prevent the knots appearing.

The operation of knotting is the first process in painting.

KNUCKLE, of a hinge, the cylindrical part, where the one strap is indented into the other, and revolves upon a pin fixed as an axis, in that of the cylinder. *See* Hinging.

KYANIZING, the term applied to the process of preserving timber and other substances from dry rot, invented by Mr. Kyan. Processes of a similar description, and for similar purposes, but differing in the chemical agents employed, have also been patented by Sir William Burnett and others, and called from the respective inventors, Burnettizing, Payanizing, Bethellizing, &c.

Kyan's preparation consists in immersing the substance to be preserved in a solution of corrosive sublimate, which is said to neutralize the primary element of fermentation, and render the fibre of the wood indestructible. The principal advantage, however, claimed for the process, is, that it seasons the timber in so short a time; what, in ordinary circumstances, occupies two or three years, being, by means of Kyanizing, effected in as many months. It is also said to protect the wood from the ravages of insects. We desire to offer no opinion on the comparative merits of these several methods of effecting the same objects. All have been in turn lauded and decried, as all have been in turn used and condemned. They are used extensively in railway sleepers and other engineering works, which, from their exposure, are very liable to premature decay.

It is generally understood, however, among practical men, that timber, though prepared by any of these processes, cannot be depended upon for a certainty to resist the combined effects of moisture and great heat.

L.

LABEL, an ornament placed over an aperture, in the castellated style of building, consisting of a horizontal part over the head, with two parts returning downwards at a right angle, one on each side of the aperture: sometimes these are terminated at the bottom with a bead, but most frequently return again at a right angle outwards, and, consequently, parallel to the part over the head.

LABOUR, in measuring, the value put on a piece of work, in consideration only of the time required to perform it.

LABRUM, a vase or basin placed in the caldarium of the ancient baths, to contain hot water for persons who had used the vapour bath.

LABURNUM, a well-known tree; the wood of the tree-laburnum is much prized by cabinet-makers and turners.

LABYRINTH, (Greek, λαβυρινθος) among the ancients, a large and intricate edifice cut into various isles and meanders running into each other, so as to render it difficult to get out.

Four celebrated labyrinths were noted by the ancients, and by Pliny ranked amongst the wonders of the world: viz., the Cretan, the Egyptian, the Lemnian, and the Italian. That of Crete is the most famed; it was built, as Diodorus Siculus conjectures, and Pliny positively asserts, by Dædalus, by command of king Minos, who kept the Minotaur shut up in it, on the model of that of Egypt, but on a less scale; but both affirm, that in their time it no longer existed, having been either destroyed by time, or purposely demolished. It was from this labyrinth that Theseus is said to have made his escape by means of Ariadne's clue.

Diodorus Siculus and Pliny represent this labyrinth as having been a large edifice; while others have considered it as merely a cavern hollowed in the rock, and full of winding passages. "If the labyrinth of Crete," says the Abbé Barthelemi, "had been constructed by Dædalus under the order of Minos, whence is it that we find no mention of it either by Homer, who more than once speaks of that prince, and of Crete, or by Herodotus, who describes that of Egypt, after having said that the monuments of the Egyptians are much superior to those of the Greeks; or by the more ancient geographers; or by any of the writers of the ages in which Greece flourished? This work was attributed to Dædalus, whose name," says our author, "is sufficient to discredit a tradition. His name, like that of Hercules, had become the resource of ignorance, whenever it turned its eyes on the early ages. All great labours, all works which required more strength than ingenuity, were attributed to Hercules; and all those which had relation to the arts, and required a certain degree of intelligence in the execution, were ascribed to Dædalus." According to Diodorus and Pliny, no traces of the labyrinth of Crete existed in their time, and the date of its destruction had been forgotten. Yet it is said to have been visited by the disciples of Apollonius of Tyana, who was contemporary with those two authors. The Cretans, therefore, believed that they possessed the labyrinth. "At Nauplia, near the ancient Argos," says Strabo, "are still to be seen vast caverns, in which are constructed labyrinths, that are believed to be the work of the Cyclops;" the meaning of which, as Barthelemi understands him, is, that the labours of men had opened in the rock passages which crossed and returned upon themselves, as in quarries. Such, he says, is the idea we ought to form of the labyrinth of Crete. He then suggests an inquiry, whether there were several labyrinths in that island? Ancient authors speak only of one, which most of them place at Cnossus, and some few at Gortyna. Belon and Tournefort describe a cavern situated at the foot of mount Ida, on the south side of the mountain, at a small distance from Gortyna: which, according to the former, was a quarry, and, according to the latter, the ancient labyrinth. Besides this, another is supposed to have been situated at Cnossus, and, in proof of the fact, it is alleged, that the coins of that city represent the plan of it. The place where the labyrinth of Crete was situated, according to Tournefort, was, as Barthelemi supposes, one league distant from Gortyna; and, according to Strabo, it was distant from Cnossus six or seven leagues; with respect to which our author concludes, that the territory of the latter city extended to the vicinity of the former. In reply to the inquiry, what was the use of the caverns, denominated labyrinths, Barthelemi imagines, that they were first excavated in part by nature; that in some places stones were extracted from them for building cities, and that, in more ancient times, they served for an habitation or asylum to the inhabitants of a district exposed to frequent incursions. According to Diodorus Siculus, the most ancient Cretans dwelt in the caves of mount Ida. The people, when inquiries were made on the spot, said, that their labyrinth was originally a prison. It might indeed have been applied to this use; but it is scarcely credible that, for preventing the escape of a few unhappy wretches, such immense labours would have been undertaken.

In Walpole's collection of *Travels in various Countries of the East*, there is an account by Mr. Cockerell of an excursion from the town of Candia to a curious excavation in a mountain about three miles from Agio Deka, a village near the site of Gortys, and 20 miles inland from Candia, which the inhabitants call by the name of the labyrinth. It is a very intricate maze, cut through a freestone rock; many of the passages are very low and narrow, but the principal way is about 8 feet wide, and as many in height. There are several square chambers at the ends of some of the passages, and piers have been left in the middle to support the superincumbent rock. Mr. Cockerell has explored all the excavation that was accessible, of which he gives a plan; it is in its whole length, including the windings, about three-quarters of a mile, but this is evidently only part of the whole, as many of the passages are stopped up in consequence of the falling in of the rock. Some have supposed this to have been the labyrinth of Minos.

The labyrinth of Egypt, according to Pliny, was the oldest of all; and was subsisting in his time, after having stood, according to tradition, as he says, 4,600 years. He says it was built by king Petesucus, or Tithoës; but Herodotus makes it the work of several kings: it stood on the southern bank of the lake Mœris, near the town of Crocodiles, or Arsinoe, and consisted of twelve large contiguous palaces, in which the twelve kings of Egypt assembled to transact affairs of state and religion, containing 3,000 apartments, 1,500 of which were under ground.

This structure seems to have been designed as a pantheon, or universal temple of all the Egyptian deities, which were separately worshipped in the provinces. It was also the place of the general assembly of the magistracy of the whole nation; for those of all the provinces or nomes met here to feast and sacrifice, and to judge causes of great consequence. For this reason, every nome had a hall or palace appropriated to it; the whole edifice containing, according to Herodotus, 12; Egypt being then divided into so many kingdoms. Pliny makes the number of these palaces 16, and Strabo makes them 27. All the halls were vaulted, and had an equal number of doors opposite to one another, six opening to the north, and six to the south, all encompassed by the same wall. The exits, by various passages and innumerable returns, afforded to Herodotus a thousand occasions of wonder. The roofs and walls within were encrusted with marble, and adorned with sculptured figures. The halls were surrounded with pillars of white stone finely polished; and at the angle, where the labyrinth ended, stood the pyramid, which Strabo asserts to be the sepulchre of the prince who built the labyrinth. According to the description of Pliny and Strabo, this edifice stood in the midst of an immense square, surrounded with buildings at a great distance. The porch was of Parian marble, and all the other pillars of marble of Syene; within were the temples of their several deities, and galleries, to which was an ascent of 90 steps, adorned with many columns of porphyry, images of their gods, and statues of their kings, of a colossal size: the whole edifice was constructed of stone, the floors being laid with vast flags, and the roof appearing like a canopy of stone: the passages met, and crossed each other with such intricacy, that it was impossible for a stranger to find his way, either in or out, without a guide; and several of the apartments were so contrived, that on opening of the doors, there was heard within a terrible noise of thunder. Although the Arabs, since the days of Pliny, helped to ruin this structure, yet a considerable part of it is still standing. The people of the country call it the palace of Charon.

Strabo, Diodorus Siculus, Pliny, and Mela, speak of this monument with the same admiration as Herodotus; but not one of them says it was constructed to bewilder those who attempted to pass through it; though it is manifest, that, without a guide, they would have been in danger of losing their way. The Abbé Barthelemi suggests, that this danger introduced a new term into the Greek language. The word *labyrinth*, taken in the literal sense, signifies a circumscribed space, intersected by a number of passages, some of which cross each other in every direction, like those in quarries and mines, and others make larger or smaller circuits round the place from which they depart, like the spiral lines that are visible on certain shells. Hence it has been applied, in a figurative sense, to obscure and captious questions, to indirect and ambiguous answers, and to those discussions, which, after long digressions, bring us back to the point from which we set out.

The labyrinth of Lemnos is mentioned by Pliny as having existed on the island, like those of Egypt and Crete. It was said to have been supported by 150 columns of wonderful beauty, and to have gates so well poised, that a child could throw them open. Pliny adds, that it was constructed by three native architects, and that some remains of it were still in existence.

The labyrinth of Italy was built, it is said, by Porsenna, king of Etruria, for his tomb, but the accounts of it partake so much of the fabulous, that it has been doubted by many authors whether it ever existed at all.

Labyrinth Fret, a fret with many turnings, in the form of a labyrinth; one of the most ancient ornaments in the world.

LACHRYMATORY, the name of a small glass or bottle, like a phial, sometimes found in the sepulchres of the ancients, in which it was supposed the tears of the deceased person's friends were collected and preserved.

LACONICUM, a recess in the caldarium, in which the labrum for the ablutions of those using the vapour-bath was placed. Some writers apply the term merely to the cupola in the floor of the hot-bath, in which the flame from the hypocaust played, to heat the apartment.

LACUNARIS, Lacunaria or Lacunars, in architecture, the panels of coffers formed on the ceilings of apartments, and sometimes on the soffits of the corona of the Ionic, Corinthian, and Composite orders.

In the temple of Minerva at Athens, the lacunars are placed immediately above the frieze within the portico, and formed with a single recess, having an ovolo at the top, which moulding terminates the vertical plane sides, and the horizontal heads of the lacunars. The lacunars are not square, but longer in the longitudinal than in the transverse direction of the building.

In this they are formed in one recess, with an ovolo at the top of the recess, or the farthest extremity of the sides. The lacunars are longer from front to rear of the portico, than in the transverse direction of the building.

In the temple of Theseus at Athens, the lacunars are formed above the frieze, in two rows, between large beams which reach from the rear to the front of the pronaos: their figures are of a square horizontal section, and have only a single recess upwards, with an ovolo above it. The side of the square of each coffer is about one-fifth part of the diameter of the column, and their recess upwards of half the side of their square. The distance between the beams is equal to the breadth of the antæ at the bottom, or nearly equal to the diameter of the columns. The beams are not regulated by the columns, but placed at equidistant intervals, to receive the two rows of lacunars, or coffers. Within the temple or cella, the beams reach transversely, from side to side; but without, and under the soffit of the pronaos, they extend longitudinally from the front to the rear of the pronaos, and the lacunars in the same direction.

In the soffit of the temple of Pandrosus at Athens, the lacunars are formed immediately above the architrave, each into three recesses, with an ovolo at the bottom of each, nearly as broad as the perpendicular surface. The whole depth of the recess is nearly half the side of the square of its lower part. Each part diminishes gradually in breadth in a sloping straight line, till the side of the square of the upper part is so contracted as to be only half that of the lower. Each succeeding third part diminishes regularly in altitude, so that, accounting the bottom the first, the altitude of the second, or the one next above, is something less, and the third about the same quantity less than the second. Each ovolo is something less in height than the vertical surface below it, and has the same ratio to its respective surface.

The cella of the temple of Vesta at Rome is surrounded with a circular colonnade. The ceiling of the portico has a double row of lacunars, being two in the breadth of the portico. The lacunars approach as nearly to a square as is consistent with their diminution, formed by radiations towards the centre of the building, and are constructed in two recesses. The greatest breadth of the outside lacunar is about nine-thirteenths of the diameter of the columns. The whole depth of the recess upwards is about one-seventh of a diameter. The radiating sides are in vertical planes, and the other two sides of each arc vertical cylindric concentric surfaces. The greatest breadth of the upper recess is about two-thirds of the lower. The hollow of this recess is occupied by a rose of a circular form. The recess or cradle vaults of the temple of Peace at Rome are arched, and enriched with octagonal lacunars, each formed in three recesses, which diminish in their margins as they recede upwards. Between the octagonal lacunars are others of a square form in a diagonal position. The ceiling of the middle of the chapel of the said temple, is comparted with hexagonal and rhomboidal lacunars.

The lacunars of the arch of Titus at Rome are square, the side of each being about three-quarters of the diameter of the column.

LADDER, a well-known contrivance used in building operations &c., it is formed of two long side pieces of wood, connected by rounds or treads, forming the steps by which the workmen ascend.

LADY-CHAPEL, a name invented by modern architects and virtuosi, to signify the chapel which is generally found in our ancient cathedrals behind the screen of the high altar. It is denominated from its being generally dedicated to the Virgin Mary, called *Our Lady*.

LANCET ARCH, the same as pointed arch.

Lancet Window, that of which the head is a lancet arch; but the term is more generally applied to those windows which are long and narrow, with lancet arches.

LANDING, the first part of a floor at the head of a stair, also a resting place in a series of flights of steps.

LANTERN, in architecture, a turret raised above the roof with windows round the sides, in order to light the apartment below. Lanterns are much more convenient than skylights; for as the surface of the glass stands vertical, they are not so liable to be broken, nor so subject to the rattling noise of heavy rains and hail. The word lantern is also applied to light erections at the top of towers or domes, as at Boston church, Lincolnshire, and St. Paul's, London.

LANTERN, is also used for a square cage of timber, with glass in it, placed over the ridge of a corridor, or a gallery between two rows of shops, to illuminate them.

LAP, the junction of two bodies where they mutually cover each other.

LARDER, or SAFE, a place in which undressed meat is kept for the use of a family.

It ought to be so large, as to hold a quantity proportioned to the number of the family, and should be well ventilated through the roof, so as to keep a continued circulation of air; the light must be from windows in the wall, which ought to have a northern aspect. The roof ought to be double, so as to contain a cavity for air, in order to preclude the heat of the sun, and the whole building constructed of wood. The windows should be wired, or of perforated zinc, rather than glazed, and the interstices so small as not to admit of any flies. In order to prevent the sun from getting in, the exterior roof should over-hang the safe, so as to keep off the sun's rays, which will only be in the morning and afternoon of the day. If a northern aspect cannot be obtained for light, other means must be employed to preclude the sun's rays. The floor should be elevated above the ground, to prevent dampness, say two or three feet, as may be found convenient; and the safe here spoken of should not adjoin any other building, since its use is to keep the meat cool. The safe should be fitted up with a row of shelves and several rows of hooks, in the manner that butchers hang up joints of meat, &c. The shelves are necessary to lay the meat on when wanted. The hooks must be fastened to beams, and not to the sides of the safe; and the beams should be placed so high as to keep the meat above the head of any person.

LARMIER (from the French) signifying tears; the word is of the same import as CORONA, which see.

LATCH, the catch for holding a door fast.

LATH, a slip of wood used in plastering, tiling, and slating. These are what Festus calls *ambrices;* in other Latin writers they are denominated *templa;* and by Gregory of Tours, *ligaturæ.*

In plastering, the narrower the laths are, the better they are for the purpose, so that they be of sufficient breadth to hold the nails, as the more the number of interstices is increased, the more readily will the lime or stuff hang; and the thicker they are, the better will they be adapted to resist violence; but then they would be much more expensive. The laths are generally made of fir, in three, four, and five feet lengths, but may be reduced to the standard of five feet. Laths are single or double; the latter are generally about three-eighths of an inch thick, and the former barely one quarter, and about an inch broad. Laths are sold in bundles; the three-feet are eight score to the bundle, four-feet, six score, and the five-feet, five score.

The lath for plain tiling is the same as that used in plastering. Laths are also distinguished into *heart* and *sap laths;* the former should always be used in plain tiling, and the latter, of an inferior quality, are most frequently used by the plasterer. Heart-of-oak laths, by the statute Edw. III. should be one inch in breadth, and half an inch in thickness; but now, though their breadth be an inch, their thickness is seldom more than one quarter of an inch; so that two, as they are now made, are but equal to one. According to the same statute, pantile laths are nine or ten feet long, three-quarters of an inch thick, and one and a half inch broad, and should be made of the best yellow deal: the bundle consists of twelve such laths. A square of plain tiling will require a bundle of laths, more or less, according to the pitch. The distance of laying laths one from another is various, differing more in some places than in others; but three and a half, or four inches, are usual distances, with a counter-lath between rafter and rafter; but if the rafters stand at wide intervals, two counter-laths will be necessary. Laths are employed for various other purposes besides plastering and tiling, as in filleting for sustaining the ends of boards; in naked flooring and roofing, for furring up the surfaces; and in every kind of small work, where the dimensions of the parts do not exceed the scantling of laths.

In lathing for plastering, it is too frequent a custom to lap the ends of the laths upon each other, where they terminate upon a quarter or batten, to save the trouble of cutting them; but though this practice saves a row of nails, it leaves only a quarter of an inch for plaster, and if the laths are very crooked, as they frequently are, there will be no space whatever left to straighten the plaster; the finished surface must, therefore, be rounded, contrary to the intention and to the good effect of the work; but if the ends are to be laid upon each other, they should be thinned at the lapping out to nothing at the extremity, or otherwise they should be cut to exact lengths.

Laths should be as evenly split as possible; those that are very crooked should not be used, or the crooked part should be cut out; and such as have a short concavity on the one side, and a convexity on the other, not very prominent, should be placed with the concave side outwards. The following is the method of splitting laths: the lath-cleavers having cut their timber into lengths, they cleave each piece with wedges into eight, twelve or sixteen pieces, according to the scantling of the timber: the pieces thus cloven are called *bolts;* then in the direction of the felt-grain, with their dowl-axe, into sizes for the breadth of the laths: this operation they call *felting;* and, lastly with their chit, they cleave them into thicknesses by the quarter-grain.

In the United States of America, machinery has been employed for rending as well as for sawing out laths: there is nothing original in the latter operation, but there is apparently something worthy of notice by our countrymen in the annexed report of American patents, which we extract from the *Franklin Journal* of Philadelphia.

In Rice's machine, "a stock is fixed in a frame, in which it slides freely backward and forward; it is moved by a cog-wheel, which works in cogs on one side of the stock, in the manner of a rack and pinion. A knife, is fixed upon the stock, and the timber to be cut into laths, &c., is fixed in a frame, and is made to bear against the stock and the lath is cut by the traversing motion of the stock. The knife, it is said, many have a double edge, so as to cut a lath by the forward and backward motion."

Lynch's machine "consists of a long plank, which operates as a plane stock; this plank is made to slide upon its edge between upright standards upon a firm platform; a wide iron like a plane-iron, is fixed so as to cut on one face of this plank much in the manner of the cutters of some single machines; the throat of the plane, if we may so call it, has other cutters standing at right angles with the first cutter, and at such distances apart as to reduce the laths to a proper width. The cutter plank is made to traverse by means of a pitman at one end, operated upon by any suitable power.

Lath-Bricks are bricks made much longer than the ordinary sort, and used instead of laths for drying malt upon, for which purpose they are extremely convenient, as not being liable to catch fire, and retaining the heat much longer than those made of wood, so that a very small fire is sufficient after they are once heated.

LATHE, a very useful engine for the turning of wood, ivory, metals, and other materials. The invention of the lathe is very ancient. Diodorus Siculus says, the first who used it was a grandson of Dædalus, named Talus. Pliny ascribes it to Theodore of Samos, and mentions one Thericles who rendered himself very famous by his dexterity in managing the lathe. With this instrument the ancients turned all kinds of vases, many whereof they enriched with figures and ornaments in basso relievo. The lathe is composed of two wooden cheeks or sides, parallel to the horizon, having a groove or opening between; perpendicular to these are two other pieces called puppets, made to slide between the cheeks, and to be fixed down to any point at pleasure. These have two points, between which the piece to be turned is sustained; the piece is turned round, backwards and forwards, by means of a string put round it, and fastened close to the end of a pliable pole, and underneath to a treadle or board, moved with the foot. There is also a rest which bears up the tool, and keeps it steady.

LATTICE, from lath; wood or iron work made by crossing bars, rods, or laths, in such a manner as to form open chequered or reticulated work.

LATTICE-WINDOWS are those made of bars or strips of iron which cross one another like net-work: windows of lattice or lath were once general in England.

LAUNDRY, a large room, wherein linen after washing is mangled and ironed (and sometimes dried, if there is not a drying-room for the purpose.) The chief and most important utensil in a laundry, is a good stove to heat the irons, likewise dry the linen, besides which there should also be a large range of grating, to air the linen after being ironed or mangled. The stove ought to stand nearly in the middle of the room, and have a long iron pipe for the smoke to ascend, which should be carried several times backward and forward, and at length terminate in the flue of the chimney near the ceiling, by which means it will throw a considerable heat into the room. As it is a known property of heat to ascend, large racks or horses are made so as to be drawn up by pulleys horizontally to the ceiling, where the linen will dry very soon. There should be a mangle, a mangling table, and a large board or dresser fixed to the window side of the room, which ought to be fitted up underneath with large drawers and cupboards for holding linen in, after finished. There should be an adjoining room for the laundry-maids to sleep in. There ought to be a place to hold a sufficient quantity of coals to serve for a day or two, which is filled from the coal-house, near the wash-house; there ought also to be a place fitted up for the maids to wash their hands.

LAVATORY, a cistern or conduit attached to the cloisters in monastic establishments, and used by the monks and other members of the communities for their ablutions; several of these lavatories are still in existence, as in the cloisters of Norwich, Wells, Gloucester and other cathedrals. The name lavatory, or *lavadero*, is also given to certain places in Peru and Chili, where gold is obtained from the earth by washing.

LAVER. The basin or vessel, placed in the court of the Jewish tabernacle, where the officiating priests washed their hands, and feet, and cleansed the entrails of victims.

LAWN, an open space of short-grass ground, in the front of a residence, or in a garden, park, or other pleasure-ground. These, when extended in the principal fronts of habitations, add considerably to the neatness and grandeur of their appearance, by laying them open, and admitting more extensive prospects. Where there is a sufficient scope of ground, they should be as large as the nature of the situation will admit, always being planned in the most conspicuous parts immediately joining the houses, and extended outward as far as convenient, allowing width in proportion; having each side or verge bounded by elegant shrubbery compartments in a varied order, separated in some parts by intervening spaces of grass-ground, of varied dimensions, and serpentine gravel-walks, gently winding between and through the plantations, for occasional shady, sheltered, and private walking: or similar walks carried along the fronts of the boundary plantations, and immediately joining the lawns, for more open and airy walking in; and in some concave sweeps of the plantations there may be recesses and open spaces both of grass and gravel, of different forms and dimensions, made as places of retirement, shade, &c.

Though the usual situations of lawns are those just mentioned; yet if the nature of the ground admit, or in cases where there is a good scope of ground, they may be continued more or less each way; but always the most considerably on the principal fronts, which, if they be to the south, or any of the southerly points, are the most desirable for the purpose.

With respect to the dimensions, they may be from a quarter of an acre, or less, to six or eight acres, or more, according to the extent and situation of the ground. Sometimes lawns are entended over *ha-has*, to ten, twenty, or even to fifty or sixty acres, or more. But in these cases they are not kept mown, but eaten down by live stock.

The form must be directed by the nature of the situation; but it is commonly oblong, square, oval, or circular. But in whatever figure they are designed, they should widen gradually from the house outward to the farthest extremity, to have the greater advantage of prospect; and by having that part of them within the limits of the pleasure-ground, bounded on each side by plantations of ornamental trees and shrubs, they may be continued gradually near towards each wing of the habitation, in order that the inhabitants may be sooner in the walks of the plantations, under shade, shelter, and retirement. The terminations at the farther ends may be either by *ha-has* to extend the prospect, or by a shrubbery or plantation of stately trees, arranged in sweeps and concave curves. But where they extend towards any great road, or distant agreeable prospect, it is more in character to have the utmost verge open, so as to admit of a grand view from and to the main residence.

The side-boundary verges should have the plantations rurally formed, airy and elegant, by being planted with different sorts of the most ornamental trees and shrubs, not in one continued close plantation, but in distinct separated compartments and clumps, varied larger or smaller, and differently formed, in a somewhat natural imitation, being sometimes separated and detached, less or more, by intervening breaks, and open spaces of short grass, communicating both with the lawns and interior districts; and generally varied in moderate sweeps and curves, especially towards the lawns, to avoid stiff, formal appearances, both in the figure of the lawns and plantations. In planting the trees and shrubs, which should be both of the deciduous and evergreen kinds, where intended to plant in distinct clumps, either introduce the deciduous and evergreens alternately in separate parts, or have some of both interspersed in assemblage; in either method, placing the lower growth of shrubs towards the front, and the taller backwards, in proportion to their several statures, so as to exhibit a regular gradation of height, that the different sorts may appear conspicuous from the main lawns. They may be continued backwards to a considerable depth, being backed with trees and shrubs of more lofty growth. The internal parts of the plantations may have gravel or sand walks, some shady, others open ; with here and there some spacious short-grass openings, of different dimensions and forms.

It is seldom that extensive lawns in parks or paddocks, &c. have any boundary plantations close to what may be considered as a continuation of them beyond the pleasure-ground, but they are sometimes dotted with noble trees, dispersed in various parts, at great distances, so as not to obstruct the view; some placed singly, others in groups, by twos, threes, fives, &c. and some placed irregularly, in triangles, sweeps, straight lines, and other different figures, to cause the greater variety and effect, each group being diversified with different sorts of trees, all suffered to take their natural growth. Where small, these kinds of openings should always be kept perfectly neat, by being often poled, rolled, and mown ; but where they are of larger extent, this is scarcely ever the case.

LAYER. *See* Course.

LAZARETTO, or, Lazar-House, a public building, in manner of an hospital, for the reception of poor sick : or in some countries, an edifice, or sometimes a ship, appointed for persons coming from places suspected of the plague, to perform quarantine.

The name " Lazaretto," is derived from St. Lazarus, who, in the Romish calendar, is patron of lepers. Leprosy during the middle ages was a common disease in Italy and other parts of Europe, and the lepers, or persons afflicted with it, were called lazzari. Hence the term lazaretto applied to the hospitals where such persons were confined. In England similar receptacles were often called lazar-houses, or houses of lepers.

John Howard, the distinguished philanthropist, whose services in the cause of humanity can never be forgotten, was the first who drew public attention to the state of the lazarettos on the continent. In the year 1785, he personally inspected most of these institutions, and in his work entitled " An account of the principal Lazarettos in Europe," has given a complete exposition of the plans of the buildings, and their chief regulations. The result of this inspection was the adoption of many of the valuable suggestions made by Howard : and many a weary traveller, suffering under the annoyances of the quarantine system, has had reason to bless the name of the man who did so much to alleviate them. Although some improvements have been made since Howard's time, the main features of these buildings remain nearly the same. His description of those he visited, therefore, may, even at the present day, be considered a faithful one, and interesting to those who, " living at home at ease," have little idea of what it is to be in quarantine. The first lazaretto he inspected was that at Marseilles, which is situated on an elevated rock near the city, at the end of the bay, fronting the south-west, and commanding the entrance of the harbour. It is a spacious building, and its situation renders it very commodious for the purposes of trade. Within the lazaretto is the governor's house, a chapel, in which divine service is generally performed, and a tavern, from which persons under quarantine may be supplied with necessaries. In order to prevent any communication not allowed by the regulations of the establishment, there is a double wall round the lazaretto ; and at the gate there is a bell for calling any person within this enclosure ; and by the number and other modifications of the strokes, every individual knows when he is called. At Genoa the lazaretto is situated on the sea-shore, near the city, detached from other buildings, and encompassed by a double wall. Another lazaretto, belonging to the Genoese, stands on a rising ground at Varignano, near the gulf of Spezia. At Leghorn there are three lazarettos. At Naples, the lazaretto is very small, and is situated on a peninsula near the city. Vessels having *clean* bills of health, lie at the entrance of the port, near the health-office, but those with foul bills, are required to perform their quarantine at the lazaretto. At Messina, the lazaretto stands on an island near the city. The health-office at Zante, is in the city, at the water-side. The old lazaretto is distant about half a mile from the city, and situated on a rising ground near the sea. There is another, called the new lazaretto, which is appropriated to a numerous body of peasants, who pass over to the Morea, to work in harvest time ; on their return, they perform here a seven days' quarantine : and other persons perform fourteen days quarantine in the old lazaretto. The lazaretto at Corfu is finely situated on a rock surrounded with water, about a league from the city. The lazaretto of Castel-Nuova, in Dalmatia, is on the shore about two miles from the city ; at the back of it there is a delightful hill, which belongs to a convent of friars. Persons in quarantine, after a few days, are allowed to walk there, and divert themselves with shooting, &c.

In order to obtain the most complete and satisfactory information, by performing the strictest quarantine, Howard determined to go to Smyrna, and there to take his passage to Venice in a ship with a foul bill. He was thus enabled to give a particular account of his reception and accommodation in the new lazaretto of this city, which is chiefly assigned to Turks and soldiers, and the crews of those ships which have the plague on board ; and this he thought the more necessary, as the rules and tariffs of the other lazarettos in Europe have been evidently formed from those established at Venice. The city of Venice has two lazarettos, appropriated to the expurgation of merchandise susceptible of infection, coming from suspected parts and for the accommodation of passengers in performing quarantine, as also for the reception of persons and effects infected in the unhappy times of pestilence. The old lazaretto is two miles, and the new about five miles, distant from the city, both on little islands, separated from all communication, not only by broad canals surrounding them, but also by high walls ; they are of large extent, being about 400 geometrical paces in circumference. Of these Mr. Howard has given a particular description ; with an account of the regulations and mode of government to which they are subject, and a plan of the old lazaretto. At Trieste there are two lazarettos ; one new, but both clean, and a contrast to those which he had seen at Venice. Of the new one he has given a plan. It is surrounded, at the distance of about twenty yards, by a double wall, within which are separate burying places for Roman Catholics, Greeks, and Protestants. Howard closes his account of the principal lazarettos in Europe, with the outlines of a proper lazaretto, and an engraved sketch of a plan for its construction. He has likewise subjoined, in minute detail, various pertinent remarks respecting quarantine and lazarettos in general.

Within the last few years, however, more enlightened views on the whole subject of the quarantine system have begun to prevail, and are gradually obtaining support. Eminent medical authorities, both in this country and on the Continent, have expressed the strongest opinions, as to its total inefficacy in preventing the introduction of disease ; while on the other hand the injury done by it to the interests of commerce, injury which cannot be adequately estimated, is earnestly and justly insisted upon by the merchants of all nations. It may be hoped, then, that these considerations may have their proper effect with those in authority, and that laws so oppressive and so injurious may shortly be abolished. A greater attention to sanitary regulations will go far to prevent the generation of disease at home; and then, even without quarantine laws, we need have little apprehension of contagion from abroad.

LEAD, (from the Saxon *læd.*) The colour of lead is of a bluish white; when tarnished, it becomes yellowish-white, then bluish, and at last bluish-black. Lustre when untarnished, 3; hardness, 5; and specific gravity, somewhere between 11 and 12. According to Brisson, it was 11·352: and a specimen tried by Gellert, which was found at Freyburg, was estimated at 11·445. Next to gold, platina, and mercury, it is the heaviest metal, being upwards of eleven times heavier than an equal bulk of water. The heaviest is reckoned the best. It stains paper and the fingers. Next to tin, it is the most fusible of all the metals. It is soluble in most of the acids, though more readily so in the nitrous diluted than the others. By exposure to the moist atmosphere, it rusts or oxides. It is malleable and unelastic, and its oxide is easily fusible into a transparent yellow glass

Lead is most used in building, particularly for coverings, gutters, pipes, and in glass windows. For which uses, it is either cast into sheets in a mould or milled; which last, some have pretended, is the least serviceable, not only on account of its thinness, but also because it is so exceedingly stretched in milling and rendered so porous and spongy, that when it comes to lie in the hot sun, it is apt to shrink and crack, and consequently will not keep out the water. Others have preferred the milled lead, or flatted metal, to the cast, because it is more equal, smooth, and solid.

The lead used by glaziers is first cast into slender rods, twelve or fourteen inches long, called *canes;* and these, being afterwards drawn through their vice, come to have a groove on either side for the panes of glass; and this they call *turned* lead.

The method of paling or soldering lead for fitting on of embossed figures, &c., is by laying the part whereon the figure is to be paled, horizontally, and strewing on it some pulverized rosin: under this they place a chafing-dish of coals till such time as the rosin becomes reddish, and rises in pimples; then the figure is applied, and some soft solder rubbed into the joinings; when this is done, the figure will be paled on, and as firm as if it had been cast on. For other uses in building, see the article SHEET LEAD.

LEAN-TO, a small building with a shed-roof attached to a larger one.

LEAVER. *See* LEVER.

LEAVER BOARDS. *See* LEVER BOARDS.

LEAVES, a representation in marble, stone, brass, wood, or other material of natural leaves. *See* ORNAMENT.

LEDGE, a surface on which to support a body in motion or to support a body at rest.

The ledges of a door are the narrow surfaces wrought upon the jams and soffit parallel to the wall, in order to stop the door, so that when the door is shut, the ledges coincide with the surface of the door.

The ledges of a door are therefore one of the sides of the rebate, each rebate having only two sides. In temporary works the ledges of doors are formed by fillets.

LEDGEMENT, the development of a surface, or the surface of a body stretched out on a plane, so that the dimensions of the different sides may easily be ascertained.

LEDGERS, in scaffolding for brick buildings, the horizontal pieces of timber parallel to the wall, fastened to the standards by chords, in order to support the put-logs, on which are laid the boards for working upon.

LEGAL COLUMN. *See* COLUMN.

LEGS, of a right-angled triangle, the two perpendicular sides.

LEGS of an hyperbola, the two parts on each side of the vertex.

LENGTH (from the Saxon *leng.*) the greatest extension of a body. In a right prism, the length is the distance between the ends: in a right pyramid, or cone, the length is the distance between the vertex and the base.

LENGTHENING, of timber, is the method of joining several beams, so as to form a long beam of any given length. *See* SCARF.

LESBIUM MARMOR, a name given by the ancients to a species of marble of a bluish white, sometimes used for vases, and other ornamental works, but principally in the walls of public buildings.

LEVEL, a mathematical instrument, used for drawing a line parallel to the horizon and continuing it out at pleasure, and by this means, for finding the true level, or the difference of ascent or descent between any two places, for conveying water, levelling the surface of floors, and for various other purposes in architecture, hydraulics, surveying, &c.

LEVEL, *Carpenter's*, consists of a long rule, straight on its lower edge, about ten or twelve feet in length, with an upright piece fixed to its upper edge, perpendicular to, and in the middle of the length, having its sides in the same plane with those of the rule, and a straight line drawn on one of its sides perpendicular to the straight edge of the rule. This standing piece is generally mortised into the other, and firmly braced on one side, in order to secure it from accidents, and has its upper end kerfed in three places, viz., through the perpendicular line, and on each side. The straight edge of the transverse piece has a hole or notch cut out on the under side, equal on each side of the perpendicular line. A plummet is suspended by a string from the middle kerf at the top of the standing piece, so that, when hanging at full length, it may vibrate freely in the hole or notch. When the straight edge of the level is applied to two distant points, with its two sides placed vertically, if the plummet hangs freely, and coincides with the straight line on the standing piece, the two points are level; but if not, suppose one of the points to be at the given height, the other point must be lowered or heightened, as the case may require, until the third is brought to a coincidence with the perpendicular line. By two points is meant two surfaces of contact, as two blocks of wood, or chips, or the upper edges of two distant beams.

The use of the level in carpentry, is to lay the upper edges of joints in naked flooring horizontal, by first levelling two beams as remote from each other as the length of the level will allow; the plummet may then be taken off, and the level be used as a straight edge. In the levelling of joints, it is best to make two remote joints first level in themselves, that is, each throughout its own length, then the two level with each other; after this, bring one end of the intermediate joists straight with the two which have been levelled; then the other end in the same manner; then try the straight edge longitudinally on each intermediate joist, and such as are found to be hollow must be furred up straight.

To adjust the level.—Place it in its vertical situation upon two pins or blocks of wood; then, if the plummet, hanging freely, settle upon the line on the standing piece, (or, if not, one end being raised, or the other end lowered, to make it do so,) turn the level end for end, and if the plummet fall upon the line, the level is just; but if not, the bottom edge must be shot straight, and as much taken off the one end as you may think necessary; then trying the level first one way and then the other, as before, if a coincidence takes place between the thread and the line, the level is adjusted; but if not, the operation must be repeated till it come true.

The most convenient class of levels is the *spirit level*, called also the *air level*, which is more accurate than any other kind, and is most extensively used. The invention of this instrument has been ascribed to M. Thevenot. Others have attributed this application of a bubble of air to Dr. Hooke. The instrument consists of a cylindrical glass tube filled with spirits of wine, except leaving in it a small bubble of air; its ends being hermetically sealed to keep in the fluid. This bubble, being the lightest of the contents of the tube, will, by the laws of hydrostatics, always run towards that end of the tube which is most elevated; but when the tube is perfectly horizontal, the bubble will have no tendency towards either end. The tube is not strictly cylindrical withinside, though it bears that appearance, but is slightly curved, the convex side being upwards, and by this means the bubble will rest in the middle of the tube when it is horizontal, but approaches either end if elevated above the other. The simplest form of a spirit level for fixing any plane truly horizontal, consists of a glass tube of the above description, called a *bubble tube*, fixed into a block of wood, as at A B, *Figure* 1. The lower surface, D E, of the block is made flat; and when the bubble, C, stands between two scratches marked on the glass at *a b*, the line D E is horizontal. The method of making it correct is this: the tube is first fitted into the block, the lower edge, D E, of which is placed on a bench or table as nearly horizontal as can be determined, so that the bubble stands between the scratches *a b*. The level is now reversed, that is, the end D is put where E was at first. In this position, if the bubble stands in the middle, it proves the level to be correct, and the table horizontal; but if it runs to either end of the tube, it shows that end to be too much elevated: suppose it D, for instance; this end of the tube must therefore be let deeper into the wood, or the surface D E rectified to produce the same effect: one-half the error must be compensated by this means, and the other half by rectifying the table or support; for D E, the level, must now be reversed again to verify these corrections; and when they are so made that the bubble stands at *a b*, either way, the level is correct. To illustrate this more plainly, see *Figure* 2, which represents a section of the bubble tube; but, for elucidation, is shown as if curved much more than they are ever made. Suppose the convex or upper surface of the tube to be a segment of a large circle, B C D; from the laws of hydrostatics, it is plain that the bubble of air, being the lightest body in the tube, will certainly occupy the highest point of the circle at C; and the two points, B, D, being equally distant therefrom, will be in the same horizontal line B E D. The larger the radius of the circle D B, so will the level be the more sensible of any deviation from the horizontal, because the bubble will have to traverse a greater distance along the tube, in proportion to any partial elevation of either end.

LEVELLING, the art or act of finding a line parallel to the horizon, at one or more stations, in order to determine the height of one place with respect to another; for the laying grounds even, regulating descents, draining morasses, conducting waters for the irrigation of land, &c.

LEVER, or LEAVER (from the French *levier*, formed of the verb *lever*, derived from the Latin, *levare*, "to raise") in mechanics, an inflexible straight bar, supported, in a single point, on a fulcrum, or prop, and used for the raising of weights.

The lever is the first of those called *mechanical powers*, or simple machines, as being, of all others, the most simple; and is chiefly applied to the raising of weights to small heights.

In a lever three things are to be considered: the weight to be raised, or upheld; the power by which it is to be raised, or sustained; and the fulcrum, or prop, by which the lever is supported, or rather on which it moves round, the fulcrum remaining fixed.

Levers are of three kinds: sometimes the fulcrum, or centre of motion, is placed between the weight and the power. This is called a *lever of the first kind*, or *vectis heterodromus;* to which may be reduced scissors, pincers, snuffers, &c.: sometimes the weight is between the fulcrum and the power, which is called a *lever of the second kind;* such are the oars and rudder of a boat, the masts of ships, cutting knives fixed at one end, and doors whose hinges are as the fixed point: and sometimes the power acts between the weight and the fulcrum, which is the *lever of the third kind;* such is a ladder lifted by the middle to rear it up against a wall: these two are called *vectes homodromi.*

In this last, the power must exceed the weight in proportion as its distance from the centre of motion is less than the distance of the centre from the weight. And as the first two kinds of lever serve for producing a slow motion by a swift one, so the last serves for producing a swift motion of the weight by a slow motion of the power. It is by this kind of lever that the muscular motions of animals are performed, the muscles being inserted much nearer to the centre of motion than the point where the centre of gravity of the weight to be raised is applied; so that the power of the muscle is many times greater than the weight which it is able to sustain. Though this may appear at first a disadvantage to animals, because it makes their strength less; it is, however, the effect of excellent contrivance; for if the power were, in this case, applied at a greater distance than the weight, the figure of animals would be not only awkward and ugly, but altogether unfit for motion; as Borelli has shown in his treatise *De Motu Animalium.*

The knowledge of the properties of the lever is of the utmost use in ascertaining the laws of the resistance of timber; we shall therefore begin with the first principles of motion, from which the properties of the lever are obtained; and also the principles of the centre of gravity of one, or of a system of bodies.

1. Force is the power exerted on a body to move it.

2. Direction of motion or tendency is the effort which one body makes to move another towards a given point.

3. Line of direction is the straight line in which a body moves, or has a tendency to move, without having any regard to the point to which it tends.

4. Angle of direction is the angle contained between two lines of direction.

5. When two or more bodies act against each other without any of them being overcome by the rest, this state of quiescence is called *equilibrium.*

6. Opposite directions, or opposite tendencies, are when each of two bodies move, or have a tendency to move, to a different point in the same line of direction.

7. Opposite forces are those that act upon each other in the same line of direction, but have a tendency to contrary points in the line, by which tendency an equilibrium is produced, or otherwise a change of motion.

8. Contrary directions are when two bodies move, or have a tendency to move, in lines parallel to two opposite planes.

Axiom 1.—Every body endeavours to preserve its present state, whether of rest or of moving uniformly in a right line, till it is compelled to change that state by some external force.

Axiom 2.—The alteration of motion either generated or destroyed in a body, is proportional to the force applied, and is made in the direction of that right line in which the force acts.

Axiom 3.—Action and reaction are equal between two bodies in opposite directions.

Axiom 4.—Two equal forces acting against each other, or against a body, in opposite directions, destroy each other's effect.

Axiom 5.—If a body is acted upon by two forces in opposite directions, it is the same thing as if it were only acted upon by one force equal to their difference, in the direction of the greater force.

Axiom 6.—If a body is kept in equilibrio by three or more forces, the sums of the contrary forces, when reduced to parallel directions, are equal.

Axiom 7.—When a right line is drawn in a direction of its length by two forces acting at its extremities, the line may either be flexible or inflexible.

Axiom 8.—When a right line is pressed or pushed by two forces in the direction of its length, and retains its straightness, the right line is inflexible.

Axiom 9.—When a right line is stretched by two forces, the right line draws each of the forces with the same intensity that the forces stretch the line; because action and reaction are equal and contrary.

Axiom 10.—When a right line is pressed by any two forces at its extremities in the direction of the line, it repels the force with the same intensity with which it is pressed by the forces.

Axiom 11.—If two forces act upon a body and keep it in equilibrio, their lines of direction are in the same right line, and the two forces are equal, and have opposite tendencies.

Axiom 12.—A force pulling by a string or flexible line upon one side of a body, has the same effect in moving or in keeping it in equilibrio, as an equal force pushing or pressing on the same line of direction on the other side.

Axiom 13.—A force acting upon a body has the same power in whatever point of the line of direction it is applied.

Axiom 14.—If a line be pressed or drawn by two opposite forces in the direction of the line, all its parts will be equally stretched or compressed.

Postulate.—Grant that the intensities of forces may be represented by right lines, as well as their directions.

Proposition I.—Plate I. *Figure* 1.—If any body, A, be moved by any impulse which would cause it to describe the right line A B, uniformly in a given time; and if the same body, A, be moved by another impulse, which would cause it to describe the right line A D, uniformly in an equal time: these two impulses, acting at the same instant, would carry the body through the diagonal, A C, of a parallelogram A B C D.

For the impulse which is given in the direction A B, will not prevent the body from coming to D C, by the action of the impulse in the direction A D, in an equal time to that in which A D would have been described by the separate impulse: for the same reason the impulse which is given in the direction A D, will not prevent the body from coming to B C, by the action of the impulse in the direction A B, in an equal time to that in which A B would have been described by the separate impulse: therefore, as the body will meet the lines D C and B C at the same time, it will meet in the intersection C; but because the lines A B and A D, are uniformly described in the same time, any two parts, A E and A F, taken from these lines in the ratio of the lines themselves, will also be described in equal times; and because B C is equal to A D, and E G equal to A F; A B : B C : : A E : E G; therefore the body moves in a straight line which is the diagonal of the parallelogram.

Corollary 1.—Hence, if the direction, intensity, and tendency, of any two forces acting upon a solid are given, a single force may be found, which shall be equivalent to the two.

Corollary 2.—Any single force, whose quantity and line of direction are given, may be resolved into two forces, which shall act at a given point in that line, in two given directions.

Proposition II.—Given, the tracts, intensities, and tendencies of two forces making any angle with each other, to find a single force equivalent to them.

Case I. *Figure* 2.—When each of the two given forces have a tendency, from the points A and C towards B, or from B towards A and C. Complete the parallelogram A B C D, and draw the diagonal B D, and it will represent the quantity and direction of the third force, that will be equivalent to A B and C B; and its tendency will be from B towards D, when the extreme forces tend towards B; but towards B when the extreme forces have a tendency from B.

Case II. *Figure* 3.—When the two given forces tend to two different points. Let A B and B C be the two given forces, let the tendency of A B be from B towards A, and that of B C from C towards B; produce either, as A B, to E: make B E equal to A B, and complete the parallelogram B C D E; draw the diagonal B D, and it will be equivalent to B C and B E, or because B E is equal to B A, and both in the same straight line: and since both forces tend to the same point, A, the force B D is equivalent to B A and B C.

It is evident, that though the angles and directions given were the same in both cases, yet the tendency and quantity would be different in each.

Proposition III.—To resolve any force into two others, in any given directions, which shall act against any point of the line of direction of the given force. *Figure* 4.

Let B E be the line of direction of the given force, B the given point, from which the required intensities are to act, and B F, B G their directions. Make B D equal to the intensity of the given force; complete the parallelogram A B C D; then B A is the force acting in the line B F; B C that in the line B G; and their tendencies are contrary to the middle force.

Proposition IV.—If any two forces keep a third in equilibrio, the direction of the third has the same point of concourse, and is in the same plane with the other two, and all the three forces are to each other as the sides and diagonal of a parallelogram formed on their lines of direction, *Figure* 5.

Let A B, B C, be the two forces; complete the parallelogram A B C D; then the force D B is equivalent to A B and B C; but if any force be in equilibrio with D B, it must be equal and opposite; therefore, make B E equal and opposite, and the two forces B D and B E are in equilibrio: take away the force D B, and let its equivalent forces A B and B C counteract B E, then the three forces A B, C D, and B E, are also in equilibrio: because B D and B E are in a straight line, the direction of E B passes through the point B, and is in the same plane with A B and B C; for D B is in that plane: and because B E is equal to B D, the three forces A B, C B, E B, are expressed by the two sides A B and B C, and the diagonal D B of the parallelogram A B C D, formed on their lines of direction.

Corollary 1.—Hence, if any three forces be in equilibrio with each other, they are as the sides of a triangle drawn parallel to their directions.

Corollary 2.—If the directions of any three forces, acting against the same point, keeping it in equilibrio, be given, and one of the intensities; the intensities of the other two may be found.

Proposition V.—The lines of direction of three forces keeping each other in equilibrio, or a solid, and the intensity and tendency of one of them being given; to find the intensity and tendency of the other two.

Case I. *Figure* 4.—When two of the angles formed by the three lines of direction are less than two right angles. Let the three directions be B F, B E, B G, and let the given intensity be in the line B E, and let its tendency be from E towards B. Make B D equal to the given intensity, and complete the parallelogram A B C D. A B is the intensity in its own line of direction B F, its tendency being from B towards F; and B C is the intensity of the force in its line of direction B G, its tendency being from B towards G: for produce E B to H, since the force acting in the line E B presses the point B, then, by *Axiom* 12, it is the same thing, whether the force in the line E B press the point B, or an equal force on the other side of B: in E H draw the point B, and instead of the force pressing the point B by a force at E, let the point B be drawn by a force at H; thus the point B will be drawn by three forces, which are in equilibrio by the last Proposition. Or if the point B had been drawn by a force acting at E, the two forces acting in the lines B F and B G would have pressed these lines, and consequently three forces acting at F, G, H, would be all pressing the point B; it therefore appears, when three forces keep each other in equilibrio, and their lines of direction make two angles less than two right angles, that the force acting in the intermediate line will be contrary to those in the two extreme lines.

Though this example only shows how to find the two extreme forces when the intermediate force is given; yet the intermediate force and one of the extreme forces may as readily be found by having the other extreme force given: because when one of the angles of a parallelogram is given, and the position of a diagonal passing through that angle, it may be described as readily by having either of the sides as the diagonal.

Case II. *Figure* 5.—When any two angles of direction are greater than two right angles.

Let A B, E B, C B, be the three directions, whereof any two angles made by these lines are greater than two right angles, and consequently the remaining one less than two right angles. Let the given force act in E B; produce E B through the opposite angle to D, so as to divide it into two angles; make B D to represent the intensity in E B, then by completing the parallelogram A B C D, as before, B A will represent the intensity in B A, and B C in B C; and as the forces are supposed to act at the points A, E, C, they are either all drawing the point B or all pressing it.

Proposition VI.—Given, the directions of four forces in the same plane, keeping a solid in equilibrio, and one of the intensities, to find the intensities of the other three.

Produce any two directions till they meet each other; also, produce the other two directions till they meet each other; join the two angular points; then by means of the given force, find the other two at the same point: then, because two forces acting at each point of concourse in the same right line must be equal, and have opposite tendencies, the force in this line acting at the other point of concourse will now be given: therefore, find the two remaining intensities in the same manner as at the first point of concourse.

Example I. *Figure* 6.—Let E A, F B, G C, H D, be the direction of the forces that support the body A B C D, and let the given force be in E A. Produce E A, F B, till they meet in I; also produce G C, H D, till they meet in Q. Join I Q, and produce it to P; then let I K represent the given force, and complete the parallelogram I K L M. Make Q P equal to I L, and complete the parallelogram O P Q R; then will I M represent the intensity in F B, O Q in G C, and R Q in H D.

Example II. *Figure* 7.—Let A B D be a lever with three arms, A C, B C, D C, revolvable about C, as a fulcrum, supported in the direction C O; and let forces act at the extremities A, B, D, in given directions, A K, D E, E B, and keep it in equilibrio: it is required to find the proportion of the forces. Produce two of the directions till they meet; also produce the other direction, and that of the prop, till they meet; join the two angular points, and proceed as in Example I., and find the parallelograms H E F G, and K L M N: then L K is the force acting at A, and M K that in the direction of the prop, H E, the force acting at B, and F E that at D. The tendencies of these forces are thus distinguished: let the point B be drawn towards E, then the line E B is in a state of tension; and because the angles H E G and G E F are less than two right angles, the force in the direction E D will also be in a state of tension, and the middle one, E K, in a state of compression. Again, because the angles L K M and M K N are less than two right angles, and because E K is in a state of compression, K A is likewise in a state of compression, and the middle one C K, is in a state of tension; or the post, C O, on the opposite side, is in a state of compression, acting on the other side of G.

It must be observed, when any force acts upon any point of a solid body, that to draw on one side of the point is the same as to press upon the other side, or to press upon one side is the same as to draw upon the opposite; therefore, as the point C is drawn by the force M K, the prop, C O, is compressed by the fulcrum at C. The arms C A, C B, C D, are supposed to be void of weight. If the forces acting at A, B, D, be weights, P, Q, R, going over the pulleys S, T, U, all the lines, A S, B T, D U, will be in a state of tension.

Proposition VII.—Given, the direction of five forces in one plane, keeping a solid in equilibrio, and the intensities and tendencies of two of them, to find the intensities and tendencies of the rest.

Find a force equivalent to the two given forces; then unite this given force with the three remaining ones, and the directions of four forces, with the intensity of one of them, will be given to find the rest, which may be found by the last problem.

Let A B C D F, *Figure* 8, be a lever, with four arms, F A, F B, F C, F D, revolvable about E, and let it be acted upon by five forces, four of which act upon the arms at the points A, B, C, D, in lines of direction A Q, B S, C K, D I, and the other upon the centre at F, in the line of direction F P; then the intensities and tendencies of the two forces acting in the directions C K, and D I, are given; the one from C to K, and the other from I to D. Produce the two directions C K and D I to meet each other at G, and complete the parallelogram G K I H, as in *Case* 2, Problem II., and G H will be the direction and quantity of the force equivalent to G I and G K: then proceed, as in Problem VI., with the given force G H now found, and the three remaining directions, A Q, B S, P F, and complete the parallelograms M N O P and Q R S T; then N P is the quantity that supports the point or axis F in the direction N F, and S R that which supports B in the direction B R.

From this example it appears, that when the direction of any number of forces is given, and all the intensities and tendencies but three, the intensities and directions of these three may be found by compounding any two of the given forces, then uniting the force found with another of the given forces, and again compounding these, and so on until all the given forces are compounded: then proceeding with the last compounded force and the three remaining directions, as in Problem.

Proposition VIII.—If there be two straight lines, A B, B C, *Figure* 9, making any angle, A B C, with each other, and if two forces, equal and opposite in the directions A X, C Y, in the same straight line be applied, and three others in the directions A W, B Z, C J, then if the whole be in equilibrio, the directions Z B, A W, C J, will have the same point of concourse, or otherwise they will be parallel. Join A C, cutting Z B produced in T; take any distance, A D, and complete the parallelogram A O D F; make B H equal to A F, and complete the parallelogram B H I K: make C L equal to B K, and C E equal to A D, and complete the parallelogram C M E L; then all the points A, B, C, are in equilibrio by forces proportional to, and in the directions of the sides and diagonals of the respective parallelograms at these points; now there can be no equilibrium unless C J coincide with C M, for no other force but C M, both in direction and quantity, will balance the two given forces C L and C E; suppose therefore that C J coincides with C M, produce the directions A W and C J to meet Z B produced; then if A W and C J do not meet it in the same point, they will meet it in two different points, U and V; for draw O F, R L, N G, S M, parallel to B V, cutting A C at O, R, N, S; also draw H P, K Q, parallel to A C, cutting B V at P and Q; then will A O=H P=K Q=C R, and therefore A N=S C;

now the triangles A B T and A F O are similar,
therefore . . . . T A : T B : : Q A : O F
likewise in the triangles C T B and C R L. . . . . T B : T C : : R L : a C
therefore . . . . T A : T C : : R L : O F
but because L R is equal to S M, and O F to N G . . . . . T A : T C : : S M : N G
then again, by similar triangles, A U T, and A G N . . . . T U : T A : : N G : N A
and it has been proved that . . . . T A : T C : : S M : N G
also by the similar triangles T C V and S C M . . . . . . T C : T V : : S C : S M
therefore . . . . T U : T V : : S C : N A

but because S C and N A are equal; T U is equal to T V, therefore the points U and V coincide; consequently the three directions meet in the same point.

Corollary 1.—F O + L R is equal to B I; for the triangle A F O is equal and similar to the triangle H B P equal and similar to the triangle K Q I; and the triangle C L R is equal and similar to the triangle K B Q.

Corollary 2.—If V *a* be made equal to A G, and V *c* to C M, and the parallelogram V *a b c*, be completed, the forces in the directions A W, Z B, and C J, are as V *a*, V *b*, and V *c*, viz., the three parts of a parallelogram in these directions; for draw *a e* and *c d* parallel to A C, meeting V B in *e* and *d*, then will V *e*=G N=O F=B P, and *e b*=V *d*=M S=R L=B Q=P I, therefore B P+P I=V *e*+*e b*; but B P+I P is the force in the direction Z B, consequently the three forces V *a*, V *b*, V *c*, are equal to those that act in A W, Z B, and C J.

Corollary 3.—If the points A and C are joined by an inflexible line, A C, it is evident that the equilibrium will still be maintained, for this line (by the last proposition) acts the same as the two opposite forces in A X and C Y.

Corollary 4.—When A W, B Z, and C J, are parallel, F D will coincide with F O, G A with G N, L E with L R, and C M with S M: now L R : O F : : T A : : T C; it will therefore be C M : A G : : T A : T C; consequently, the force A G=force C M=force B I.

Corollary 5.—Hence, if the directions of three forces acting in the plane of a triangle, at the angles, be in equilibrio, the three intensities are as the parts of a parallelogram formed on their lines of direction.

Proposition IX.—If three forces acting against the same point be in equilibrio with each other, and if any point F, *Figures* 10 *and* 11, taken in the line of direction of any one of the forces, the other two forces are to each other reciprocally as the distances of their lines of direction from that point.

Let the lines of direction of the three forces be A D, B D, and C D.

CASE I. *Figure* 10.—When the point, F, is taken in the line of direction of the middle force. Complete the parallelogram D E F G; draw F H perpendicular to A D, and F I to C D. Then because the opposite angles D E F and D G F of the parallelogram are equal, the angles H E F and I G F are equal; and because E H F and G I F are right angles, the triangles E H F and G I F are similar; therefore F G : F E : : F I : F H; but E D is equal to F G, and G D is equal to F E, therefore E D : G D : : F I : F H; that is, the force acting at A is to the force acting at C, as F I to F H.

CASE II. *Figure* 11.—When the point F, is taken in one of the extreme lines of the direction, A D. On D F, as a diagonal, complete the parallelogram D E F G; draw F H perpendicular to D B, and F I to D C; then because G F H and E F I are right angles, and the angle I F H is common, the remaining angles I F G and H F E are equal; and because the angles F I G and F H E are right angles, the triangles G I F and E H F are similar; therefore F G : F E : : F I : F H; that is, the forces at B and C are reciprocally as the distances of their lines of direction taken from any point in the lines of direction of the other force. Therefore, universally, if any three forces be in equilibrio, any two of them are reciprocally as the distances of their lines of direction, taken from any point in the line of direction of the other force.

Proposition X. *Figures* 12 and 13.—If a solid, A B C, be supported by three forces in the lines of direction Z B, A W, C J, these three lines will have the same point of concourse, or be parallel to each other.

Join A B, B C, C A; now the triangle A B C cannot be in equilibrio, unless the directions have the same point of concourse, or be parallel, and also in the plane of the triangle: otherwise the forces at the two points in each of the sides of the triangle would not be equal in opposite directions; therefore the equilibrium of the triangle would be destroyed, as has been shown by Proposition VIII., and consequently that of the solid would also be destroyed.

Corollary 1.—The intensities of any three forces keeping a solid in epuilibrio, will be as the parts of a parallelogram formed on their lines of direction.

Corollary 2.—Likewise the intensities of any two forces are reciprocally as the distances of their lines of direction from any point in the line of the other force, whether their directions meet or are parallel to each other.

Corollary 3.—Hence, in three forces acting upon a prismatic solid, or lever, in parallel directions, any two forces will be to each other in the reciprocal ratio of the distances of their lines of direction, on the opposite side of the solid, to the direction of the other force.

Proposition XI.—If a solid be in equilibrio by three forces, and if any point be taken in the line of direction of any one of them: the products of each of the other two, by the distance of their respective lines of direction from that point, will be equal. *Figure* 14.

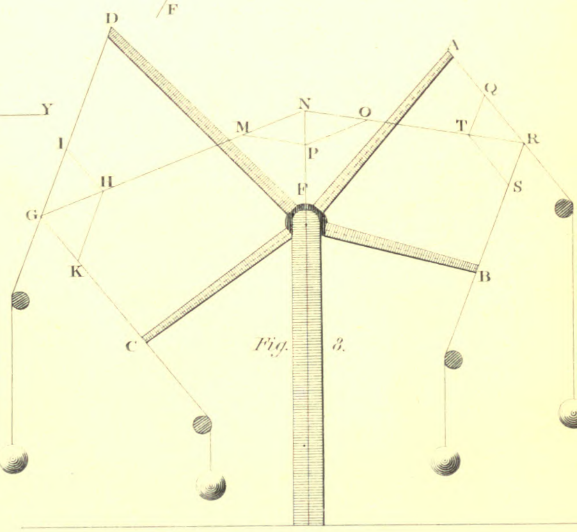

Fig. 8.

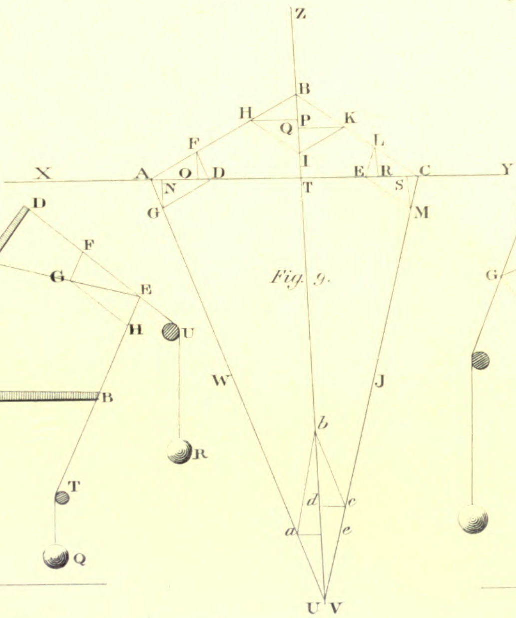

Fig. 9.

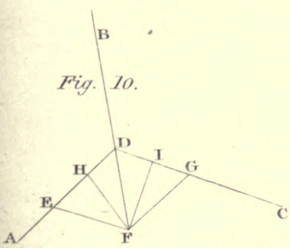

Fig. 10.

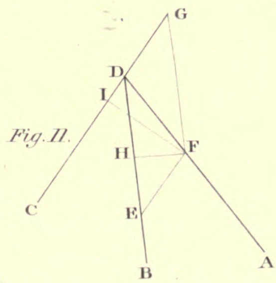

Fig. 11.

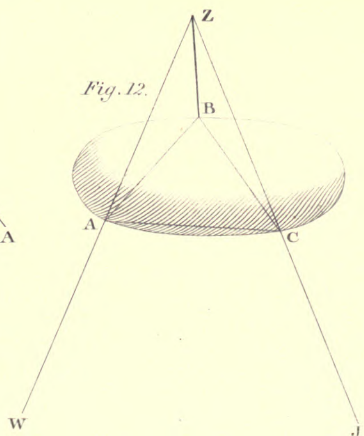

Fig. 12.

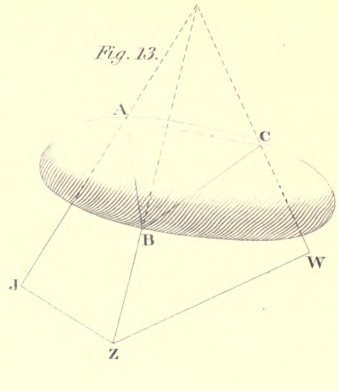

Fig. 13.

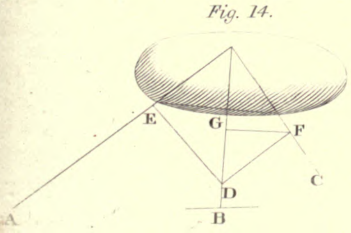

Fig. 14.

Let A, B, C, represent the intensities at A, B, C, in the directions E A, G B, F C. Take any point, D, in the middle line of direction, and draw D E, D F perpendicular to the other two lines of direction; then (*Corollary* 2, last Problem) A : C : : D F : D E; therefore A D E = C × D F. Again, from any point, F, in one of the extreme lines of direction, draw F G and F H perpendicular to the other two, then A : B : : F G : I H; therefore A × F H = B × F G.

Corollary 4.—Hence, if three forces act perpendicular to a prismatic rod, or beam, the products of any two, each by its distance on the beam from the third, are equal.

Corollary 5.—Hence, if three forces act perpendicular to a prismatic rod, or beam, the products of any two of their distances from the third, in the direction of the beam, are equal; for in this case all the lines, F D, D E, F G, F H, coincide in one straight line, and become parallel to the beam, and the segments intercepted by the directions are equal to those on the beam.

LEVER BOARDS, a set of boards so fastened together that they may be turned at any angle to admit of more or less air or light, or to lap upon each other, so as to exclude all air or light through apertures.

LIBRARY, an edifice or apartment destined for holding a considerable number of books placed regularly on shelves; or the books themselves lodged in it. Some authors refer the origin of libraries to the Hebrews; and observe, that the care those people took for the preservation of their sacred books, and the memory of what concerned the action of their ancestors, became an example to other nations, particularly to the Egyptians. Osimandyas, king of Egypt, is said to have taken the hint first; and, according to Diodorus, had a library built in his palace, with this inscription over the door, ΨΥΧΗΣ ΙΑΤΡΕΙΟΝ. Nor were the Ptolemys, who reigned in the same country, less curious and magnificent in their books.

The scripture also speaks of a library of the kings of Persia, Ezra v. 17. vi. 1., which some imagine to have consisted of the historians of that nation, and of memoirs of the affairs of state; but, in effect, it appears rather to have been a repository of laws, charters, and ordinances of the kings. The Hebrew text calls it the house of treasures, and afterwards the house of the rolls, where the treasures were laid up. We may, with more justice, call that a library, mentioned in the second of Esdras to have been built by Nehemiah, and in which were preserved the books of the prophets, and of David, and the letters of their kings.

The first who erected a library at Athens was the tyrant Pisistratus: and yet Strabo refers the honour of it to Aristotle. That of Pisistratus was transported by Xerxes into Persia, and was afterwards brought back by Seleucus Nicanor to Athens. Long after, it was plundered by Sylla, and re-established by Adrian. Plutarch says, that under Eumenes there was a library at Pergamus, containing 200,000 books. Tyrannion, a celebrated grammarian, contemporary with Pompey, had a library of 30,000 volumes. That of Ptolemy Philadelphus, according to A. Gallius, contained 700,000 rolls, which were burnt by Cæsar's soldiers.

Constantine, and his successors, erected a magnificent library at Constantinople; which in the eighth century contained 300,000 volumes, all burnt by order of Leo Isaurus; and among the rest, a copy of the Iliad and Odyssey, written in letters of gold, on the entrails of a serpent.

The most celebrated libraries of ancient Rome. were the Ulpian, and the Palatine. They also boast much of the libraries of Paulus Æmilius, who conquered Perseus; of Lucilius Lucullus, of Assinius Pollio, Atticus, Julius Severus, Domitius Serenus, Pamphilius Martyr, and the emperors Gordian and Trajan.

Anciently, every large church had its library; as appears by the writings of St. Jerome, Anastasius, and others. Pope Nicholas laid the first foundation of that of the Vatican, in 1450.

The Bodleian library at Oxford, built on the foundation of that of duke Humphrey, exceeds that of any university in Europe, and even those of all the sovereigns of Europe, except the emperor's and the royal library of France, which are each of them much older. It was first opened in 1602, and has since found a great number of benefactors; particularly Sir Robert Cotton, Sir H. Savil, Archbishop Laud, Sir Kenelm Digby, Mr. Allen, Dr. Pococke, Mr. Selden, and others. The Vatican, the Medicean, that of Bessarion at Venice, and those just mentioned, exceed the Bodleian in Greek manuscripts; which yet outdoes them all in Oriental manuscripts.

As to printed books, the Ambrosian at Milan, and that of Wolfenbuttle, are two of the most remarkable, and yet both inferior to the Bodleian. The principal public libraries in London, beside that of the Museum, are those of the College of Heralds, of the College of Physicians, and of Doctors' Commons, to which latter every bishop, at the time of his consecration, gives at least £20, sometimes £50, for the purchase of books; those of Gray's Inn, Lincoln's Inn, Inner Temple, and Middle Temple; that of Lambeth, founded by archbishop Bancroft, in 1610, for the use of succeeding archbishops of Canterbury, and increased by the benefactions of archbishops Abbot, Sheldon, and Tennison, and said to consist of at least 15,000 printed books, and 617 volumes in manuscript; that of Redcross-street, founded by Dr. Daniel Williams, a presbyterian divine, and since enriched by many private benefactions; that of the Royal Society, called the Arundelian, or Norfolk library, because the principal part of the collection formerly belonged to the family of Arundel, and was given to the society by Henry Howard, afterwards duke of Norfolk, in 1666, which library has been increased by the valuable collection of Francis Aston, Esq., in 1715, and is continually increasing by the numerous benefactions of the works of its learned members, and others: those of St. Paul's, and of Sion College; the Queen's library, erected by Queen Caroline in 1737; and the Surgeons' library, kept in their hall in Lincoln's Inn Fields. In order to give some idea of the construction of a library, it will be necessary to know the different sizes of paper, and for this purpose the following table will be found useful:

	Inches.	
1. Foolscap	13½ by	16½
2. Crown	15	20
3. Demy	17½	22
4. Medium	18	23
5. Royal	19¼	24
6. Super-royal	19¼	27
7. Elephant	23	28
8. Imperial	22	30
9. Columbier	23½	34
10. Atlas	26½	34½
11. Double Elephant, or Grand Eagle	26½	40

The dimensions of the shelves, and their distances from each other, will therefore be determined by the kind of books intended to be deposited on them.

Library, *the King's*, at St. James's, was founded by Henry, eldest son of James I. and made up partly of books, and partly of manuscripts, with many other curiosities, for the advancement of learning. It has received many additions from the libraries of Isaac Casaubon, and others.

Library, *Cottonian*, originally consisted of 958 volumes of original charters, grants, instruments, letters of sovereign princes, transaction between this and other kingdoms and states, genealogies, histories, registers of monasteries, remains of Saxon laws, the book of Genesis, thought to be the most ancient Greek copy extant, said to have been written by Origen in the second century, and the curious Alexandrian copy or manuscript in Greek capitals. This library is kept in the British Museum, with the large valuable library of Sir Hans Sloane, amounting to upwards of 42,000 volumes, &c. There are many public libraries belonging to the several colleges at Oxford and Cambridge, and the universities of North Britain.

LIGHTHOUSE, a marine building, erected for the purpose of exhibiting a light, to warn seamen in the night of their approach to any sand, promontory, or insulated rock: as those on the South Foreland, Flamborough Head, the Eddystone, &c.; or a building erected at the entrance of a harbour, to direct the ingress and egress of vessels during the night, as at Ramsgate, and other places. The latter kind are generally smaller than the former, and are called *harbour-lights*.

Lighthouses are generally built in the form of circular towers, from 50 to 100 feet in height, arched over at the top with a projecting platform surrounded by an iron railing. On this platform a framing of stone is fixed higher than the railing, containing an excavation for the reception of the bottom of the lantern; the space between this frame and the railing, is called *the gallery*, into which the light-keepers ascend to clean the outside of the glass.

When lighthouses are erected on the main land, there is nothing peculiar in their construction; in some cases, however, they are required in situations difficult of access, and exposed to the accumulated fury of winds and waves; and to erect a permanent building on a spot of this description, requires uncommon resources, and necessarily brings every energy of the architect into action.

The most celebrated antique building of this description was the Pharos of Alexandria in Egypt, the work of Sostratus of Cnidus, under the patronage of Ptolemy Lagus, and his successor Philadelphus, about 283 years before the Christian æra; it is ascertained to have existed for a period of about 1,600 years, and is supposed to have been thrown down by an earthquake. This lighthouse obtained its name from the Island of Pharos, on which it stood; and from its great celebrity, other structures of a similar kind have frequently obtained the same name; as the *Faro di Messina*, and others; but among the moderns, the most remarkable are the *Tour de Corduan* off the French coast, and the *Eddystone Lighthouse*, near the coast of Cornwall. The former of these, begun in the reign of Henry II., and finished under Henry IV. in 1610, stands upon a small island near the mouth of the Garonne, in the Bay of Biscay, and was the work of Luis de Foix, a celebrated French architect. The latter, which has been very justly considered as the *chef-d'œuvre* of this species of architecture, was constructed by the celebrated Smeaton; and still stands an enduring monument of his genius. A full description of this remarkable structure has already been given under the article Eddystone Lighthouse.

Among other remarkable buildings of this kind may be noted the Bell-rock lighthouse, off Arbroath, in the mouth of the Frith of Tay.

The reef of rocks on which the Bell-rock lighthouse is founded, is about 427 feet long and 230 feet broad; at the ordinary height of spring tides it is about 12 feet under water; and from the floating sea-weed, the ridge can be traced 1,000 feet farther in a south-westerly direction, when the tides are very low. It is situated on the eastern coast of Scotland, about 16 miles south by east from the Red-head; 12 miles south-east from Arbroath; 17 miles north by east from the isle of May; and 38 miles north by west from Abbs-head. Its geographical position is in 56° 29′ of north latitude, and 2° 22′ of west longitude. The reef presents an exceedingly rugged and uneven surface. The rock is composed of red sand-stone, similar to the strata of the contiguous promontory of Red-head and of the opposite shores of Dunglas in Berwickshire. The present vegetation of the rock consists only of sea-plants; some of them not of common occurrence on our coast. It is the occasional resting-place of the seal and the cormorant; and is the chosen residence of numerous marine *vermes*. At the distance of 100 yards, when the tide is low, the water varies from two to three fathoms in depth. The greatest depth between the rock and the opposite shores of Fife is 23 fathoms. This rock, though a mere spot on the surface of the ocean, produces all the remarkable phenomena of in-shore and off-shore tides, which exist on the projecting coasts of the mainland, or among the Scottish islands.

In the erection of the Eddystone lighthouse, the dangers and difficulties which were encountered and overcome, owing to the smallness of the surface of the rock, were great and numerous; and although the surface of the Bell-rock was considerably larger, still, being more sunk, and only discovered at low water, the dangers to be encountered were equally great and overwhelming. Owing to the enlarged diameter of the rock, the engineer was enabled to make the masonry of this building more than double the cubical contents of the Eddystone. The following short table will exhibit to our readers the relative dimensions, &c. of the two lighthouses:—

	Eddystone.	Bell-rock.
Height of the rock, about	Level with high water mark.	Level with low water mark
Height of masonry above the rock ..	70 feet.	100 feet.
Diameter of the first entire course ..	26 feet.	42 feet.
Cubic contents in feet, about	13,147.	28,530
		Ascertained.
Expense understood to have been about	£21,000.	£61,331 9 2

Very early, no doubt, attempts were made to obviate the dangers of this fatal spot; and accordingly, tradition reports that the monks of the Abbey of Arbroath erected a bell on the rock, which was to be rung by machinery affected by the flowing and ebbing of the tides, whence the present name of the rock, it is said, took its rise.

After many complaints of the want of a lighthouse, and especially after the violent storm in 1799, during which many ships were driven from their moorings in Yarmouth Roads, and even the Downs, and so many of them destroyed on the Scotch coast, that, when the storm subsided all the bays were margined by broken timber, it was at last resolved to construct a lighthouse. A bill for this purpose was passed in 1806, which enabled the commissioners of the northern lighthouses to levy three-halfpence a ton upon all British vessels trading to and from the ports between Berwick and Peterhead, and twice as much upon foreign vessels. The bill also empowered the commissioners to borrow £25,000 from government; and they had £20,000 of accumulated surplus, which showed that the provision of lights had not previously been kept up to the amount of the tax upon navigation. Still, however, this enabled the commissioners to begin the work with a fund of £45,000. While the proposal was in agitation, various projects for lighthouses were advanced by different individuals; but it was ultimately resolved that the structure should be of stone, somewhat similar to the Eddystone lighthouse, and conducted under the principal superintendence of the late Mr. Rennie. It was well for the stability of the structure, and the benefit of trade, that this eminent and judicious engineer was appointed, for there were other parties who occasionally interfered in the progress of the work; and some of the courses of stone intended for, and actually prepared in the workyard at Arbroath, were; for want of central dovetailing, so faulty, that, had they been used, the work could not have stood. These courses of stone were condemned by Mr. Rennie, and ordered to be broken up for rubble, as appeared by the signature of Mr. Rennie, on the plans. By the necessary condemnation of these faulty courses of stone, a considerable sum of money was lost, but the stability of the lighthouse was not endangered, which was the grand matter; and this shows how very careful eminent engineers, who are not constantly on the spot, ought to be, in examining every working drawing of such structures as this, and allowing no drawing to be used which is not authenticated by their signature. We do not now recollect all the faults of these condemned courses; and since the death of Mr. Logan, who was in possession of the plans with Mr. Rennie's signatures, we know not where these drawings can be referred to, (and reference to them is of little consequence, except as a warning;) but we do remember, that what struck us at the time as the grand imperfection, was the omission of the square central stone with dovetails, to which the four stones next in order were attached, and also joggled by stone to the end joints, thus making the five one mass of stone, to which the whole of the surrounding stones were attached. In place of this central stone, which was of course the key and fastening of the whole, there was substituted in the drawings, a plain hexagon or octagon, we forget which; by means whereof the whole bonding of the course was loosened, and, had water percolated into it, it would have been destroyed by the hydrostatical pressure. An accident of this kind happened to another structure which the engineer to the commissioners of the northern lighthouses had planned, and was in the course of erection upon the Carr rocks, off the east point of Fife. This structure was to be furnished with a bell, to be rung by a float; and in order to contain the float, a hollow column was erected, having a lateral opening at the bottom. The column was, we believe, pretty well secured against the external action of the water, but it should seem that the danger of hydrostatical pressure from within had been overlooked, for, after the work had advanced so far as to be distinctly visible from the land, the sea beating over it during a violent storm, had thrown in rubbish which blocked up the lower aperture, and the hollow of the column filled with water, which burst it into pieces, so that it vanished before it was finished. As this structure is gone, and has left no memorial, it would be of little consequence to inquire into any particulars of it; but the fact is worthy of record, as tending to show how very careful engineers should be in attending to every principle in the planning and executing marine structures; and also how careful those who direct the building of such structures ought to be in the selection of their engineers. To suffer, in any lighthouse or beacon-tower for the warning of mariners of the perils of the sea, any weak portion or point which shall endanger the stability of the structure, may be attended with more calamitous effects, at least for a time, than having no lighthouse or beacon at all; for the lighthouse or beacon gives the seaman a certain security, which prevents him from avoiding the danger so assiduously as he would do, were there no lighthouse there; and, therefore, he is tempted toward the rocks; and wrecked upon them, if the lighthouse falls before his arrival. The Bell-rock lighthouse is as secure against any casualty of this kind as a structure of human erection can be; and, from what we have stated, those who navigate the dangerous coast on which it stands cannot be too thankful to Rennie, who had the superintendence of the building, or hold the memory of that eminent and most judicious engineer in too high estimation.

While, however, this tribute is justly due, and ought to be paid, to the memory of Mr. Rennie, Mr. Logan, under whose care the work was more immediately executed, ought not to be forgotten. Perhaps no man was ever more capable of executing stone-work to bear the violence of the sea; and, let the plan be ever so good, a work may be rendered unstable by ignorant or negligent execution. Logan had been trained from his infancy in aquatic architecture, more especially in the construction of bridges which had to resist the action of violent floods; and, therefore, though a very young man when employed in the Bell-rock Lighthouse, he well knew the nature of the work, and was most faithful in the execution of it. His execution of the Dundee harbour, under Telford, and of the packet harbours between Ireland and Scotland, under Rennie, are lasting monuments of his ability; and had he not been prematurely cut off, there is no doubt that his operations on the Clyde would have been of the greatest benefit to Glasgow, and to all who are any way connected with it. Indeed, his professional zeal may be considered as the real cause which shortened his days; for when laying the foundations of the Dundee harbour, some of which was in very deep water, he was constantly on the ground when the tide permitted, and standing in the water for hours, directing and encouraging the men, whether it was night or day, and whatever was the state of the weather. This labour and exposure, which would very soon have killed most men, brought upon him a severe and long-protracted rheumatic fever; and, though the natural strength of his constitution enabled him to survive this for many years, he never thoroughly recovered from it.

In enumerating those who were chiefly instrumental in making the Bell-rock Lighthouse what it is, there is another and a different character, whom it would be injustice to pass over in silence: this was Watt, the machinist, or, more strictly speaking, the man of all work, or rather of all contrivance in cases of emergency. As is but too frequently the case with workmen of great inventive talent, Watt was somewhat dissipated, and passed not a little of his time in ale-houses. In this matter he was allowed to have his way, only to be always ready at a call; and when the course of the work rendered a crane, or crab, or other engine of peculiar construction, necessary, Watt was sent for, and instantly sketched out, rudely enough in some instances, the very machine which answered the purpose; and having done so, he returned to his potations. Among his contrivances we may mention two cranes, which are certainly superior to any other for laying heavy stone in difficult situations. One of those was a "jib-crane," of great power and easy management: it was supported by four gye-ropes in the usual manner, and traversed freely all round. The jib or arm was jointed to the pillar, so that it could be brought into all positions from horizontal to vertical; and, to prevent it from lapping to the pillar when raised, or beyond a certain elevation, the jib-chain by which it was raised or lowered passed over a pully in the bight, so as always to give a downward pressure on the point of the jib, where the pully of the crane chain was attached. It was worked by wheel and pinion, and, of course, required two sets of "geer"—one for working the jib, and the other for working the crane. By means of these contrivances, the largest stones—some of which were two tons in weight—could be brought to any point within the range of the jib, with great certainty, and very little manual labour.

While the building was solid, and of such moderate height as that the gye-ropes could be fastened, this crane answered exceedingly well; but after the structure had advanced some height, and especially after it began to be hollow, a crane of this description could not be so fastened as to command the whole surface and have sufficient security. Consequently, the invention of Watt had to be called in; and he contrived his counterpoise crane. This crane was supported on a hollow pillar of cast-iron, which was lengthened by adding additional pieces as the progress of the work required. The crane, which was a platform with two equal arms, traversed upon this pillar, and was of sufficient length to command the whole work, and as much more as sufficed for raising the stones. To the one arm was attached the chain for this purpose, while the other carried a hook, upon which weights could be placed, to counterbalance that of the stone; and the working parts were so arranged, that when the stone required to be moved outwards or inwards to bring it to its proper bed, the weights were also moved outwards or inwards, and thus the leverage of both ends of the crane was always equal, as well as the weight. Thus it traversed freely, was easily worked, and perfectly stable. One of the barrels also raised the platform of the crane by means of a pulley and chain on the top of the pillar; and there were apertures through both sides of the pillar, for supporting the platform when raised to the proper height. When the pillar itself required to be lengthened, the pulley was removed from the top of the pillar, a new piece of pillar added, the pulley replaced, and the chain lengthened and passed over it as before. In this way, by adding length after length, the laying of the stones by means of the counterpoise crane was carried on to the required height with ease, expedition, and safety, which could not have been maintained without such an apparatus.

The lighthouse itself is a splendid structure, of which the external contour is good, and also the execution. The height of the masonry is 100 feet, and the light-room or lantern is 15 feet more. The diameter at the base is 42 feet; but at the parapet of the lantern, is only 13 feet. The first 30 feet consist of solid masonry, the lower courses let in, and treenailed to the rock, and all the solid courses are dovetailed, joggled, and treenailed; and as they are laid in strong mortar, which sets readily and firmly, the whole of this 30 feet has very nearly the cohesion of one solid mass of stone.

The entrance and lowest apartment is at the top of this solid masonry, and there is an external stair and platform for landing when the tide suits. The walls of this apartment are 7 feet thick; it is occupied by the water-tanks, fuel, and other heavy necessaries. The second, which is much more ample, in consequence of the reduced thickness of the walls, contains the oil and other stores necessary for the lights. The third floor is the kitchen, and the fourth the bedroom for the keepers; and the fifth room is the library, and place for the reception of such strangers as have hardihood to visit this sea-girt pillar. Over all these is the light-room, with double glazed windows, and wholly fire-proof, except the external dead-lights, which are put on as occasion requires. The balcony around the light-room is well secured by a cast-iron railing, supported with brass, and having a strong top-rail of that metal. The parapet of the light-room is six feet high, and from it a door opens to the balcony. The sashes of the windows are of cast-iron, the glazing strong plate double, as we have said, and the dome is of copper. The lights are revolving ones, and show alternately a white and red light, produced by stained glass. They are very powerful, and can readily be seen at a distance of 20 miles or more, unless when the atmosphere is foggy; and unfortunately, no light has yet been discovered which can so far penetrate a thick fog as to warn a ship of danger in time for even a chance of escaping.

As the best substitute that circumstances admit of, two bells of 12 cwt. each are tolled constantly day and night, when the atmosphere is foggy, by means of the same machinery which moves the lights. In calm weather, during which fogs are most frequent, the sound of these bells can be heard all over the surface of the rock which is absolutely dangerous; and thus they justify the appellation of Bell-rock lighthouse, and remind one of the Abbot of St. Thomas.

The rise of the tide over the foundations of the lighthouse is about 16 feet at ordinary spring floods; and when the sea is perfectly tranquil, the structure seems resting on the waters. Altogether, indeed, the Bell-rock lighthouse is a structure of great interest, and one which has been the means of saving many lives and much property. Considering that the workmen had to contend with the violence of the sea, upon a rock 12 miles from land, and with its highest point 12 feet below the surface of high water; it will be readily understood that the commencement of the work, and all the early stages of it, must have been attended with great difficulty and no small danger. A faithful history of its construction, drawn up with even the tithe of the talent which Smeaton displays in his report on Eddystone, would be an interesting and instructive work; unfortunately, there was no Smeaton conversant with all the details of the Bell-rock; and the result is, that all the published accounts of it are meagre, and some of them perhaps not true.

Another noble erection of this kind is that on the Skerrymore rock, off the west coast of Scotland. This building was constructed from the designs of Mr. Alvan Stevenson, the talented engineer to the Scottish Lighthouse Board, and cost in its erection, with the harbour for the tender and other necessaries, £87,000; it was first illuminated in 1844. The light is 150 feet above the sea, and the structure and its appliances exhibit every refinement and improvement hitherto effected by modern science in the varied particulars of the system.

Although, however, the talent and practical ability of such men as Smeaton and Rennie enabled them to overcome all the difficulties of constructing such buildings as we have described, other situations, where also it was desirable to erect them, presented obstacles of another character, perhaps even still more troublesome to deal with; we allude to the erecting lighthouses on such shifting and dangerous sands as the Goodwin, &c. Here the engineer has no solid rock to build on; instead of a substantial foundation on which to base his work, he has to work on a treacherous material, which slides from under him, and engulfs all that is placed on it.

Of the means for meeting such difficulties, the first to be noticed is the *screw-pile* of Mr. Alexander Mitchell, C. E. of Belfast. This principle was first employed in the construction of the foundation of the Maplin Lighthouse, on the north side of the mouth of the Thames, on which is now exhibited a red light. This was commenced in 1838, and is as firm now as when first erected; it stands on the outer edge of the Maplin Sand. This dangerous shoal is composed of sand at the surface, and afterwards of sand and mud; it is exceedingly soft and penetrable, and therefore the erection of a lighthouse upon such a foundation must be considered as a great achievement.

The principle of this screw-pile lighthouse, is having a series of piles nine in number—eight in the angles of an octagon, and one in the centre. These piles consist of a shaft of hammered iron, five or six inches in diameter, having a single turn of the flange of a screw four feet in diameter. This pile is screwed with great facility into the sand, to the depth of 22 feet; and each, it was calculated, would bear a weight of 64 tons. Nine piles were fixed in nine consecutive days in the summer of 1838, and upon this foundation of Mr. Mitchell's, the light-room was erected under the direction of Mr. Walker, the engineer to the Trinity Board.

A structure similar to this was proposed by Mr. Robert Stevenson in 1800, for the Bell-rock lighthouse. It was intended to affix the foundation to the rocks, and that the iron shafts should support several stories; whereas the Maplin and Wyre lights have but a single story. A similar structure is also now building on the rocks of Minot's Ledge off Boston, in the United States; and another is constructing in London for the Bishop Rock off Scilly, designed by Mr. Walker. Mr. Mitchell previously completed a lighthouse upon a similar foundation at the mouth of the Wyre river, in Morecambe bay, about 30 miles north of Liverpool. It was commenced in November, 1839, and lighted in June, 1840. The foundation is formed of seven screw-piles, six in a circle, and one in the centre, each pile being five inches in diameter, with a screw of three feet diameter. The screws were sunk 13 feet into the bank, which is composed of exceedingly hard sand. On these screws is supported the lighthouse, consisting of one floor only, and the lantern above it.

Another plan has been carried into effect, at the Point of Air lighthouse, at the entrance of the river Dee, near Chester. This, which is similar in superstructure to the Maplin lighthouse, is by Messrs. Walker and Burgess, and consists of nine hollow iron cylinders, 3 feet 9 inches in diameter, sunk 12 feet into the sand by aid of an instrument known to well-sinkers as "the Miser," which extracts the sand contained in the cylinder. In these the bases of the piles are inserted, and then filled with concrete. But this, it must be observed, is erected above low water-mark.

While on this point of the subject we may notice an admirable plan for forming a foundation for a bridge or pier of similar structure described by Mr. Charles Fox, of the firm of Fox, Henderson, and Company, in his evidence before the Committee on the Westminster Temporary Bridge bill in 1850.

This plan has been adopted with great success in the several bridges on different lines of railway, built by Messrs. Fox and Company, under the direction of Mr. Cubitt and other engineers; and though not yet, as we believe, applied to the building of lighthouses, seems well adapted to that purpose.

We cannot better describe this plan than in Mr. Fox's own words, in the following extract from the printed evidence of the Committee above mentioned.

"Will you describe to the Committee the mode of construction?—Perhaps the simplest mode of describing it is to say, that instead of using the old-fashioned wooden coffer-dam, which was always a temporary work, we make use of cylinders of iron, which are in themselves coffer-dams, and which remain permanently as a portion of the structure. We adopt various modes of getting them down, but the more general one is this: we have a large receiver of wrought-iron, very much like a cylindrical high-pressure boiler, and from that receiver we exhaust the atmosphere, and when we get the cylinder put into its place, just carefully lowered down on to the bed of the river, surrounded by temporary frames of timber, so as to be sure that it shall be kept in a vertical position, we put a cap on to the top, having an elastic pipe from the top cap to the exhausted receiver, and we, at the proper time, open the communication between the two, and the pressure of the atmosphere on the surface of the water in the river produces such a rush to fill up the tube, as to get rid of any vacuous space, that it carries on a constant state of excavation under the bottom edge of the cylinder, from the pressure of the atmosphere on the top. The atmosphere takes care to push down the pile, aided by its own weight, so as to take up any little space that may have been excavated. When this mode was first spoken of, it was treated with a great deal of ridicule, and people naturally said, 'Why, if the pressure of the atmosphere will push the pile down, when the pile is down it will not carry more than a weight equivalent to the pressure of the atmosphere;' and a very practical man raised that objection; not a very scientific man, but a man of very great experience; and I said to him, 'Now you are quite wrong, for the principle is, that it acts as a sort of excavating process; it is quite true that the pressure of the atmosphere on the top is useful, as it gets over any little friction on the sides of the tube so as to enable it to follow into the excavated space, and without that principle we could not push the cylinder down at all.' To prove this, we took a six-feet cylinder, and calculated what the pressure of the atmosphere upon that cylinder would be, and taking the whole pressure of the atmosphere, it amounted to about 30 tons. I had 30 tons of iron rails placed on the top of the cylinder, and the only result was, that it pushed it down about three-quarters of an inch into the gravel and brought it to a bearing, but it did no more.

"Was that upon a cylinder of six feet in diameter?—Yes; we then took off the 30 tons of iron-rails and put on the cap and opened the communication with the exhausted receiver, and the cylinder immediately descended into the solid gravel 6 feet 6 inches by one impulse.

"Having descended only three-quarters of an inch before?—Only three-quarters of an inch; it just pressed it a little into the ground with the dead pressure of 30 tons. We then removed the cap, and put on the top of the pile 100 tons of rails; but we could get no depression, except some three-quarters of an inch, which was done by the little compression that you would have from the weight of the edge of the cylinder on the gravel. That is the general mode of sinking these cast-iron cylinders. But as it will be obvious to the Committee, in the event of our meeting with, say, the trunk of an old tree, or a very large stone, we could not proceed any further, and we have had to devise many means of getting over any difficulty of that kind. In the case of the bridge at the Nene, we have had to go through not only a layer or two of gravel, but through 2 feet 6 inches of solid rock, and that rock not lying in a horizontal position, has offered difficulties which, under other circumstances, would be very expensive to overcome. To enable us to get through any unforeseen matter, it is necessary to get into the cylinder and excavate any material that may be within it, and cut through the obstruction; and, to do that, we have devised a means by which we convert the cylinder virtually into a diving-bell; that is to say, we fix a cap on the top of the cylinder, and the air-pumps are constructed so that they are, when required, compressing-pumps, and we can pump just enough air into the cylinder to make it counterbalance the pressure of the column of water without, by which means we keep the work perfectly dry, and the men can get at it just as well as if they were working in this room.

"What is the greatest depth to which you have driven a single cylinder?—I think the greatest depth to which we have driven a single cylinder is about 19 feet; but one has been driven in the Goodwin Sands 65 feet by the same process.

"The Committee understand that the cylinders are not single, but are piled one upon each other to the required depth?—Exactly so; they are generally used in nine-feet lengths; the piles for the bridge at Rochester are of two diameters, they are six feet and seven feet, and they are cast in lengths of nine feet, with flanges at the top and bottom, which are accurately turned and fitted together, so that they drop on to one another; there is a projection.

"The external water will be found to be effectually excluded by such a mode of junction?—Perfectly; we never have a drop through them; they require nothing more than a single coat of paint, and when we use one of the castings we clean the flange carefully and give it one coat of good red lead paint, and put another down upon it, which is prepared in the same way; they never leak a drop.

"Do you recommend as a general principle the adoption of a cylinder or of a square form?—Generally a cylinder, for several reasons.

"Will you state the reasons?—In the first place, because it is the cheapest form to construct in the preparation of the casting itself; and, in the second place, because it is better capable of bearing pressure, and therefore can be cast with a much less quantity of material in it; the object in a foundation being to get the largest bearing surface at the least possible cost; in the third place, because we have found in practice that it is difficult to sink square caissons close together, because, having a very small space between them, one having been sunk, it is very apt to make it difficult to sink an adjoining one; we have no ground between them to work upon.

"The Committee understand, likewise, that there is round each cylinder a girdle of timber, which is necessary in order to keep the cylinder in its perpendicular position?—Yes; I have made use of piles upon which temporary frames are fixed, and put two rows of what we call wallings, forming a square space, in which the cylindrical pile is placed and driven by means of the pressure on the cap of the cylinder.

"Are the Committee to understand that the surface, or the bed of the river, is in the first instance level, in order to receive the cylinder?—Not at all; we deal with it as we find it.

"You use no mechanical means, except in the experiment to which you have adverted, of 30 tons and 100 tons of actual weight; you have recourse rather to physical means of exhausting the air, and of admitting the pressure of the atmosphere?—Yes, because it is so much cheaper. It is a serious job to put 30 tons on to a pile, whereas a simple cast-iron cap, as I have before described, put on to the top is so exceedingly easy."

In another part of his evidence, Mr. Fox says, "There is no doubt that the cheapest foundation you can put in is to use the largest size cylinders, so as to have them within the compass of ordinary means of moving about. If you had a pile two feet in diameter it would bear a certain load, supposing it to be in any semifluid foundation; if you double the diameter, you would only double the weight of the cylinder, but it would carry four times the load." Again,—and this is peculiarly applicable to foundations on sands, &c., for lighthouses—"If you give me a piece of ground, and first there is a layer of mud, and then a layer of gravel, and then a layer of rock, and then a sheet of cast-iron, and then anything else, I will put a cylinder through it. I also will bring up the foundations of the bridge to low-water level, for something like the same cost as would have been expended under the old plan, in the mere material used for that purpose, saving coffer-dams altogether."

Mr. Bush's "Light of all nations," though it failed so signally, deserved notice. This was again a proposal to construct a lighthouse on the Goodwin, ever a locality for experiments of this nature. The site at last chosen was, for any good effect to be derived from it, as bad as could possibly be, being on the middle of the sand, and consequently calculated rather to lead vessels into danger, than to preserve them from it.

"The Light of all nations" was intended to be an iron tower erected by means of an iron caisson, which was to afford the means of forming a substantial foundation. This caisson, the frustum of a cone 30 feet in diameter, and 28 feet high, weighing about 150 tons, was towed out from Deal by one of Her Majesty's vessels to its station, about the centre of the Goodwin Sands, on July 27, 1842. The caisson was made water-tight, in order that, as it settled down, the workmen might be enabled to construct the foundation on the chalk substratum of the sand. This substratum, however, was never reached; the caisson did settle down, but not perpendicularly, and after it had been knocked about by several gales of wind, it was found impracticable to carry out the original design, and it was therefore necessarily abandoned. On the wreck of the caisson, however, Mr. Bush succeeded in erecting a smaller shaft, surmounted by a small light-room, and in this room he and his wife remained during a night in the beginning of 1845.

The lighthouse was never completed. And the Trinity House was at last obliged to interfere, to prevent, from its dangerous situation, its being used as a light-beacon.

Another adaptation of iron to the construction of lighthouses has met with far greater success, and promises to be of the greatest utility, whether as regards economy, or facility of construction. This is the iron lighthouse designed by Mr. Gordon.

It is rather singular that iron should not have been employed in this form before, when we consider the multifarious variety of purposes to which it is now applied. In the year 1805, however, a cast-iron lighthouse was suggested by Mr. Rennie, for the Bell-rock, and also by Mr. Robert Stevenson in 1800. The first tower of this construction, was erected on the eastern end of the island of Jamaica, and another of a similar kind for Bermuda. The latter is 105 feet 9 inches high, formed with iron plates, the entire weight of which is nearly 100 tons. The building has seven stories, and the lower portion is filled in with concrete to the height of 22 feet, to give it stability. Nearly every portion of the edifice is of iron, and the erection of the tower was completed in ten months, finished October 9, 1845. These lighthouses were constructed in London, put together and erected, and then taken to pieces again and forwarded to their destination.

The light in the Bermuda lighthouse is from a beautiful dioptric first order apparatus, constructed by Messrs. Wilkins and Son, of Long Acre; the lenses composing it were made by M. H. Lepaute of Paris, and is one of the most efficient and powerful lights in the world.

Having thus shown some of the different methods employed in the erection of lighthouses, and the improvements which modern art has introduced, we now turn to another important part of our subject, that of the *illumination* of lighthouses.

The first lighthouses, such as the Cordouan, and the North Foreland, were illuminated by open fire-places, or chauffers, placed on the summit of the towers. In the former, they burnt billets of oak-wood; and in the latter, coal. It will be readily seen how incompletely such arrangements must have performed their office. Of course the time at which a lighthouse becomes most serviceable is, during tempestuous weather, and a wind blowing towards the land, causes that dread of mariners—a lee-shore; yet this wind would drive the flames of an open fire away from the very direction in which they were most required to be seen; thus the bars of the grate were often nearly melted to leeward, while towards the sea the coals remained untouched by the fire. One advantage, however, there certainly was sometimes in the open fire, viz., that, during fog or rain, the glare of the fire was visible by reflection in the atmosphere, though the fire itself could not be seen.

The North Foreland lighthouse, between Ramsgate and Margate will be more familiar to many of our readers than any other, and will serve as an excellent example of the progress of illumination. This lighthouse was erected for indicating the proximity of the Goodwin Sands. The first intimation we have of its existence is in 1636, in Charles the First's reign, when license was granted to Sir John Meldrum to renew and continue this and the South Foreland lighthouse for the same purpose. At this time it was merely a large glass lantern on the top of a timber-and-plaister house, which was burnt in 1683. Towards the end of the same century, the present tower was partially erected; a strong octagonal structure, having the iron grate, or chauffer, for burning coals. From the difficulty of keeping up a proper flame in windy or rainy weather, it was covered about the year 1732, with a sort of lantern, with large sash windows, and the coal fire was kept alight by means of large bellows which the attendants blew throughout the night. This was found not to answer, and the reflected glare above-mentioned was thought desirable. Accordingly, the lantern was removed, and the fire restored to its original condition. Matters went on thus till 1790, when the tower was raised to the height of 70 feet, and further improvements made in the lantern, by the introduction of lamps and other apparatus, hereafter to be described.

After some alterations of the Cordouan wood-fire, the mariners complained that they could not see the light at a distance of two leagues, as formerly. But Smeaton informs us, that the coal-fire of the Spurn Point lighthouse, at the mouth of the Humber, which was constructed on a good principle for burning, had been seen thirty miles off.

The only exceptions to the fires were the noble Eddystone lights, which then exhibited a chandelier of twenty-four wax candles, five of which weighed 2lbs., and the Liverpool lighthouses, which had oil lamps, with rude reflectors.

The coal lights are now quite abolished. The last was at one station belonging to Sweden, on the little island of Nidingen, on the east side of the Categat, near the entrance to the Baltic sea. These were two light towers, showing coal fires, but surrounded by sides of glass, to shelter them from the wind, and open at the top. They were altered at the beginning of the year 1846.

The introduction of the Argand lamp was the first great advance towards the perfection of lighthouses. This improvement in artificial light was the greatest, previous to the introduction of gas. It was discovered by M. Argand, a citizen of Geneva, about 1780 or 1785. It has remained as he left it, and in principle appears as perfect as can be looked for. Its perfection as an experiment was almost accidental. The younger brother of Argand thus describes its accidental discovery. "My brother," he says, "had long been trying to bring his lamp to bear. A broken-off neck of a flask was lying on the chimney-piece; I happened to reach it over the table, and to place it over the circular flame of the lamp; immediately it rose with brilliancy. My brother started from his seat in exstasy, rushed upon me with a transport of joy, and embraced me with rapture." Thus originated the Argand lamp.

On the introduction of a more efficient means of illumination, and the consequent abandonment of the coal fires, lighthouses assumed a more important position in maritime affairs, and they were, accordingly, largely increased in number. This extension rendered necessary another improvement—the means of readily distinguishing one light from another. Although many suggestions have been made for doing this more effectually—some practicable, others not so, and some are in actual operation—this part of the science is far from being in a perfect state. Much remains to be done, before the mariner can be certain of determining, by its distinctive features, each light when seen.

The variety of lights that have been proposed and experimented on for lighthouse purposes is very great, particularly, we may mention, the Drummond, the electric, voltaic, &c., but few have stood the test of experience; and the lamps now in universal use are still but modifications of the original Argand burner.

Amongst the means for increasing the intensity of light, the use of reflectors is most important. In the year 1786, reflectors and oil lamps were first proposed at a meeting of the Scottish lighthouse commissioners. The first metallic reflectors used in the northern lighthouses were constructed by Mr. Thomas Smith, of Edinburgh. The figure was given to them by a plaster mould, and the cavity was afterwards filled in, by means of cement, with small facets of mirror-glass. This must have done its work very imperfectly, although the general figure was capable of considerable accuracy. In 1803, the first polished *metal* reflectors used in Scotland, were placed in Inch-Keith lighthouse; since then, various slight alterations and improvements have been made, but substantially, the system of illuminating lighthouses remains the same.

We cannot conclude this article without acknowledging our obligations in its preparation to the valuable paper on lighthouses, &c., by Mr. Findlay.

LIKE ARCS, in the projection of the sphere, the parts of lesser circles containing an equal number of degrees with the corresponding arcs of greater circles.

LIKE FIGURES, in geometry, such as have their angles equal, and the sides about the equal angles proportional.

LIKE SOLIDS, such as are contained under like planes.

LIMESTONE, a calcareous stone, which being sufficiently burned or calcined, falls into powder on the application of water; and being then mixed with water and sand in certain proportions, forms a strong cement.

Limestone is either pure or mixed. The best for the use of building is that which contains a certain portion of clay and iron. *See* CEMENT.

LIME-KILN, a kiln for the purpose of burning lime. Kilns for this purpose are constructed in a variety of ways, to save expense, or to answer to the particular nature of the fuel. *See* KILN.

LIME, *quick*, a term applied to lime in its most powerful or caustic state, before it has been rendered mild by the absorption of carbonic acid gas, or fixed air. *See* CEMENT-KILN.

LINE, (from the Latin, *linea*,) a quantity extended in length only. A line may be conceived to be formed by the motion of a point. Lines have no real existence except at the termination or terminations of the surface of a body: thus, a line is the junction of two surfaces, and therefore can have no thickness.

Lines are of two kinds, viz., *straight* or *curved*. Straight lines are all of the same species; the species of curves, which are infinite, are divided into *geometrical* and *mechanical*.

LINE, also denotes a French measure, containing the 12th part of an inch, or the 144th part of a foot.

LINE, *Equinoctial*, the common intersection of the equinoctial and the dial planes.

LINE, *Geometrical*, in perspective, any straight line in the geometrical or primary line.

Line, *Horary*, or Hour Lines, in dialing, the intersection of the hour-planes with the dial plane.

Line, *Horizontal*, a line parallel to the horizon. In perspective, it is the vanishing line of horizontal planes.

Line, *Vertical*, the intersection of a vertical plane with the picture, passing along the station-line.

Line, *Visual*, a ray of light reflected from the object to the eye.

Line of Direction, in mechanics, the line in which motion is communicated.

Line of Light, in light and shade, a line on the curved surface of a body, such that any point taken in it will be lighter than an adjacent point taken out of it indefinitely near.

Line of Measures, a term used by Oughtred to denote the line on the primitive circle, in which the diameter of any circle to be projected falls.

In the stereographic projection of the sphere, the line of measures is that in which the plane of a great circle perpendicular to the plane of projections, and the oblique circle which is to be projected, intersect the plane of projection; or, it is the common section of a plane passing through the eye and the centre of the primitive at right angles to any oblique circle to be projected, in which the centre and pole of such circle are to be found.

Line of Shade, in light and shade, a line on the curved surface of a body, formed by a tangent surface of rays from the luminary to that of the body.

Line of Station, the intersection of a plane passing through the eye perpendicular to the picture and to the geometrical or primary plane, with the primary plane itself.

Lines, *Division*, or *Gradation of*, the various proportions into which lines may be divided; as arithmetical proportion, geometrical proportion, the squares of the distances from the beginning, and harmonical proportion.

Lines of the Proportional Compasses, are those of lines, of circles, of polygons, of planes, and of solids.

Lines on the Plain Scale, are the following, viz., of chords, of sines, of tangents, of secants, of semi-tangents, and of equal parts.

Lines of the Sector, are the following, viz., of equal parts, of lines, of chords, of sines, of tangents, of secants, of polygons, of numbers, of hours, of latitudes, of meridians, of planes, and of solids.

LINEAR PERSPECTIVE, the title given by Brook Taylor to his two celebrated essays on perspective.

LINING, the covering of the interior surface of a hollow body. When the exterior surface is covered with any thin substance, the body is said to be *cased*.

Lining, in canal making, the thickness or coat of puddle sometimes applied to the bottoms and sides of canals, to prevent them from leaking.

Lining of a Wall, a timber boarding, the edges of which are either rebated or grooved and tongued. Shops are generally lined; as are likewise water-closets, to the height of five or six feet.

Lining-out Stuff, the drawing of lines on a piece of timber, board, or plank, so as to cut it into boards, planks, scantlings, or laths.

Linings of Boxings, for window-shutters, the wooden boards or wainscoted framings which form the backs of the recesses into which the shutters are depressed. In good work, the linings are not only grooved and tongued into the inside lining of the sash-frame, but also into the framed ground around the margin of the window, and inner surface of the wall.

Linings of a Door, the internal facings of joinery surrounding the aperture of a door, placed in the thickness, and at right angles to the face of the wall, through which the aperture is made. The linings which cover the sides of the door are called *jambs*, or *jamb-linings*, and that which covers the head is called the *soffit*.

Lining of a Sash Frame, the vertical pieces of wood, parallel to the surface of the wall. In good work, the linings are always grooved to receive the tongues in the pulley-piece.

LINTEL, (from the French, *linteau*,) a beam of timber over an aperture, for sustaining the superincumbent part above, and the soffit, whether of wood or plaster, underneath.

The number of timbers required to lintel an aperture depends on the thickness of the wall: their depth, or altitudinal dimension, consists, in general, of as many inches as there are feet in the horizontal dimension of the aperture under them. If the wall be solid, without apertures above, the depth should be still greater. Lintels should be laid close to each other.

Lintels, are also a species of wall-timbers, and which, with bond-timbers and wall-plates, are all called by the general name of Fir-in-Bond.

Lintels, in some old books on carpentry, are also called *wall-plates;* but the word is not now used in this sense unless the joisting or tie-beams rest upon it; and then it is both a lintel and a wall-plate.

LIST, (from the Saxon, *lystan*,) or Listelo, (Italian.) *See* Fillet.

LISTING, in carpentry and joinery, the act of cutting away the sap-wood from one or both edges of a board.

LOBBY, (from the German *laube*,) a small hall or waiting-room, or the entrance into a principal apartment, where there is a considerable space between it and a portico or vestibule, but the length or dimensions will not allow it to be considered as a vestibule or ante-room.

LOCK, (from the Saxon, *loc*) a well-known instrument used for fastening doors, chests, &c., generally opened by a key. The lock is reckoned the master-piece in smithery; a great deal of art and delicacy being required in contriving and varying the wards, springs, bolts, &c., and adjusting them to the places where they are to be used, and to the several occasions of using them. From the various structure of locks, accommodated to their different intentions, they acquire various names. Those placed on outer doors are called *stock-locks;* those on chamber-doors, *spring-locks;* those on trunks, *trunk-locks*, *padlocks*, &c. Of these the spring-lock is most considerable, both for its frequency and the curiosity of its structure. Its principal parts are the main-plate, the cover-plate, and the pin-hole: to the main-plate belong the key-hole, top-hook, cross-wards, bolt-toe, or bolt-knab, drawback-spring tumbler, pin of the tumbler, and the staples; to the cover-plate belong the pin, main-ward, cross-ward, step-ward, or dap-ward; to the pin-hole belong the hook-ward, main cross-ward, shank, the pot or bread-bow-ward and bit.

The principle on which all locks depend is the application of a lever to an interior bolt, by means of a communication from without; so that by means of the latter, the lever acts upon the bolt, and in such a manner as to secure the lid or door from being opened by any pull or push from without. The security of locks in general therefore depends on the number of impediments we can interpose betwixt the lever (the key) and the bolt which secures the door; and these impediments are well known by the name of *wards*, the number and intricacy of which alone are supposed to distinguish a good lock from a bad one. If these wards, however, in an effectual manner, preclude the access of all other instruments beside the proper key, it is still possible for a mechanic of equal skill with the lockmaker, to open it without the key, and thus to elude the labour of the other. The excellence of locks consists in the security they afford; and as numberless schemes are continually brought forward by designing men, to elude every contrivance of the most ingenious mechanics, the invention of a durable lock, so constructed as to render it impossible for any person to open it without its proper key, has ever been an object of considerable importance.

Lock, or Weir, in inland navigation, all those works of wood or stone, or of both combined, for the purpose of confining and raising the water of a river.

The term *lock*, or *pound-lock*, more particularly denotes a contrivance, consisting of two gates, or two pairs of gates, called the *lock-gates*, and a chamber between them, in which the surface of the water may be made to coincide with that of the upper or lower canal, according as the upper or lower gates are opened; by which means boats are raised or lowered from one level to another.

Lock Paddles, the small sluices used in filling and emptying locks.

Lock Sills, the angular pieces of timber at the bottom of the lock, against which the gates shut.

Lock Weirs, or Paddle Weirs, the over-falls behind the upper gates, by which the waste water of the upper pond is let down through the paddle-holes into the chamber of the lock.

LOCKER, a small cupboard.

LOCUS (Latin), in geometry, the line described by the intersection of two lines in motion.

LOFT, a raised gallery, or room in roof.

LOG HOUSES, the huts constructed by the Americans of the trunks of trees.

LOGARITHMS, are series of artificial numbers, so arranged with reference to a set of natural numbers, that the addition of the logarithms shall correspond with the multiplication of the natural numbers belonging to them; and subtraction of logarithms answers for division; while involution, or the raising of powers, is performed by the multiplication of logarithms; and evolution, or the extraction of roots, by the division of logarithms.

LOGEUM, that part of the theatre where were placed the chorus, and others who were not to take an active part in the performance.

LOGGIA, a gallery or avenue, with open colonnade or arcade, on one or both sides.

LOGISTIC SPIRAL, or Proportional Spiral, one whose radii are in continued proportion where the radii are at equal angles; or it may be defined, a spiral whose radii everywhere makes equal angles with the tangents.

LOMBARDIC ARCHITECTURE, a style of architecture prevalent in Italy from the commencement of the seventh to the thirteenth century; it succeeded the debased Roman, and forms the intermediate link between it and the Gothic. It derives its name from the circumstance of its prevalence during the supremacy of the Lombards in Italy, and not from any notion of its invention or introduction by that people, for they had no architecture of their own, as is evident from the fact of their being compelled to employ native artists in the construction of their works. The style is indeed nothing more than a natural and gradual development of Roman architecture; and the principles involved in it had already begun to manifest themselves ere the fall of the empire. This mode of building, as well as those which preceded and followed it, owe their existence to the invention and adaptation of the arch to constructive purposes; and as the latest exhibits this new principle perfected and fully developed, so does the second manifest an improvement to and more perfect development than the earliest.

The Lombards, during whose dynasty this style prevailed, established themselves in Italy at the close of the sixth century, and remained in undisturbed possession of the country for two hundred years, when it was wrested from them by Charlemagne, who in 774 put an end to that dynasty, and united Italy to the new western empire. Italy does not seem to have suffered much, but rather the reverse, from their government, and during their possession, the arts flourished and were cultivated with greater success than during the periods either immediately preceding or following. It is certain that they gave a great impetus to building, for during the two hundred years of their sway, the northern and central portions of Italy had become studded with churches and baptisteries, amongst which we may give as examples, San Michele, Pavia; San Thomaso in limine, near Bergamo, and the baptistery at Florence. The influence of the style does not seem, however, to have been much felt at Rome, for during all this period, we know of only one Lombardic building in that city, the church of San Giovanni é Paolo.

The change of dynasty in A. D. 774, does not appear to have had any very great effect upon the arts, during the existence of the Carlovingian line, but when that line became extinct, A. D. 875, the troubles caused by the disputed claims of rival princes in the north, and by the incursions of the Saracens in the south, greatly impeded the progress of architecture. Matters were not greatly improved by the government of the German emperors, for at this time Italy was distracted with discord and civil commotions. The Carlovingian dynasty ceased, A. D. 875, and the German emperors acquired sovereignty in Italy about the middle of the tenth century, during all which time, and for half a century longer, architecture made but little or no progress. When the arts again flourished in the eleventh century, some little alterations had been introduced into the style of architecture, which were again increased and multiplied in the twelfth. Many churches were built in the Lombardic style during these two centuries, but in the next the Pointed style began to make appearance, and partially superseded its predecessor; we say partially, for the Pointed style never took very deep root in Italy, nor were the features of the Round style ever entirely effaced.

The Lombardic style may be classed under the general title of Romanesque, which comprises the debased Roman and all those styles which emanated from it, until we come to the Pointed or Gothic, including the Byzantine and Lombardic, as also the Norman and Saxon, which are essentially Lombardic in character, and may be considered as forming a subdivision of that style. The last two, however, will not be considered in the present article, but will be treated of separately.

The style under consideration, was employed almost exclusively in ecclesiastical structures; to them therefore we must look for its characteristic peculiarities. It was the adaptation of the arch to purposes of construction, as we have before stated, which gave rise to the grand revolution in classical architecture; it was the various modifications of the same feature which gave origin to the subdivisions of the new system. Of these, the Lombardic is characterized by the constant use of the semicircular arch for the purposes of construction and decoration, and more especially by the excessive employment for the latter purpose in the exteriors of buildings. The external walls were frequently almost covered by a series of arcades rising in stories one above the other, on one or more sides, and sometimes all round the building. These were either blank arcades, that is, attached to the surface of the wall, and employed solely for ornament, or else they were detached and stood out from the wall, forming a sort of gallery or portico; they were more frequent in the façades of buildings than elsewhere, in which situation may sometimes be observed five or more tiers one above the other, as at Pisa cathedral, and in other examples, in which the front is literally covered with them. There is another peculiarity observable in the arrangement of these arcades, where they run under gables or raking cornices; for in such cases the arcades follow the line of the gable, the arches rising in succession one above another; and this is effected either by raising the shafts which support the arches on steps rising with the slope of the roof, or else by elongating the shafts as they approach the apex, their bases being upon the same horizontal line. These arches are supported on shafts, either plain or ornamented, with capitals and bases, the arches likewise being with or without archivolts: sometimes the arcade itself and the spandrels are elaborately enriched. This peculiar arrangement of arcades under the gable, forms a very decided characteristic of the style, such decoration being generally found in this part of the building, if nowhere else: another position in which it is commonly seen, is round the angular or semicircular apsides which were frequent at the east end of churches in this style; but we not unfrequently find the same decoration employed on the sides of the building, covering the entire surface of wall as at Pisa cathedral. Corbel-tables at the top of the walls immediately under the roof, are also very common, and these again follow the same rule as arcades when carried under a gable; they are generally formed of a series of very small arches, sometimes interlaced, so as to present a scolloped appearance underneath. Each story of a building is generally marked by a horizontal string-course.

The face of the wall, whether ornamented with arcades or left plain, but more especially in the latter case, is generally divided into panels as it were by pilasters or buttresses, if we may so term them, being carried vertically up the face of the building without interruption, and projecting slightly in front of the general surface of the wall. Such projecting strips of wall are generally plain, but sometimes very much ornamented, as in the front of San Michele at Pavia. They are very narrow in comparison to their height, except at the angles of buildings, where they are usually wider; they reach also from the top to the bottom of the building, breaking through horizontal cornices, arcades, and anything which comes in their way, all of which are for the most part stopped by them, except the corbel table into which they merge, the surfaces of both being flush. They certainly give an appearance of strength, especially when placed at the angles, and resemble buttresses to some extent, but probably were not intended to serve their purpose; they would appear to be added rather for ornament than for any other end, as they are too shallow to afford much real strength to the walls.

Pinnacles are by no means frequent, and when present have the appearance of being set on the part they rise above, from which they are divided by horizontal string-courses; they are also very low, and look more like pedestals than pinnacles.

Windows in this style are generally very narrow, and sometimes mere slits. They consist of one, two, or more lights divided by shafts, and having semicircular heads. Where there are more than two lights, the centre one is not unfrequently higher than the others, and the whole are often included under one larger arch. At a late period in the style we find wheel or circular windows common in the west façades; they are composed of spokes radiating from a centre, connected at the further extremities by small arches, and enclosed within a moulded circle. These windows were first introduced in this style, and though adopted in later styles, may be said to be characteristic of Lombardic architecture.

While windows were sparingly introduced, and of small dimensions, and at the same time seldom enriched, so as to contribute but slightly towards the embellishment of the buildings; doorways, on the other hand, became important features, and were much decorated. The aperture was mostly plain and square-headed, but it was enclosed in a recess formed by a series of arches standing one behind and within the other, and supported upon columns. The spandrel also above the openings, was sometimes enriched with sculpture. The dressing to the doorway was occasionally so deep as to be nearly as wide at the opening. The façade had frequently a central and two side doors.

The stone used in the construction of the walls, consisted of comparatively small blocks, but these were well tooled and put together. In the latter part of the eleventh century, the walls were composed of alternate courses of materials of different colours; sometimes stone alternating with marble, and sometimes marbles of different hues being employed in the same manner. The walls were often white and black, and sometimes red and brown. During the twelfth century, brick was in general use, but still preserved the same parti-coloured appearance, by alternating with stone or marble. It is not improbable that this practice was borrowed from the Saracens.

In the eleventh century, another feature of some importance and character was introduced, which was a projecting porch of imposing appearance, some such porches consisting of two stories in height. They had a large arched aperture, and were usually covered with a vaulted roof supported on pillars, of which the two foremost rested on the back of lions or other animals, a feature which is characteristic of the style. Some of these porches are of the most elaborate description.

In the interior of churches, the peculiarities of style are not so readily observed, but are to be sought for rather in matters of detail, which are equally observable on the exterior. The arrangement is much the same as in the preceding methods of building. The plan is usually if not universally cruciform, the intersection of the two arms of the cross being covered by an octagonal or circular dome, somewhat similar to the Byzantine practice; but the shape of the cross generally differs from the Byzantine, in having one of the arms longer than the other, whereas, in the other case, the arms are all of equal length. Hence one form is termed the Greek, the other the Latin cross. Here we observe a mixture of the Byzantine and Roman styles, the dome of the one and the ground plan of the other being combined, and this is not the only particular in which the combination of the two styles is observable; the triforia, which are common in Lombardic churches, are an emanation from the Byzantine, while a great many minor features are essentially Roman. The east end is for the most part terminated in an apse, either semicircular or octagonal, as are also occasionally the aisles. Crypts are seldom omitted. The windows, as we before observed, are of small dimensions, and hence the buildings have a somewhat gloomy appearance in the interior.

In matters of detail are to be found some of the principal characteristics of the style. The shape of the arch still remains for the most part semicircular, but other forms are also found; such are the horse-shoe, the trefoiled, and stilted arch, the last being by no means uncommon, especially in the external arcades which run beneath the gable. In some instances, the stilting is effected by raising the arch on one or more blocks or abaci, placed upon the capitals of the columns, and upon these blocks again are sometimes added small heads or masks, so as to fill up the space between the arches, and continue the vertical line of the columns. Such abaci are not ungraceful, for they give a greater appearance of strength to the construction, than if the arch sprung immediately from the capital; the practice of stilting also has its advantages, in adding to the importance of small arches, which being narrow, would appear depressed and heavy if mere semicircles. Large arches were mostly semicircular, and differed from those of the preceding period, inasmuch as they sprang directly from the columns, without the intervention of entablature or architrave. It is true this practice had been introduced once or twice in the Roman examples, but it was not by any means common, and even in cases where the entablature was omitted, there was usually a square block between the arch and the capital. Two or more arches are frequently included under one common arch, the smaller ones being separated by small shafts: the same arrangement is not uncommon in Byzantine architecture. Arches were very often perfectly plain, without archivolt mouldings of any kind, but not unfrequently finished with an archivolt, which consisted either of a simple moulding enclosing a plain band round the arch, or else divided into faciæ, and otherwise enriched. Arched corbel-tables were very frequently employed, and the arch used for every purpose of decoration. Compound arches, consisting of a series, placed in recession one behind and projecting beyond the other, are frequent in this style.

The bases of pillars were sometimes mere blocks, round at the summit, and square at the sides, but frequently moulded in rude imitation of the Attic base. Sometimes, as we observed in speaking of projecting porches, the pillars were supported on figures of animals, and this peculiarity is almost confined to this situation. but we have examples of it in other positions; at Worms' cathedral, an entire colonnade is supported in this manner. It has been suggested that the use of this kind of base was occasioned by the employment of materials and fragments taken from the ruins of more ancient edifices. where columns being found too short for their intended situation, were raised or stilted up by being set on other fragments, for which purpose remains of sculpture may have been adopted, either because they chanced to be at hand, or because considered more ornamental, and as adding richness to the column itself, and it is supposed that this irregularity, thus occasioned in the first instance, grew by degrees to be a matter of taste, and was adopted out of choice. This supposition is ingenious, and not without some show of reason on its side; but if such were indeed the case, it would seem strange that this practice was not adopted earlier, for it is a characteristic of late work, and seems to be almost peculiar to the projecting porches, which were not introduced for two centuries after the commencement of Lombardic architecture. The fact of such columns being almost invariably found in this situation, and seldom in any other, would give some weight to the supposition which discovers their origin and use in symbolism, the two lions being placed at the entrance as the guardians of the church, or else as representing the strength and vigilance of the church.

The shafts were of various shapes and proportions, they are by far the most frequently cylindrical, without being tapered, but some few examples of tapered shafts are to be found, which are probably of an early date. Instances of fancifully-shaped and decorated shafts are not uncommon, especially in the smaller columns, or such as are applied to merely ornamental purposes. Of these, some are polygonal in plan, some fluted or reeded, some twisted or cut into spiral grooves or mouldings, of which some consists of more than one slender shaft rising from a common base, and twisted round each other as they rise, and others of a single shaft twisted like a spiral: other examples again are zigzagged horizontally, and sculptured in various devices. Tall slender shafts are not unfrequently banded in the middle.

Capitals are of equal diversity, and sometimes there are scarcely to be found two capitals of the same design in one building. They were frequently formed of foliage; and these, as regards the general mass and outline, and also the decoration, bear some resemblance to the Corinthian: the foliage, however, is usually of a more stiff and formal character than the classic, more heavy, and not so graceful. Scroll-work is frequently introduced, as a means of ornamentation for capitals; monsters, too, and grotesque and other images, are so commonly used for this purpose, as to become characteristic of the style. Some capitals, however, are nearly plain, and these are often in the shape of an inverted cone, cut so as to present four flat faces, which are occasionally more or less ornamented. Monstrous imagery was very prevalent in this and other situations, until the eleventh century, when a more classical taste prevailed, and figures of dragons and demons gave way to sculpture of a more graceful design; this remark applies, however, only to the south of Italy.

The bulk of columns had no reference to the height, as we find pillars of all proportions, from the low, stunted shaft to the long, slender moulding, as it may be termed; the pilasters on the external walls are often so slender, in proportion to their height, as to have the appearance of mere strips; and half-columns of a similar proportion are not unfrequently carried up the internal walls, to support the vaulting. Columns are often single, especially when massive, but they are not unfrequently doubled in breadth or depth, and sometimes quadrupled. Compound piers, in lieu of single columns, are of very common occurrence, and serve to distinguish this from preceding styles; such arrangement is very usual where great strength is required, and clustered columns are not unfrequently placed against walls. Nook-shafts are common in doors, windows, and other apertures, as are also edge-shafts.

Buttresses are not employed in this style, unless indeed we choose to apply the term to the slightly projecting strips or pilasters which appear to divide the walls into panels.

There is one feature common to Lombardic churches, of which we have not taken notice; it is the campanile, or bell-tower, which was a common and picturesque addition. There is a remarkable difference in the design of these towers in the different parts of Italy; at Ravenna they are cylindrical, with a horizontal string-course at each floor, some of which are lighted by single round windows, others by clusters of two or three: they have low roofs. At Venice all the steeples are square, and without string-courses, each side being divided into two or three panels running uninterruptedly from base to top. At Rome such towers are square, but have horizontal string-courses, the divisions or stories between each two having a number of small arches with or without columns. These towers have low roofs.

Having now given a rapid sketch of the main features and peculiarities of the style under consideration, it will be well to give a short description of a few of the more remarkable examples executed in that style; and in this division, as well as in the preceding, we must express ourselves greatly indebted to the standard works of Gally Knight and Hope, on the subject, to which works we would also refer the reader for more detailed information and more copious illustrations. The former work is beautifully got up.

The church of San Michele, at Pavia, is of the basilican plan, and is provided with transepts; it measures 189 feet in length by 81 in extreme width, the nave being 45 feet wide. The chancel has a semicircular apse, and is approached by several steps, and beneath it is a crypt, a very common addition to Lombardic churches. Above the intersection of nave and transept rises a Byzantine cupola. "The walls of the building are of stone, massive and thick, and on the exterior are ornamented, with small open galleries, which follow the shape of the gable in front, and crown the semicircular apse. The portals are covered with imagery, nor are the ornaments confined to the portals. Bands enriched with imagery are carved along the whole of the front, and modillions are let into the walls. The windows are round-headed, and are divided by small pillars. The drum of the dome is enriched externally with two tiers of arcades.

In the interior, the arches on either side of the nave are supported by compound piers, all the capitals of which are enriched with capitals and symbols. Above the aisles, on each side of the nave, is a triforium, and, above it, the roof is vaulted in stone, but the pilasters which run up to support the vault are of later character than the older portions of the building, and confirm the impression suggested by the nature of the roof itself, that the present vaulted roof must have been substituted for an older roof of wood.

The plan of San Thomaso in limine is circular, and on the exterior, the walls are divided into compartments by pilasters, and have an arcaded corbel-table under the roof. A rectangular portion projects from the circle, and is terminated by a semicircular apse, which is decorated in a similar manner to the other part of the church. Above the circular part rises a dome, which is not supported by pendentives, but by a drum or circular wall rising above the roof: the whole is surmounted by a cupola. The windows throughout are small and insignificant. Internally, the drum of the dome is supported on eight pillars, which are simple, round, and stunted with capitals grotesquely carved; the arches spring immediately from the capitals. The walls are very thick.

The church of San Ambrogio, Milan, is a very good example. The plan is basilican, the arcade of the nave being supported on compound piers, above which runs an arcaded corbel-table, and above this again a triforium, the arches being supported on very stunted compound pillars. The roof is vaulted with the pointed arch, but this is of late date. The capitals of the arches are almost, in all cases, foliated, and there is considerable freedom from the monstrous imagery usually apparent. This is one of the few churches which retains the atrium, which consists of an arcade resting on a series of compound pillars with capitals, and covered with a roof, under which is an arcaded corbel-table.

S. Geron's church presents a somewhat curious plan, consisting of a vast circular vestibule, with a rectangular nave behind it, terminating in a semicircular apse, on each side, and a little in front of which is a campanile. Above the circle rises an octagonal cupola, the supporting pillars of which are prolonged upwards in ribs, which, centering at the summit, meet at one point. Opposite the entrance, in the interior, are steps leading to the church, at the further end of which are steps leading to the apse or altar. In the baptistery and vestry are steps leading to the area between the two high square towers, and to the roof of the apse, over the semicircular east end, which is belted round, as well as the cupola, by galleries with small arches, and pillars on a panelled balustrade. The entrance-door at the vestibule has a square lintel, low pediment, and pointed arch, which are elegant, and the crypts show some remains of handsome mosaics; but the porphyry columns were carried away by the French. Several of the finishings in the interior are pointed.

The Cathedral of Pisa is a very remarkable building, erected during the latter half of the eleventh century; and although it presents to us features of the Lombard style on the exterior, in the interior the details approach more nearly to the Roman, the columns being all simple, and finished with Corinthian caps; the style, too, is throughout the interior more simple than that of Lombardic buildings in general. The plan is that of a Latin cross, having two aisles on each side of the nave transepts, and a cupola over the intersection. The colonnade on each side of the nave consists of 12 columns of a single block of marble, and of 24 feet 10 inches in height, and 2 feet 3 inches in diameter, with Corinthian capitals skilfully worked. The total height, including capitals and base, is 30 feet 10 inches. An architrave is carried all along the nave above the arches, which spring from the capitals, and above this is a triforium consisting of a series of arcades, each arch containing two arched apertures divided by a shaft with Corinthian capital. Above the triforium is a clere-story of semicircular-headed windows. The four aisles have also Corinthian columns, but they are much smaller, and raised on plinths. The walls are composed of alternate courses of red and white marble. The width of nave and four aisles is 106 feet, of the nave 41 feet, the total internal length 311 feet, and the width across the transepts 237 feet 4 inches; the width of the transepts, with its aisles, 58 feet, height of nave 91 feet, of transept 84, of aisles 35 feet. In the centre of the nave are four piers, from which rise four large arches supporting the elliptical cupola.

On the exterior, the entire church is raised upon a series of steps which gives increased grandeur to its magnificent elevation. The width of the western façade is no less than 116 feet, and its height 112 feet. It comprises five stories, of which the first or lowermost consists of seven arches supported by six Corinthian columns and two pilasters, the middle arch being larger than the others. There are three entrances or doorways in the central and alternate arches. The second story contains twenty-one arches supported by twenty columns and two pilasters. At the third story the façade contracts where the two aisles finish, and form two lateral inclined planes, whence towards the centre are columns with arches on them as below, but the columns on each side under the inclined planes gradually diminish in height. The fourth story is contracted, and contains only eight arches similar to those below. The fifth forms the pediment, and consists likewise of eight arches, the columns which support them gradually diminishing in height as they recede from the centre. The sides all round the building have two orders of pilasters one above the other. The roof of the nave is supported externally by a wall decorated with columns and arches; and the drum of the cupola is enriched with eighty-eight columns and arches, each of which is surmounted by a pediment.

The Duomo Modena is a good specimen of the Lombard style, and belongs to the close of the 11th century. "External arcades ornament both the west end and the great semicircular apse. In the interior, monsters and grotesque images are still retained in the capitals of some of the pillars. But a feature which is not found in old Lombard churches, may be remarked here, in a large projecting porch two stories in height, which advances before the principal entrance; and in the lions, on the backs of which the pillars of the porch repose. Though projecting porches were an essential part of the primitive churches, they seem to have been abandoned

under the Lombard dynasty, and not to have been resumed till the 11th century, when they became universal. The lions are symbolical. They were intended to represent the strength and vigilance of the church. At a later period, the animals which were introduced in the porches, often represented the arms of the state to which the building belonged." "On either side of the nave of this cathedral are galleries. Under the chancel there is a lofty crypt, the chancel being approached by several steps, as at San Miniato and other churches."

The campanile is 315 feet high, and is one of the four towers of which the north of Italy has reason to be proud. The date is uncertain, but the tower must have been complete in the early part of the 13th century. The upper portion is of later date.

S. Zenone, Verona, was finished in the latter part of the 12th century, and forms a fair specimen of the style. The plan is that of a Latin basilica, without transepts. The walls are constructed of alternate courses of marble and brick, but the façade is entirely of marble. The entire face of the building is divided vertically into bays by long strips or pilasters, and horizontally by arched corbel-tables and arcades. The façade is remarkable for containing one of the earliest specimens of wheel-windows, as also for a very rich projecting porch, profusely decorated with sculpture. There is a good bas-relief within the portal over the door. The pillars as usual rest on the backs of lions. In the interior the nave is divided from the aisles by an arcade, each bay containing two arches supported by a central single shaft, and by compound shafts at the sides, so that pillars and piers alternate in the length of the arcade; the capitals of the single shafts still retain the monstrous imagery of an earlier period. There is no triforium, and the clere-story is lighted by small windows. There is a campanile, of somewhat later date.

San Michele, Lucca, is a very rich example of the Lombard style, but although the building itself is of early date, the enrichments are much later. The principal feature is the enriched façade which was added in 1188 by Guidetto. It is somewhat similar to the façade of Pisa cathedral, but of a more florid description. The lower story is ornamented with attached arcades, and above this are four tiers of galleries with detached arcades, the shafts, capitals, archivolts, and spandrels being enriched with elaborate carving. In the third gallery is a rose window. The sides of the building contain two tiers of arcades, of which the upper one was added at a late period, and is of very good design.

For further particulars on this subject, we must refer to Saxon, Norman, and Romanesque Architecture.

LONGIMETRY, (from the Latin, *longus*, length, and Greek, *μετρέω*, *to measure*,) the art of measuring lengths, accessible and inaccessible.

LOOP HOLES, the small narrow windows in castellated buildings, from which to discharge missiles. They were usual near entrances, and sometimes on the merlons of the battlement. They are sometimes in the shape of a cross, and usually have a circular enlargement at top and bottom, and sometimes in the middle. When splayed, they were also used to give light.

LORME, PHILIBERT DE, an eminent French architect, born at Lyons, in the early part of the sixteenth century. He went to Italy when he was but fourteen years of age, to study the art for which he seemed to have a natural taste, and there his assiduity attracted the notice of Cardinal Cervino, afterwards Pope Marcellus II., who took him into his palace, and assisted him in his pursuits. He returned to France in 1536, and was the means of banishing the Gothic taste in buildings, and substituting in its place the Grecian. He was employed by Henry II., for whom he planned the Horseshoe at Fontainebleau, and the châteaus of Anet and Meudon. After the demise of that king, he was made inspector of the royal buildings by Catharine de Medicis; and, under her direction, he repaired and augmented several of the royal residences, and began the building of the Tuileries. In 1555 he was created counsellor and almoner in ordinary to the king; and, as a recompense for his services, he was presented with two abbacies. These honours, it is said, made him arrogant, which occasioned the poet Ronsard to satirize him in a piece, entitled *La Truelle Crossée*, or "The Croziered Trowel." De Lorme took his revenge, and shut the garden of the Tuileries against him; but the queen took part with the poet, and severely reprimanded the reverend architect. De Lorme died in 1577. He published *Dix Livres d' Architecture*, and *Nouvelles Inventions pour bien Bâtir et à petits Frais*.

LOUVRE, a turret or lantern on the top of roofs, open to the interior of the building, and also to the external air by means of apertures in the sides. They were formerly used for carrying off the smoke, when the hearth was in the centre of the hall; probably also for ventilation in general.

LOZENGE, (from the French,) a quadrilateral figure of four equal sides with oblique angles.

Lozenge Moulding, a moulding in the shape of a lozenge, common in Norman work.

LUCULLEUM MARMOR, a hard stony kind of marble, of a good fine black, and capable of an elegant polish, but little regarded from its want of variegations. When fresh broken, it is seen to be full of small but very bright shining particles, appearing like so many small spangles of talc. It had its name from the Roman consul Lucullus, who first brought it into use in that city. It is common in Italy, Germany, and France. We have much of it imported, and our artificers call it the *Namur marble*; the Spaniards call it *marble of Buga*.

LUFFER BOARDING, a series of boards placed in an aperture so as to admit air into the interior, but to exclude rain. It is frequently used in lanterns. A very celebrated one is that upon the church of St. Martin Outwich, in Bishopsgate street, opposite the City of London Tavern. The plan is circular, and the apertures four in number, with pilasters between them.

LUNE, or Lunula, (from the Latin, *luna*, the moon,) the space between two unequal arcs of a circle.

LUNETTE, (French,) apertures in a cylindric, cylindroidic, or spherical ceiling, the head of the aperture being also cylindric or cylindroidic, as the upper lights in the nave of St. Paul's Cathedral.

LUTHERN, (from the Latin *lucerna*, light or lantern,) a kind of window over the cornice in the roof of a building, standing perpendicularly over the naked of the wall, and serving to illuminate the upper story.

The French architects distinguish them into various forms, as square, semicircular, bull's eyes, flat arches, and Flemish.

LYCH-GATE, or Lich-Gate, a covered gate at the entrance of church-yards, at which the bier was rested.

LYING PANELS, those in which the fibres of the wood are placed horizontally.

M.

MACHICOLATIONS, openings made through the roofs of portals to the floor above, or in the floors of projecting galleries, for the purposes of defence, by pouring through them boiling lead, pitch, &c., upon the enemy. In the galleries they are formed by the parapet, or breast-work, being set out on corbels beyond the face of the wall, the spaces between that open throughout are the machicolations. From its striking appearance, the corbelled parapet was frequently used where machicolations were not required for the purposes of defence, and the apertures so called were omitted. Machicolations do not appear to have been used earlier than the end of the twelfth century.

MACHINE, signifies anything used to augment or to regulate moving forces or powers; or it is any instrument employed to produce motion, in order to save either time or force. The word is of Greek origin, and implies *machine*, *invention*, *art;* it is therefore properly applied to any agent, in which these are combined, whatever may be the strength or solidity of the materials of which it is composed. The term *machine* is, however, generally restricted to a certain class of agents, which seem to hold a middle place between the most simple tools or instruments, and the more complicated and powerful engines; this distinction, however, has no place in a scientific point of view; all such compound agents being generally classed under the term *machines*, the simple parts of which they are compounded being termed MECHANICAL POWERS.

Machines are again classed under different denominations, according to the agents by which they are put in motion. the purposes they are intended to effect, or the art in which they are employed, as—*Electric*, *Hydraulic*, *Pneumatic*, *Military*, *Architectural*, &c., Machines.

The maximum effect of machines, is the greatest effect which can be produced by them. In all machines, working with a uniform motion, there is a certain velocity and a certain load of resistance that yield the greatest effect, and which are therefore more advantageous than any other. A machine may be so heavily charged, that the motion resulting from the application of any given power will be only sufficient to overcome it; and if any motion ensue, it will be very trifling, and the effect small. Again, if the machine is very lightly loaded, it may give great velocity to the load; but, from the smallness of its quantity, the effect may still be very considerable, consequently between these two loads there must be some intermediate one that will render the effect the greatest possible. And this is equally true in the application of animal strength, as in machines, and both have been submitted to strict mathematical investigation, the former being founded on numerous experiments and observations on the best method of applying animal strength, and the measure of it when applied in different directions.

MADERNO, CHARLES, an eminent Italian architect, born at Bissona, in Lombardy, in 1556. He went at a very early age to Rome, where his uncle, Dominico Fontana, was at that time in full employment as an architect. His genius for sculpture became manifest, and he was placed with an artist in that branch of the fine arts. His progress in modelling was such as led his uncle to confide to him the management of some buildings then in hand, which he executed with so much skill, that he was advised to devote himself entirely to architecture. On the death of Sixtus V., Maderno was appointed to design and execute the magnificent tomb for his interment. The public works which were carried on under Clement VIII. were chiefly committed to the care of this artist, and so high was his reputation in the succeeding pontificate, that, on the succession of Paul V. in 1605, he was appointed to finish the building of St. Peter's; his plans being preferred to those of eight competitors, and the work was placed under his direction. He was afterwards employed upon the pontifical palace on the Quirinal mount. Another work, for which he is celebrated, was the raising a fine fluted column found in the ruins of the Temple of Peace, and placing it on a marble pedestal in the square of St. Maria Maggiore. His genius was by no means confined to architecture, he was sent by the pope on a commission to examine the ports of the Ecclesiastical States, and afterwards surveyed the lake of Perugia, and surrounding country, in order to divert the inundations of the river Chiana. He was consulted upon most of the great edifices undertaken in his time in France and Spain, as well as in the principal towns of Italy. His last work of consequence was the Barberini palace of Urban VIII., which he did not live to complete. He died of the stone in 1629, when he had attained to the age of seventy-three. He had seen ten popes, by most of whom he had been regarded with favour.

MAGAZINE, *Powder*, a building constructed for keeping large quantities of powder. These magazines were formerly towers erected in the town-walls; but many inconveniences attending this situation of them, they are now placed in different parts of the town. They were at first constructed with Gothic arches; but M. Vauban, finding these too weak, constructed them in a semicircular form, of the following dimensions: 60 feet long within, and 25 broad; the foundation 8 or 9 feet thick; and 8 feet high from the foundation to the spring of the arch; the floor about two feet from the ground, to prevent damp; and consequently six feet for the height of the story.

The thinnest part, or haunch of the arch, is three feet thick, and the arch made of four lesser ones one over the other, the outside of the whole terminating in a slope to form the roof; from the highest part of the arch to the ridge is eight feet, which makes the angle somewhat greater than ninety degrees; the two wings, or gable ends, are four feet thick, raised a little higher than the roof, as is customary in other buildings: the foundations are five feet thick, and as deep as the nature of the ground required. The piers, or long sides, are supported by four counterforts, each six feet broad, and four feet long, and their interval twelve feet; between the intervals of the counterforts are air-holes, in order to keep the magazine dry, and free from dampness; the dices of these air-holes are commonly a foot and a half every way, and the vacant round them three inches, the insides and outsides being in the same direction. The dices serve to prevent an enemy from throwing fire in to burn the magazine; and, for a farther precaution, it is necessary to stop these holes with several iron plates, that have small holes in them like a skimmer, otherwise fire might be tied to the tail of some small animal, and so drive it in that way; this would be no hard matter to do, since, where this precaution had been neglected, egg-shells have been found within, that have been carried there by weasels.

To keep the floor from dampness, beams are laid lengthwise, and to prevent these beams from being soon rotten, large stones are laid under them; these beams are eight or nine inches square, or rather ten high and eight broad, which is better, and eighteen inches distant from each other; their interval is filled with dry sea-coal, or chips of dry stones; over these beams are others laid crosswise, four inches broad and five high, which are covered with two-inch planks.

M. Belidor would have brick walls made under the floor, instead of beams, and a double floor laid on the cross-beams; but the plan above described is, we think, preferable.

To give light to the magazine, a window is made in each wing, which is shut up by two shutters of two or three inches thick, one within and the other without it; that which is on the outside is covered with an iron plate, and is fastened with bolts, as well as that on the inside. These windows are made very high, for fear of accidents, and are opened by means of a ladder, to give air to the magazine in fine dry weather.

There is likewise a double door, made of strong planks, the one opens on the outside, and the other within; the outside one is also covered with an iron plate, and both are locked by a strong double lock; the store-keeper has the key of the outside, and the governor that of the inside: the door ought to face the south nearly, if possible, in order to render the magazine as light as can be, and that the wind blowing in may be dry and warm. Sometimes a wall of ten feet high is built round the magazine about twelve feet distant from it to prevent anything from approaching it without being seen. Mr. Muller has proposed some alterations, by way of improvement, in M. Vauban's construction.

If large magazines are required, the piers or side walls which support the arch should be ten feet thick, seventy-two feet long, and twenty-five feet high; the middle wall, which supports the two small arches of the ground floor, eight feet high, and eighteen inches thick, and likewise the arches: the thickness of the great arch should be three feet six inches, and the counterforts, as well as the air-holes, the same as before. Magazines of this kind should not be erected in fortified towns, but in some inland part of the country near the capital, where no enemy is expected.

It has been observed, that after the centres of semicircular arches are struck, they settle at the crown and rise up at the haunches; now, as this shrinking of the arches must be attended with ill consequences, by breaking the texture of the cement after it has been partly dried, and also by opening the joints of the voussoirs at one end, Dr. Hutton proposed to remedy this inconvenience, with regard to bridges, by the arch of equilibration; and as the ill effect is much greater in powder magazines, he also proposed to find an arch of equilibration for them also; and to construct it when the span is twenty feet, the pitch or height ten, which are the same dimensions as those of the semicircle, the inclined exterior walls, at top, forming an angle of 113°, and the height of their angular point above the top of the arch equal to seven feet; this curious question was answered, in 1775, by the Rev. Mr. Wildbore, and the solution of it may be found in Hutton's *Miscellanea Mathematica*.

MAHOGANY, the beautiful reddish-brown coloured wood, of which household furniture is now chiefly made. It is a native of the warmest parts of America and the West Indies. It thrives in most soils in the tropical climates, but varies in texture and grain according to the nature of the soil. On rocks it is of a smaller size, but very hard and weighty, of a close grain, and beautifully shaded; while the produce of the low and richer lands is observed to be more light and porous, of a paler colour, and open grain; and that of mixed soils, to hold a medium of both.

The mahogany-tree is stated to be of very rapid growth, and makes a very fine appearance. Its trunk often exceeds 40 feet in length, and 6 feet in diameter. The Honduras mahogany is cut down at two periods in the year; that is, at Christmas, and in the autumn; the trees are cut off at about 12 feet from the ground, the workmen having a stage to work upon. The trunk furnishes wood of the largest dimensions; but for ornamental purposes, the branches are preferable, the grain in them being closer and the veins more variegated. Mahogany was first brought to London in the year 1724.

In a dry state, mahogany is very durable, and not subject to worms. It does not last long when exposed to the weather. It is a kind of wood that would make excellent timbers for floors, roofs, &c., but on account of its price its use is chiefly confined to furniture and doors for rooms, for which purposes it is the material most in use. It is sometimes used for some parts of window-frames, and for sashes, but from its not standing the weather well, it is not so fit for these purposes. It has also been extensively used in the framing of machinery for cotton-mills, &c.

The variety called Spanish mahogany, is imported from Cuba, Jamaica, Hispaniola, and some other of the West India islands, and in smaller logs than the Honduras. The size of the logs is in general about 20 to 26 inches square, and about 10 feet in length. The Spanish mahogany is close-grained and hard, generally of a darker colour than Honduras; free from black specks, and sometimes strongly figured; and its pores appear as if chalk had been rubbed into them.

The Honduras mahogany is imported in logs of a larger size, that is, from 2 to 4 feet square, and 12 or 14 feet in length; sometimes planks have been got 6 or 7 feet wide. The grain of the Honduras kind is generally very open, and often irregular, with black or gray spots. The veins and figures are frequently very fine and showy; the best kind is that which is most free from gray specks, and of a fine golden colour. It holds with glue better than any other wood.

The cohesive force of a square inch of Spanish mahogany is 7560 pounds, and of Honduras mahogany 11475 pounds.

The weight of the modulus of elasticity of mahogany, is 1,255,500 pounds, for a square inch for Spanish; and 4,593.000 for Honduras. The weight of a cubic foot of mahogany is from 35 to 53 pounds. Representing the—

Strength of oak by 100, that of Span. mahog. is	67; of Honduras is	96.
Stiffness of oak by 100,	73;	93.
Toughness of oak by 100	61;	99.

MAIN COUPLES. *See* Couples.

MALLET, (from the Latin *malleus*) a large kind of hammer, made of wood, much used by artificers who work with a chisel, as stone-cutters, masons, carpenters, joiners, &c.

MANSARD ROOF. *See* Curb Roof. The word is derived from Mansart, the inventor.

MANSART, FRANCIS, an eminent French architect, born at Paris in 1598, was son of the king's carpenter, and received those instructions which led him to eminence as an architect, from the celebrated Gautier; but for the high rank to which he attained in his profession, he was indebted to the force of his own genius. His taste and judgment, united with a fertile imagination and sublime ideas, enabled him to equal the greatest masters in his plans; he was, however, too apt to alter his designs, and even, in aiming at perfection, to demolish what was already not only well done, but scarcely to be surpassed. This character was the means of preventing him the honour of finishing the fine abbey of Val-de-Grace, founded by Anne of Austria, which he had commenced in 1645, and which, when raised to the first story, the queen put into other hands, to prevent its destruction by him who had reared it. He was employed by the president Longueil to build his great Château des Maisons, near St. Germain's; and, when a considerable part of it was erected, he pulled it down again, without acquainting the master with his intentions. After this, it is to his credit, that he finished it in a very noble style, and it is reckoned one of the finest architectural monuments of that age. A better idea cannot be given of his character than this: Colbert applied to him for a design of the principal front of the Louvre, and Mansart produced many sketches of great beauty, but when told he must fix upon one to be invariably followed, if approved, he declined the business. His last work was the portal of the Minims in the Place Royale; he died in 1666, at the age of sixty-nine. He is known as the inventor of a particular kind of roof, called the *mansarde.* He had a nephew, Jules-Hardouin, who was also eminent in his profession as an architect, and was educated by his uncle. He became a favourite of Louis XIV., and was enabled, under his patronage, to realize a large fortune. Some of his principal works were the Château de Clugny, the palace of Versailles, the house of St. Cyr, the gallery of the Palais Royal, the places of Louis-le Grand and des Victoires, and the dome and finishing of the Invalides. He died suddenly at Marly, in the year 1708.

MANSION, (from the Latin *mansio*, an inn) a dwelling-house, or habitation, especially in the country. Among the ancient Romans, *mansio* was a place appointed for the lodging of the princes, or soldiers, in their journey; and in this sense we read *primum mansionem*, &c. It is with us most commonly used for the lord's chief dwelling-house within his fee, otherwise called the capital messuage, or manor-place: and mansion-house is taken in law for any house or dwelling of another, in case of committing burglary, &c.

MANTLE-TREE, or MANTEL-TREE, (from the Welsh) the lower part of the breast of a chimney; formerly consisting of a piece of timber, laid across the jambs, for supporting the breastwork; but, by a late act of parliament, chimney-breasts are not to be supported by a wooden mantle-tree, or turning piece, but by an iron bar, or brick or stone arch.

MARBLE, a variety of lime-stone, of so compact a texture as to admit of a beautiful polish. The different kinds of marble are infinite, therefore any attempt to describe them in detail would necessarily occupy much more space than we can allow to this article: they all agree in being opaque, excepting the white, which becomes transparent when cut into thin pieces. In the Borghese palace, at Rome, are some specimens of marble exquisitely white, so flexible, that if poised horizontally on any resisting body placed on a plane, a salient curve will be formed by the two ends touching the plane. A similar property is acquired in a small degree by statuary marbles exposed to the action of the sun, which no doubt weakens the adhesion of the particles. It is this which frequently occasions the exfoliation of projecting parts, and the artist would do well to ascertain, by experiments, the kind of marble that has the least tendency to this desiccation.

The greater part of the quarries, which supplied the ancients with marble, are entirely unknown; in the Napoleon Museum are preserved the most exquisite specimens of many of them, the grand repositories of which are consigned to oblivion, unless chance should guide some penetrating eye to their dark recesses.

Da Costa, in his "Natural History of Fossils," gives a large catalogue of marbles, disposed in a methodical order, which we shall follow in the following brief notices of this extensive subject:—

Division I.—Marbles of one plain colour.

Section 1.—Black marbles. Most of these contain bitumen, and are fetid when bruised.

Examples.—The Namur Marble, the marble of Ashford in Derbyshire, Dent in Yorkshire, near Crickhowell, Tenby, Kilkenny, &c. The marble, anciently called Marmor Luculleum, and now Nero Antico.

Section 2.—White Marbles.

Examples.—The marble of Poros, in which the Laocoon and Antinous are executed; the Carrara marble, of finer grain, much used in modern sculpture; the Skye marble, noticed by Dr. MacCulloch; that of Inverary, Assyut, Blair Athol, &c.

Section 3.—Ash and gray marbles.

Examples.—A beautiful marble, of compact oolitic texture, at Orelton, near the Clee Hills, in Shropshire, deserves mention.

Section 4.—Brown and red marbles.

Examples.—The Rosso Antico, a rival to which, at least in colour, has been found on the estate of the Duke of Devonshire, near Buxton. The mottled brown marble of Beetham Fell, near Milnthorp, is of good quality.

Section 5.—Yellow marbles.

Example.—The Giallo Antico. Siena marble, also dug at Mafra, near Lisbon. That used in ancient Rome is said to be from Numidia.

Section 6.—Blue marbles.

Example.—Near St. Pons, in Languedoc.

Section 7.—Green marbles.

Example.—The Marmor Lacedæmonicum of Pliny. It is dug near Verona.

Division II.—Marbles of two colours.

Section 1.—Black marbles, variegated with other colours.

Example.—Near Ashburton, in Devonshire; Torbay, in the same county; Bianco, or Nero Antico, the African Breccia of the ancients; Giallo e Nero Antico.

Section 2.—White marbles, variegated with other colours.

Example.—Marble imported from Italy. Marbles of this general character occur in Siberia; at Plymouth; at Killarney; in Sweden, &c.

Section 3.—Ash and gray marble, variegated with other colours. These are very numerous, and occur in various parts of Europe.

Section 4.—Brown and red marbles, variegated with other colours.

Section 5.—Yellow marbles, variegated with other colours.

Section 6.—Green marbles, variegated with other colours.

Example.—Egyptian marbles. The Marmor Tiberium and Augustum of Pliny; some Verde Antico, as that dug near Susa, in Piedmont; the beautiful marble of Anglesey (called Mona marble); the marble of Kolmerden, in Sweden.

Division III.—Marbles variegated with many colours.

Example.—Some of the Plymouth marble; the beautiful brocatello, or brocade marble, of Italy and Spain.

Marbles containing shells, corals, and other extraneous bodies.

In this division of marbles, the British islands are rich. Some of the Plymouth, Ashburton, and other Devonian limestones, are extremely beautiful, from the abundance of fine corals exquisitely preserved in them; the crinoidal marbles of Flintshire, Derbyshire, and Garsdale in Yorkshire, are elegant examples of the carboniferous limestone; the shell marbles of Rance, Northamptonshire, Buckingham, Whichwood Forest, Stamford, Yeovil, may be noticed from the oolitic rocks; that of Petworth and Purbeck, from the Wealdon strata, has been extensively used by the architects of the middle ages. In general, the working of the English marbles is costly, and their use limited.

Marble, *Polishing of.* The art of cutting and polishing marble was, of course, known to the ancients, whose mode of proceeding appears to have been nearly the same with that employed at present; except, perhaps, that they were unacquainted with those superior mechanical means which now greatly facilitate the labour, and diminish the expense of the articles thus produced.

An essential part of the art of polishing marble is the choice of substances by which the prominent parts are to be removed. The first substance should be the sharpest sand, so as to cut as fast as possible, and this is to be used till the surface becomes perfectly flat. After this the surface is rubbed with a finer sand, and frequently with a third. The next substance after the finest sand is emery, of different degrees in fineness. This is followed by the red powder called tripoli, which owes its cutting quality to the oxide of iron it contains. Common ironstone, powdered and levigated, answers the purpose very well. This last substance gives a tolerably fine polish. This, however, is not deemed sufficient. The last polish is given with putty. After the first process, which merely takes away the inequalities of the surface, the sand employed for preparing it for the emery should be chosen of a uniform quality. If it abounds with some particles harder than the rest, the surface will be liable to be scratched so deep as not to be removed by the emery. In order to get the sand of uniform quality, it should be levigated and washed. The hard particles, being generally of a different specific gravity to the rest, may by this means be separated. This method will be found much superior to that of sifting. The substance by which the sand is rubbed upon the marble is generally an iron plate, especially for the first process. A plate of an alloy of lead and tin is better for the succeeding processes, with the fine sand and emery. The rubbers used for the polishing, or last process, are of coarse linen cloths, such as hop-bagging, wedged tight into an iron plane. In all these processes, a constant supply of small quantities of water is absolutely necessary.

The sawing of marble is performed on the same principle as the first process of polishing. The saw is of soft iron, and is continually supplied with water and the sharpest sand. The sawing, as well as the polishing of small pieces, is performed by hand. The large articles, such as chimney-pieces and large slabs, are manufactured by means of machinery, working by water or steam.

Several patents have been taken out for sawing and polishing marble. In 1822, Sir James Jelf patented a combination of machinery for cutting any description of parallel mouldings upon marble slabs, for ornamental purposes; in which tools, supplied with sand and water, are made to traverse to and fro. Mr. Tullock obtained a patent, in 1824, for improvements in machinery for sawing and grooving marble; and in 1829, Mr. Gibbs, also, for an invention for working ornamental devices in marble.

MARGIN (from the Latin *margo*) of a door or shutter, the surface surrounding the frame between the moulding and the extreme arris which terminates the face.

MARQUETRY (from the French), inlaid work; a curious kind of work, composed of pieces of hard fine wood, of different colours, fastened in thin slices on a ground, and sometimes enriched with other matters, as tortoise-shell, ivory, tin, and brass.

There is another kind of marquetry made, instead of wood, of glasses of various colours; and a third, where nothing but precious stones and the richest marbles are used; but these are more properly called *mosaic work.* The art of inlaying is very ancient, and is supposed to have passed from the east to the west, among the spoils brought by the Romans from Asia. Indeed, it was then but a simple thing; nor did it arrive at any tolerable perfection till the fifteenth century, among the Italians. It seems finally to have arrived at its height in the seventeenth century, among the French.

MASONRY, the art of preparing stones, so as to tooth or indent them into each other, and form regular surfaces, either for shelter, convenience, or defence: as the habitations of men, animals, the protection and shelter of goods, &c.

The chief stone used in London is Portland, which comes from the island of Portland, in Dorsetshire. It is used for public edifices, not only in ornaments, mouldings, and strings, but in all the exterior parts. In private buildings, where brickwork predominates, it is used in strings, window-sills, balusters, steps, copings, &c. It must be observed, however, that under a great pressure it is apt to splinter or flush at the joints, and for this reason the joints cannot be made so close as many other kinds of stones will admit of. When it is recently quarried it is soft, and works easily, but acquires great hardness in length of time. The cathedral of St. Paul, Westminster-bridge, and almost every public edifice in London, are constructed wholly, or in part, of Portland stone.

Purbeck stone comes from the island of Purbeck, in Dorsetshire also. It is mostly employed in rough work, as steps and paving.

Yorkshire stone is also used where strength and durability are requisite, as in paving and coping. Ryegate stone is used for hearths, slabs, and copings.

In Edinburgh, a very fine stone, called Craigleith, brought from a village of the same name, in the neighbourhood of that city, is most commonly used in the construction of edifices. They have also very good stone from the Hails quarry, but rather inferior in point of colour.

The Craigleith quarry produces two kinds of rock, one of a fine cream or buff colour, called the *liver rock*, which is almost unchangeable, even though exposed in a building to the weather.

The city of Glasgow is built of various kinds of stone, the best of which are the Possel and the Lord President's quarry; most other kinds are not only perishable, but liable to change their colour.

In the north of England, stone fit for hewn work is chiefly of a reddish colour. There is a very good white stone, however, in the vicinity of Liverpool, of which several of the public buildings are constructed.

All the stone fit to be squared, or squared and rubbed smooth, for the use of building, is mostly composed of sand. The stone used for the same purposes in the south of England is, in some parts, entirely chalk, and in other parts limestone. The Bath and Oxfordshire stone has so little grit in its texture, as to be wrought into mouldings with planes, as in joinery, and the surfaces are finished with an instrument called *a drag.*

Marbles, with regard to their contexture and variegation of colour, are almost of infinite variety: some are black, some white, some of a dove colour, and others beautifully variegated with every kind of rich colour. The best kind of white marble is that called *statuary*, which, when cut into thin slices, becomes almost transparent, a property the others do not possess. The texture of marble, with regard to working, is not generally understood, even by the best workmen, though upon sight they frequently know whether it will receive a polish or not. Some marbles are easily wrought, some are very hard, and other kinds resist the tools altogether.

Mortar is another principal material used in cementing the stones of a building. The reader who wishes to obtain a full knowledge of this department of masonry, may consult the articles CEMENT, MORTAR.

Wherever it is intended to build upon, the ground must be tried with an iron crow, or with a hammer: if found to shake, it must be pierced with a borer, such as is used by well-diggers; and if the ground generally prove to be firm, the loose or soft parts, if not very deep, must be excavated until a solid bed appears.

If the ground prove soft in several places to a great depth under apertures, and firm upon the site of the piers, inverted arches must be turned under the apertures, so that if the foundation sink, the arches may resist the re-action of the ground: and then the whole wall will sink uniformly, or descend in one body. And even where the ground is of a uniform texture, it is always eligible to turn inverted arches under apertures, wherever there is a part of a wall carried up from the foundation to the sill of that aperture: it is from neglect in this circumstance, that the sills of windows in the ground-stories of buildings are frequently broken; indeed it is seldom or never otherwise.

Arches adequate to this purpose should rather be of a parabolic form than circular, the figure of the parabola being better adapted to preserve an equilibrium than the arc of a circle, which is of uniform curvature. If unfortunately the soft parts of the ground prove to be the site of the piers, and, consequently, the hard places under the apertures, piers should be built under the apertures, and arches suspended between the piers, with their concave side towards the trench, as usual.

The use of concrete has, however, made a great change in the art of preparing foundations, the general practice now being to excavate the trenches for the footings of the walls, and put in a bed of concrete, on which is laid the masonry.

For more information upon this subject, see the articles FOUNDATION, CONCRETE.

In walling, the bedding joints have most commonly an horizontal position in the face of the work, and this disposition ought always to take place when the top of the wall terminates in an horizontal plane or line. In bridge building, and in the masonry of fence-walls upon inclined surfaces, the bedding-joints on the face sometimes follow the upper surface of the wall or terminating line.

The footings of stone-walls ought to be constructed of large stones, which, if not naturally nearly square, should be reduced by the hammer to that form, and to an equal thickness in the same course; for if the beds of the stones in the foundation taper, the superstructure will be apt to give way, by resting upon mere angles or points with inclined beds instead of horizontal. All the vertical joints of any upper course should break joint, that is, they should fall upon the solid part of the stones in the lower course, and not upon the joints.

When the walls of the superstructure are thin, the stones which compose the foundation may be so disposed, that their length may reach across each course, from one side of the wall to the other. In thicker walls, where the difficulty is greater in procuring stones of sufficient length to reach across the foundation, every second stone in the course may be a whole stone in the breadth, and each interval may consist of two stones of equal breadth, that is, placing header and stretcher alternately. But when those stones cannot be had conveniently, from one side of the wall, lay a header and stretcher alternately, and from the other side lay another series of stone in the same manner, so that the length of each header may be two-thirds, and the breadth of each stretcher one-third of the breadth of the wall, and so that the back of each header may come in contact with the back of an opposite stretcher, and the side of that header come in contact with the side of the header adjoining the said stretcher. In broad foundations, where stones cannot be procured for a length equal to two-thirds of the breadth of the foundation, build the work so that the upright joints of any course may fall on the middle of the length of the stones in the course below, and so that the backs of each stone in any course may fall upon the solid of a stone or stones in the course below.

The foundation should consist of several courses, of which each superior course should be of less breadth than the inferior one, say four inches on each side in ordinary cases, and the upper course project four inches on each side of the wall. The number of courses must be regulated by the weight of the wall, and by the size of the stones of which the foundation consists.

A wall, which is built of unhewn stone, is called a *rubble-wall*, whether with or without mortar. Rubble work is of two kinds, coursed and uncoursed. Coursed rubble is that of which the stones are gauged and dressed by the hammer, and thrown into different heaps, each heap containing stones of the same thickness; then the masonry is laid in courses or horizontal rows, which may be of different thicknesses. The uncoursed rubble is that where the stones are laid promiscuously in the wall, without any attention to placing them in rows. The only preparation which the stones undergo, is that of knocking off the sharp angles with the thick end of the scabbling hammer.

Walls are most commonly built with an ashlar facing, and backed with brick or rubble work. Brick backings are common in London, where brick is cheaper; and stone backing in the north of England and in Scotland, where stone is plentiful. Walls faced with ashlar, and backed with brick or uncoursed rubble, are liable to become convex on the outside from the greater number of joints, and from the greater quantity of mortar placed in each joint, as the shrinking of the mortar will be in proportion to the quantity; and therefore a wall of this description is much inferior to one of which the facing and backing are of the same kind, and built with equal care, even though both sides were uncoursed rubble, which is the worst of all walling. Where the outside of a wall is an ashlar facing, and the inside coursed rubble, the courses of the backing should be as high as possible, and set with thin beds of mortar. In Scotland, where stone abounds, and where perhaps as good ashlar facings are constructed as any in Great Britain, the backing of their walls most commonly consists of uncoursed rubble, built with very little care. In the north of England, where the ashlar facings of walls are done with less neatness, they are much more particular in the coursing of their backings. Coursed rubble and brick backings are favourable for the insertion of bond timbers: but in good masonry, wooden bonds should never be in continued lengths, as in case of fire or rot, the wood will perish, and the masonry, being reduced by the breadth of the timber, will be liable to bend at the place where it is inserted. When it is necessary to have wall timber for the fastening of battens for lath and plaster, the pieces of timber ought to be built with the fibres of the wood perpendicular to the surface of the wall, or otherwise in unconnected short pieces, not exceeding nine inches in length.

In an ashlar facing, the stones generally run from twenty-eight to thirty inches in length, twelve inches in height, and eight or nine inches in thickness. Although both the upper and lower beds of an ashlar, as well as the vertical joints, should be at right angles to the face of the stone, and the face-bed and vertical joints at right angles to the beds in an ashlar facing, where the stones run nearly of the same thickness, it is of some advantage, in respect of bond, that the back of the stone be inclined to the face, and that all the backs thus inclined should run in the same direction, as this gives a small degree of lap in the setting of the next course; whereas, if the backs were parallel to the front, there could be no lap where the stones run of an equal depth in the thickness of the wall. It is of some advantage likewise to select the stones, so that a thicker one and a thinner one may follow each other alternately. The disposition of the stone in the next superior course should follow the same order as in the inferior course, and every vertical joint should fall as nearly as possible in the middle of the stone below.

In every course of ashlar facing, with brick or rubble backing, *thorough-stones*, (as they are technically termed,) should be introduced, and their number should be proportioned to the length of the course, and every such stone of a superior course should fall in the middle of every two similar stones in the course below; this disposition of bonds should be strictly attended to in all long courses. Some wallers, in order to show or demonstrate that they have introduced sufficient bonds in their work, choose their bond-stones of greater length than the thickness of the wall, and knock or cut off their ends afterwards. This method is far from being eligible, as the wall is not only liable to be shaken by the force applied to break the end of the stone, but the stone itself is apt to be split.

In every pier where the jambs are coursed with the ashlar in front, every alternate jamb-stone ought to go through the wall, with its beds perfectly level. If the jamb-stones are of one entire height, as is frequently the case when architraves are wrought upon them, and upon the lintel crowning them, in the stones at the ends of the courses of the pier which are to adjoin the architrave jamb, every alternate stone ought to be a thorough-stone; and if the piers between the apertures be very narrow, no other bond-stones will be necessary in such short courses. But where the piers are wide, the number of bond-stones must be proportioned to the space; thorough-stones must be particularly attended to in the long courses below and above windows.

Bond-stones should have their sides parallel, and of course be perpendicular to each other, and their horizontal dimension in the face of the work should never be less than the vertical one. All the vertical joints, after receding about three quarters of an inch from the face with a close joint, should widen gradually to the back, and thereby form hollow wedge-like figures for the reception of mortar and packing. The adjoining stones should have their beds and vertical joints filled with oil putty from the face to about three-quarters of an inch inwards, and the remaining part of the beds with well-prepared mortar. Putty cement will stand longer than most stones, and will even remain prominent when the stone itself is in a state of dilapidation from the influence of the corroding power of the atmosphere. It is true that in all newly-built walls cemented with oil putty, the first appearance of the ashlar work is rather unsightly, owing to the oil of the putty disseminating itself into the adjoining stones, which makes the joints appear dirty and irregular: but this disagreeable effect is soon removed; and if care has been taken to make the colour of the putty suitable to that of the stone, the joints will hardly appear, and the whole work will seem as if one piece. This is the practice in Glasgow, but in London and in Edinburgh fine water putty is used instead of it.

All the stones of an ashlar facing should be laid on their natural beds. From a neglect of this precaution, the stones frequently flush at the joints, and this disposition of the laminæ sooner admits the corrosive power of the atmosphere to take effect.

In building walls or insulated pillars of very small horizontal dimensions, every stone should have its bed level, and without any concavity in the middle; because if the beds are concave, when the pillars begin to sustain the weight of the fabric, the joints will in all probability flush. It ought likewise to be observed, that every course of masonry of such piers ought to consist of one stone.

An arch, in masonry, is a part of a building suspended over a given plan, supported only at the extremities, and concave towards the plan.

The supports of an arch are called the *spring walls*.

The whole of the under surface of the arch opposite to the plan is called the *intrados* of the arch; and the upper surface is called the *extrados*.

The boundary line or lines of the intrados or those common to the supports and the intrados, are called the *springing lines* of the arch.

A line extending from any point in the springing line on one side of the arch, to the springing line on the opposite side of the arch, is called the *chord* or *span* of the arch.

If a vertical plane be supposed to be contained by the span and the intrados of the arch, it is called the *section of the hollow* of the arch.

The vetrical line drawn on the section from the middle of the spanning line to the intrados, is called the *height* of the arch, as also the *middle line* of the arch; and the part of the arch at the upper extremity of this line is called the *crown* of the arch.

Each of the curved parts on the top of the section, between the crown and either extremity of the spanning line, is called the *haunches* or *flanks* of the arch.

The section of almost every given arch used in building has the following properties: the upper part is one continued curve, concave towards the span, or two curves forming an interior angle at the crown, both concave towards the spanning line. Every two vertical lines on the section equidistant from each extremity, and parallel to the middle line, are equal.

The foregoing definitions and propositions not only apply to arches with level bases, but also to arches which stand upon inclined bases.

When the base of the section or spanning line is parallel to the horizon, the section will consist of two equal and similar parts, so that if one were conceived to be folded upon the other, the boundaries of both would coincide.

Arches, whose intrados is the surface of a geometrical solid that would fill the void, are variously named, according to the figure of the section of that solid perpendicular to the axis, as *circular*, *elliptical*, *cycloidal*, *catenarian*, *parabolical*, &c.

Arches of the circular kind have two distinctions, viz., the *semicircular*, and those of segments less than a semicircle; the latter are called *scheme* or *skene* arches.

There are also *pointed*, *composite*, *lancet*, or *Gothic* arches, which are formed in the face of the wall, or in sections parallel thereto, with the intrados of the arch.

When the extremities of an arch rise from supports at unequal heights, it is called a *rampant* arch.

When vertical lines are drawn upwards, through each extremity of the spanning line, so as to cut off equal and similar parts of the intrados, the arch is called a *horse-shoe* arch, or *moresque* arch. Hence, in this kind of arch, the spanning line is less than any other line or chord drawn parallel to the span, but under the top of each of the vertical lines.

When the upper line or side of an arch is parallel to the under line or side, it is called an *extradossed* arch.

A simple vault is an interior concavity extended over two parallel opposite walls, or over all the diametrically opposite parts of one circular wall. An arch or vault is frequently understood as synonymous; but the distinction which we shall here observe is, that an arch, though it may be extended over any space, has a very narrow intrados, not exceeding four or five feet; whereas a vault may be extended to any limit more than four or five feet. Thus we frequently say an arch in a wall, but we never say a vault in a wall; though nothing is more common than to say a vaulted apartment, a vaulted room, a vaulted cellar, &c. So that a vault, as Sir Henry Wotton has observed, is an extended arch; we shall therefore apply *arch* to the head of the aperture in a wall which shows curvilinear intersections with the faces of the wall, and the word *vault* to arched apartments. We frequently, however, call the stone-work suspended over an apartment an arch as well as a vault; so that every vault is an arch, but every arch is not a vault.

The intrados of a simple vault is generally formed of the portion of a cylinder, cylindroid, sphere, or spheroid, never greater than the half of the solid; and the springing lines which terminate the walls, or where the vault begins to rise, are generally straight lines parallel to the axis of the cylinder, or cylindroid, or the circumference of a circle or ellipsis.

A circular wall is generally terminated with a spherical vault, which is either hemispherical, or a portion of a sphere less than a hemisphere.

A vaulted apartment, surrounded by an elliptic wall, is generally covered with a spheroidal vault, which is either a hemispheroid, or a portion less than a hemispheroid.

A conic surface is seldom employed in vaulting; but when the vault is to have this kind of intrados, the intrados should be the half of a cone with its axis in a horizontal position, or a whole cone with its axis in a vertical position.

All vaults which have a horizontal straight axis, are called *straight vaults.*

Besides what we have already denominated an arch, the concavities which two solids form at an angle, are called *an arch.*

If one cylinder pierce another of a greater diameter, the arch is called a *cylindro-cylindric arch;* the cylindro being applied to the cylindric part which has the greater diameter, and the cylindric to that which has the less.

If a cylinder pierce a sphere of greater diameter than the cylinder, the arch is called *a sphero-cylindric arch;* and, on the contrary, if a sphere pierce a cylinder of greater diameter than the sphere, the arch is denominated *a cylindro-spheric arch.*

If a cylinder pierce a cone, so as to make a complete perforation through the cone, two complete arches will be formed, called *cono-cylindric arches;* and, on the contrary, if a cone pierce a cylinder, so as to make the interior concavity through the cylinder a complete conic surface, the arch is called *a cylindro-conic arch.*

If a straight wall be pierced with a cylindric aperture quite through, two arches will be formed, called *plano-cylindric arches.*

Every species of arches is thus denoted by two preceding words; the former ending in *o*, signifying the principal vault or surface cut through, and the latter in *ic*, signifying the kind of aperture which pierces the wall or vault.

When two cylindric vaults, or two cylindroidic vaults, or a cylindric or cylindroidic vault, pierce each other, and also their axis, so that the diameter of each hollow may be the same, when measured perpendicular to a plane passing through the axis of both surfaces, the figure so formed is called a *groin;* but for more particular information on this point see the article GROIN.

The formation of stone arches, in various cases, has always been looked upon as a most curious and useful acquisition to the operative mason, or to the architect, or other person who is appointed to superintend the work. In order to remove the difficulties experienced in the construction of cylindric or cylindroidic arches, both in straight and circular walls, we shall here show an example of each.

First, let it be required to construct a semi-cylindroidic arch, cutting a straight wall with its axis oblique to the surface of the wall, but parallel to the horizon.

Plate I. Figure A.—Let A B C D be the plan of the aperture, A D and B C being the plan of the jambs, and A B and D C the plan of the sides of the wall; produce D A and C B to G and F; draw the straight line I G M F E at right angles with A G and C F; bisect G F at M; draw M H K perpendicular to C F; make M H equal to the height of the intrados of the arch, and describe the semi-ellipsis G H F, which is the section of the intrados of the arch; make G I, H K, and F E, equal to the breadth of the beds of the arch-stone, and describe the semi-ellipsis I K E, which is the section of the extrados of the arch. Now, suppose the distances between the joints around the intrados of the arch to be all equal, and all the joints to tend to the centre M; divide the semi-ellipsis into such an odd number of equal parts, that each part may be in breadth equal to what is intended for the thickness of the stones at that part; produce E I to S, and extend the whole number of these parts from O to S; and through the points of division draw lines perpendicular to G S, or parallel to A G. Through all the points of division of the ellipsis G H F, draw lines parallel to G A to meet A B; then take the lengths of all the parts of the lines so drawn that are terminated by G F and A B, as follows, viz., make the first line on the left of G A equal to the first on the right of G A, and the point *b* will be obtained; make the second on the left of G A equal to the second on the right of G A, and the point *c* will be obtained; proceed in this manner, until all the other points are obtained; then a curve being drawn through all the points A, *b*, *c*, *d*, &c. to T, will give the one edge of the envelope of the intrados of the arch; and by producing the perpendiculars erected upon G S to the points *e*, *f*, *g*, &c., and making the several distances *b e*, *c f*, *d g*, &c. equal to A D or B C, the points D, *e*, *f*, *g*, &c. to U, will give the other edge of the envelope by tracing a curve through them; then A *b c d*, *b c f e*, *c d g f*, &c. are the soffits of the stones.

To find any bevel which the joints on the face of the arch makes with that on the intrados.

Let *p q* be one of the joints tending to the centre, M, of the section of the arch; with the radius M G describe an arc, G N O, cutting *p q* at N; draw N P parallel to G A, cutting A B at P; draw P Q parallel to F G, cutting G A at Q; draw M L parallel to G A, cutting A B at L, and join L O; then Q L M is the bevel required. In the same manner may all the remaining bevels be found.

Again, let *p q r s* be the section of an arch-stone; then making two bevels, one to *q p s*, and the other to *r s p*, will be all the bevels that are necessary for that stone. Having obtained the several bevels, we shall now proceed to work the arch-stone, whose section is *p q r s:* first work the lower bed of the stone corresponding to the joint *p q*, then draw a

line for the soffit, which work also by means of the bevel *q p s;* then gauge the soffit to its breadth, and work the upper bed of the stone by means of the bevel *r s p;* take the soffit mould from the envelope, and draw the ends of the stone which coincide with the faces of the wall; with the face bevels Q L M and V L M work the face of the stone.

Note.—That finding the bevels for half the arch will be sufficient, by reversing them.

Plate II. shows the construction of a semi-cylindric arch, which is performed by a similar process to the preceding.

The other arch, standing upon D C, shows the ends of the stones in the face of the wall; its boundaries are two ellipses of equal height to those of the section.

To construct a cylindro-cylindric arch, or a cylindric arch, in a cylindric wall, the axis of the aperture being at right angles to the axis of the cylindric wall. See PLATE III.

Let A B C D be the half plan of the wall; B C being half of the convex curve, A D half of the concave curve, C D the middle line of the aperture tending to the centre of the concentric circles which form the plan; and A B parallel to C D, being the jamb. Through C draw E F perpendicular to C D; make C E and C F half the breadth of the aperture; from the centre, C, with the radius C E or C F, describe the semicircle E G F, which will be the section of the intrados; produce C E and C F to H and I, making E H and F I each equal to the breadth of the beds, and describe the semicircle H K I; divide the intradossal curve, E G F, into the number of parts answering to the number of arch-stones, and proceed to find the envelope, as described, for the straight wall, which will give the moulds for the soffits of the stones, as before.

To find the curves of the ends of the beds upon the face of the arch.

Let L M represent a joint: draw L N and M O perpendicular to H I, cutting the plan of the wall at N and O: draw N P parallel to C I, cutting M O at P: in L M take any number of points, *t* and *y*, and draw *t s* and *y w* parallel to L N, cutting the plan at *s* and *w*, and N P at *r* and *v*: draw M Q, *t u*, *y x*, perpendicular to L M: make M Q, *t u*, *y x*, respectively equal to P O, *r s*, *v w*, and L *x u* Q will be the curve of the joint required, which gives the face-line of the upper bed of the lower stone, and the face-line of the lower bed of the upper stone. In the same manner all the other face-lines of the beds are to be found. The templet must be cut in the shape of L M Q.

To form an arch-stone.

First make one of the beds; make the soffit, form the other bed, and the face-lines of each bed; then run a draught round the three face-lines, and between them work the face of the stone in lines perpendicular to the horizon. This will be easily found by drawing a vertical line upon the section of each stone.

It is only necessary to draw the moulds for one half of the arch, as the reversing of them in their application gives the other half.

The joints of any arch whatever may be found in the same manner, provided the planes of the beds intersect a vertical plane perpendicular to the curve in the middle of the aperture.

It is obvious, on finding the face-lines of the beds, that the lowest face-line is the quickest, and part of the plan of the wall itself; the next face-line is flatter, or has less curvature, and thus each successive face-line has less curvature as it comes nearer to the top; and, if there were a joint in the top, the face-line of the beds would be quite a straight line. Indeed, the face-lines of two or three courses might be wrought with straight edges, as the difference could hardly be perceived. For the tools used by masons. *See* TOOLS.

MATERIALS, (from the French, *materiel,*) in architecture, the different kinds of bodies, or substances, used in the construction of edifices, as wood, stone, brick, mortar, &c.

It is chiefly from the valuable work of Vitruvius, that we are furnished with information respecting the nature of the materials used by the Greeks and Romans, and of the particular modes in which they were disposed in their buildings. From the accounts published by modern travellers and scientific artists, we are also furnished with farther information respecting the practice of these people.

The materials chiefly made use of by them were timber, marble, stone, bricks, lime, and metals.

With regard to timber, the proper time for felling was reckoned from the beginning of autumn to the latter end of February, when the moon was in the wane. They considered wood, when quite green, or too much dried, as equally unfit for working. For joists, doors, and windows, they required that it should have been cut three years, and kept for a considerable time covered with cow-dung.

The Greeks most usually made use of white marbles as Pentelic, Parian, and that of Chios. The latter was very transparent.

The Romans employed many sorts, of various colours, and procured from different countries under their sway in Asia, Africa, and Europe.

The ancients frequently included, under the term *marble,* all hard stones which would receive a smooth fine polish; the moderns confine the name to such calcareous stones as are capable of receiving a fine polish.

Alabaster resembles marble in taking a smooth fine polish, but is much softer and more easily worked. Gypseous alabaster, when polished, is slippery to the touch; and frequently contains so much carbonate of lime as to cause it to effervesce with acids; it was procured from Upper Egypt between the Nile and Red Sea, also from Syria and Caramania. The calcareous alabaster is white, yellow, red, and bluish gray; the fracture is striated or fibrous, in hardness inferior to marble; it is known under the denomination of *common* and *oriental;* Italy and Spain produce the best.

The stone which was employed appears to have differed very materially in its qualities; some, becoming considerably harder on being exposed to the air, was worked immediately on being taken from the quarry; but there was some of a softer kind, which, previous to being used, required to have its quality proved by two years' exposure to the effects of the atmosphere.

Of tiles, they had, 1. The unburnt kind, which were dried five years in the sun; and, 2. Those baked by fire, after having been made two years.

In the manufacture of these, they preferred a white chalky earth, dug in the autumn, exposed during the winter, and made into tiles and bricks in the spring. The Greeks proportioned the size of their bricks to the nature of the edifice: the largest for public buildings, were five spans each way; those of the middle class were four spans; and the smallest called by Vitruvius, *diodori,* or by Pliny, *lydii,* were two spans long and a foot broad; the last were for private houses.

It appears that the bricks dried in the sun were mixed with chopped straw. Dr. Pococke describes one of the pyramids constructed of brick: he measured some thirteen inches and a half long, six inches and a half broad, and four inches thick; others were fifteen inches long, seven inches broad, and four inches and three-quarters thick. At Rome they were found by De Quincey of three different sizes; the least were seven inches and a half square, and one inch and a half thick; the middle-sized were sixteen inches and a half square, and eighteen to twenty lines in thickness; and the largest were twenty-two inches square, and twenty-one to twenty-two lines in thickness.

Three kinds of sand are mentioned, that is, pit, river, and sea sand; of these, pit sand was reckoned the best; the white was preferred to the black or red coloured, and the carbuncle to all; of the river sand, that was considered best which was found near torrents; the least value was put upon sea sand, and it was required to be well washed, to dissolve the saline matter, before it was used in plastering or rough-casting walls.

Lime for plastering walls was made from shells, river pebbles, or a sort of pumice-stone; the best sort of lime was accounted that made from white stone, which was dense and hard, and lost one-third of its weight in burning in a kiln, where it was kept about sixty hours. Their mortar was composed of one part lime and three parts of pit, or two of river sand.

Metals used were, 1. Iron for chains, hinges, handles, and nails. 2. Lead for roofs and pipes. 3. Copper and brass were still more used for many of these purposes: or, 4. Copper, brass, and lead, mixed into a bronze for statues, bases, and capitals of columns, and in doors.

Amongst the moderns, change of climate, the convenience of local productions, and the habits of mankind, have from time to time led to considerable changes in the kinds of materials used for the various purposes of architecture, as well as in their modes of preparation, and the application of them. With regard to timber, oak, for the greatest strength and durability, should be chosen from those soils where it has taken the longest time in arriving at maturity; and of two pieces equally dry, that should be chosen which has the greatest specific gravity, or that which will have its specific gravity least changed by being soaked in water: this observation will indeed apply to timber in general. A decay of the top is almost a certain indication of a decay of the tree; and a decayed branch, or rotten stump, bespeaks a defect in that part of the tree where it is situated. In a similar soil, trees which grow near the outside of a forest will be more durable than those near the middle of it; and in the same tree, the side which grew towards the north will be stronger than the south side.

When perfection of strength and texture is alone consulted, all sorts of timber are cut down in the winter, being at that time freest of sap, and most readily seasoned, and rendered fit for the purposes of building; but on account of the bark of the oak being of great use in tanning leather, that wood is always, in England, cut in the spring, from April to June, according to the state of the season, and soon after the sap begins to ascend and the leaf to appear; if cut before the sap rises, the bark adheres to the wood, and cannot be stripped off, and if left until the leaf is quite expanded, the bark is less valuable; when the tree is felled and suffered to lie in the trunk, it will shrink in size; but this is probably from its discharging water, because, if a dry tree be laid in a damp place, it will increase both in weight and size. The part called *sap* varies in quantity in different trees; it is least in bad soils, where the growth is slow, and is of very little use.

Oak used in damp situations, appears to decay gradually from the external surface to the centre of the tree; the outside ring or addition it received in the last year of its growth decaying first, and afterwards that next within it, and then the following one. This appears to proceed from two causes; first, from the outward ring being, where whole trees are used, first exposed to the action of the atmosphere, which cannot reach the second until the first is destroyed; secondly, from the central part of the tree having arrived at a greater degree of maturity than the outward rings, which are many years younger. But this must be understood only of trees which are not past their prime before they are cut down; for when a tree begins to decay from age, that part of the tree which is oldest, namely, the central part, decays first; to this succeeds the parts which are next oldest, being the ring next the centre, and the other annual rings in succession gradually approaching the bark. A judicious builder will, therefore, in the choice of his timber, always carefully examine the central part of the tree, especially that part which is next the root, and more particularly if the tree be large, and have the appearance of great age.

The best mode of seasoning oak is to put it in water. This, if in the log, should be done for a whole year or more, but, if cut in planks, less time is necessary; in either case alternate soaking and drying is to be preferred. This, in planks, is very practicable; but, in regard to logs, one soaking and drying gradually in the shade, is, on account of the great labour attending the operation, most generally practised. After the planks have been soaked in water, they are dried by placing a strong pole in a horizontal position, at such a height as will admit of one end of each plank being placed on the ground, and the other to rest against it edgewise; placing a plank first on one side of the pole, and another on the other side alternately, thus leaving a space for the air to pass freely between them; and being exposed edgewise to the sun, they are not liable to split.

Modern science, however, has discovered many other ways of seasoning timber than these. The processes of Sir W. Burnett, Kyan, and others, are now generally resorted to for this purpose; and are found effective to a certain extent, if not quite realizing all their advocates claim for them.

In ash, there is little difference in the quality through the whole thickness of the tree, the outside is rather the toughest: it soon rots when exposed to the weather, but will last long when protected.

Of elm, some sorts will decay sooner than the brown or red. It is improper for roofs or floors, being generally cross-grained, and very liable to warp; it also shrinks very considerably, not only in breadth, but lengthwise; but it answers well when used under water; is not liable to split; and bears the driving of bolts and nails better than any other timber.

Beech is hard and close. There is a black or brown, and a white kind: the brown is tough, and sometimes used as a substitute for ash; it is improper for beams, because a small degree of dampness in the walls very soon rots the ends; it is most suitable for furniture, or for works constantly under water.

Poplar, though of a very close quality, is liable to the same objections as the beech in beams, but is well adapted for floors and stairs, being not easily ignited: however, it rots soon when exposed to the weather.

Ash resembles the poplar in appearance; is soft and tough; lasts when exposed to the weather; and is equally good through the body of the tree. The sycamore and lime are subject to the same objections, in roofing and flooring timbers, as the poplar and beech. The lime is something like the ash in quality, and, like it, is greasy when worked smooth: it is suitable for furniture.

Birch is equal in quality quite across the body of the tree; is very tough, but does not last when exposed to the weather; it is also subject to be destroyed by worms.

Chesnut, viz., the sweet, or Spanish, (not the horse-chesnut,) is frequently found in old buildings in England: and although difficult to be distinguished from oak, differs from it in this respect, wherever a nail or bolt has been driven into oak before it was dry, a black substance appears round the iron, which is not the case in chesnut.

The walnut-tree is now, in this country, too valuable to be used in the framings of roofs or floors; and in furniture it has long been superseded by mahogany; it is used chiefly in stocks of firelocks, fowling-pieces, pistols, &c.

Mahogany is used chiefly in furniture, and also sometimes in doors and window-sashes; it is sawn out and seasoned by perching out in the winter, and drying in the open air; the use of fire is not advisable. This beautiful timber was introduced into England about the beginning of the last century: its first application was in a box for holding candles, made by a Mr. Wollaston for a Dr. Gibbons, who had afterwards a bureau of it; the Duchess of Buckingham had the second bureau. It very soon came into general use. It is divided chiefly into Jamaica and Honduras; the former is by much the hardest and most beautiful; they may be readily distinguished before they are oiled; the pores of the Honduras appear quite dark, those of the Jamaica as if filled with chalk. *See* MAHOGANY.

Fir, being cheaper, and more easily wrought than oak, and next to it in usefulness, is more used in Britain than any other kind of timber. That most generally employed in carpentry is distinguished by the name of Memel, (which includes Dantzic and Riga;) Norway, (which also includes Swedish,) is much used for the smaller timbers, and answers well either when exposed to the air, or under ground. Dranton, or Dram, is suitable for flooring. All these are very durable. American fir is much softer, but suits inside joinery work, such as panels and mouldings. What is termed in England *white deal*, and in Scotland *pine-wood*, that is, fir deprived of its resinous part, being very durable when kept dry, is much used by cabinet-makers; but, as it will not stand the weather, it is little used in carpentry or joinery.

Evelyn makes the following observation on the use of fir:—"That which comes from Bergen, Swinsund, Mott, Longland, Dranton, (called Dram,) being long, straight, and clear, of a yellow and more cedary colour, is esteemed much before the white for flooring and wainscot; for masts, those of Prussia, which we call spruce, and Norway, especially from Gottenburg, and about Riga, are the best."

The *torulus*, as Vitruvius terms it, and heart of deal, kept dry, rejecting the alburnum or white, is everlasting; nor is there any wood which so well agrees with the glue, or which is so easy to be wrought. It is also excellent for beams, and other timber-work in houses, being both high and exceedingly strong, and therefore of very great use for bars and bolts of doors, as well as for doors themselves; and, for the beams of coaches, a board of an inch and a half thick will carry the body of a heavy coach with great ease, by reason of a natural spring, which is not easily injured. It was formerly used for carts and other carriages, and also for the piles to build upon in boggy grounds. Most of Venice and Amsterdam is built upon such piles. For scaffolding also, there is none comparable to it. Under the head of fir may be classed cedar, a wood of great durability, but too expensive to be used in Britain.

Evelyn makes the following observations upon timber; some of which are well worthy of attention:—

"Lay up your timber very dry, in an airy place, yet out of the wind or sun, and not standing upright, but lying along, one piece upon another, interposing some short blocks between them, to preserve them from a certain mouldiness which they usually contract while they sweat, and which frequently produces a kind of fungus, especially if there be any sappy parts remaining.

"Some there are yet, who keep their timber as moist as they can by submerging it in water, where they let it imbibe to hinder the cleaving; and this is good in fir, both for the better stripping and seasoning, yea, and not only in fir, but other timber. Lay, therefore, your boards a fortnight in the water, (if running the better, as at some mill-pond head,) and then setting them upright in the sun and wind, so as it may freely pass through them, (especially during the heats of summer, which is the time of finishing buildings,) turn them daily, and thus treated, even newly-sawn boards will floor far better than many years' dry-seasoning, as they call it. But, to prevent all possible accidents, when you lay your floors, let the joints be shot, fitted, and tacked down only for the first year, nailing them for good and all the next; and by this means they will lie stanch, close, and without shrinking in the least, as if they were all one piece. And upon this occasion, I am to add an observation, which may prove of no small use to builders; that if one take up deal-boards that may have lain in the floor a hundred years, and shoot them again, they will certainly shrink, (*toties quoties.*) without the former method. Amongst wheelwrights, the water-seasoning is of especial regard; and in such esteem amongst some, that I am assured the Venetians, for their provision in the arsenal, lay their oak some years in water before they employ it. Indeed, the Turks not only fell at all times of the year, without any regard to the season, but employ their timber green and unseasoned; so that, though they have excellent oak, it decays in a short time by this only neglect.

"Elm felled ever so green, for sudden use, if plunged four or five days in water, (especially salt water,) obtains an admirable seasoning, and may immediately be used. I the oftener insist on this water-seasoning, not only as a remedy against the worm, but for its efficacy against warping and distortions of timber, whether used within or exposed to the air. Some, again, commend burying in the earth, others in wheat; and there be seasonings of the fire, as for the scorching and hardening of piles, which are to stand either in the water or in the earth.

"When wood is charred, it becomes incorruptible; for which reason, when we wish to preserve piles from decay, they should be charred on their outside. Oak posts, used in enclosures, always decay about two inches above and below the surface. Charring that part would probably add several years to the duration of the wood, for that to most timber it contributes much to its duration. Thus, do all the elements contribute to the art of seasoning.

"And yet even the greenest timber is sometimes desirable for such as carve and turn, but it chokes the teeth of our saws; and for doors, windows, floors, and other close works, it is altogether to be rejected, especially where walnut-tree is the material, which will be sure to shrink. Therefore, it is best to choose such as is of two or three years' seasoning, and that is neither moist nor over dry; the mean is best. Sir Hugh Plat informs us, that the Venetians used to burn and scorch their timber in a flaming fire, continually turning it round with an engine, till they have gotten upon it a hard black coaly crust; and the secret carries with it great probability, for the wood is brought by it to such a hardness and dryness, that neither earth nor water can penetrate it; I myself remembering to have seen charcoal dug out of the ground amongst the ruins of ancient buildings, which had in all probability lain covered with earth above fifteen hundred years.

"Timber which is cleft is nothing so obnoxious to reft and cleave, as what is hewn; nor that which is squared, as what is round; and therefore, where use is to be made of huge and massy columns, let them be bored through from end to end. It is an excellent preservative from splitting, and not unphilosophical; though, to cure the accident, painter's putty is recommended; also, the rubbing them over with a wax-cloth is good; or before it be converted, the smearing the timber over with cow-dung, which prevents the effects both of sun and air upon it, if, of necessity, it must lie exposed. But, besides the former remedies, I find this for the closing of the chops and clefts of green timber, to anoint and supple it with the fat of powdered beef-broth, with which it must be well soaked, and the chasms filled with sponges dipt into it. This to be twice done over.

"Some carpenters make use of grease and sawdust mingled; but the first is so good alway," says my author, "that I have seen wind-shock timber so exquisitely closed, as not to be discerned where the defects were. This must be used when the timber is green.

"We spake before of squaring; and I would now recommend the quartering of such trees as will allow useful and competent scantlings, to be of much more durableness and effect for strength, than where (as custom is, and for want of observation) whole beams and timbers are applied in ships or houses, with slab and all about them, upon false suppositions of strength beyond these quarters. For there is in all trees an evident interstice or separation between the heart and the rest of the body, which renders it much more obnoxious to decay and miscarry, than when they are treated and converted as I have described it; and it would likewise save a world of materials in the building of great ships, where so much excellent timber is hewed away to spoil, were it more in practice. Finally,

"I must not omit to take notice of the coating of timber in work used by the Hollanders, for the preservation of their gates, portcullises, draw-bridges, sluices, and other huge beams and contiguations of timber, exposed to the sun and perpetual injuries of the weather, by a certain mixture of pitch and tar, upon which they strew small pieces of cockle and other shells, beaten almost to powder, and mingled with sea-sand, or the scales of iron, beaten small and sifted, which encrusts, and arms it, after an incredible manner, against all these assaults and foreign invaders; but if this should be deemed more obnoxious to firing, I have heard that a wash made of alum has wonderfully protected it against the assault even of that devouring element; and that so a wooden tower or fort at the Piræum, the port of Athens, was defended by Archelaus, a commander of Mithridates, against the great Sylla.

"Timber that you have occasion to lay in mortar, or which is in any part contiguous to lime, as doors, window-cases, groundsels, and the extremities of beams, &c., have sometimes been capped with molten pitch, as a marvellous preserver of it from the burning and destructive effects of the lime; but it has since been found rather to heat and decay them, by hindering the transudation which those parts require: better supplied with loam, or strewings of brick-dust, or pieces of boards; some leave a small hole for the air. But though lime be so destructive whilst timber lies thus dry, it seems they mingle it with hair, to keep the worm out of ships, which they sheath for southern voyages, though it is held much to retard their course. Wherefore, the Portuguese scorch them with fire, which often proves very dangerous; and, indeed, their timber being harder, is not so easily penetrable.

"For all uses, that timber is esteemed the best which is the most ponderous, and which, lying long, makes deepest impression on the earth, or in the water, being floated; also, what is without knots, yet firm, and free from sap, which is that fatty, whiter, and softer part, called by the ancients *alburnum*, which you are diligently to hew away.

"My Lord Bacon, Exper. 658, recommends for trial of a sound or knotty piece of timber, to cause one to speak at one of the extremes, to his companion listening at the other; for if it be knotty, the sound, says he, will come abrupt.

"For the place of growth, that timber is esteemed best which grows most in the sun, and on a dry and hale ground; for those trees which suck and drink little, are most hard, robust, and longer-lived instances of sobriety. The climate contributes much to its quality; and the northern situation is preferred to the rest of the quarters; so as that which grew in Tuscany was, of old, thought better than that of the Venetian side; and yet the Biscay timber is esteemed better than what they have from colder countries; and trees of the wilder kind and barren, than the over much cultivated and great bearers."

Dr. Parry published an excellent paper on the causes of the decay of wood, and the means of preventing it, which, though written many years ago, is worth a careful perusal by those who wish for further information on the subject.

Wood, Dr. Parry supposes to be subject to destruction from two causes—rotting, and the depredations of insects. Of rot there are two supposed kinds: the first takes place in the open air; the second under cover.

When perfectly dry, and in a certain degree of temperature, both animal and vegetable matters seem scarcely capable of spontaneous decay. On this principle, fish and other animal matter is often preserved.

"Similar causes produce the same effect on wood. Even under less rigid circumstances of this kind, as in the roofs and other timber of large buildings, it continues for an astonishing length of time unchanged. Witness the timber of that noble edifice, Westminster-hall, built by Richard II. in 1397; and the more extraordinary instance quoted by Dr. Darwin, in his ingenious work, the *Phytologia*, of the gates of the old St. Peter's Church in Rome, which were said to have continued without rotting, from the time of the Emperor Constantine to that of Pope Eugene IV., a period of eleven hundred years. On the other hand, wood will remain for ages, with little change, when continually immersed in water, or even when deeply buried in the earth, as in the piles and buttresses of bridges, and in various morasses. These latter facts seem to show, that if the access of atmospherical air is not necessary to the decay of wood, it is at least highly conducive to it."

Putrefaction is the cause of rotting; and putrefaction is occasioned by stagnant air and moisture. The moisture of the air, coming in contact with wood of a lower temperature, is condensed in the same manner, as is more visible in our glass windows. In order to prevent the bad effects of this condensation, currents of dry air ought to be made to pass in contact with the timber. Of the advantages of this, the Gothic architects seemed aware; for it was common with them to leave openings for this purpose; a practice which we would strongly recommend in cellars, &c.

"It appears that the contact of water and air are the chief causes of the decay of wood. If, therefore, any means can be devised by which the access of moisture and air can be prevented, the wood is so far secure against decay. This principle may be illustrated, by supposing a cylinder of dry wood to be placed in a glass tube or case which it exactly fills, and the two ends of which are, as it is called, hermetically sealed, that is, entirely closed, by uniting the melted sides of each end of the tube. Who will doubt that such a piece of wood might remain in the open air unchanged! Or let us take a little more apposite illustration of this fact, that of amber, a native bitumen or resin, in which a variety of small flies, filaments of vegetables, and others of the most fragile substances, are seen imbedded, having been preserved from decay much longer probably than a thousand years, and with no apparent tendency to change for ten times that period."

These observations lead to the theory of painting timber, for the purpose of preserving it.

Mr. Batson of Limehouse is of opinion, that the dry-rot proceeds from a plant, called *boletus lachrymans*, one of the fungus tribe, and is one of the few that have leaves, as the mistletoe. But Dr. Parry justly observes, that these plants "begin merely because decayed wood is their proper soil."

"The smell which we perceive in going into vaults or cellars, where this process is going on, arises partly from the extrication of certain gases, mingled perhaps with some volatile oil, and partly from the effluvia of those vegetable substances which have already been said to grow on it, and which, though they begin merely because the decayed wood is their proper soil, yet afterwards tend probably to the more speedy decomposition of the wood itself.

"The following, then, appears to be the whole theory of the dry-rot, that it is a more or less rapid decomposition of the substance of the wood, from moisture deposited on it by condensation, to the action of which it is more disposed in certain situations than in others; and that this moisture operates most quickly on wood which most abounds with the saccharine or fermentable principles of the sap." *See* DRY-ROT.

Charring of wood is known to be a most effectual mode of preservation against rotting.

The incorruptibility of charcoal is attested by numerous unquestionable facts. At the destruction of the famous temple at Ephesus, it was found to be erected on piles that had been charred; and the charcoal in Herculaneum, after almost 2,000 years, was entire and undiminished.

To this property of charred wood Sir C. Wren does not seem to have attended, when about to build St. Paul's. It is said, he thought piles were not to be depended on for a foundation, excepting when always wet; and therefore dug to a great depth through a dry soil, in order to come at a solid foundation for part of that cathedral.

Charcoal has also been found useful as a defence to the surface of wood, when used as a paint. We lately had a good instance of the effect of sand used for this purpose. At Studly Royal, we saw a temple to appearance of stone, but which, on examination, we found to be wood covered with paint and dusted over with sand. We were informed it had stood about 50 years; and the deception was still so complete, that the spectators supposed the pillars to be stone, till minutely examined.

The following table of the properties of different kinds of timber is extracted from Tredgold's valuable work on Carpentry, and will be found to contain, in a condensed form, every information as to the comparative merits of the various descriptions of wood used for building or similar purposes:—

Table of the Properties of different kinds of Timber.

		Kind of wood, and State.	Specific gravity.	Weight of the modulus of elasticity in pounds per sq. inch.	Cohesive force in pounds per sq. inch.	Comparative.		
						Stiffness.	Strength.	Resilience.
Class I.	Div. I.	Common oak (*Quercus robur*) dry	.750	1,714,500	11,880	100	100	100
		Riga oak, dry	.688	1,610,496	12,888	93	108	125
		Dantzic oak, seasoned	.755	1,998,000	12,780	117	107	99
		American oak	.867	1,958,700	10,253	114	86	64
	Div. II.	Beech (*Fagus Sylvatica*) dry	.690	1,316,000	12,225	77	103	138
		Alder (*Betula alnus*) dry	.555	1,086,750	9,540	63	80	101
		Plane (*Platanus occidentalis*) dry	.648	1,343,250	10,935	78	92	108
		Sycamore (*Acer pseudo-platanus*) dry	.590	1,036,000	9,630	59	81	111
Class II.	Div. I.	Chesnut (*Fagus castanea*) dry	.535	1,147,500	10,656	67	89	118
		Ditto, green	.875	924,570	8,100	54	68	85
		Ash (*Fraxinus excelsior*) dry	.753	1,525,500	14,130	89	119	160
		Elm (*Ulmus campestris*) dry	.544	1,343,000	9,720	78	82	86
		Acacia (*Robinia pseudo-acacia*) green	.820	1,687,500	11,227	98	95	92
	Div. II.	Spanish mahogany, dry	.853	1,255,500	7,560	73	67	61
		Honduras ditto, dry	.560	1,593,000	11,475	93	96	99
		Walnut (*Juglans regia*) green	.920	837,000	8,775	49	74	111
		Teak (*Tectona grandis*)	.744	2,167,074	12,915	126	109	94
		Poona, dry	.613	1,689,800	12,350	99	104	82
		Turtosa, or African Teak, dry	.954	1,728,000	17,200	101	144	138
		Poplar, (*Populus dilatata*) dry	.374	763,000	5,928	44	50	57
		Abele (*Populus alba*) dry	.511	1,134,000	10,260	66	86	112
	Div. III.	Cedar of Libanus (*Pinus cedrus*) dry	.486	486,000	7,420	28	62	106
		Riga fir (*Pinus sylvestris*) dry	.480	1,687,500	9,540	98	80	64
		Memel fir (ditto) dry	.544	1,957,750	9,540	114	80	56
		Mar Forest fir (ditto)	.684	845,066	7,323	49	61	76
		Planted Scotch fir (ditto) dry	.460	951,750	7,110	55	60	65
		Christiana white deal (*Pinus abies*) dry	.512	1,804,000	12,346	104	104	104
		American white spruce (*Pinus alba*) dry	.465	1,244,000	10,296	72	86	102
		Planted Spruce (*Pinus abies*) dry	.555	1,393,975	8,370	81	70	60
		Weymouth pine (*Pinus strobus*) dry	.460	1,633,500	11,835	95	99	103
		Pitch pine	.660	1,252,200	9,796	73	82	92
		Larch (*Pinus larix*) dry	.643	1,363,500	12,240	79	103	134
		Cowrie (*Dummara australis*)	.79	1,982,400	10,960	116	92	74

In the last three columns of this table, oak is made the standard of comparison.

For marble, being plentiful in Italy and France, these countries have been able to make a considerable use of it, even in the main walls of their edifices; but being seldom found in sufficient quantities, and of proper quality, in the more northern parts of Europe, it has been here chiefly confined to interior columns, pavements, chimney pieces, and sometimes stairs.

The kinds of stone are as various as the countries in which the buildings are constructed. Sand-stone being very generally found stratified, even in thin laminæ, being readily cut into different forms, and being, if properly selected and used, sufficiently durable, it has, in northern countries, been in most frequent use. It is a general accompaniment of coal strata, and is also often found where the latter does not occur. It varies in its component parts, being at different places argillaceous, siliceous, and calcareous. Its position in the earth assumes all directions, from the horizontal to a vertical plane. The proportional thickness of its strata, laminæ, or beds, varies from that of thin slate to many feet each. The upper beds are usually very thin or soft, or both; if sufficiently hard, they are employed in floor pavements, and for covering roofs. Under these the beds generally, in useful quarries, increase in thickness, hardness, and tenacity. The position of the laminæ always requires strict attention, that the worked stone may, if possible, be laid in the building upon its natural bed; for although some instances occur, as in the Isle of Portland and at Grinshill, in Shropshire, where the difference is not apparently great, yet in all stone (even granite) it is sufficiently well known to workmen. Some stone, as that of Bath, is so soft when taken out of the quarry as to be very conveniently worked with tools resembling those used by carpenters; yet when exposed for some time to the atmosphere, it becomes hard and durable. This last, indeed, cannot be deemed sand-stone, being nearly altogether calcareous.

Besides the before-mentioned, there is a very beautiful stone, dug in the hills near Dunstable, in the parish of Tottenhoe, from whence the stone receives its name. It has the appearance of indurated chalk. It is easily worked, and hardens by exposure to the weather. It should, however, be placed upon a plinth of some other stone, or kept by other means from contact with the ground; otherwise it is, in this situation, liable to be injured by the frosts. The house of the Duke of Bedford, at Woburn Abbey, is built chiefly with this stone, as are various other large houses in the neighbourhood of the quarries. Proofs of its durability may be seen in many old churches. From the closeness of its texture, the beauty of its colour, and the facility with which it is worked into mouldings, &c., it is peculiarly fit for house-building, both externally and internally.

The very perfect preservation of many beautiful churches in the countries of Lincoln, Rutland, and Northampton, are evidences of the excellence of the stone of which they are built.

In the central parts of Scotland, different varieties of sand-stone, which accompany coal, are used extensively in building houses, &c.; and this circumstance has not a little contributed to the fine appearance of the new streets, squares, and public buildings in the cities of Edinburgh and Glasgow. Flints, where they abound, and where other stone is scarce, are sometimes used in walls of considerable height; and notwithstanding their small size and irregularity of shape, are broken so as to compose a face of considerable smoothness. The church and steeple of Rickmansworth, in Hertfordshire, affords a fine specimen of this kind of building. But brick or squared stones are generally used as quoins of this sort of work.

In Scotland and Sweden, granite is made use of as a building material. It lies in large masses, generally separated by gunpowder into moderate, though still large dimensions, which are again cut into suitable scantlings, by means of iron instruments called *plugs and feathers.* They are not only worked into plain square forms, but also mouldings of considerable delicacy, by means of pointed tools, of different size and weights. At Aberdeen, in Scotland, where excellent granite is produced, and the working of it brought, perhaps, to the greatest perfection, there are handsome porticos, consisting of columns, bases, caps, and entablatures, executed in granite with great nicety. In the middle of the city, a public building, whose front is composed of a full Doric order, is wholly completed with this excellent material. There are two sorts of granite, the one gray and the other red; the last, being the hardest, is most difficult to work—consequently the former is most frequently employed; it consists of feldspar, mica, and quartz. It is much employed for paving the carriage-way of streets, and in the curbing of the flat side-pavements; also for piers and footpaths of bridges; and for facings and copings to quays and wharfs. At Aberdeen, it is employed in constructing very extensive piers, for protecting the entrance of the harbour; and in the Eddystone and Bell-rock lighthouse, it composes the facings, where they are exposed to the action of the sea.

Whin, basalt, and schistus, are also used in rubble work. The former dressing freely with the hammer, in one direction, may readily be formed with good faces, but not being stratified, their beds are uncertain, and not easily improved by art; the latter—that is, schistus—is just the reverse, having naturally good beds, but being in few instances willing to dress square across the laminæ: they are, indeed, where expense is not an object, worked to a face by the laborious operation of striking perpendicularly with a wedge-mouthed hammer or stone axe: both kinds are laid, sometimes promiscuously, and at others in regular courses.

Limestone, where found regularly stratified, affords good building stone, and combines the advantages of both the former, having naturally good beds, and dressing readily for a face.

A species of schistus affords a covering for roofs, totally unknown to the ancients, and which, when good of its kind, and properly prepared and laid on, is both very effectual and beautiful; for a farther account of which, *see* Slate.

Bricks have, in England, become a material very generally employed in constructing all kinds of buildings. The country is provided by nature with abundant supplies of coal for burning bricks, which can, by means of the sea or numerous inland navigations, be, with great facility, conveyed to the large towns and populous districts, where the demand has long been very great. Clay of proper quality is usually found either upon the spot or immediate vicinity; a very limited number of workmen, properly arranged, can manufacture a great number of bricks in a stated time; these can readily be removed to the place where they are to be employed; being light to handle, and of a rectangular shape, the workmen lay them with facility and ease. By means of bricks, walls can be made much thinner than with almost any kind of stone; they are therefore cheaper, and occupy less space; in forming doorways, windows, chimneys, apertures, and angles of all kinds, the facility they afford is greater than that of any other durable material. A building whose walls are made with bricks dries soon, is free from damp; and, if properly made and thoroughly well burnt, bricks endure equal to most, and longer than many kinds of stone. For the best modes of manufacturing them, *see* Brick.

Tiles having long been employed in England for covering the roofs of buildings situated in towns, and of farm-houses and cottages in the country; but of late years the use of them has been much circumscribed by the extension of that of slates. For the mode of manufacturing and using them, *see* Tile.

Respecting sand, the ancient and modern practices agree nearly in all that need be said; that which is of an angular shade, hard texture, and perfectly free from earthy particles, is admitted to be best. For the circumstances necessary to be attended to in employing it, as well as lime, *see* Cement.

In regard to metals, in modern times, the use of copper and bronze has, for building purposes, been mostly abandoned. Brass has been continued in locks, pulleys, sash-windows, handles, sliding plates, connected with bells, and sundry other purposes in fitting up the interior of apartments.

Iron has been applied to many purposes unthought of in former times. The improvement and general introduction of cast-iron bids fair to create a totally new school of architecture. It has already been extensively employed in bridges, pillars, roofs, floors, chimneys, doors, and windows; and the facility with which it is moulded into different shapes will continue to extend its application. The before-mentioned purposes, to which it has already been applied, are more particularly noticed in the discussions of practice in the different branches of architecture, under their respective heads.

Glass, as a building material, was little if at all known to the ancients; and its introduction alone has been productive of comforts and elegances to which the most refined of the Greeks and Romans were utter strangers. Their oiled paper, transparent horn, talc, shells, and linen, would now, even to an English peasant, appear a miserable expedient. For an account of its manufacture, and application to architectural purposes, *see* Glass.

Besides the materials which have already been enumerated as composing the principal members, as walls, roofs, floors, doors, windows, chimneys, stairs, and pavements; hair is also necessary in the composition of mortar for plastering the surface of walls and ceilings; likewise various paints and papers, for covering them and other parts of the work; all which are described, with the modes of applying them, in their proper places.

MATHEMATICS (from the Greek μαθηματικῄ), the science which treats of the ratio and comparison of quantities, whence it is defined the *science of ratios;* some writers call it the *science of quantities;* but this is inacurate, since quantities themselves are not the subject of mathematical investigation, but the ratio which such quantities bear to each other.

The term *mathematics* is derived from μαθησις, *mathesis*, discipline, science, representing with justness and precision, the high idea that we ought to form of this branch of human knowledge. In fact, mathematics are a methodical concatenation of principles, reasonings, and conclusions, always accompanied by certainty, as the truth is always evident, an advantage that particularly characterizes accurate knowledge and the true sciences, with which we must be careful not to associate metaphysical notions, conjectures, nor even the strongest probabilities.

The subjects of mathematics are the comparisons of magnitude, as numbers, velocity, distance, &c. Thus, geometry considers the relative magnitude and extension of bodies; astronomy, the relative velocities and distances of the planets; mechanics, the relative powers and force of different machines, &c. &c., some determinate quantity being fixed upon in all cases, as a standard of measure.

The study of mathematics is highly useful to the architect, particularly arithmetic, geometry, mensuration, and mechanics. Geometry enables him to take his dimensions under the most difficult circumstances, and to lay out the various parts of his design, while it furnishes him with rules for executing the same. Mensuration is the application of arithmetic to geometry, and shows him how to find the exact proportion of his labour, according to the difficulty of executing a certain uniform portion of a work, and to estimate the quantity of materials employed therein: that branch of mathematics called *mechanics*, enables him to compute the strength and strain of the materials he employs. In short, without the aid of mathematics, he is unfit for his profession; and the more he understands, the fewer difficulties he will have to encounter in the prosecution of his art.

Mathematics are naturally divided into two classes; the one comprehending what we call *pure* and *abstract;* and the other the *compound* or *mixed*. Pure mathematics relate to magnitudes generally, simply, and abstractedly, and are therefore founded on the elementary ideas of quantity. Under this class are included arithmetic, or the art of computation; geometry, or the science of mensuration and comparison of extensions of every kind; analysis, or the comparison of magnitudes in general; to which we may add geometrical analysis, which is a combination of the two latter. Mixed mathematics are certain parts of physics, which are, by their nature, susceptible of being submitted to mathematical investigation. We here borrow from incontestable experiments, or otherwise suppose bodies to possess some principal and necessary quality, and then, by a methodical and demonstrative chain of reasoning, deduce from the principles established conclusions as evident and certain as those which pure mathematics draw immediately from axioms and definitions, observing, that these results are always given with reference to the experiments on which they are founded, or the hypothesis which furnished the first datum. To illustrate this by an example: numberless experiments have shown us, that all bodies near the earth's surface fall with an accelerated velocity, and that the spaces passed through are as the squares of the time they have occupied in falling. This, then, the mathematician considers as a necessary and essential quality of matter, and with this datum he proceeds to examine what will be the velocity of a body after any given time, in what time it will have acquired a given velocity, what time is necessary for it to have generated a given space, &c., and in all these investigations his conclusions are as certain and indisputable as any of those which geometry deduces from self-evident truths and definitions. Again, in optics, having established it as a principle of light, that it is transmitted in right lines while no obstacle is opposed to the passage of the rays; that when they become reflected, the angle of incidence is equal to the angle of reflection; that in passing from one medium to another, of different density, they fly off from their first direction, but still follow a certain geometrical law; these principles, or qualities of light, being once admitted, whatever may be its nature, be it material or immaterial, or whatever may be the medium through which it passes, or the surface by which it is reflected, are matters totally indifferent to the mathematician; he considers the rays only as right lines, the surfaces on which they impinge as geometrical planes, of which the form only enters into his investigation: and from this point all his inquiries are purely geometrical, his investigation clear and perspicuous, and his deduction evident and satisfactory. To this class of mathematics belong mechanics, or the science of equilibrium and motion of solid bodies: hydrodynamics, in which the equilibrium and motion of fluids are considered; astronomy, which relates to the motion, masses, distance, and densities, of the heavenly bodies; optics, or the theory and effects of light; and, lastly, acoustics, or the theory of sounds.

Such are the subjects that fall under the contemplation of the mathematician; and, as far as a knowledge of these may be considered beneficial to mankind, so far, at least, the utility of the science on which they depend, must be admitted. It is not, however, the application of mathematics to the various purposes of society, that constitutes their particular excellency; it is their operation upon the mind, the vigour they impart to our intellectual faculties, and the discipline which they impose upon our wandering reason. "The mathematics," says Dr. Barrow, "effectually exercise, not vainly delude, nor vexatiously torment studious minds with obscure subtilties, but plainly demonstrate everything within their reach, draw certain conclusions, instruct by profitable rules, and unfold pleasant questions. These disciplines also inure and corroborate the mind to a constant diligence in study; they wholly deliver us from a credulous simplicity, and most strongly fortify us against the vanity of scepticism; they effectually restrain us from a rash presumption, most easily incline us to a due assent, and perfectly subject us to the government of right reason. While the mind is abstracted and elevated from sensible matter, it distinctly views pure forms, conceives the beauty of ideas, and investigates the harmony of proportions; the manners themselves are sensibly corrected and improved, the affections composed and rectified, the fancy calmed and settled, and the understanding raised and excited to more divine contemplations."

List of the most celebrated Mathematicians, with the names of their works, or the sciences in which they were eminent, and the countries where they flourished; chronologically arranged.

B. C.	Name.	Science.	Country.
960	Chiron the Centaur.	Astronomy	Thessaly
747	*Era of Nabonassar*		Babylon

Mathematical Instruments, see Instruments.

MAUSOLEUM, is the term now generally used to designate a sepulchral chapel or edifice erected for the reception of a monument; but it originally applied only to the magnificent structure raised by Artemisia, as the tomb of her husband Mausolus, king of Caria, at Halicarnassus, B.C. 352. Of this monument, once reckoned among the wonders of the world, no remains now exist; but from Pliny's description (xxxvi. 5,) it appears to have been nearly square in its plan, measuring 113 feet on its sides, and 93 on each of its ends or fronts, and to have been decorated with a peristyle of 36 columns (supposed by Hardouin to have been 60 feet, or upwards), above which the structure was carried up in a pyramidal form, and surmounted, at its apex, by a marble quadriga, executed by Pythis, who, according to Vitruvius, was joint architect with Satyrus in the building. It was also richly decorated with sculptures and reliefs, by Scopas, Bryaxis, Timotheus, and Leochares. The entire height was 140 feet.

The mausoleum erected at Babylon by Alexander the Great, in honour of Hephæstion, appears to have been still more magnificent, and somewhat extravagant in its decorations, as far as can be gathered from the account of it by Diodorus (xvii. 115). Below it was adorned by the gilded rostra, or beaks, of 240 ships, and every successive tier or story was enriched with a profusion of sculpture, representing various animals, fighting centaurs, and other figures, all of which were gilt. On the summit were statues of sirens, made hollow, in order that the singers who chanted the funeral dirge might be concealed within them.

Those of Augustus and Hadrian, at Rome, were also structures of great magnitude and grandeur, and resembled each other in form, being circular on the plan. The first stood in the Campus Martius, where remains of it yet exist in the two concentric circles forming the first and second stories of the building, and the vaulted chambers between, which supported the first or lowest terrace. Of these terraces there were three, consequently four stages in the building, gradually decreasing in diameter, the uppermost of which was crowned by a colossal statue of the emperor. The terraces themselves were planted with trees. From traces of something of the kind that yet remain, it is conjectured that there was originally an advanced portico attached to the building, in the same manner as that of the Pantheon, though considerably smaller in proportion to the rest of the plan, as it could not have been carried up higher than the first stage of the building. According to Hirt's representation of it, in his "Baukunst bei den Alten," it was a Corinthian hexastyle, advanced one intercolumn before the side-walls connecting it with the circular edifice behind it.

Hadrian's mausoleum, now converted into the Castello di St. Angelo, in which shape it is familiar to almost every one, is a work of most massive construction, and originally presented an unbroken circular mass of building, erected upon a larger square basement, lofty in itself, yet of moderate height in proportion to the superstructure, the latter being about twice as high as the former. This nearly solid rotunda, which was originally coated with white marble, had on its summit numerous fine statues, which were broken to pieces, and the fragments hurled down by the soldiers of Belisarius upon the Goths, who attempted to take the building by storm. Neither are any remains now left of the uppermost stage of the edifice, which assumed the form of a circular peripteral temple, whose diameter was about one-third of the larger circle. According to tradition, its peristyle consisted of the 24 beautiful Corinthian columns, which afterwards decorated the basilica of San Paulo fuori delle Mura (partially destroyed some years ago by fire, but now nearly restored); and its tholus or dome was surmounted by a colossal pine-apple in bronze, now placed in the gardens of the Vatican.

Such places as Henry VII.'s chapel, and the Pantheon of the Escurial, may also be considered as mausoleums; but the term is generally restricted to a detached edifice erected merely as a private burying-place, or to contain tombs. There are several structures of the kind in the parks of our nobility; among the most remarkable is that at Castle Howard, the seat of the earl of Carlisle, and one of Hawksmoor's best works, a noble circular edifice in the Roman-Doric style, elevated upon a basement, and crowned by a dome: plans, sections, &c. of this structure have been beautifully engraved by Moses. The marquis of Rockingham's mausoleum, by Carr, is another ornamental structure of the kind, composed of three stories, Doric, Ionic, and Corinthian. We may also mention those at Cobham, in Kent, and Brocklesby, in Lincolnshire, by the late James Wyatt. The mausoleum of Louisa, queen of Prussia, at Charlottenburg, near Berlin, has a Grecian-Doric portico, but is not so remarkable as a building as for containing the sarcophagus, on which is the recumbent figure of that princess, the chef d'œuvre of Rauch's chisel.

MEASURE (from the Latin *mensura*), in geometry, any certain quantity assumed as one, or unity, to which the ratio of other homogeneous or similar quantities is expressed.

This definition is somewhat more agreeable to practice than that of Euclid, who defines measure as "a quantity, which, being repeated any number of times, becomes equal to another;" which only answers to the idea of an arithmetical measure, or quota part.

Measure of an Angle, an arc described from the vertex in any place between its legs. Hence angles are distinguished by the ratio of the arcs, described from the vertex between the legs, to the peripheries.

Angles, then, are distinguished by those arcs; and the arcs are distinguished by their ratio to the periphery. *See* Angle.

It is, however, in many cases, a more simple and more convenient method to estimate angles, not by the arcs subtending them, but by their sines, or the perpendicular falling from one leg to the other. Thus it is usual, among those who are taking the level of the ground, to say that it rises or falls one foot, or one yard, in ten, when the sine of the angle of its inclination to the horizon is one-tenth of the radius. Angles of different magnitudes, are, indeed, proportional to the arcs, and not to the sines; so that in this sense the sine is not a true measure of the comparative magnitude of the angle; but in making calculations, we are more frequently obliged to employ the sine or cosine of an angle than the angle or arc itself. Nevertheless it is easy to pass from one of these elements to the other, by means either of trigonometrical tables, or of the scales engraved on the sector.

Measure of a Figure, or Plane Surface, a square, whose side is one inch, foot, yard, or other determinate length.

Among geometricians it is usually a rod, called a *square rod*, divided into ten square feet, and the square feet into square digits. Hence square measures. See Mensuration.

Measure of Force, *for perforating metal and other substances.* The measure of the force necessary to punch a hole through a plate of metal or other substance, must be an interesting subject to scientific readers. We shall therefore here insert the result of Mr. Bevan's experiments made on that subject. A good cylindrical steel punch was made and fitted to a guide or director, so as to move correctly to a cylindrical hole in a steel plate connected with the guide; with this instrument, the artist was able to force cylinders of metal very uniform, and with little or no bur to the hole, both by simple pressure and percussion. The results of some experiments made on the force of simple pressure, to make a hole through a metal plate of one-eighth of an inch in thickness, and one-fourth of an inch in diameter, are as follows:—Plate iron, 3,900 lbs.; cast brass, 3,200 lbs.; hammered brass, 3,600 lbs.; copper, 2,800 lbs. The following are the results from the same machine, on specimens of wood, in the direction of the grain, of the same thickness and diameter:—Christiana deal, 135 lbs.; mahogany, 170 lbs.; dry boxwood, 356 lbs.; beech, 204 lbs.; ash, 197 lbs.; oak, 156 lbs.; elm, 122 lbs.

Measure of a Line, any right line taken at pleasure, and considered as unity.

Measures, *Line of*, see Line.

Measure of the Mass, or Quantity of Matter, in mechanics, is its weight; it being apparent, that all the matter which coheres and moves with a body, gravitates with it; and it being found by experiment that the gravities of homogeneal bodies are in proportion to their bulks: hence, while the mass continues the same, the absolute weight will be the same, whatever be its figure; but as to its specific weight, it varies as the quantity of surface varies. *See* Weight.

Measure of a Number, in arithmetic, a number which divides another, without leaving any fraction; thus 9 is a measure of 27.

Measure of a Solid, a cube whose side is one inch, foot, yard, or other determined length.

Among geometricians it is sometimes a rod, or perch, called a *cubic perch;* divided into cubic feet, digits, &c. Hence cubic measures, or measures of capacity. *See* Cube and Mensuration.

Measure of Velocity, in mechanics, the space passed over by a moving body in any given time. To measure a velocity, therefore, the space must be divided into as many equal parts as the time is conceived to be divided into. The quantity of space answering to such an interval of time is the measure of the velocity.

Measure, *Universal and Perpetual*, a kind of measure unalterable by time, to which the measures of different nations and ages might be reduced, and by which they might be compared and estimated. Such a measure is very desirable, if it could be attained. Huygens, in his *Horol. Oscill.*, proposes, for this purpose, the length of a pendulum vibrating seconds, taken from the point of suspension to the point of oscillation. The third part of such a pendulum may be called the *horary foot*, and serve as a standard to which the measure of all other feet may be preferred. Thus, *e. g.* the proportion of the Paris foot to the horary foot would be that of 864 to 881; because the length of three Paris feet is 864 half lines, and the length of a pendulum vibrating seconds contains three horary feet, or 3 feet 8½ lines, *i. e.* 881 half lines. But this measure, in order to its being universal, supposes, that the action of gravity is everywhere the same, which is contrary to fact; and, therefore, it would really serve only for places under the same parallel of latitude; and in order to its being perpetual, it supposes that the action of gravity continues always the same in the same place.

Measure, in a legal, commercial, and popular sense, denotes a certain quantity or proportion of anything bought, sold, valued, or the like. It denotes also a vessel of capacity employed in measuring grain and other articles: the fourth part of a peck. The regulation of weights and measures ought certainly to be the same throughout the kingdom, and therefore be reducible to some fixed rule or standard; the prerogative of so fixing it was vested, by our ancient law, in the crown. This standard was originally kept at Winchester; and we find, in the laws of king Edgar, cap. 8, near a century before the Conquest, an injunction, that the one measure, which was kept at Winchester, should be observed throughout the realm. With respect to measures of length, our ancient historians (Wil. Malm. *in Vita. Hen. I.* Spelm. *Hen. I. apud Wilkins*, 299) inform us, that a new standard of longitudinal measure was ascertained by king Henry I., who commanded that the ulna, or ancient ell, which answers to the modern yard, should be made of the exact length of his own arm; and one standard of measures of length once gained, all others are easily derived from hence: those of greater length by multiplying; those of less by subdividing the original standard. Thus, by the statute called "*Compositio ulnarum et perticarum*," 5½ yards make a perch; and the yard is subdivided into 3 feet, and each foot into 12 inches, which inches will be each of the length of 3 grains of barley. The standard of weights was originally taken from corns of wheat, whence the lowest denomination of weights which we have still expressed by a "grain," 32 of which are directed by the statute called "*Compositio mensurarum*," to compose a pennyweight, of which 20 make an ounce, 12 ounces a pound, and so upwards. Upon these principles the standards were first made, which, being originally so fixed by the crown, their subsequent regulations have been generally made by the king in parliament. Thus, under king Richard I., in his parliament holden at Westminster, A. D. 1197, it was ordained that there should be only one weight and one measure throughout the kingdom, and that the custody of the assize, or standard of weights and measures, should be committed to certain persons in every city and borough. In king John's time, this ordinance of king Richard was frequently dispensed with for money (Hoved. A. D. 1201), which occasioned a provision to be made for enforcing it, in the great charters of king John and his son.—*Stat.* 9. *Hen. III. c.* 25.

The statute of Magna Charta, cap. 25, ordains that there shall be but one measure throughout England, according to the standard in the Exchequer, which standard was formerly kept in the king's palace; and in all cities, market-towns, and villages, it was kept in the churches. (4 Inst. 273.) By 16 Car. I. cap. 19, there is to be one weight and measure, and one yard, according to the king's standard; and whoever shall keep any other weight or measure, whereby anything is bought or sold, shall forfeit for every offence five shillings; and by 22 Car. II. cap. 8, water measure (viz., five pecks to the bushel), as to corn, or grain, or salt, is declared to be within the statute 16 Car. I.; and if any sell grain, or salt, &c., by any other bushel or measure than what is agreeable to the standard in the Exchequer, commonly called Winchester measure, he shall forfeit 40s. (22 Car. II. c. 8. 22 and 23 Car. II. c. 12.) Notwithstanding these statutes, in many places and counties there were, till within the last few years, many different measures of corn and grain, and also of length and solidity. Great inconvenience being felt in consequence, the government at length interfered, and introduced a bill into parliament for the establishment of a uniform system throughout the country.

This system, called the Imperial, came into operation on the 1st May, 1825, on which day a total alteration took place in the weights and measures hitherto used in Great Britain. The principles upon which this alteration was founded we shall now proceed briefly to describe.

The Rationale of the Imperial System.—Take a pendulum which will vibrate seconds in London, on a level of the sea, in a vacuum; divide all that part thereof which lies between the axis of suspension and the centre of oscillation into 391·393 equal parts; then will ten thousand of those parts be an imperial inch, twelve whereof make a foot, and thirty-six whereof make a yard.

The *Standard Yard* is "that distance between the centres of the two points in the gold studs in the straight brass rod, now in the custody of the clerk of the House of Commons, whereon the words and figures 'standard yard, 1760,' are engraved, which is declared to be the genuine standard of the measure of length called a yard; and as the expansibility of the metal would cause some variation in the length of the rod in different degrees of temperature, the act determines that the brass rod in question shall be of the temperature of 62 degrees Fahrenheit. The measure is to be denominated the 'imperial standard yard,' and to be *the only standard whereby all other measures of lineal extension shall be computed.* Thus the *foot*, the *inch*, the *pole*, the *furlong*, and the *mile*, shall bear the same proportion to the imperial standard yard as they have hitherto borne to the yard measure in general use." The act also makes provision for the restoration of the standard yard, in case of loss, destruction, or defacement, by reference to an *invariable* natural standard, which is to be that proportion which the yard bears to the length of a pendulum vibrating seconds of time in the latitude of London, in a vacuum at the level of the sea, which is found to be as 36 inches (the yard) to 391·393 (the pendulum); thus a sure means is established to supply the loss which might by possibility occur.

Take a cube of one such inch of distilled water at 62° of temperature by Fahrenheit's thermometer; let this be weighed by any weight, and let such weight be divided into 252·458 equal parts, then will one thousand of such parts be a troy grain; and seven thousand of those grains will be a pound avoirdupois, the operation having been performed in air. Ten pounds such as those mentioned, of distilled water, at 62° of temperature, will be a gallon, which gallon will contain two hundred and seventy-seven cubic inches, and two hundred and seventy-four one-thousandth parts of another cubic inch.

The Standard Pound is determined to be that standard pound *troy* weight made in the year 1758, in the custody of the clerk of the House of Commons: such weight is to be denominated the "imperial standard troy pound;" and after the first of May, 1825, is to be "*the only standard measure of weight, from which all other weights shall be derived, computed, and ascertained*, and that one twelfth part of the said troy pound shall be *an ounce*, and one twentieth part of such ounce shall be *a pennyweight*, and that one twenty-fourth part of such pennyweight shall be *a grain;* so that 5760 such grains shall be *a pound troy*, and 7000 such grains shall be declared to be *a pound avoirdupois*, and one sixteenth part of the said pound avoirdupois shall be *an ounce avoirdupois*, and one sixteenth part of such ounce shall be *a drachm*."

If the standard pound shall be lost, destroyed, or defaced, the act directs that it shall be recovered by reference to the weight of a cubic inch of water: it having been ascertained that a cubic inch of distilled water, weighed in air by brass weights, at the temperature of 62° Fahrenheit, and the barometer at 30 inches, is equal to 252·458 grains; and, as the standard troy pound contains 5760 such grains, it is therefore established that the original standard pound may be at any time recovered by making another weight to bear the proportion just mentioned to a cubic inch of water.

The Standard Gallon is determined by the act to be such measure as shall contain ten pounds avoirdupois of distilled water, weighed in air, at the temperature of 62° Fahrenheit, and the barometer at 30 inches, and such measure is declared to be the "imperial standard gallon, and shall be the unit and *only standard measure of capacity to be used, as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heaped measure;* and that other measures shall be taken in parts, or multiples, of the said imperial standard gallon—the quart being the fourth part of such gallon, and *the pint* one eighth part—two such gallons making *a peck*, eight such gallons *a bushel*, and eight such bushels *a quarter* of corn, or other dry goods not measured by heaped measure.

The Standard for Heaped Measure, for such things as are commonly sold by heaped measure, such as coal, culm, lime, fish, potatoes, fruit, &c., shall be "*the aforesaid bushel*, containing eighty pounds of water, as aforesaid, the same being made round with a plane and even bottom, and being 19½ inches from outside to outside;" and goods thus sold by heaped measure shall be heaped "in the form of a cone, such cone to be of the height of at least six inches, the outside of the bushel to be the extremity of the base of such cone;" three such bushels shall be a *sack*, and twelve such sacks shall be a *chaldron.*

Stricken Measure.—The last mentioned goods may be sold either by the heaped measure, or by the standard weight as before mentioned; but all other kinds of goods not usually sold by heaped measure, which may be sold or agreed for by measure, the same standard measure shall be used; but it shall not be heaped, but stricken with a round stick or roller, straight, and of the same diameter from end to end.

N.B.—Copies and models of the standard of length, weight, and measure, are to be made and verified under the direction of the Treasury, and every county to be supplied with them for reference whenever required; and after the first of May, 1825, all contracts for sale, &c., by weight or measure, shall relate to the standard, unless the contrary is specified. Existing weights and measures may be used, being marked so as to show the proportion they have to the standard measures and weights. Tables of equalization of the weights to be made by the Treasury; tables, also, for the customs and excise, by which the duties will be altered so as to make them equal to what they are at present, in consequence of the alterations in the weights and measures. *See* WEIGHTS.

The following extracts from the bill for ascertaining and establishing uniformity of weights and measures will explain this subject fully:—"Whereas it is necessary, for the security of commerce, and for the good of the community, that weights and measures should be just and uniform; and whereas, notwithstanding it is provided by the great charter, that there shall be but one measure and one weight throughout the realm; and, by the treaty of union between England and Scotland, that the same weights and measures should be used throughout Great Britain as were then established in England; yet different weights and measures, some larger and some less, are still in use in various places throughout the United Kingdom of Great Britain and Ireland; and the true measure of the present standard is not verily known, which is the cause of great confusion and of manifest frauds; for the remedy and prevention of those evils for the future, and to the end that certain standards of weights and measures should be established throughout the United Kingdom of Great Britain and Ireland, "Be it therefore enacted, by the king's most excellent majesty, by and with the consent of the lords spiritual and temporal, and commons, in this present parliament assembled, and by the authority of the same, that a cubic inch of distilled water in a vacuum, weighed by brass weights, also in a vacuum, at the temperature of 62° of Fahrenheit's thermometer, is equal to two hundred and fifty-two grains and seven hundred and twenty-four thousandth parts of a grain.

"And be it further enacted, that the standard measure of capacity, as well for liquid as for dry goods not measured by heaped measure, shall be the gallon containing ten pounds avoirdupois weight of distilled water, weighed in air, at the temperature of 62° of Fahrenheit's thermometer, the barometer being at thirty inches, to be used as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heaped measure; and eight such gallons shall be a bushel, and eight such bushels a quarter—of corn, or other dry goods not measured by heaped measure.

"And be it further enacted, that the standard measure of capacity for coals, culm, lime, fish, potatoes, or fruit, and all other goods and things commonly sold by heaped measure, shall be the aforesaid bushel, containing eighty pounds avoirdupois of water as aforesaid, the same being made round with a plane and even bottom, and being nineteen and a half inches from outside to outside of such standard measure as aforesaid.

"And be it further enacted, that all contracts, bargains, sales, and dealings, which shall be made or had within any part of the United Kingdom of Great Britain and Ireland, for any work to be done, or for any goods, wares, merchandise, or other thing to be sold, delivered, done, or agreed for, by weight or measure, where no special agreement shall be made to the contrary, shall be deemed, taken, and construed, to be made and had according to the weights and standard measures ascertained by this act; and in all cases where any special agreement shall be made, with reference to any weight or measure established by any local custom, the ratio or proportion which every such local weight or measure shall bear to any of the said standard weights or measures, shall be expressly declared and specified in such agreement, or otherwise such agreement shall be null and void.

"And whereas it is expedient, that persons should be allowed to use the several weights and measures which they may have in their possession, although such weights and measures may not be in conformity with the standard weights and measures established by this act; be it therefore enacted, that it shall and may be lawful for any person or persons to buy and sell goods and merchandise by any weights or measures, established either by local custom or founded on special agreement; provided always, that in order that the ratio or proportion which all such measures and weights shall bear to the standard weights and measures established by this act, shall be and become a matter of common notoriety, the ratio or proportion which all such customary measures and weights shall bear to the said standard measures, shall be painted or marked upon all such customary weights and measures respectively; and that nothing herein contained shall extend, or be construed to extend, to permit any makers of weights or measures, or any person or persons whomsoever, to make any weight or measure at any time after, except in conformity with the standard weights and measures established under the provisions of this act.

"And be it further enacted, that accurate tables shall be prepared and published, showing the proportions between the weights and measures heretofore in use, as mentioned in such inquisitions, and the weights and measures hereby established; and after the publication of such tables, all future payments to be made shall be regulated according to such tables.

"And whereas the weights and measures by which the rates and duties of the customs and excise, and other his majesty's revenue, have been heretofore collected, are different from the weights and measures of the same denominations directed by this act to be universally used; and whereas the alteration of such weights and measures may, without due care had therein, greatly affect his majesty's revenue, and tend to the diminishing of the same; for the prevention thereof, be it therefore enacted, that, so soon as conveniently may be, accurate tables shall be prepared and published, in order that the several rates and duties of customs and excise, and other his majesty's revenue, may be adjusted and made payable according to the respective quantities of the legal standards directed by this act to be universally used; and that from and after the publication of such tables, the several rates and duties thereafter to be collected by any of the officers of his majesty's customs or excise, or other his majesty's revenue, shall be collected and taken according to the calculations in the tables to be prepared as aforesaid."

Table of the several Standard Measures.—English Long Measure.

Barleycorns.	Inches.	Feet.	Yards.	Poles.	Fur.	Mile.
3 =	1					
36 =	12 =	1				
108 =	36 =	3	1			
594 =	198 =	16½	5½ =	1		
23,768 =	7,920 =	660 =	220 =	40 =	1	
190,080 =	63,360 =	5,280 =	1,760 =	320 =	8 =	1

ALSO:—

4	Inches	= 1	Hand
6	Feet	= 1	Fathom
3	Miles	= 1	League
60	Geographical miles	= 1	Degree
69⅓	English miles	= 1	Degree nearly
360	Degrees, or 25,000 miles, is equal to the circumference of the earth, nearly.		

Cloth Measure.

Inches.	Nails.	Quarters.	
2½ =	1		
9 =	4 =		
36 =	16 =	4 =	1 yard
27 =	12 =	3 =	1 ell Flemish
45 =	20 =	5 =	1 ell English
54 =	24 =	6 =	1 ell French

The French standard was formerly the aune, or ell, containing 3 Paris feet, 7 inches, 3 lines, or 1 yard 2-sevenths English; the Paris foot-royal exceeding the English by 68 thousandth-parts. This ell is divided two ways, viz., into halves, thirds, sixths, and twelfths, and into quarters, half-quarters, and sixteenths.

The standard in Holland, Flanders, Sweden, and a good part of Germany—many of which were formerly called the Hans-towns, as Dantzic and Hamburg, and at Geneva, Frankfort, &c.—is likewise the ell; but the ell in all these places differs from the Paris ell. In Holland, it contains one Paris foot eleven lines, or four-sevenths of the Paris ell. The Flanders ell contains two feet one inch five lines and half a line, or seven-twelfths of the Paris ell. The ell of Germany Brabant, &c. is equal to that of Flanders.

The Italian measure is the branchio, brace, or fathom. This obtains in the states of Modena, Venice, Florence, Lucca, Milan, Mantua, Bologna, &c., but is of different lengths. At Venice, it contains one Paris foot eleven inches three lines, or eight-fifteenths of the Paris ell. At Bologna, Modena, and Mantua, the brace is the same as at Venice. At Lucca, it contains one Paris foot nine inches ten lines, or half a Paris ell. At Florence, it contains one foot nine inches four lines, or forty-nine hundredths of a Paris ell. At Milan, the brace for measuring of silks is one Paris foot seven inches four lines, or four-ninths of a Paris ell; that for woollen cloths is the same with the ell of Holland. Lastly, at Bergamo, the brace is one foot seven inches six lines, or five-ninths of a Paris ell. The usual measure at Naples, however, is the canna, containing six feet ten inches and two lines, or one Paris ell and fifteen-seventeenths.

The Spanish measure is the vara, or yard—in some places called the bara—containing seventeen twenty-fourths of the Paris ell. But measure in Castile and Valencia is the pan, span, or palm, which is used, together with the canna, at Genoa. In Arragon, the vara is equal to a Paris ell and a half, or five feet five inches six lines.

The Portuguese measure is the cavedos, containing two feet eleven lines, or four-sevenths of a Paris ell; and the vara, an hundred and six whereof make an hundred Paris ells.

The Piedmontese measure is the ras, containing one Paris foot nine inches ten lines, or half a Paris ell. In Sicily, their measure, the canna, the same with that of Naples.

The Muscovy measures are the cubic, equal to one Paris foot four inches two lines; and the arcin, two whereof are equal to three cubits.

The Turkish and Levant measures are the picq, containing two feet two inches and two lines, or three-fifths of the Paris ell. The Chinese measure, the cobre, ten whereof are equal to three Paris ells. In Persia, and some parts of the Indies, the gueze, whereof there are two kinds; the royal gueze, called also the *gueze monkelser*, containing two Paris feet ten inches eleven lines, or four-fifths of the Paris ell; and the shorter gueze, called simply *gueze*, only two-thirds of the former. At Goa and Ormuz, the measure is the vara, the same with that of the Portuguese, having been introduced by them. In Pegu, and some other parts of the Indies, the cando, or candi, equal to the ell of Venice. At Goa, and other parts, they use a larger cando, equal to seventeen Dutch ells; exceeding that of Babel and Balsora by $\frac{7}{8}$ per cent., and the vara by $6\frac{1}{2}$. In Siam, they use the ken, short of three Paris feet by one inch. The ken contains two soks, the sok two keubs, the keub twelve nious, or inches, the niou to be equal to eight grains of rice, *i. e.* to about nine lines. At Camboia, they use the haster; in Japan, the tatam; and the span on some of the coasts of Guinea.

Square Measure.

Inches.					
144 =	1 foot				
1,296 =	9 =	1 yard			
39,204 =	$272\frac{1}{4}$ =	$36\frac{1}{4}$ =	1 pole		
1,568,160 =	10,890 =	1,210 =	40 =	1 rood	
6,272,640 =	43,560 =	4,840 =	160 =	4 =	1 acre

Also: $5\frac{1}{2}$ yards . . . . = 1 pole
40 poles . . . . = 1 rood
4 roods . . . . = 1 acre

Square, Superficial, or Land Measure.—English square measures are raised from the yard of 36 inches multiplied into itself, and thus producing 1,296 square inches in the square yard; the divisions of this are square feet and inches; and the multiples, poles, roods, and acres. Because the length of a pole is $5\frac{1}{2}$ yards the square of the same contains $30\frac{1}{4}$ square yards. A square mile contains 640 square acres. In measuring fens and woodlands, 18 feet are generally allowed to the pole, and 21 feet in forest-land. A hide of land, frequently mentioned in the earlier part of the English history, contained about 100 arable acres; and five hides were esteemed a knight's fee. At the time of the Norman conquest, there were 243,600 hides in England.

Scotch square or land measure is regulated by the Scotch ell: 36 square ells = 1 fall; 40 falls = 1 rood; 4 roods = 1 acre. The proportion between the Scotch and English acre, supposing the feet in both measures alike, is as 1,369 to 1,089, or nearly as five to four. If the difference of the feet be regarded, the proportion is as 10,000 to 7,869. The length of the chain for measuring land in Scotland is 23 ells, or 74 feet. A husband-land contains six acres of sock and scythe land—that is, of land that may be tilled with a plough, or mown with a scythe; 13 acres of arable land make one ox-gang; and four ox-gangs make a poundland of old extent.

French square measures are regulated by 12 square lines in the inch square, 12 inches in the foot, 22 feet in the perch, and 100 perches in the arpent or acre.

In the following tables, the reader will find enumerated the various general standing measures—long, square, and cubic, now or heretofore in use, with their proportions and reductions.

TABLES OF DIFFERENT MEASURES, ACCORDING TO VARIOUS AUTHORITIES, REDUCED TO ENGLISH MEASUREMENT.

LONG MEASURES.

Table I.—Scripture Long Measure.

			English Ft.	English In.
1 Digit	. . . .	=	0	0.912
4 Digits	= 1 Palm	=	0	3.648
3 Palms	= 1 Span*	=	0	10.944
2 Spans	= 1 Cubit †	=	1	9.888
4 Cubits	= 1 Fathom	=	7	3.552
$1\frac{1}{2}$ Fathoms	= 1 Reed (Ezekiel's) . .	=	10	11.328
$1\frac{1}{3}$ Reeds	= 1 Pole (Arabian) . . .	=	14	7.104
10 Poles	= 1 Scænus, or measuring line	=	145	1.104

* The Orientals used another span, equal to one-fourth of a cubit.

† See Table II.

Table II.—Jewish Long, or Itinerary Measures.

			English Miles.	English Paces.	English Feet.
1 Cubit*	. . . .	=	0	0	1.824
400 Cubits . . .	= 1 Stadium . . .	=	0	145	4.6
5 Stadii . . .	= 1 Sab. day's journ.	=	0	729	3.0
2 Sab. day's journ.	= 1 Eastern mile .	=	1	403	1.0
3 Eastern miles .	= 1 Parasang . .	=	4	153	3.0
8 Parasangs . .	= 1 Days' journey	=	33	172	4.0

* Dr. Hutton reckons the Hebrew cubit as follow: Eng. feet.
Common Cubit . . . . = 1.817
Sacred cubit . . . . = 2.002
Great cubit = 6 common cubits . . . . . = 10.902
The Hebrew foot, according to Dr. Hutton, was equal to 1.212 English foot.

Table III.—Grecian Long Measures.

				English Pa.	English Ft.	English Inches.
1	Dactylus or Digit		=	0	0	$0.7554\frac{1}{10}$
4	Dactyli . .	= 1 Doron, or Dochme, or Palesta	=	0	0	$3.0218\frac{3}{4}$
$2\frac{1}{2}$	Palestæ, &c.	= 1 Lichas . . .	=	0	0	$7.5546\frac{7}{8}$
$1\frac{1}{10}$	Lichas . .	= 1 Orthodoron .	=	0	0	$8.3101\frac{9}{10}$
$1\frac{1}{11}$	Orthodoron	= 1 Spithame . .	=	0	0	$9.0656\frac{1}{4}$

			Pa.	Ft.	English Inches.
$1\frac{1}{3}$ Spithame	= 1	Pous, or foot*	0	1	0.0875
$1\frac{1}{8}$ Pous	= 1	Pygme, or cubit	0	1	$1.5984\frac{3}{8}$
$1\frac{1}{9}$ Pygme	= 1	Pygon	0	1	$3.109\frac{3}{8}$
$1\frac{1}{5}$ Pygon	= 1	Pecus, or larger cubit	0	1	6.13125
4 Pecus	= 1	Orgya, or pace	0	6	0.525
100 Orgya, or paces	= 1	Stadium, aulus, or furl.	100	4	4.5
8 Stadii, &c.	= 1	Million, or mile	805	5	0

* The Greek foot is variously estimated; thus:

	Eng. foot.
By Dr. Hutton†	= 1.009
By Folkes, who reckons it equal to $1\frac{1}{24}$ Roman foot	= 1.006 / 1.007
By Cavallo	= 1.007

† Dr. Hutton reckons the Phyleterian foot = 1.167; Macedonian foot = 1.160

N. B. Two sorts of long measures were used in Greece, viz., *the Olympic* and *the Pythic*: the former in Peloponnesus, Attica, Sicily, and the Greek cities in Italy; the latter in Thessaly, Illyria, Phocis, Thrace, and at Marseilles in Gaul.

		Eng. In.
The Olympic foot (properly called *Greek*) contains, according to	Dr. Hutton	12.108
	Folkes	12.072
	Cavallo	12.084
The Pythic foot, (called also *natural foot*,) contains, according to	Dr. Hutton	9.768
	Paucton	9.731

Hence it appears, that
The Olympic stadium is $201\frac{1}{2}$ English yards, nearly.
The Pythic or Delphic stadium, $162\frac{1}{2}$ yards, nearly.
And the other measures in proportion.
The Phyleterian foot is the Pythic cubit, or $1\frac{1}{2}$ Pythic foot.
The Macedonian foot was 13.92 English inches.
The Sicilian foot of Archimedes, 8.76 English inches.

Table IV.—Roman Long Measures.

			English Pa.	Ft.	In.
6 Scrupula	= 1	Sicilicum			
8 Scrupula	= 1	Duellum			
$1\frac{1}{2}$ Duellum	= 1	Seminaria			
18 Scrupula	= 1	Digitus transversus	0	0	$0.725\frac{3}{4}$
$1\frac{1}{3}$ Digiti	= 1	Uncia, or inch	0	0	0.967
3 Unciæ	= 1	Palma minor	0	0	2.901
4 Palmæ	= 1	Pes, or foot*	0	0	11.604
$1\frac{1}{4}$ Pes, or foot	= 1	Palmipes	0	1	2.505
$1\frac{1}{5}$ Palmipes	= 1	Cubit	0	1	5.406
$1\frac{2}{3}$ Cubits	= 1	Gradus	0	2	5.01
2 Gradus	= 1	Passus	0	4	10.02
2 Passus	= 1	Decempeda	1	4	8.04
125 Passus	= 1	Stadium	120	4	4.5
8 Stadii	= 1	Milliare, or Mile †	967	0	0

* The length of the Roman foot, in English inches, is stated by various writers as follows:

	Eng In.
By Bernard	11.640
By Picard and Hutton	11.604
By Folkes	11.592
By Raper (before Titus)	11.640
By the same (after Titus)	11.580
By Shuckburgh, from rules	11.6064
By the same, from buildings	11 6172
By the same, from a tomb-stone	11.6352

Hence 11.6 Eng. in. seem to be a medium; and, therefore, the Roman mile = 1611 English yds., being 149 yds. less than the English mile.

Its proportion to the English foot is thus stated:—

By Bernard	.970	By Raper	Before Titus	.970
By Picard and Greaves	.976		After Titus	.965
		By Shuckburgh	From Rules	.9672
			From Build.	.9681
By Folkes	.966 / .967		From a Stone.	9696
		By Dr. Hutton		.967

† The Roman mile of Pliny (according to Cavallo) contained 4840.5 English feet; and that of Strabo 4903.

Table V.—Ancient Long Measures, according to Dr. Hutton.

	Eng. Feet.
Arabian foot	= 1.095
Babylonian foot	= 1.144 / 1.135
Drusian foot	= 1.090
Egyptian foot	= 1.421
——— stadium	= 7.308
Natural foot	= .814
Ptolemaic = the Greek foot (see Table III.)	
Sicilian foot of Archimedes	= .730

Table VI.—Scottish Long Measures.

	Eng. Inches.
An Ell	= 37.2
A Fall	= 223.2
A Furlong	= 8928.
A Mile	= 71424.
A Link	= 8.928
A Chain, or Short Rood	= 89.28
A Long Rood	= 1339.2

Table VII.—French Long Measures, before the First Revolution.

	Eng. Inches.
A Point	= .0148025, or nearly $\frac{2}{135}$.
A Line	= .088815, or nearly $\frac{8}{90}$.
An Inch, or Pouce	= 1.06578, or, $\frac{1}{93828}$, or $\frac{81}{76}$.
A Foot	= 12.78933
An Ell, or Aune*	= 46.8947, or 44 French In.; or, according to Vega, 43.9
A Sonde	= 63.9967, or 5 French feet, about $\frac{8}{9}$ English fathom.
A Toise, or Fathom	= 76.7360, or 6 French feet.†
A Perche	= 230.2080, or 18 French feet.
A Perche, mesure royale	= 22 French feet.
A League	= 2282 toises, or $\frac{1}{25}$ of a degree

* The aune, or ell, of Paris, varies, being for silk stuffs 527.5 lines, or $46\frac{17}{20}$ English inches; for woollens, 526.4 French lines, or $46\frac{3}{4}$ English inches; for linens, 524 French lines, or $46\frac{11}{20}$ English inches; and it varies still more in other parts of France.

† Formerly 76.71, *Phil. Trans.* for 1742.

Table VIII.—French Long Measures, according to the Present System.

	Eng. Inches.
Millimetre	= .03937
Centimetre	= .39371
Decimetre	= 3.93710
Metre	= 39.37100, or 3.281 feet, or 1.09364 yards, or nearly 1 yard $1\frac{1}{2}$ nail, or 443.2959 French lines, or .513074 toise.
Decametre	= 393.71000, or 10 yards, 2 feet, 9.7 inches.
Hecatometre	= 3937.10000, or 100 yards, 1 foot, 1 inch.
Chiliometre	= 39371.00000, or 4 furlongs, 213 yards, 1 foot 10.2 inches: so that 8 chiliometres are nearly 5 miles.
Myriometre	= 393710.0000, or 6 miles, 1 furlong, 136 yards, 0 feet, 6 inches.

N.B. An inch is .0354 metres; 2441 inches 62 metres; 1000 feet nearly 305 metres.

In order to express decimal proportions in this new system, the following terms have been adopted. The term *Deca* prefixed denotes 10 times; *Heca*, 100 times; *Chilio*, 1000 times; and *Myrio*, 10,000 times. On the other hand, *Deci* expresses the tenth part; *Centi*, the hundredth part; and *Milli*, the thousandth part; so that *Decametre* signifies 10 metres; and a *Decimetre*, the 10th part of a metre, &c. &c. The *Metre* is the element of long measures; *Are*, that of square measures; *Stere*, that of solid measures; the *Litre* is the element of all measures of capacity; and the *Gramme*, which is the weight of a cubic centimetre of distilled water, is the element for all weights.

Table IX.—Proportions of several Long Measures to each other, by M. Picard.

	Parts.
The Rhinland, or Leyden foot, (12 whereof make the Rhinland perch) supposed	696
The English foot	675½
The Paris foot	720
The Amsterdam foot, from that of Leyden, by Snellius	629
The Danish foot (two whereof make the Danish ell)	701 8/10
The Swedish foot	658¼
The Brussels foot	609⅗
The Dantzic foot, from Hevelius's Selenographia	636
The Lyons foot, by M. Auzout	757⅔
The Bologna foot, by the same	843
The braccio of Florence, by the same, and father Mersenne	1290
The palm of the architects at Rome, according to the observations of Messrs. Picard and Auzout	494¼
The Roman foot in the Capitol, examined by Messrs. Picard and Auzout	653 or 653½
The same from the Greek foot	652
From the vineyard Mattei	657½
From the palm	658¼
From the pavement of the Pantheon, supposed to contain 10 Roman feet	653
From a slip of marble in the same pavement, supposed to contain 3 Roman feet	650
From the pyramid of Cestius, supposed to contain 95 Roman feet	653½
From the diameters of the columns in the arch of Septimius Severus	653⅓
From a slip of porphyry in the pavement of the Pantheon	653⅓

Table X.—Proportions of the Long Measures of several Nations to the English Foot, taken from Greaves, Auzout, Picard, and Eisenchmid.

The English standard foot being divided into 1000 equal parts, the other measures will have the proportions to it which follow:—

	Parts.	Inches.
English foot	1000	12.

Westphalia	Miles	14.56	12151

SUPERFICIAL, or SQUARE MEASURES.

Table XIV.—Ancient Greek superficial Measures.

Olympic Land Measure.

36	Olympic square feet	= 1	Hexapodon.
6	Hexapoda	= 1	Hemihectos.
2	Hemihecti	= 1	Hectos or Modius.
6	Modii	= 1	Medimnus or Jugerum.

Hence it appears, that the Olympic jugerum was equal to 103 English perches, or nearly five-eighths of an acre.

Pythic Land Measure.

$1666\frac{2}{3}$	Square cubits	= 1	Hemihectos.
2	Hemihecti	= 1	Modius.
6	Modii	= 1	Medimnus or Jugerum.

Hence the Pythic jugerum appears to have been equal to 109 English perches, or nearly $\frac{11}{16}$ths of an acre.

N.B. The plethron, or acre, is said by some to contair 1444, by others 10,000 square feet; and aroura, the half of the plethron. The aroura of the Egyptians was the square of 100 cubits.

Table XV.—Ancient Roman Land Measures.

100	Square Roman feet	= 1	Scrupulum of land.
4	Scrupula	= 1	Sextulus.
$1\frac{1}{5}$	Sextulus	= 1	Actus*
6	Sextuli, or 5 Actus	= 1	Uncia of land.
6	Unciæ	= 1	Square Actus.
2	Square Actus	= 1	Jugerum.†
2	Jugera	= 1	Heredium.
100	Heredia	= 1	Centuria.

* The actus was a slip of ground four Roman feet broad, and 120 long.

† The jugerum, or acre, was considered as integer, and divided, like the libra, or as, in the following manner:

		Unciæ.	Jugerum contained Roman. Sq. Ft.	Scrup.	English. Rds.	Pol.	Sq. Ft.
1	As	= 12	= 28800	288	= 2	18	250.05
$\frac{11}{12}$	Deunx	= 11	= 26400	264	= 2	10	183.85
$\frac{5}{6}$	Dextans	= 10	= 24000	240	= 2	2	117.64
$\frac{3}{4}$	Dodrans	= 9	= 21600	216	= 1	34	51.42
$\frac{2}{3}$	Bes	= 8	= 19200	195	= 1	25	257.46
$\frac{7}{12}$	Septunx	= 7	= 16800	168	= 1	17	191.25
$\frac{1}{2}$	Semis	= 6	= 14400	144	= 1	9	125.03
$\frac{5}{12}$	Quincunx	= 5	= 12000	120	= 1	1	58.82
$\frac{1}{3}$	Triens	= 4	= 9600	96	= 0	32	264.85
$\frac{1}{4}$	Quadrans	= 3	= 7200	72	= 0	24	198.64
$\frac{1}{6}$	Sextans	= 2	= 4800	48	= 0	16	132.43
$\frac{1}{12}$	Uncia	= 1	= 2400	24	= 0	8	66.21

N. B. If we take the Roman foot at 11.6 English inches (*See* Table V.) the Roman jugerum was = 5980 English square yards, or 1 acre 37½ perches.

Table XVI.—English Square Measures.

144	Inches	= 1 Foot.
9	Feet	= 1 Yard.
$2\frac{7}{9}$	Yards	= 1 Pace.
10.89	Paces	= 1 Pole.
40	Poles	= 1 Rood.
4	Roods	= 1 Acre.

N.B. English square or superficial measures are raised from the yard of 36 inches, multiplied into itself; and this producing 1296 square inches in the square yard, the divisions of this are square feet and inches; and the multiples, poles, roods, and acres, as in the Table. The Scottish acre is 55353.6 square feet English, or 1.27 English acres.

Measures used by different Artificers.

144	Square inches	= 1 Square foot.
9	Square feet	= 1 Square yard.
63	Square feet=7 Sq. yards	= 1 Rood.
100	Square feet	= 1 Square of work.
272¼	Square feet=30¼ Sq. yards	= 1 Rod, perch, or square pole.

Table XVII.—French Square Measures before the First Revolution.

A Square Inch . . . . = 1.13582 English sq. inches.
An Arpent . . . . . = 100 Square perches, French, about ⅚ acre English, used near Paris.
An Arpent, mesure royale* = about 1¼ English acre.

* The perch (*See* Table VIII.) which determines the measure of the acre, varies in different parts of the country: but the arpent of woodland is everywhere the same, the perch being 22 feet long; and this arpent contains 48,400 French square feet, or 6108 English square yards, or one acre, one rood, one perch. The arpent for cultivated land, in the vicinity of Paris, contains 900 square toises, or 4088 English yards; so that 43 such arpents are equal to 38 English acres nearly.

Table XVIII.—French Square Measures, according to the present System.

Are, a square decametre . =	3.95 English perches, or 119.6046 Square yards.
Decare . . . . =	1196.0460 Square yards.
Hecatare . . . . . . =	11960.4600 Square yards, or 2 acres, 1 rood, 35.4 perches.

Cubical Measures, or Measures of Capacity, for Liquids.—The English measures were originally raised from troy weight: it being enacted by several statutes, that eight pounds troy of wheat, gathered from the middle of the ear, and well dried, should weigh a gallon of wine measure, the divisions and multiples whereof were to form the other measures; at the same time it was also ordered, that there should be but one liquid measure in the kingdom; yet custom has prevailed, and there having been introduced a new weight, viz., the avoirdupois, we have now a second standard gallon adjusted thereto; and therefore exceeding the former in the proportion of the avoirdupois weight to troy weight. From this latter standard are raised two several measures, the one for ale, the other for beer. The sealed gallon at Guildhall, which is the standard for wines, spirits, oils, &c. was supposed to contain 231 cubic inches; but by actual experiment, made in 1688, before the lord mayor and the commissioners of excise, it was found to contain only 224 cubic inches, it was, however, agreed to continue the common supposed contents of 231 cubic inches; so that all computations stood on their own footing. Hence as 12 is to 231, so is $14\frac{12}{20}$ to 281½, the cubic inches in the ale gallon: but in effect the ale quart contained 70½ cubic inches, on which principle the ale and beer gallon will be 282 cubic inches. The barrel of ale in London is 32 gallons, and the barrel of beer 36 gallons. In all other places of England, the barrel, both for ale and beer, was wont to be 34 gallons.

Scotch liquid measure is founded on the pint. The Scotch pint was formerly regulated by a standard jug of cast metal, the custody of which was committed to the borough of Stirling. This jug was supposed to contain 105 cubic inches; and though, after several careful trials, it has been found to contain only about 103½ inches, yet in compliance with established custom, founded on that opinion, the pint stoups are still regulated to contain 105 inches, and the customary ale measures are about $\frac{1}{16}$ above that standard. It was enacted by James I. of Scotland, that the pint should contain 41 ounces trone weight of the clear water of Tay, and by James VI. that it should contain 55 Scots troy ounces of the clear water of Leith. This affords another method of regulating the pint, and also ascertaining the ancient standard of the trone weight. As the water of Tay and Leith is alike, the trone weight must have been to the Scots troy weight, as 55 to 41, and therefore the pound trone must have contained about $21\frac{1}{2}$ ounces Scots, troy.

4 Gills	=	1 Mutchkin.
2 Mutchkins	=	1 Chopin
2 Chopins	=	1 Pint
2 Pints	=	1 Quart
4 Quarts	=	1 Gallon.

The Scotch quart contains 210 inches, and is therefore about $\frac{1}{10}$ less than the English wine gallon, and about $\frac{1}{4}$ less than the ale gallon.

As to the liquid measures of foreign nations, it is to be observed, that their several vessels for wine, vinegar, &c. have also various denominations, according to their different sizes and the places wherein they are used. The woeders of Germany, for holding Rhenish and Moselle wines, are different in their guages; some containing 14 aumes of Amsterdam measure, and others more or less. The aume is reckoned at Amsterdam for 8 steckans, or 20 verges, or for $\frac{1}{5}$ of a tun of 2 pipes, or 4 barrels of French or Bordeaux, which $\frac{1}{6}$ at this latter place is called *tierçon*, because three of them make a pipe, or two barrels, and six the said tun. The steckan is 16 mingles, or 32 pints; and the verge is, in respect of the said Rhenish and Moselle, and some other sorts of wine, 6 mingles, but in measuring brandy it consists of $6\frac{1}{4}$ mingles. The aume is divided into 4 anckers, and the ancker into 2 steckans, or 32 mingles. The ancker is taken sometimes for $\frac{1}{24}$ of a tun, or 4 barrels; on which footing the Bordeaux barrel ought to contain at Amsterdam (when the cask is made according to the just guage,) $12\frac{1}{2}$ steckans, or 200 mingles, wine and lees; or 12 steckans, or 192 mingles, racked wine; so that the Bordeaux tun of wine contains 50 steckans, or 800 mingles, wine and lees; and 48 steckans, or 768 mingles, of pure wine. The barrels, or poinçons, of Nantes, and other places on the river Loire, contain only 12 steckans, Amsterdam measure. The wine tun of Rochelle, Cogniac, Charente, and the Isle of Rhé, differs very little from the tun of Bordeaux, and consequently from the barrels and pipes. A tun of wine of Chalosse, Bayonne, and the neighbouring places, is reckoned 60 steckans, and the barrel 15, Amsterdam measure.

The old muid of Paris contains 150 quarts or 300 pints, wine and lees; or 280 pints clear wine; of which muids three make a tun.

The butts, or pipes, from Cadiz, Malaga, Alicant, Benecarlo, Saloe, and Mataro, and from the Canaries, Lisbon, Oporto, and Fayal, are very different in their guages, though in affreightments they are all reckoned two to the tun.

Vinegar is measured in the same manner as wine, but the measures for brandies are different, these spirits, from France, Spain, Portugal, &c., are generally shipped in large casks, called pipes, butts, and pieces, according to the places from whence they are imported, &c. In France, brandy is shipped in casks called pieces at Bordeaux, and pipes at Rochelle, Cogniac, the Isle of Rhé, and other neighbouring places, which contain some more and some less, even from 60 to 90 Amsterdam verges or veertels, according to the capacity of the vessel, and the places they come from.

Dry Measure.

Pints.							
8 =	1 Gallon						
16 =	2 =	1 Peck					
64 =	8 =	4 =	1 Bushel				
256 =	32 =	16 =	4 =	1 Coomb			
512 =	64 =	32 =	8 =	2 =	1 Quarter		
2560 =	320 =	160 =	40 =	10 =	5 =	1 Wey	
5120 =	640 =	320 =	80 =	20 =	10 =	2 =	1 Last.

$268\frac{4}{5}$ Cubic Inches = 1 Gallon
36 Bushels = 1 Chaldron of Coals.

Measure of Capacity for things Dry, was the Winchester gallon heretofore; as for corn, salt, coal, and other dry goods, in England. The gallon contains $272\frac{1}{4}$ cubic inches. The bushel 8 gallons, or 2178 inches. A cylindrical vessel, $18\frac{1}{2}$ inches diameter, and 8 inches deep, is appointed to be used as a bushel in levying the malt tax. A vessel of these dimensions is rather less than the Winchester bushel of 8 gallons, for it contains only 2150 inches, though probably there was no difference intended. The denominations of dry measure commonly used, are given in the first of the subjoined tables. Four quarters of corn make a chaldron, five quarters make a wey or load, and ten quarters make a tun. In measuring seacoal, five pecks make a bushel, nine bushels make a quarter or vatt, four quarters make a chaldron, and twenty-one chaldrons make a score.

40 feet hewn timber make a load.
50 feet unhewn timber make a load.
32 gallons make a herring barrel.
42 gallons make a salmon barrel.
1 cwt. gunpowder makes a barrel.
256 lbs. soap make a barrel.
10 doz. candles make a barrel.
12 barrels make a last.

Scotch dry measure. There was formerly only one measure of capacity in Scotland; and some commodities were heaped, others straiked, or measured exactly to the capacity of the standard. The method of heaping was afterwards forbidden as unequal, and a larger measure appointed for such commodities as that custom had been extended to. The wheat firlot, used also for rye, pease, beans, salt, and grass seeds, contains 21 pints 1 mutchkin, measured by the Stirling jug. The barley firlot, used also for oats, fruit, and potatoes, contains 31 pints. A different method of regulating the firlot was appointed from a cylindrical vessel. The diameter for both measures was fixed at $19\frac{1}{4}$ inches, the depth $7\frac{1}{2}$ inches for the wheat firlot, and $13\frac{1}{2}$ for the barley firlot. A standard constructed by these measures is rather less than when regulated by the pint; and as it is difficult to make vessels exactly cylindrical the regulation by the pint has prevailed, and the other method gone into disuse.

If the Stirling jug contains $103\frac{1}{2}$ inches, the wheat firlot will contain 2109 inches, which is more than two per cent. larger than the legal malt bushel of England, and about one per cent. larger than the Winchester bushel; and the barley firlot will contain 3208 inches. The barley boll is nearly equal to six legal malt bushels. In Stirlingshire, 17 pecks are reckoned to the boll; in Inverness-shire, 18 pecks; in Ayrshire, the boll is the same as the English quarter. And the firlots in many places are larger than the Linlithgow standard.

French dry measure, are the litron, bushel, minot, mine, septier, muid, and tun. The litron is divided into two demilitrons, and four quarter litrons, and contains 36 cubic inches of Paris. By ordonnance, the litron is to be three inches and a half high, and three inches ten lines broad. The litron for salt is larger, and is divided into two halves, four quarters, eight demi-quarters, and 16 measurettes. The French bushel is different in different jurisdictions. At Paris it is divided into demi-bushels, each demi-bushel into two quarters, the quart into two half-quarts, and the half-quart into two litrons, so that the bushel contains 16 litrons. By ordonnance the Paris bushel is to be 8 inches 2½ lines high, and 10 inches broad, or in diameter within side. The minot consists of 3 bushels, the mine of 2 minots or 6 bushels, the septier of 2 mines or 12 bushels, and the muid of 12 septiers, or 144 bushels. The bushel of oats is estimated double that of any other grain; so that there go 24 bushels to make the septier, and 288 to make the muid. It is divided into 4 picotins, the picotin containing 2 quarts, or 4 litrons. The bushel for salt is divided into 2 half-bushels, 4 quarters, 8 half-quarters, and 16 litrons; 4 bushels make a minot, 16 a septier, and 192 a muid. The bushel for wood is divided into halves, quarters, and half-quarters. 8 bushels make the minot, 19 a mine; 20 mines, or 320 bushels, the muid. For plaster, 12 bushels make a sack, and 36 sacks a muid. For lime, 3 bushels make a minot. and 48 minots a muid. The minot is by ordonnance to be 11 inches 9 lines high, and 14 inches 8 lines in diameter. The minot is composed of 3 bushels, or 16 litrons; 4 minots make a septier, and 48 a muid. The French mine is no real vessel, but an estimation of several others. At Paris, the mine contains 6 bushels, and 24 make the muid; at Rouen, the mine is 4 bushels; and at Dieppe, 18 mines make a Paris muid. The septier differs in different places: at Paris, it contains 2 mines, or 8 bushels, and 12 septiers the muid; at Rouen the septier contains 2 mines or 12 bushels. Twelve septiers make a muid at Rouen as well as Paris; but 12 of the latter are equal to 14 of the former. At Toulon, the septier contains a mine and a half; three of which mines make the septier of Paris. The muid, or muy of Paris, consists of 12 septiers, and is divided into mines, minots, bushels, &c. That for oats is double that for other grain, *i. e.*, contains twice the number of bushels. At Orleans, the muid is divided into mines, but those mines only contain two Paris septiers and a half. In some places they use the tun instead of the muid, particularly at Nantes, where it contains 10 septiers of 16 bushels each, and weighs between 2,200 and 2,250 pounds. Three of these tuns make 28 Paris septiers. At Rochelle, &c., the tun contains 42 bushels, and weighs two per cent. less than that of Nantes. At Brest, it contains 20 bushels, is equal to 10 Paris septiers, and weighs about 2,240 pounds.

Dutch, Swedish, Polish, Prussian, and Muscovite. In these places, they estimate their dry things on the foot of the *last*, *lest*, *leth*, *lecht*; so called according to the various pronunciations of the people who use it. In Holland, the last is equal to 19 Paris septiers, or 38 Bordeaux bushels, and weighs about 4,560 pounds; the last they divide into 27 muids, and the muid into 4 scheples. In Poland, the last is 40 Bordeaux bushels, and weighs about 4,800 Paris pounds. In Prussia, the last is 133 Paris septiers. In Sweden and Muscovy, they measure by the great and little last, the first containing 12 barrels, and the second half as many. In Muscovy, they likewise use the chefford, which is different in various places; that of Archangel is equal to three Rouen bushels.

Italian. At Venice, Leghorn, and Lucca, they estimate their dry things on the foot of the staro or staio. The staro of Leghorn weighs 54 pounds; 112⅞ are equal to the Amsterdam last. At Lucca, 119 staros make the last of Amsterdam. The Venetian staro weighs 128 Paris pounds; the staro is divided into four quarters. Thirty-five staros and one-fifth, or 140 quarters and four-fifths, make the last of Amsterdam. At Naples, and other parts, they use the tomolo, or tomalo, equal to one-third of the Paris septier. Thirty-six tomoli and a half make the carro, and a carro and a half, or 54 tomoli, make the last of Amsterdam. At Palermo, 16 tomoli make the salma, and 4 mondili the tomolo. Ten salmas and three-sevenths, or 171 tomoli and three-sevenths, make the last of Amsterdam.

Flemish. At Antwerp, &c., they measure by the viertel, 32½ whereof make 19 Paris septiers. At Hamburg, the schepel; 90 whereof make 19 Paris septiers.

Spanish and Portuguese. At Cadiz, Bilboa, and St Sebastian, they use the fanega; 23 whereof make the Nantes or Rochelle tun, or 9½ Paris septiers, though the Bilboa fanega is somewhat larger, insomuch that 21 fanegas make a Nantes tun. At Seville, &c., they use the anagoras, containing little more than the Paris mine; 36 anagoras make 19 Paris septiers. At Bayonne, &c., the concha; 30 whereof are equal to 9½ Paris septiers. At Lisbon, the alquiver, a very small measure; 240 whereof make 90 Paris septiers, 60 the Lisbon muids.

MEASURING, or MENSURATION, defined geometrically, is the assuming any certain quantity, and expressing the proportion of other similar quantities to the same.

MEASURING, defined popularly, is the using of a certain known measure, and determining thereby the precise extent, quantity, or capacity, of anything. In general, it constitutes the practical part of geometry. *See* MENSURATION.

MEASURING OF LINES, or quantities of one dimension, is called *longimetry*; and when those lines are not extended parallel to the horizon, *altimetry*. When the different altitudes of the two extremes of the lines are alone regarded, it is termed *levelling*.

MEASURING OF SUPERFICIES, or quantities of two dimensions, is variously denominated according to its subjects: when lands are the subject, it is called *geodesy*, or *surveying*; in other cases, simply *measuring*. The instruments used are the ten-foot rod, chain, compass, circumferentor, &c.

MEASURING OF SOLIDS, or quantities of three dimensions, is called *stereometry*; but where it relates to the capacities of vessels, or the liquors they contain particularly, *gauging*. The instruments for this art are the gauging-rod, sliding-rule, &c.

From the definition of measuring, where the measure is expressed to be similar or homogeneous to, *i. e.* of the same kind with, the thing measured, it is evident that, in the first case, or in quantities of one dimension, the measure must be a line; in the second, a superficies; and in the third, a solid. For example, a line cannot measure a surface; the art of measuring being no more than the application of a known quantity to the unknown, till the two become equal. Now, a surface has breadth, and a line has none; and if one line have no breadth, two or a hundred have none. A line, therefore, can never be applied so often to a surface as to be equal to it, *i. e.* to measure it. And from the like reasoning it is evident, a superficies, which has no depth, cannot become equal to, *i. e.* cannot measure, a solid which has.

While a line continues such, it may be measured by any part of itself; but when the line begins to flow, and to generate a new dimension, the measure must keep pace, and flow too; *i. e.* as the one commences superficies, the other must do so too. Thus we come to have square measures, and cubic measures.

Hence we see why the measure of a circle is an arc or part of the circle, for a right line can only touch a circle in one point, but the periphery of a circle consists of infinite points. The right line, therefore, to measure the circle must be applied infinite times, which is impossible. Again the right line only touches the circle in a mathematical point, which has no parts nor dimensions, and has consequently no magnitude; but a thing that has neither magnitude nor dimensions bears no proportion to another that has, and cannot therefore measure it. Hence we see the reason of the division of circles into 360 parts or arcs, called *degrees*. *See* ARC, CIRCLE, and MENSURATION.

MECHANICS (from the Greek *μηχανη*, *art*) that branch of practical mathematics which treats of motion and moving powers, their nature, laws, effects, &c. This term, in a popular sense, is applied equally to the doctrine of the equilibrium of powers, more properly called *statics*, and to that science which treats of the generation and communication of motion, which constitutes *dynamics*, or mechanics strictly so called. *See* FORCE, MOTION, POWER, and STATICS.

This science is divided by Newton into *practical* and *rational* mechanics, the former of which relates to the mechanical powers, viz., the lever, balance, wheel and axis, pulley, wedge, screw, and inclined plane; and the latter, or rational mechanics, to the theory of motion; showing, when the forces or powers are given, how to determine the motion that will result from them; and, conversely, when the circumstances of the motion are given, how to trace the forces or powers from which they arise.

Mechanics, according to the ancient sense of the word, considers only the energy of organs, or machines. The authors who have treated the subject of mechanics systematically have observed, that all machines derive their efficacy from a few simple forms and dispositions, which may be given to organs interposed between the agent and the resistance to be overcome; and to those simple forms they have given the name of *mechanical powers*, *simple powers*, or *simple machines*.

The practical uses of the several mechanical powers were undoubtedly known to the ancients, but they were almost wholly unacquainted with the theoretical principles of this science till a very late period; and it is therefore not a little surprising that the construction of machines, or the instruments of mechanics, should have been pursued with such industry, and carried by them to such perfection. Vitruvius, in his 10th book, enumerates several ingenious machines, which had then been in use from time immemorial. We find, that for raising or transporting heavy bodies, they employed most of the means which are at present commonly used for that purpose, such as the crane, the inclined plane, the pulley, &c.; but with the theory or true principles of equilibrium, they seem to have been unacquainted till the time of Archimedes. This celebrated mathematician, in his book of *Equiponderants*, considers a balance supported on a fulcrum, and having a weight in each scale; and taking as a fundamental principle, that when the two arms of the balance are equal, the two weights supposed to be in equilibrio are also of necessity equal, he shows, that if one of the arms be increased, the weight applied to it must be proportionally diminished. Hence he deduces the general conclusion, that two weights suspended to the arms of a balance of unequal length, and remaining in equilibrio, must be reciprocally proportional to the arms of the balance; and this is the first trace anywhere to be met with of any theoretical investigation of mechanical science. Archimedes also further observed, that the two weights exert the same pressure on the fulcrum of the balance, as if they were directly applied to it; and he afterwards extended the same idea to two other weights suspended from other points of the balance, then to two others, and so on; and hence, step by step, advanced towards the general idea of the centre of gravity, a point which he proved to belong to every assemblage of small bodies, and consequently to every large body, which might be considered as formed of such an assemblage. This theory he applied to particular cases, and determined the situation of the centre of gravity in the parallelogram, triangle, trapezium, parabola, parabolic trapezium, &c. &c. To him we are also indebted for the theory of the inclined plane, the pulley, and the screw, besides the invention of a multitude of compound machines; of these. however, he has left us no description, and therefore little more than their names remain.

We may judge of the very imperfect state in which the theory of mechanics was at that time, by the astonishment expressed by King Hiero, when Archimedes exclaimed, "Give me a place to stand on, and I will move the earth!" a proposition which could have excited no surprise in any person possessing a knowledge of the simple property of the lever. Of the theory of motion, however, it does not appear that even Archimedes possessed any adequate idea; the properties of uniform motion seem only to have engaged the attention of the ancients, and with those of accelerated and variable motion they were totally unacquainted: these were subjects to which their geometry could not be applied, the modern analysis being necessary to bring this branch of the science to perfection.

From the time of Archimedes till the commencement of the sixteenth century, the theory of mechanics appears to have remained in the same state in which it was left by this prince of Grecian science, little or no additions having been made to it during so many ages; but about this time, Stevinus, a Flemish mathematician, made known directly, without the introduction of the lever, the laws of equilibrium of a body placed on an inclined plane: he also investigated with the same success, many other questions on statics, and determined the conditions of equilibrium between several forces concurring in a common point, which comes, in fact, to the celebrated proposition relating to the parallelogram of forces; but it does not appear that he was at all aware of its consequences and application. In 1592, Galileo composed a treatise on statics, which he reduced to this single principle, viz:—It requires an equal power to raise two different bodies to heights having the inverse ratio of their weights: that is, whatever power will raise a body of two pounds to the height of one foot, will raise a body of one pound to the height of two feet. On this simple principle he investigated the theory of the inclined plane, the screw, and all the mechanical powers: and Descartes afterwards employed it in considering the statical equilibriums of machines in general, but without quoting Galileo, to whom he had been indebted or the first idea. After Stevinus and Galileo, Torricelli, Descartes, Huygens, Wallis, Wren, Newton, Liebnitz, Dechales, Oughtred, Keil, Delahire, Lagrange, Atwood, Prony, Emerson, Watt, Gregory, Young, &c., have in succession, since the period to which we have alluded, explained and applied the principles of this civilizing science in a wonderful manner.

MECHANICAL CARPENTRY, that part of the art of construction in timber which treats of the proper disposition of framing, so as to enable it to resist its own weight, or any additional load or pressure that may be casually laid upon it.

MECHANICAL CARPENTRY is so called from the principles of mechanics being employed in the construction of truss-framing, or other parts of the art; while CONSTRUCTIVE CARPENTRY shows the rules for cutting and framing the timbers according to the proposed design. *See* that article.

The mechanical principles of a piece of carpentry are therefore first to be considered; because they must, in some measure, regulate the disposition and size of the timbers in the design, after which they are to be prepared or formed according to the rules of constructive carpentry.

We shall here state a few of the elementary propositions, with the principles of trussing, and offer some observations on the best forms of bodies constructed of timber work, to be used under various circumstances. And as it is impossible, in complex parts, to give all the minutiæ with mathematical precision, this deficiency will, in a great measure, be compensated by general information.

The application of mechanical principles to carpentry was first introduced in this country by Professor Robinson, of Edinburgh, in the *Encyclopædia Britannica*, whose elaborate papers on this subject prepared the way for that investigation which has since been so ably followed out by others. In 1814, Mr. P. Nicholson drew up a complete article in every department of carpentry, for Rees's *Encyclopædia*, where this branch of the art, as depending upon the principles of mechanics, was particularly inculcated; and though several of the plates have been engraved and published some years ago, the manuscript relative to this particular branch has been retained for the article Roof, in this work, to which, indeed, it chiefly pertains.

In this application of mechanical science, Alex. Nimmo, Esq., F. R. S. E., the celebrated engineer, also published a very neat and well-connected theory of mechanical carpentry, under the article Carpentry, in the *Edinburgh Encyclopædia*; but perhaps the best work extant on this subject is Tredgold's Elementary Principles of carpentry, which contains a mass of the most valuable information, in the most convenient and available form.

Under the article Curb Roof, of the present Work, the reader will find an investigation of the best forms for a roof, restricted to certain data. The observations on the strength of timber are reserved for that article; but the practical rules derived therefrom will be here introduced preparatory to the general design of mechanical carpentry; and as these will be chiefly applicable to practice, we shall show the rules under their most simple form; discarding such as, though accurate, would be too complex for common use.

To find the comparative strength of timber.

Definition.—The depth of a piece of timber is its dimension in the direction of the pressure.

Proposition I.—*To find the comparative strength of different timbers.*

Rule.—Multiply the square of the depth of each piece into its thickness; and each product being divided by its respective lengths, will give the proportional strength of each.

Example.—Suppose three pieces of timber of the following dimensions:

The first 6 inches deep, 3 inches thick, and 12 feet long.
The second 5 inches deep, 4 inches thick, and 8 feet long.
The third 9 inches deep, 8 inches thick, and 15 feet long.
The comparative weight that will break each piece is required.

OPERATIONS.

First.	Second.
6 deep	5 deep
6	5
36	25
3 thick	4 thick
Length 12) 108	Length 8) 100
9	12 and a half.

Third.
9 deep
9
81
8 thick
Length 15) 648 (43 and a fifth.
60
48
45
3

Therefore, the weights that will break each are nearly in proportion to the numbers 9, 12, and 43, leaving out the fractions; in which it is to be observed, that the number 43 is almost five times the number 9; therefore the third piece of timber will bear almost five times as much weight as the first; and the second piece nearly once and a third the weight of the first piece; because the number 12 is one and a third greater than the number 9.

The timber is supposed to be everywhere of the same texture, otherwise these calculations cannot hold true.

Proposition II.—*Given the length, breadth, and depth of a piece of timber; to find the depth of another piece, whose length and breadth are given, so that it shall bear the same weight as the first piece, or any number of times more.*

Rule.—Multiply the square of the depth of the first piece into its breadth, and divide that product by its length: multiply the quotient by the number of times you would have the other piece to carry more weight than the first: and multiply the product by the length of the last piece, and divide the product by its width; out of this last quotient extract the square root, which is the depth required.

Example 1.—Suppose a piece of timber 12 feet long, 6 inches deep, 4 inches thick; another piece 20 feet long, 5 inches thick; required its depth, so that it shall bear twice the weight of the first piece.

	Proof.
6 deep	9.7
6	9.7
36	67.9
4	873
12) 144	94.09
	1.91 remainder added
12	96.00
2 times	5
24	20) 480
20 length	24
5) 480	

96 (9.7, or 9.8 nearly, for the depth.
81
187) 1500
1309
191

Example 2.—Suppose a piece of timber 14 feet long, 8 inches deep, 3 inches thick; required the depth of another piece 18 feet long, 4 inches thick, so that the last piece shall bear five times as much weight as the first.

As the lengths of both pieces of timber are divisible by the number 2, therefore half the length of each is used instead of the whole; the answer will be the same.

Proposition III.—*Given the length, breadth, and depth of a piece of timber; to find the breadth of another piece whose length and depth are given, so that the last piece shall bear the same weight as the first piece, or any number of times more.*

Rule.—Multiply the square of the depth of the first piece into its thickness; the product divide by its length; multiply the quotient by the number of times it is required to have the last piece support more than the first; that product multiplied by the length of the last piece, and divided by the square of its depth, gives the breadth required.

Example 1.—Given a piece of timber 12 feet long, 6 inches deep, 4 inches thick; and another piece 16 feet long, 8 inches deep; required the thickness, so that it shall bear twice as much weight as the first.

Proposition IV.—*If a piece of timber sustain a force placed unequally between the extremes on which it is supported, the strength in the middle will be to the strength in that part of the timber so divided, as one divided by the square of half the length is to one divided by the rectangle of the two unequal segments; that is, in the reciprocal ratio of their products.*

Example 1.—Suppose a piece of timber 20 feet long, the depth and width immaterial; suppose the stress or weight to lie five feet distant from one of its ends, consequently from the other end 15 feet, then the above proportion will be

$\frac{1}{10 \times 10} = \frac{1}{100} : \frac{1}{5 \times 15} = \frac{1}{75}$ as the strength at five feet from the end is to the strength at the middle, or 10 feet, or as $5 \times 15 : 10 \times 10 : \frac{100}{75} = 1\frac{1}{3}$.

Hence it appears, that a piece of timber 20 feet long is one-third stronger at 5 feet distance from the bearing than it is in the middle, which is 10 feet, when cut in the above proportion.

Example 2.—Suppose a piece of timber 30 feet long; let the weight be applied 4 feet distant from one end, or more properly from the place where it takes its bearing, then from the other end it will be 26 feet, and the middle is 15 feet; then $\frac{1}{15 \times 15} = \frac{1}{225} : \frac{1}{4 \times 26} = \frac{1}{104}$;

or as $4 \times 26 : 15 \times 15 = 2\frac{17}{104}$, or nearly $2\frac{1}{6}$.

Hence it appears, that a piece of timber 30 feet long will bear double the weight, and one-sixth more, at 4 feet distance from one end, than it will do in the middle, which is 15 feet distant.

Example 3.—Allowing that 266 pounds will break a beam 26 inches long, required the weight that will break the same beam when it lies at 5 inches from either end; then the distance to the other end is 21 inches; $21 \times 5 = 105$, the half of 26 inches is 13; therefore $13 \times 13 = 169$; consequently the strength at the middle of the piece is to the strength at 5 inches from the end, as $\frac{169}{169} : : \frac{169}{105}$; or as $1 : \frac{169}{105}$

The proportion is stated thus:

$$1 : \frac{169}{105} : : 266 \text{ to the weight required.}$$

```
          lb.
          169
      105  169
         ----
         2394
        1596
        266
        -----
105 ) 44954 ( 428
        420

          854
          840
          ---
           14
```

From this calculation, it appears that rather more than 428 pounds will break the beam at 5 inches' distance from one of its ends, if 266 pounds will break the same beam in the middle.

By similar propositions, the scantlings of any timber may be computed, so that they shall sustain any given weight; for if the weight that one piece will sustain be known, with its dimensions, the weight that another piece will sustain, of any given dimensions, may also be computed. The reader must observe, that although the foregoing rules are mathematically true, yet it is impossible to account for knots, cross-grained wood, &c., such pieces being not so strong as those which have straight fibres; and if care be not taken in choosing the timber for a building, so that the fibres be disposed in parallel straight lines, all rules which can be laid down will be useless. It will be impossible, however, to estimate the strength of timber fit for any building, or to have any true knowledge of its proportions, without some rule; as otherwise everything must be done by mere conjecture.

Timber is much weakened by its own weight, except it stand perpendicular to the horizon.

The bending of timber will be nearly in proportion to the weight laid on it. No beam ought to be trusted for any long time with above one-third or one-fourth part of the weight it will absolutely carry; for experiment proves, that a far less weight will break a piece of timber when hung to it for any considerable time, than what is sufficient to break it when first applied.

Problem I.—*Having the length and weight of a beam that can just support a given weight in the middle, to find the length of another beam of the same scantling, that shall just break with its own weight.*

Let l = the length of the first beam;
L = the length of the second;
a = the weight of the first beam;
w = the additional weight that will break it.

Then $w + \frac{a}{2} = \frac{2w + a}{2}$ is the weight that will break the lesser beam.

Again, let W be the weight of the beam that breaks with its own weight; and because the weights that will break beams of the same scantling are reciprocally as their lengths:

$$L : l : : \frac{2w + a}{2} : l\frac{2w + a}{2L} = W.$$

But the weights of beams of the same scantlings are to each other as their lengths;

$l : L : : \frac{a}{2} : \frac{aL}{2l} = \frac{W}{2}$, half the weight of the greater beam.

Now, a beam supported at both ends cannot break with its own weight, unless half the weight of the beam be equal to the weight that will break it;

$$\text{therefore; } \frac{aL}{2l} = l\frac{2w + a}{2L};$$

$$\text{consequently, } aL^2 = l^2(2w + a)$$

$$\text{and, } L = l\left(\frac{2w + a}{a}\right).$$

Problem II.—*Having the weight of a beam that can just support a given weight in the middle; to find the depth of another beam similar to the former, so that it shall just support its own weight.*

Let d = the depth of the first beam;
x = the depth of the second beam;
a = the weight of the first beam;
w = the additional weight that will break the first beam.

Then will $w + \frac{a}{2}$, or $\frac{2w + a}{2}$ = the whole weight that will break the lesser beam.

And because the weights that will break similar beams are as the squares of their lengths,

$$d^2 : x^2 : : \frac{2w + a}{2} : \frac{2x^2 w + x^2 a}{2d^2} = W.$$

Then because the weights of similar beams are as the cubes of their corresponding sides:

$$d^3 : x^3 : : \frac{a}{2} : \frac{a x^3}{2d^3} = W;$$

$$\text{therefore } \frac{a x^3}{2d^3} = \frac{2x^2 w + a x^2}{2d^2};$$

$$a x^3 = (2w + a) \times d;$$

consequently $a : a + 2w : : d : x^3$ = the depth required.

As the weight of the lesser beam is to that of the greater beam, together with the additional weight; so is the depth of the lesser beam to the cube of the depth of the greater.

Note.—Any other corresponding sides will answer the same purpose, being all proportional to each other.

Example.—Suppose a beam, whose weight is one pound, and its length 10 feet, to carry a weight of 399.5 pounds; required the length of a beam similar to the former, of the same matter, so that it shall break with its own weight:

then $a = 1$
$w = 39.5$
and $a + 2w = 800 = 1 + 2 \times 399.5$
$d = 10$

Then, by the last problem, it will be
$1 : 800 : : 10$
10

$8000 = x$, for the length of a beam that will break by its own weight.

Problem III.—*The weight and length of a piece of timber being given, and the additional weight that will break it; to find the length of a piece of timber similar to the former, so that this last piece of timber shall be the strongest possible.*

Put l = the length of the piece given;
w = half its weight;
w = the weight that will break it;
x = the length required.

Then, because the weights that will break similar pieces of timber are in proportion to the squares of their lengths,

$l^2 : x^2 : : \mathrm{w} + w : \frac{\mathrm{w}\,x^2 + w\,x^2}{l^2}$ = the whole weight that will break the beam.

And because the weights of similar beams are as the cubes of their lengths, or any other corresponding sides,

$l^3 : x^3 : : w : \frac{w\,x^3}{l^3}$ the weight of the beam;

consequently, $\frac{\mathrm{w}\,x^2 + w\,x^2}{l^2} - \frac{w\,x^3}{l^3}$ is the weight that breaks the beam = *a* maximum; therefore its fluxion is nothing: that is,

$$2\,\mathrm{w}\,x\dot{x} + 2\,w\,x\dot{x} - \frac{3\,w\,x^2\,\dot{x}}{l} = 0.$$

$$2\,\mathrm{w} + 2\,w = \frac{3\,w\,x}{l};$$

$$\text{hence, } x = l \times \frac{2\,\mathrm{w} + 2\,w}{3\,w}.$$

Hence it appears from the foregoing problems, that large timber is weakened in a much greater proportion than small timber, even in similar pieces, therefore a proper allowance must be made for the weight of the pieces, as in the following example.

Suppose a beam, 12 *feet long, and a foot square, whose weight is three hundred-weight, to be capable of supporting* 20 *hundred-weight; what weight will a beam* 20 *feet long,* 15 *inches deep, and* 12 *thick, be able to support?*

```

21 cwt. 56 lb. is the weight that will break the first beam, and 20 cwt. 17 lb. 8 oz. the weight that will break the second beam. Deduct out of these half their own weight:

cwt.	lb.	oz.
20	17	8
3	14	0 half
17	3	8

Now 20 cwt. is the additional weight that will break the first beam; and 17 cwt. 3 lb. 8 oz. the weight that will break the second; in which the reader will observe, that 17 cwt. 3 lb. 8 oz. bears a much less proportion to 20 cwt. than 20 cwt. 17 lb. 8 oz. bears to 21 cwt. 56 lb. From these examples, it is evident that a proper allowance ought to be made for all horizontal beams: that is, half the weights of beams ought to be deducted out of the whole weight they will carry, and the remainder is the weight which each piece will bear.

If several pieces of timber of the same scantling and length be applied one above another, and supported by props at each end, they will be no stronger than if they were laid side by side ; or, which is the same thing, the pieces that are applied one above another are no stronger than one single piece whose width is the width of the several pieces collected into one, and its depth that of one of the pieces; it is therefore useless to cut a piece of timber lengthwise, and apply the pieces so cut one above each other, for these pieces are not so strong as before, even though assisted by bolting.

Example.—Suppose a girder 16 inches deep, 12 inches thick, the length immaterial, and let the depth be cut lengthwise into two equal pieces; then will each piece be 8 inches deep, and 12 inches thick. Now, according to the rule of proportioning timber, the square of 16 inches, that is the depth before it was cut, is 256, and the square of 8 inches is 64; but twice 64 is only 128, therefore it appears that the two pieces applied one above another, is but half the strength of the solid piece, because 256 is double 128.

If a girder be cut lengthwise in a perpendicular direction, the ends turned contrary, and then bolted together, it will be but very little stronger than before it was cut; for although the ends, being turned, give to the girder an equal strength throughout, yet wherever a bolt is, there the girder will be weaker; and it is doubtful whether it will be any stronger for this process of sawing and bolting.

Figure 1.—If there be two pieces of timber of an equal scantling, the one lying horizontally and the other inclined, the horizontal piece being supported at the points *e* and *f*, and the inclined piece at *c* and *d*, perpendicularly over *e* and *f*; according to the principles of mechanics, these pieces will be equally strong. But to reason a little on this matter, let it be considered, that though the inclined piece, D, is longer, yet the weight has less effect upon it when placed in the middle, than the weight at *h* has upon the horizontal piece, C, the weights being the same; it is therefore reasonable to conclude, that in these positions the one will bear equal to the other.

From different experiments, it has been found that the law of resistance in a piece of timber does not exactly obey the foregoing rules. The labour and expense attending such experiments, on a scale likely to be at all useful, far exceed the abilities of individuals, who might otherwise be disposed to investigate this useful branch of mechanical knowledge. This grand objection, no doubt, has been the cause why so little has been done to determine the law of resistance by experiments; yet, as we are not absolutely without some lights, we shall proceed to lay them before our readers, in as concise a manner as the nature of the subject will admit.

The first authority to our purpose is what Belidor has given on the subject, in his *Science des Ingenieurs.*

Belidor's Experiments.

In the subjoined table, the column B contains the breadth of the pieces in inches; D contains their depths; the column L contains their lengths; P the weight (in pounds) which broke them, when hung on their middles.

In order to obtain the best idea of the strengths of pieces of different dimensions with more certainty, three pieces of each dimension were tried; a medium among them being more accurate than a single experiment.

The column M contains those mediums.

The experiments were made on oak, of equal quality, and tolerably well seasoned.

	B	D	L	P	M
Experiment 1, ends loose.....	1	1	18	400 415 405	406
Experiment 2, ends firmly fixed	1	1	18	600 600 624	608
Experiment 3, ends loose.....	2	1	18	810 795 812	805
Experiment 4, ends loose.....	1	2	18	1570 1580 1590	1580
Experiment 5, ends loose.....	1	1	36	185 195 180	187
Experiment 6, ends fixed.....	1	1	36	285 280 285	283
Experiment 7, ends loose.....	2	2	36	1550 1620 1585	1585
Experiment 8, ends loose.....	$1\frac{5}{8}$	$2\frac{1}{8}$	33	1665 1675 1640	1660

By comparing the 1st experiment with the 3d, the strength appears proportional to the breadth; the length and depth of each piece being the same.

By comparing the 1st and 4th experiments, the strength appears as the square of the depth, nearly; the breadth and length being always the same.

By comparing the 1st and 5th experiments, the strength is seen to be nearly as the lengths, inversely; the breadth and depth of each piece being the same.

By comparing experiments 5 and 7, the strengths will appear to be nearly in proportion to the breadth, multiplied by the square of the depth; the length being the same in both.

The 1st and 7th experiments show the strengths to be as the square of the depth, multiplied by the breadth, and divided by the length.

Experiments 1 and 2, and 5 and 6, show the increase of the strength by fastening the ends, to be in the proportion of 2 to 3.

From the foregoing experiments, it appears that the rule founded upon the Galilean hypothesis, for finding the comparative strength of timber, is nearly true. But as it would be wrong to draw conclusions from timbers of so small scantlings as in the above experiments, we shall, after making the following observation, give an abstract of the experiments of M. de Buffon, as well as of those of M. du Hamel, men of acknowledged abilities, who were directed by the French government to make experiments on this subject; and who were supplied with ample funds and apparatus for the purpose, and had the choice of the best subjects in all the forests of France. The reports of M. de Buffon may be found in the *Memoirs of the French Academy*, for the years 1740, 1741, 1742, 1768; and those of M. du Hamel, in his work, *Sur l'Exploitation des Arbres, et sur la Conservation et le Transportation de Bois.* But we observe, the chief cause of the irregularity in such experiments, is the fibrous, or rather plated texture of timber, which consists of annual additions, whose cohesion with each other is vastly weaker than that of their own fibres. Let *Figure* 2, represent the section of a tree, and A B C D, and *a b c d*, the sections of two quarterings, to be cut out of it, for experiment; let A D, and *a d*, be the depths; and D C, *d c*, the breadths; the quartering A B C D will be the strongest for the same reason that an assemblage of planks set edgewise, will be stronger than the same number of planks laid above each other.

M. de Buffon found that the strength of A B C D, was to that of *a b c d*, in oak, nearly as 8 to 7.

The authors of the different experiments, we have reason to fear, were not very careful that their bars had their plates all disposed the same way.

As great beams occupy much, if not the whole section of the tree, it has happened that their strength is less than in proportion to that of a small lath quartering or scantling; for which reason a set of experiments ought to be carefully made on each, as all large buildings require a great number of both kinds: as girders and other beams for supporting large weights, so small bars are employed in making joists, rafters, purlins, &c., all of which are for the purpose of carrying or discharging weights.

M. de Buffon's Experiments.

The following table exhibits a number of experiments on bars of sound oak, clear of knots, each bar being four inches square.

The column No. 1, contains the length of the bar in feet, between the two props.

The column No. 2, contains the weight of the bar, the second day after it was felled, in pounds.

The column No. 3, contains the number of pounds necessary for breaking the bar in a few minutes.

The column No. 4, contains the number of inches it bent down before breaking.

The column No. 5, contains the number of minutes that each respective piece was in breaking.

In this table two bars were tried of each length: each of the first three pairs consisted of two cuts of the same tree; the one next to the root was always found to be the heaviest, stiffest, and strongest; from which M. de Buffon recommends a certain and sure rule for estimating the goodness of timber by its weight: he finds that this is always the case when the timber has grown vigorously, forming thick annual layers. But he also observes, that this is only during the advances of the tree to maturity, for the strength of the different circles approaches gradually to an equality during a healthy growth.

1	2	3	4	5
7	60 56	5350 5275	3.5 4.5	29 22
8	68 63	4600 4500	3.75 4.7	15 13
9	77 71	4100 3950	4.85 5.5	14 12
10	84 82	3625 3600	5.83 6.5	15 15
12	100 98	3050 2925	7. 8.	

Experiments on other sizes were made in the same manner: a pair, at least, of each length and scantling was taken; the mean result is contained in the following table. The beams were all square, and their sizes, in inches, are placed at the head of the columns; and their length, in feet, in the first column. The column A exhibits the strength which each of the five-inch bars ought to have, by the theory.

M. de Buffon found, by numerous experiments, that oak timber lost much of its strength by drying or seasoning; and therefore, in order to secure uniformity, his trees were all felled in the same season of the year, were squared the day after, and tried on the third day. Trying them in this green state, gave him an opportunity of observing a very curious phenomenon.

When the weights were laid briskly on, nearly sufficient to break the log, a smoke was observed to issue from each end, accompanied with a hissing noise, which continued while the tree was bending and cracking; owing to the strain excited by bending: in which state it must be both compressed and extended.

16		4350	6362	11000	16375	5042
18		3700	5562	9245	13200	4482
20		3225	4950	8375	11487	4034
22		2975				3667
24		2162				3362
28		1775				2881

From the above experiments, some conclusions respecting the law of the strength of oak timber may be deduced, from which it will be seen whether the theory already established be sufficiently accurate; or, if not, they will show in what manner it ought to be corrected.

M. de Buffon considers the experiments upon the five-inch bars as the standard of comparison, having both extended these to a greater length, and having tried more pieces of each length.

The theory determines the relative strengths of bars of the same section, to be inversely as their lengths; but, if the five experiments in the first column be excepted, there will be found a very great deviation from this rule: thus the five-inch bar of 28 feet long should have half the strength of that of 14 feet, or 2650, whereas it is but 1775; the bar of 14 feet should have half the strength of the 7 feet, or 5762; whereas it is but 5300; and in like manner the fourth of 11,525 is 2881; but the real strength of the 28-inch bar is but 1775. The column A exhibits the strength that each of the five-inch bars ought to have by the theory, which decreases much slower than those shown by the experiment; and therefore it appears, that the strength of different pieces of timber decreases much quicker than that of the inverse ratio of their lengths; but in what ratio precisely the strength decreases, it would be almost impossible to know, as there is not a sufficient number of experiments for the purpose; the few that have been tried are so very anomalous, as will appear by taking the differences between those in the third column, found by the experiments, from their respective numbers under A in the seventh column, as found by the rule, which are respectively 298, 656, 943, 648, 463, 692, 782, 809, 692, 1200, 1106: by comparing these numbers together, it is easy to see the impossibility of discovering any progression, or regular increase; for example, the third difference is greater than any of the preceding, and less than any of the succeeding, except the two last; and therefore it appears, that no rule can be founded on these experiments for finding the relative strength of timber, but what will in many cases differ very considerably from that which ought to correspond to it; in the table, however, the rule given in our former calculations may, if somewhat corrected, correspond nearly with the five-inch bars, as follows:—from the length of the required piece, take the 7 feet length, and multiply the difference by the number 1474, divide that product by the length, subtract the quotient from the number of pounds found by the former rule, and the remainder will be the answer.

M. de Buffon uniformly found that two-thirds of the weight which was sufficient to break a beam at first, sensibly impaired its strength, and frequently broke it, at the end of two or three months; and one-half of this weight brought it to a certain curvature, which did not increase after the first minute or two, and may be borne by the beam for any length of time.

One-third seemed to have no permanent effect on the beam; but it recovered its rectilinear shape completely, even after it had been loaded several months, provided the timber was seasoned when first loaded: that is to say, one-third of the weight which would quickly break a seasoned beam, or one-fourth of what would break one just felled, may lie on it for ever, without giving the beam a set.

The agreement of the numbers, found by the rule of the breadth being multiplied by the square of the depth, appears to deviate less from the experiments of Buffon, than that of the inverse ratio of the length; but even this rule, applied to softer woods, will differ greatly from the truth, which must be evident when we consider a beam just breaking, that it will be strongly compressed on the side nearest to the axis of fracture, and the opposite side will be greatly extended; consequently, there must be some point between the fulcrum and the opposite side, which will neither be extended nor compressed; and all the fibres lying between this point and the fulcrum, being in a state of compression, can offer little resistance against the fracture; the fibres on the other side only being exerted.

This is fully verified by some curious

Experiments by M. du Hamel.

He took 16 bars of willow, two feet long and half an inch square, and supported them by props under the ends: he broke them with weights hung on their middle. He broke four of them by weights of 40, 41, 47, and 52 pounds; the mean is 45.

He then cut four of them one-third through, on the upper side, and filled up the cut with a thin piece of harder wood, stuck in very tight: these were broken by 48, 54, 50, and 52, the mean of which is 51.

He cut other four half through; they were broken by 47, 49, 50, and 45, the mean of which is 48.

The remaining four were cut two-thirds, and their mean strength was 42.

Another set of Experiments, still more remarkable.

Six battens of willow, 36 inches long, and 1½ square, were broken by 525 pounds, at a medium.

Six bars were cut one-third through, and the cut filled with a wedge of hard wood, struck in with little force; these broke with 551 pounds.

Six bars were cut half through, and the cut was filled up in the same manner: they broke with 542 pounds.

Six bars were cut three-fourths through, and after being loaded till nearly broken, were unloaded, the wedge was taken out of the cut, and a thicker wedge was put in tight, so as to make the batten straight again, by filling up the space left by the compression of the wood: and it then broke with 577 pounds.

Of the Absolute Strength of Timber.

The strain occasioned by pulling timber in the direction of its length is called *tension;* it frequently occurs in roofs, and is therefore worthy of consideration.

The absolute strength of a fibre, or small thread of timber, is the force by which every part of it is held together, which is equal to the force that would be required to pull it asunder; and the force which would be required to tear any number of threads asunder is proportional to that of their sum; but the areas of the sections of two pieces of timber composed of fibres of the same kinds are as the number of fibres in each; and therefore the strength of the timber is as the area of the sections.

Hence all prismatic bodies are equally strong; that is, they will not break in one part rather than in another.

Bodies which have unequal sections will break at their smallest part; and therefore, if the absolute strength which would be required to tear a square inch of each kind of timber be known, we shall be able to determine the strength of any other quantity whatever.

The following table is taken from Muschenbroëk's experiments; he has described his method of trial minutely; the woods were all formed into slips fit for his apparatus, and part of the slip was cut away to a parallelopiped one-fifth of an inch square, and therefore the twenty-fifth part of a square inch in section; the absolute strengths of a square inch were as follow:—

	lb		lb
Locust tree	20,100	Pomegranate	9,750
Jujeb	18,500	Lemon	2,950
Beech oak	17,300	Tamarind	8,750
Orange	15,500	Fir	8.330
Alder	13 900	Walnut	8,130
Elm	13,200	Pitch pine	7,650
Mulberry	12,500	Quince	6.750
Willow	12.500	Cypress	6,000
Ash	12,000	Poplar	5,500
Plum	11,800	Cedar	4,880
Elder	10,000		

M. Muschenbroëk has given a very minute detail of the experiments on the ash and walnut, stating the weight requisite to tear asunder slips taken from the four sides of the tree, and on each side in a regular progression, from the centre to the circumference. The numbers of this table corresponding to the two timbers, may therefore be considered as the average of more than fifty trials made on each; and he says that all the others were made with the same care, and therefore there is no reason for not confiding in the results.

Practical Observations.

The following observations on wood will be of great use to the practical carpenter, in making a proper choice of timber, according to the purposes for which he may want to employ it.

1. The wood immediately surrounding the pith, or heart, is the weakest; and its inferiority is so much the more remarkable as the tree is older. Muschenbroëk's detail of experiments is decidedly in the affirmative. M. de Buffon, on the other hand, says that his experience has taught him that the heart of a sound tree is the strongest, but he gives no instances. It is certain, from other experiments, on large oaks and firs, that the heart is much weaker than the exterior parts.

2. The wood next to the bark commonly called *white*, or *blea*, is also weaker than the rest; and the wood gradually increases in strength as we recede from the centre to the blea.

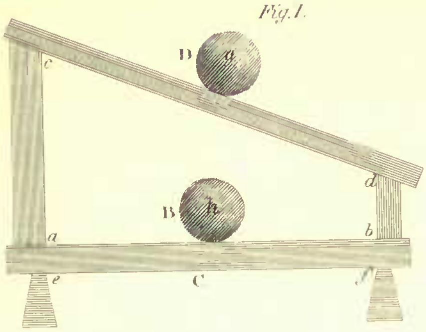

Fig. 2.

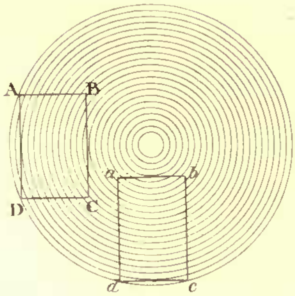

Fig. 3.

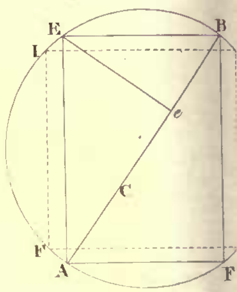

Fig. 4.

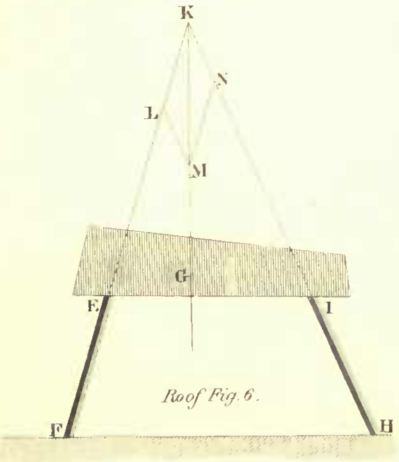

Fig. 5.

Fig. 6.

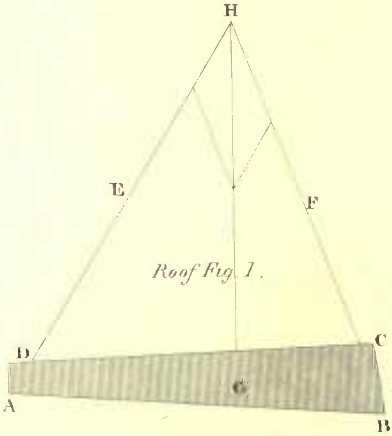

Fig. 7.

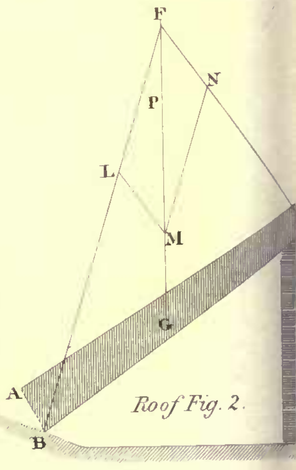

Fig. 8

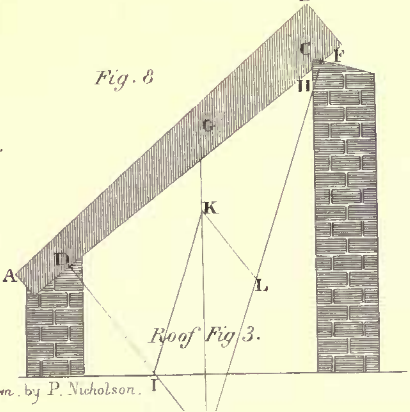

Fig. 9.

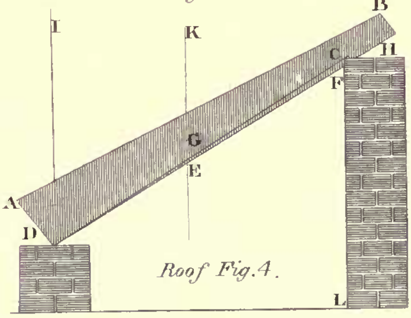

Fig. 10.

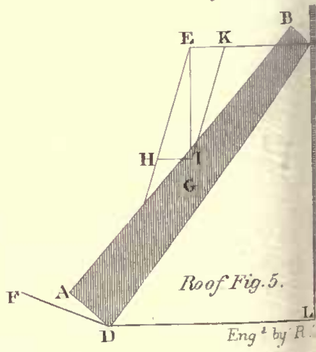


3. The wood is stronger in the middle of the trunk than at the springing of the branches, or at the root; and the wood of the branches is weaker than that of the trunk.

4. The wood on the north side of all trees, which grow in the European climates, is the weakest, and that of the south side the strongest; and the difference is most remarkable in hedge-row trees, and such as grow singly.

The heart of a tree is never in its centre, but always nearer to the north side, and the annual coats of wood are thinner on that side. In conformity to this, it is a general opinion of carpenters, that the timber is stronger whose annual plates are thicker. The tracheæ, or air-vessels, are weaker than the simple ligneous fibres. These air-vessels are the same in diameter and number of rows in all trees of the same species, and they make the visible separation between the annual plates. Therefore, when these are thicker, they contain a greater proportion of the simple ligneous fibres.

5. All woods are more tenacious while green, and lose very considerably by drying after the tree is felled.

We shall conclude these observations with the following useful problem.

To cut the strongest beam possible out of a round tree, whose section is a given circle.

Figure 3.—Let A E B F be the section; draw the diameter A B, and divide it into three equal parts at c and *e*: from either of these points, as *e*, draw *e* E perpendicular to A B, cutting the circumference at E; draw A E and E B; through the points A and B draw A F and B F respectively parallel to E B and E A, cutting each other at F; and A E B F will be a section of the strongest beam that can possibly be cut out of the tree, A E B F; for the square of the depth, A E, or F B, multiplied into the breadth, E B, or F A, is then the greatest that can be produced.

From this it is plain, that the strongest beam which can be cut out of a round tree does not contain the most timber; for the greatest rectangle that can be inscribed in a circle is a square, and therefore the square F G H I is greater than the rectangle A F B E, and yet is not the strongest.

To support a piece of timber by means of two props resting on the ground, so that it shall have no tendency to go to either side.

Figure 4.—Let E I be a piece of timber, and G its centre of gravity; then the position, E I, of the timber being given, with the direction of one of the props, H I, and the point, E, where the other is to be placed; to find its length and position, draw G K perpendicular to the horizon; produce H I to K, and draw K E to meet the ground in F, then E F is the length and direction of the post.

To ascertain the proportions between the weight of the piece of timber and the compression of the props.

On the plumb-line G K, take any distance, K M; draw M N parallel to E K, cutting I K in N; and draw M L parallel to I K, cutting E K in L; then, if K M represent the weight of the piece of timber, K N will represent its pressure on the prop I H, and K L its pressure on the prop E F.

The *compression of timber* is another consideration worthy of attention.

In considering strains of this kind, it is absolutely impossible to conceive how a piece of timber that is perfectly straight can be bent, crippled, or broken, by any force whatever acting at the extremes. But suppose the smallest force whatever, acting in the middle, on a direction perpendicular to the length, this force will be sufficient to give it a small degree of curvature; and if a strong force be supposed to act at the ends at the same time, each pressing the timber in the direction of its length, these forces may instantly contribute towards breaking it.

It is easy, therefore, to conceive, that if a piece of timber be the least bent whatever, or if the fibres of that timber be not quite straight, there is a certain force which, if acting at the ends, will break it. Thus, suppose the column, A C B, *Figure* 5, resting on the ground at B, and loaded at the top with a weight, A, acting in a vertical direction A B; and if the fibres, or the piece A C B, is in the smallest degree crooked, the degree of curvature, by the pressure of the two ends, will be increased, until the fibres are bent to their utmost extent, and the smallest addition at the ends will break it.

The first writer who considered the compression of columns with attention, was the celebrated Euler, who published, in the *Berlin Memoirs* for 1757, his Theory on the Strength of Columns. The general proposition established by this theory is, that the strength of prismatic columns is in the direct quadruplicate ratio of their diameters, and the inverse ratio of their lengths; he prosecuted this subject in the *Petersburg Commentaries* for 1778, confirming his former theory. Muschenbroëk has compared the theory with experiment, but the comparison has been very unsatisfactory; the difference from the theory being so enormous as to afford no argument for its justness; neither do they contradict it, for they are so very anomalous as to afford no conclusion or general rule whatever.

PROPOSITION V. *Figure* 6.—*If a heavy body,* A B C D, *be supported by two oblique strings,* D E *and* C F, *in a vertical plane, a straight line drawn through the intersection will pass through the centre of gravity of the body.*

It is shown under the article LEVER, that if any three forces act upon a point, or body, their directions will tend to the same point, or be parallel to each other: now every body acts with its full force in one point only, viz., in the centre of gravity of that body, and in a direction perpendicular to the horizon: that is to say, if the weight of the body be supposed to be collected into the centre of gravity, the effect would be the same, provided the directions of the other two sustaining forces remained the same: therefore, if a body be sustained at E and F, it will revolve round these points till the line, G H, passing through the intersection, H, of the two strings, D E and C E, and the centre of gravity, G, become perpendicular to the horizon.

COROLLARY 1.—Hence, if any body be supported by two strings, it may also be supported by two planes perpendicular to these strings; provided the two points of the body supported be in the direction of the strings; for every body acting upon a plane, acts in a line perpendicular to that plane.

COROLLARY 2.—Hence also a body may be supported by two props in any two directions in which it may be supported by strings; provided the surface of the body at the points of contact, at the ends of the props, be planes at right angles to the strings.

COROLLARY 3.—Hence all the properties that have been demonstrated of three forces acting upon a body supposed void of weight, will equally flow from a heavy body supported by two strings, by substituting the weight of the body for the middle force; and hence, if the direction of any force supporting a heavy body be given, the other may easily be found.

PROPOSITION VI.—*Given the position in which a body should be placed, and the position of a plane supporting the body at one end; to find the position of another plane, to support it at another given point; and to find the pressure on the planes, the weight of the body being given.*

Through the centre of gravity of the body draw a vertical line, and through the point on which the body rests on the given plane draw a line perpendicular to that plane, meeting the vertical line; from their intersection draw a line to the other point to be supported; from that point draw a plane at right angles to this line, which will be the direction of the plane required.

To find the intensity of the forces, take any distance on the vertical line to represent the weight of the beam from the intersection; on that line, as a diagonal, complete a parallelogram, whose sides are in the directions of the lines perpendicular to the supporting planes; and the side of the parallelogram perpendicular to either plane will represent the force on that plane.

Example 1. *Figure* 7.—Let the body A B C D lie upon the top of the wall, K C, at C, so as to touch the lower edge, B C, of the body at that point, B; it is required to find the direction of a plane that will support the lower end at B; and to find the pressure of the body on the wall and on the plane.

Through the centre of gravity, G, of the body, draw the vertical line G F; draw C F perpendicular to C B; join F B; and draw B I perpendicular to F B; and B I is the direction of the plane required. On the vertical line, F, make F M to represent the weight of the body, and complete the parallelogram L M N F; then F N represents the force on the wall-head in the direction C F, and F L the force acting perpendicular to the plane in the direction B F. But if the vertical and horizontal thrusts on the wall at C be required, draw N P perpendicular to F G, meeting it in P; then the force F N is resolved into two forces, F P and P N; P N representing the horizontal part of the force, viz., that which pushes the wall in a direction parallel to the horizon, and F P the other part which tends to press it downwards in a direction perpendicular to the horizon.

Example 2.—*Figure* 8.—Let the sloping body, A B C D, be supported by a wall at its lower end, D, which coincides with the surface of the body; and let G be the centre of gravity; it is required to cut a notch out of the body at the upper end, C, so that it may rest upon the top of a wall which is made to fit the notch, and to find the pressure on the walls. Draw the vertical line G E; from D draw D E perpendicular to D C; join E C, and draw C F at right angles to it; then the notch, H C F, being cut, the body, A B C D, will be at rest.

To find the pressure on the walls, complete the parallelogram E I K L, having a given angle, D E C, and its diagonal on the given line E G: now if K E represent the weight of the body, I E will represent the pressure in the direction, D E, upon the wall at D, and L E the pressure in the direction C E.

The horizontal and perpendicular pressures upon each wall may be found, as in the first example, by resolving each of the forces, I E and L E, into two, one of which is perpendicular to the horizon, and the other parallel to it.

SCHOLIUM.—It must be observed in this example, that the notch cut out at C will remove the centre of gravity nearer the lower end, D, and consequently alter the slope, C F; but as this can only be in a small degree, the equilibrium will hardly be affected by it when the notch is minute.

Example 3. *Figure* 9.—Let one of the corners of a sloping body, A B C D, rest upon the level top of a wall at D; it is required to find the position of a notch cut out of the upper end, C, so that the body may rest upon a wall made to fit the notch.

Let the small part, F C H, be so cut that C H may be parallel to the horizon, then the body will be supported by the two walls, at C and D. For if D I, G K, and C L, be drawn perpendicular to the horizon, these lines, being produced, may be supposed to meet at an infinite distance.

To find the pressure on the walls, join L C, and produce the vertical line K G to meet it in L; then, if G be supposed to be the weight of the body, the pressure on D will be $\frac{EC \times G}{DC}$, and the pressure on C will be $\frac{DL \times G}{DC}$.

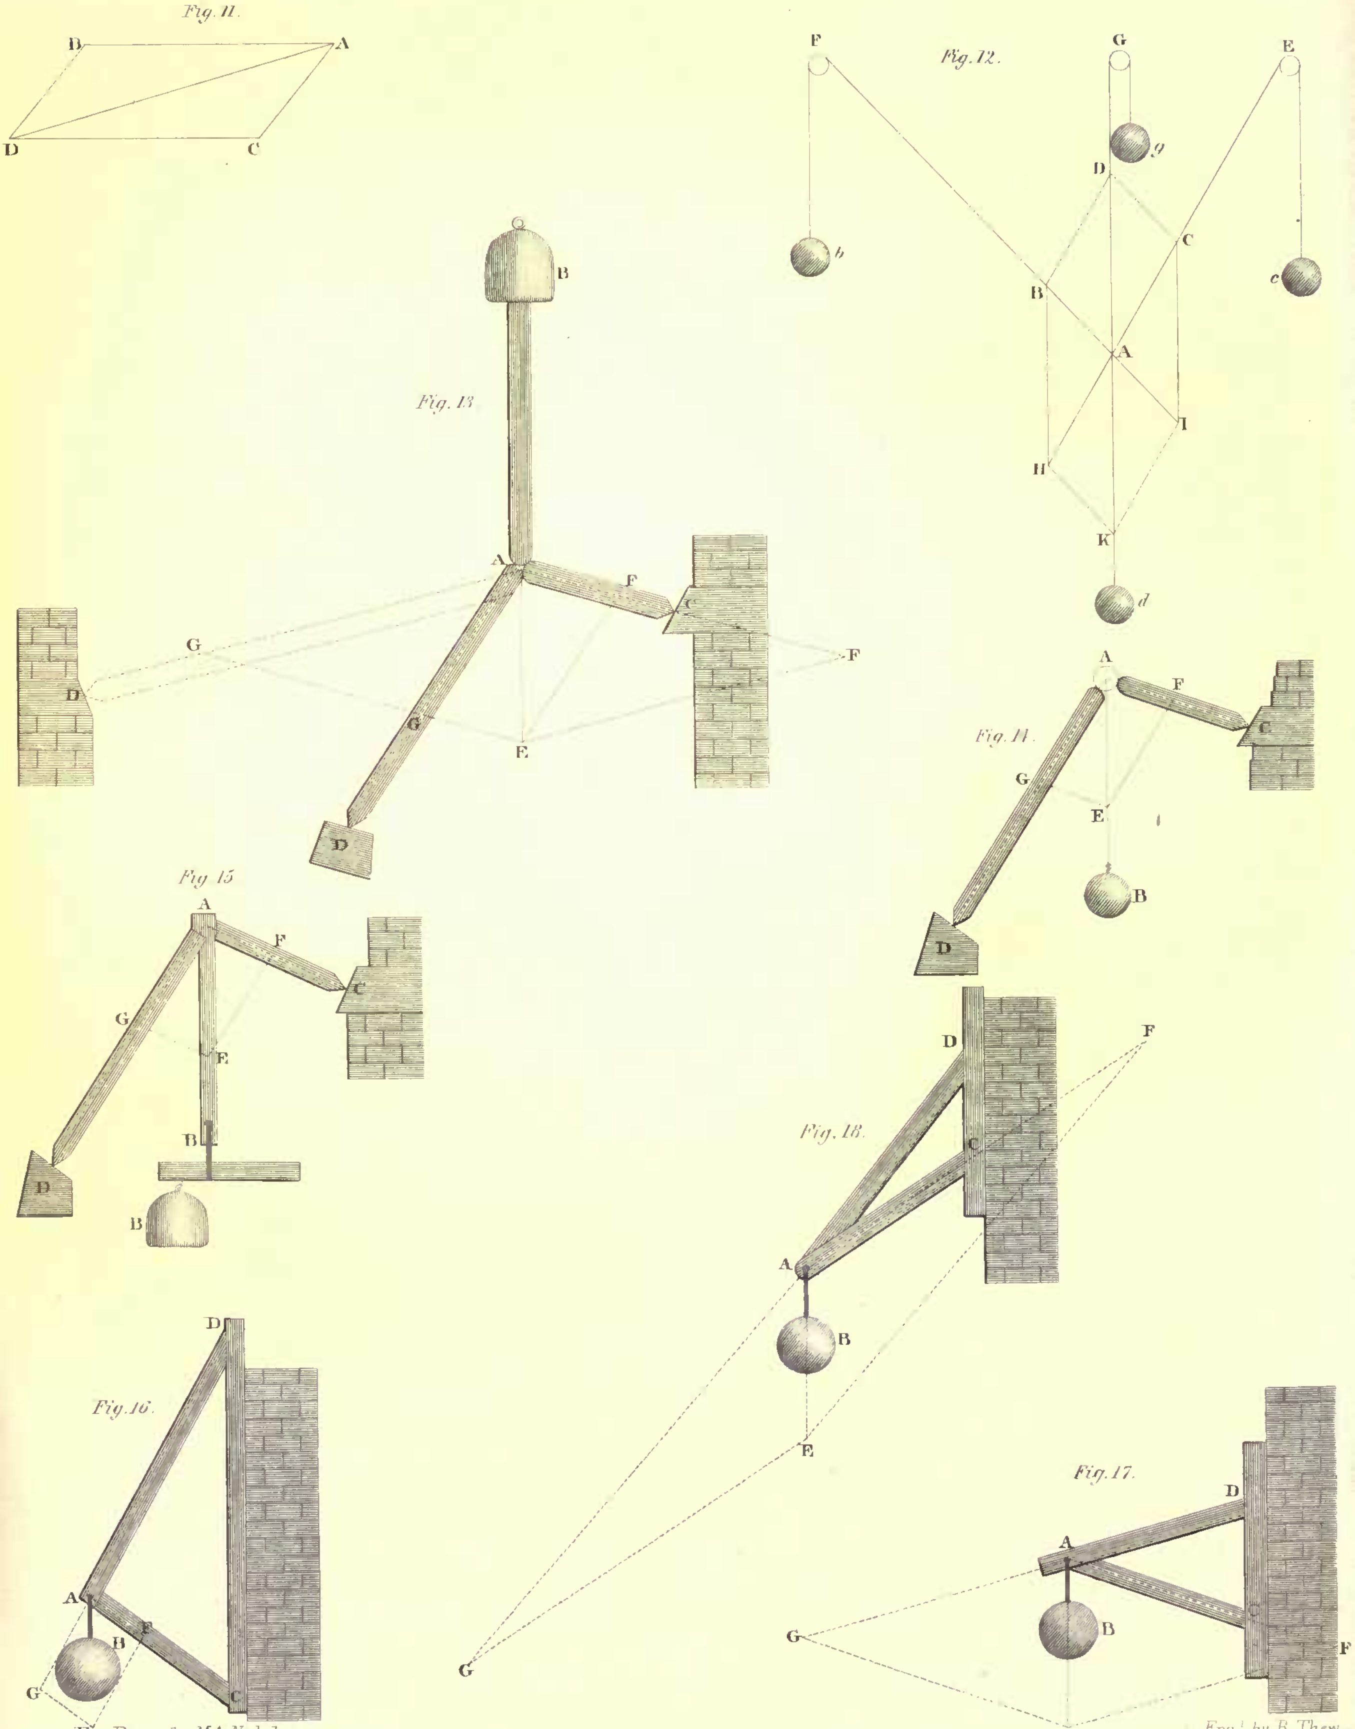
Example 4. *Figure* 10.—Let the body, A B C D, be with its upper end against the vertical face of a wall at C, it is required to find the position of a plane supporting the lower end, D, so that the body may be at rest. Draw the vertical line G E, and draw C E perpendicular to the face of the wall, C L; join E D, and draw D F perpendicular to E D; then D F is the position of the plane required. Complete the parallelogram E H I K: then the pressure on D and C, and the weight of the body, are to each other as E H, E K, E I.

The following, from Professor Robinson, will also be found interesting:

Figure 11.—If a body, or any part of a body, be at once pressed in the two directions A B, A C, and if the intensity or force of those pressures be in the proportion of these two lines, the body is affected in the same manner as if it were pressed by a single force acting in the direction A D, which is the diagonal of the parallelogram A B D C formed by the two lines, and whose intensity has the same proportion to the intensity of each of the other two that A D has to A B or A C.

This proposition has been already treated at some length under the article LEVER. And D. Bernouilli has demonstrated it in the first volume of the *Comment. Petropol.* to which, as well as to D'Alembert's improvement, in his *Opuscles*, and in the *Comment. Taurinens.* the reader is referred for a very accurate view of the subject. But nothing can possibly conduce so fully to the practitioner's advantage as to verify the theoretical demonstrations by actual experiments.

Figure 12.—Let the threads A *d*, A F *b*, and A E *c*, have the weights *d*, *b*, and *c*, appended to them, and let two of the threads be laid over the pulleys F and E. By this apparatus, the knot A will be drawn in the directions A B, A C, and A K. If the sum of the weights *b* and *c* be greater than that of the single weight *d*, the assemblage will of itself settle in a certain determined form; if the knot A be pulled out of its place, it will always return to it again, and will rest in no other position. For example, if the three weights be equal, the threads will always make equal angles, of 120 degrees each, round the knot. If one of the weights be three pounds, another four, and the third five, the angle opposite to the thread stretched by five pounds will be always square, &c. When the knot A is thus in equilibrio, we must infer, that the action of the weight *d*, in the direction A *d*, is in direct opposition to the combined action of *b*, in the direction A B, and of *c*, in the direction A C. Therefore, if *d* A be produced to any point, D, and A D be taken to represent the magnitude of the force, or pressure exerted by the weight *d*, the pressures exerted on A, by the weights *b* and *c*, in the directions A B, A C, will in fact be equivalent to a pressure acting in the direction A D, whose intensity is represented by A D. If we now measure off by a scale on A F and A E the lines A B and A C, having the same proportions to A D that the weights *b* and *c* have to the weight *d*, and if we draw D B and D C, we shall find D C to be equal and parallel to A B, and D B equal and parallel to A C; so that A D is the diagonal of a parallelogram A B D C. This will always be the case, whatever weights be made use of; only care must be taken that the weight acting without the intervention of a pulley be less than the sum of the other two: for if any one of the weights exceed



Drawn by M.A.Nicholson. Eng.d by R. Thew.

the sum of the other two, it will prevail, and drag them along with it.

Now, since we know that the weight *d* would just balance an equal weight, *g*, pulling directly upwards by the intervention of the pulley O; and that it just balances the weights *b* and *c*, acting in the directions A B, A C, we must infer, that the knot A is affected in the same manner by those two weights, or by the single weight *g*; and therefore, that two pressures, acting in the directions, and with the intensities, A B, A C, are equivalent to a single pressure having the direction and proportion of A D. In like manner, the pressures A B, A K, are equivalent to A H, which is equal and opposite to A C. Also A K and A C are equivalent to A I, which is equal and opposite to A B.

We shall consider this combination of pressures a little more particularly.

Figure 13.—Suppose an upright beam, pushed in the direction of its length by a load, B, and abutting on the ends of two beams, A C, A D, which are firmly resisted at their extreme points, C and D, which rest on two blocks, but are nowise joined to them: these two beams can only resist in the directions C A, D A; and therefore the pressures which they sustain from the beam, B A, are in the directions A C, A D. To know how much each sustains, produce B A to E, taking A E from a scale of equal parts, to represent the number of tons, or pounds, by which B A is pressed. Draw E F and E G parallel to A D and A C; then A F, measured on the same scale, will give the number of pounds by which A C is strained or crushed, and A G will give the strain on A D.

Here it deserves particular remark, that the length of A C or A D has no influence on the strain arising from the thrust of B A, while the directions remain the same. The effects, however, of this strain are modified by the length of the piece on which it is exerted. This strain compresses the beam, and will therefore compress a beam of double the length twice as much; though it may change the form of the assemblage. If A C, for example, be very much shorter than A D, it will be much less compressed: the line C A will turn about the centre, while D A will hardly change its position; and the angle C A D will grow more open, the point A sinking down. By thus changing shape, strains are often produced in places where there were none before, and frequently of the very worst kind, tending to break the beams across. The dotted lines of this figure show another position of the beam, A D′, which makes a material change, not only in the strain on A D′, but also in that on A C: both are much increased; A G being almost doubled, and A F four times greater than before. This addition was made to the figure to show what enormous strains may be produced by a very moderate force, A E, when it is exerted on a very obtuse angle.

Figures 14, 15, will assist the most uninstructed reader in conceiving how the very same strains, A F, A G, are laid on these beams, by a weight simply hanging from a billet resting on A, pressing hard on A D, and also leaning a little on A C; or by an upright piece, A E, joggled on two beams, A C, A D, and performing the office of an ordinary king-post.

Figure 15.—The proportion of these strains will be precisely the same, if everything be inverted, and each beam be drawn or pulled in the opposite direction. In the same way that we have substituted a rope and weight in *Figure* 14, or a king-post in *Figure* 15, for the loaded beam, B A, of *Figure* 13, the framing of *Figure* 16 might have been substituted, which is a very usual practice. In this framing, the batten, D A, is stretched by a force, A G, and the piece A C is compressed by a force, A F. It is evident that if a rope, or an iron rod, be fastened on at D, in place of the batten D A, the strains will be the same as before.

Figure 17.—By changing the form of this framing, the same strains are produced as in the disposition represented by the dotted lines in *Figure* 13. The strains on both the battens A D, A C, are now greatly increased.

Figure 18.—The same consequences result from an improper change of the position A C, where the strains on both are vastly increased. In short, the rule is general, that the more open we make the angle against which the push is exerted, the greater will be the strains on the struts or ties forming the sides of the angle.

The reader may not readily conceive the piece A C, of *Figure* 18, as sustaining a compression; for the weight B appears to hang from A C as much as from A D. But his doubts will be removed by considering whether he could employ a rope in place of A C; which he cannot; but A D may be exchanged for a rope. A C is therefore a strut, and not a tie.

Figure 19.—A D is again a strut, butting on the block D; A C is a tie; and the batten A C may be replaced by a rope. While A D is compressed by the force A G, A C is stretched by the force A F. Give A C the position represented by the dotted lines, the compression of A D will be A G′; while the force stretching A C′ will be A F′; both much greater than before. This disposition is analogous to *Figure* 18, and to the dotted lines in *Figure* 13. Nor will the young artist have any doubt of A C′ being on the stretch, if he consider whether A D can be replaced by a rope, which it cannot, but A C, may; and it is therefore not compressed, but stretched.

Figure 20.—All the three pieces, A C, A D, and A B, are ties on the stretch. This is the complete inversion of *Figure* 13; and the dotted position of A C′ induces the same changes in the forces A F′, A G′, as in that figure.

All calculations about the strength of carpentry are reducible to this case; for when more ties, or braces, meet in a point (a thing that rarely happens), they are to be reduced to three, by substituting for any two the force resulting from their combination, and combining this with another; and so on.

The young artist must be particularly careful not to mistake the kind of strain exerted on any piece of the framing, and suppose a piece to be a brace which is really a tie. It is very easy to avoid all mistakes in this matter by the following rule, which has no exception.

Take notice of the direction wherein the piece acts that produces the strain. Draw a line in that direction from the point on which the strain is exerted; and let its length (measured on some scale of equal parts) express the magnitude of this action in pounds, hundreds, or tons. From its remote extremity, draw lines parallel to the pieces on which the strain is exerted. The line parallel to one piece will necessarily cut the other, or its direction produced; if it cut the piece itself, that piece is compressed by the strain, and it is performing the office of a strut, or brace: if it cut its direction produced, the piece is stretched, and it is a tie. In short, the strains on the pieces A C, A D, are to be estimated in the direction of the points F and G from the strained point A. Thus, in *Figure* 13, the upright piece, B A, loaded with the weight B, presses the point A in the direction A E; so does the rope, A B, in the other figures, or the batten A B, in *Figure* 15.

In general, if the straining piece be within the angle formed by the pieces which are strained, the strains sustained by them are of the opposite kind to that which it exerts. If it be pushing, they are drawing; but if it be within the angle formed by their directions produced, the strains sustained by them are of the same kind. All the three are either drawing or pressing. If the straining piece lie within for the same reason, C B is also in a state of compression: for either A or B may be considered as the point that is impelled or withheld. Therefore D A and D B are stretched, and are resisting with attractive forces. D C and C B are compressed, and are resisting with repulsive forces. D B is also acting with repulsive forces, being compressed in like manner: and thus the support of the prop, combined with the firmness of D C, puts the frame A D B C into the condition of the two frames in *Figure* 18 and *Figure* 19. Therefore the external force at A is really in equilibrio with an attracting force acting in the direction A D, and a repulsive force acting in the direction A K. And since all the connecting forces are mutual and equal, the point D is pulled or drawn in the direction D A. The condition of the point B is similar to that of A, and D is also drawn in the direction D B. Thus the point D, being urged by the forces in the directions D A and D B, presses the beam D C on the prop, and the prop resists in the opposite direction. Therefore the line D C is the diagonal of the parallelogram, whose sides have the proportion of the forces which connect D with A and B. This is the principle on which the rest of our investigation proceeds. We may take D C as the representation and measure of their joint effect. Therefore draw C H, C G, parallel to D A, D B. Draw H L, G O, parallel to C A C B, cutting A E, B F, in L and O, and cutting D A, D B, in I and M. Complete the parallelograms I L K A, M O N B; then D G and A I are the equal and opposite forces which connect A and D; for G D = C H, = A I. In like manner D H and B M are the forces which connect D and B.

The external force at A is in immediate equilibrio with the combined forces connecting A with D and with C. A I is one of them; therefore A K is the other; and A L is the compound force with which the external force at A is in immediate equilibrium. This external force is therefore equal and opposite to A L. In like manner, the external force at B is equal and opposite to B O; and A L is to B O as the external force at A to the external force at B. The prop C resists with forces equal to those which are propagated to it from the points D, A, and C. Therefore it resists with forces C H, C G, equal and opposite to D G, D H; and it resists the compressions K A, N B, with equal and opposite forces C *p*, C *n*. Draw *p b*, *n o*, parallel to A D, B D, and draw C *b* Q, C O P: it is plain that *p* C H *b* is a parallelogram equal to K A I L, and that C *b* is equal to A L. In like manner, C *o* is equal to B O. Now the forces C *p*, C H, exerted by the prop, compose the force C *b* and C *n*, C G compose the force C *o*. These two forces C *b*, C *o*, are equal and parallel to A L and B O; and therefore they are equal and opposite to the external forces acting at A and B. But they are (primitively) equal and opposite to the pressures (or at least the compounds of the pressures) exerted on the prop, by the forces propagated to C from A D, and B. Therefore the pressures exerted on the prop are the same as if the external forces were applied there in the same directions as they are applied to A and B. Now if we make C *v*, C *z*, equal to C *b* and C *o*, and complete the parallelogram C *v* Y *z*; it is plain that the force Y C is in equilibrio with *b* C and *o* C. Therefore the pressures at A, C, and B, are such as would balance if applied to one point.

Lastly, in order to determine their proportions, draw C S and C R perpendicular to D A and D B. Also draw A *d*, B *f* pependicular to C Q and C P; and draw C *g*, G *i* perpendicular to A E, B F.

The triangles C P R and B P *f* are similar, having a common angle, P, and a right angle at R and *f*. In like manner the triangles C Q S and A Q *d* are similar. Also the triangles C H R, C G S, are similar by reason of the equal angles at H and G, and the right angles at R and S. Hence we obtain the following analogies:

C *o* : C P = *on* : P B = C G : P B
C P : C R = P B : *f* B
C R : C S = C H : C G
C S : C Q = A *d* : A Q
C Q : C *b* = A Q : *p b* : L K = A Q : C H

Therefore, by equality,

C *o* : C *b* = A *d* : *f* B
or, B O : A L = C *g* : C *i*

That is, the external forces are reciprocally proportional to the perpendiculars drawn from the prop on the lines of their direction.

This proposition is fertile in consequences, and furnishes many useful instructions to the artist. The strains L A, O B, C Y, that are excited, occur in many, if not in all framings of carpentry, whether for edifices or engines, and are the sources of their efficacy. It is also evident, that the doctrine of the transverse strength of timber is contained in this proposition; for every piece of timber may be considered as an assemblage of parts, connected by forces acting in the direction of the lines which join the strained points on the matter lying between those points, and also act on the rest of the matter, exciting those lateral forces which produce the inflexibility of the whole. Thus it appears that this proposition contains the principles which direct the artist to frame the most powerful levers; to secure uprights by shores or braces, or by ties and ropes; to secure scaffoldings for the erection of spires, and many other most delicate problems of his art. He also learns, from this proposition, how to ascertain the strains that are produced, without his intention, by pieces which he intended for other offices, and which, by their transverse action, put his work in hazard. In short, this proposition is the key to the science of his art.

There is a proposition which has been called in question by several very intelligent persons; and they say that Belidor has demonstrated, in his *Science des Ingeneurs*, that a beam firmly fixed at both ends is not twice as strong as when simply lying on the props, and that its strength is increased only in the proportion of 2 to 3; and they support this determination by a list of experiments recited by Belidor, which agree precisely with it. Belidor also says, that Pitot had the same results in his experiments. These are respectable authorities: but Belidor's reasoning is anything but demonstration; and his experiments are described in such an imperfect manner, that we cannot build much on them. It is not said in what manner the battens were secured at the ends, any farther than that it was by *chevalets*. If by this word is meant a *trestle*, we cannot conceive how they were employed; but we see this term sometimes used for a *wedge*, or *key*. If the battens were wedged in the holes, their resistance to fracture may be made what we please: they may be loose, and therefore resist little more than when simply laid on the props. They may be (and probably were) wedged very fast, and bruised or crippled.

Figure 24.—Let L M be a long beam divided into six equal parts, in the points D, B, A, C, E, and firmly supported at L, B, C, M; let it be cut through at A, and have compass joints at B and C; let F B, G C, be two equal uprights, resting on B and C, but without any connection; let A H be a similar and equal piece, to be occasionally applied at the seam A; then extend a thread, or wire, A G E, over the piece G C, and made fast at A, G, and E; do the same on the other side of A. Now, if a weight be laid on at A, the wires A F D, A G E, will be strained, and may be broken. In the instant of fracture, we may suppose their strains to be represented by A *f* and A *g*. Complete the parallelogram, and A *a* is the magnitude of the

Fig. 19.

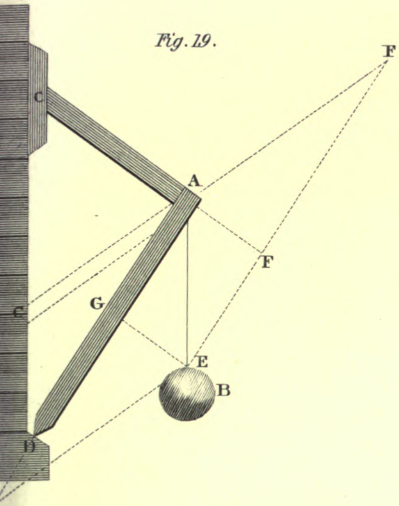


Fig. 20.

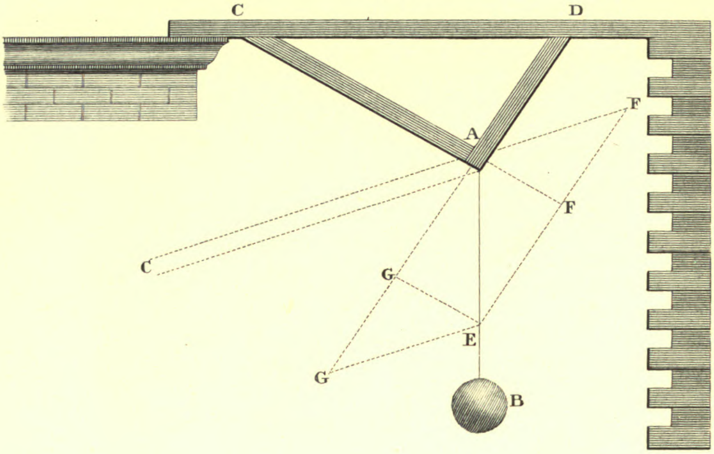

Fig. 21.

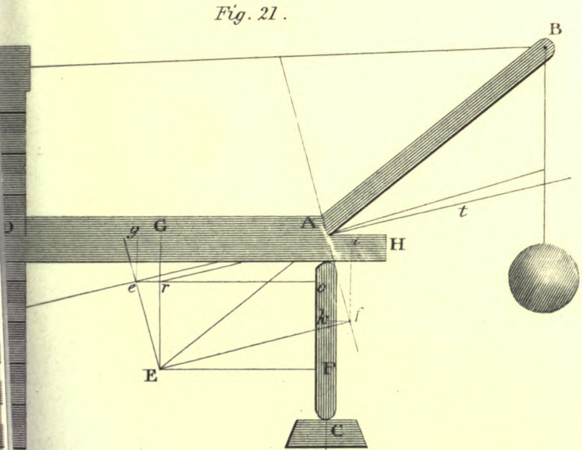

Fig. 22.

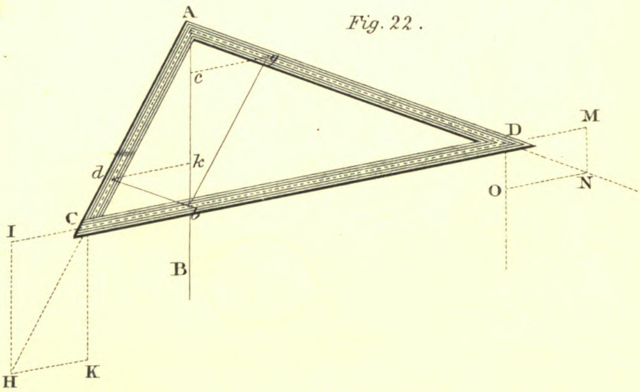

Fig. 23.

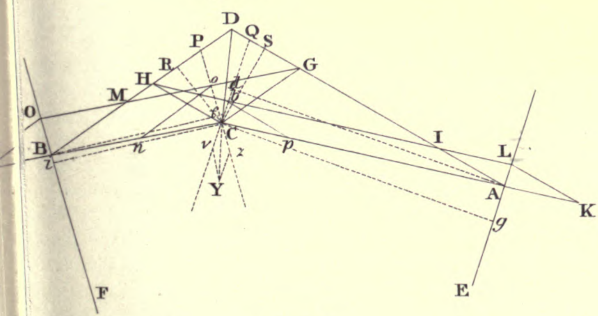

Fig. 24.

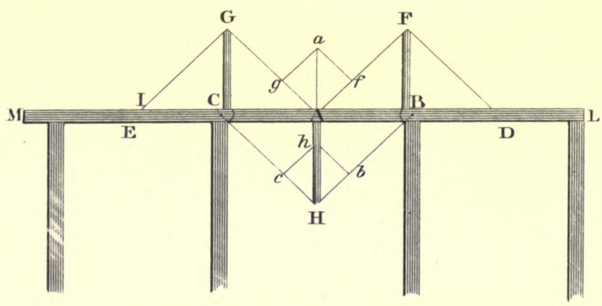

Fig. 25.

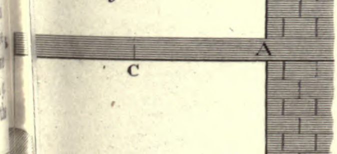

Fig. 26.

weight. It is plain that nothing is concerned here but the cohesion of the wires; for the beam is sawn through at A, and its parts are perfectly moveable round B and C.

Instead of this process, apply the piece A H below A, and keep it there by straining the same wire, B H C, over it: lay on a weight, which must press down the ends of B A and C A, and cause the piece A H to strain the wire B H C. In the instant of fracture of the same wire, its resistances, H b and H c must be equal to A f and A g, and the weight h H, which breaks them, must be equal to A a.

Lastly, employ all the three pieces, F B, A H, G C, with the same wire attached as before. There can be no doubt but that the weight which breaks all the four wires must be = a A + h H, or twice A a.

The reader cannot but see that the wires perform the very same office with the fibres of an entire beam, L M, held fast in the four holes, D B C, and E, of some upright posts.

In the experiments for verifying this, by breaking slender bars of fine deal, we get complete demonstration, by measuring the curvatures produced in the parts of the beam thus held down, and comparing them with the curvature of a beam simply laid on the props B and C; and there are many curious inferences to be made from these observations.

We may observe, by the way, that we learn from this case, that purlins are able to carry twice the load when notched into the rafters, that they carry when mortised into them, which is the most usual manner of framing them. So would the binding joists of floors; but this would double the thickness of the flooring. But this method should be followed in every possible case, such as bres-summers, lintels over several pillars, &c. These should never be cut off and mortised into the sides of every upright; numberless cases will occur which show the importance of the maxim.

We here remark, that the proportion of the spaces B C and C M, or B C and L B, has a very sensible effect on the strength of the beam B C; but we have not yet satisfied our minds as to the *rationale* of this effect. It is undoubtedly connected with the serpentine form of the curve, of the beam before fracture. This should be attended to in the construction of the springs of carriages. These are frequently supported at a middle point (and it is an excellent practice), and there is a certain proportion which will give the easiest motion to the body of the carriage. We also think that it is connected with that deviation from the best theory observable in Buffon's experiments on various lengths of the same scantling. The force of the beams diminished much more than in the inverse proportion of their lengths.

We have seen that it depends entirely on the position of the pieces in respect of their points of ultimate support, and of the direction of the external force which produces the strains, whether any particular piece is in a state of extension or of compression. The knowledge of this circumstance may greatly influence us in the choice of the construction. In many cases we may substitute slender iron rods for massive beams, when the piece is to act the part of a tie. But we must not invert this disposition; for when a piece of timber acts as a strut, and is in a state of compression, it is next to certain that it is not equally compressible in its opposite sides through the whole length of the piece, and that the compressing force on the abutting joint is not acting in the most equable manner all over the joint. A very trifling inequality in either of these circumstances (especially in the first) will compress the beam more on one side than on the other. This cannot be without the beam's bending, and becoming concave on that side on which it is most compressed. When this happens, the frame is in danger of being crushed, and soon going to ruin. It is therefore indispensably necessary to make use of beams in all cases where struts are required of considerable length, rather than of metal rods of slender dimensions, unless in situations where we can effectually prevent their bending, as in trussing a girder internally, where a cast-iron strut may be firmly cased in it, so as not to bend in the smallest degree. In cases where the pressures are enormous, as in the very oblique struts of a centre, or arch frame, we must be particularly cautious to do nothing which can facilitate the compression of either side. No mortises should be cut near to one side; no lateral pressures, even the slightest, should be allowed to touch it. We have seen a pillar of fir, 12 inches long and 1 in section, when loaded with three tons, snap in an instant when pressed on one side by 16 pounds, while another bore $4\frac{1}{2}$ tons without hurt, because it was enclosed (loosely) in a stout pipe of iron.

In such cases of enormous compression, it is of great importance that the compressing force bear equally on the whole abutting surface. The German carpenters are accustomed to put a plate of lead over the joint. This prevents, in some measure, the penetration of the end fibres. M. Perronet, the celebrated French architect, formed his abutments into arches of circles, the centre of which was the remote end of the strut. By this contrivance the unavoidable change of form of the triangle made no partial bearing upon either angle of the abutment. This always has a tendency to splinter off the heel of the beam where it presses strongest. It is a very judicious practice.

When circumstances allow it, we should rather employ ties than struts, for securing a beam against lateral strains. When an upright pillar, such as a flag-staff, a mast, or the uprights of a very tall scaffolding, are to be shored up, the dependence is more certain on those braces that are stretched by the strain than on those which are compressed. The scaffolding of the iron bridge near Sunderland had some ties very judiciously disposed, and others with less judgment.

Figure 25.—1. When a beam, A B, is firmly fixed at the end, A, and a straining force acts perpendicularly to its length at any point, B, the strain occasioned at any section, C, between B and A, is proportional to C B, and may therefore be represented by the product W × C B; that is, by the product of the number of tons, pounds, &c. which measure the straining force, and the number of feet, inches, &c. contained in C B. As the loads on a beam are easily conceived, we shall substitute this for any other straining force.

2. If the strain or load be uniformly distributed along any part of the beam lying beyond C (that is, farther from A), the strain at C is the same as if the load were all collected at the middle point of that part; for that point is the centre of gravity of the load.

Figure 26.—3. The strain on any section, D, of a beam A B, resting freely on two props, A and B, is $w \times \frac{AD \times DB}{AB}$.

4. The strain on the middle point, by a force applied there, is one-fourth of the strain which the same force would produce, if applied to one end of a beam of the same length, having the other end fixed.

5. The strain of any section, C, of a beam resting on two props, A and B, occasioned by a force applied perpendicularly to another point, D, is proportional to the rectangle of the exterior segments, or is equal to $w \times \frac{AC \times DB}{AC}$. Therefore the strain at C, occasioned by the pressure on D, is the same with the strain at D, occasioned by the same pressure on C.

6. The strain on any section, D, occasioned by a load uni-

formly diffused over any part, E F, is the same as if the two parts, E D, D F, of the load were collected at the middle points, *e* and *f*. Therefore the strain on any part, D, occasioned by a load uniformly distributed over the whole beam, is one-half of the strain that is produced when the same load is laid on at D; and the strain on the middle point, C, occasioned by a load uniformly distributed over the whole beam, is the same which half that load would produce if laid on at C.

Figure 24.—7. A beam supported at both ends on two props, B and C, will carry twice as much when the ends beyond the props are kept from rising, as it will carry when it rests loosely on the props.

8. Lastly, the transverse strain on any section, occasioned by a force applied obliquely, is diminished in the proportion of the sine of the angle which the direction of the force makes with the beam. Thus, if it be inclined to it in an angle of thirty degrees, the strain is one-half of the strain occasioned by the same force acting perpendicularly.

On the other hand, the *relative strength* of a beam, or its power in any particular section to resist any transverse strain, is proportional to the absolute cohesion of the section directly to the distance of its centre of effort from the axis of fracture directly, and to the distance from the strained point inversely.

Thus, in a rectangular section of the beam, of which b is the breadth, d the depth (that is, the dimension in the direction of the straining force), measured in inches, and f the number of pounds which one square inch will just support without being torn asunder, we must have $f \times b \times d^2$, proportional to $w \times$ C B. Or, $f \times b \times d^2$, multiplied by some number, m, depending on the nature of the timber, must be equal to $w \times$ C B. Or, in the case of the section, C, of *Figure* 46, that is strained by the force, w, applied at D, we must have $m \times f\, b\, d^2 = w \times \frac{\text{A C} \times \text{D B}}{\text{A B}}$. Thus, if the beam is of sound oak, m is very nearly $= \frac{1}{9}$. Therefore we have $\frac{f\, b\, d^2}{9} = w \times \frac{\text{A C} \times \text{C B}}{\text{A B}}$. Hence we can tell the precise force, w, which any section, C, can just resist when that force is applied in any way whatever. For the above-mentioned formula gives $w = \frac{f\, b\, d^2}{9 \text{ C B}}$, for the case represented by *Figure* 25. But the case represented in *Figure* 26 having the straining force applied at D, gives the strain at C $(= w)$ $= f \times \frac{b\, d^2 \times \text{A B}}{9 \text{ A C} \times \text{C B}}$.

Example.—Let an oak beam, four inches square, rest freely on the props A and B, seven feet apart, or 84 inches. What weight will it just support at its middle point, C, on the supposition that a square inch rod will just carry 16,000 pounds, pulling it asunder?

The formula becomes $w = \frac{16000 \times 4 \times 16 \times 84}{9 \times 42 \times 42}$ or $w = \frac{86016000}{15876} = 5418$ pounds. This is very near what was employed in Buffon's experiment, which was 5312.

Had the straining force acted on a point, D, half way between C and B, the force sufficient to break the beam at C would be equal to $\frac{16000 \times 4 \times 16 \times 84}{9 \times 42 \times 21} = 10836$ lbs.

Had the beam been sound red fir, we must have taken $f =$ 10,000 nearly, and m nearly 8; for although fir be less cohesive than oak in the proportion of 5 to 8 nearly, it is less compressible, and its axis of fracture is therefore nearer to the concave side.

Having considered at sufficient length the strains of different kinds which arise from the form of the parts of a frame of carpentry, and the direction of the external forces which act on it, whether considered as impelling or as supporting its different parts, we must now proceed to consider the means by which this form is to be secured, and the connections by which those strains are excited and communicated.

The joinings practised in carpentry are almost infinitely various, and each has advantages which make it preferable in some circumstances. Many varieties are employed merely to please the eye. We do not concern ourselves with these, nor shall we consider those which are only employed in connecting small works, and can never appear on a great scale; yet, even in some of these, the skill of the carpenter may be discovered by his choice; for, in all cases, it is wise to make every part of his work, even in the smallest details, as strong as the materials will admit. He will be particularly attentive to the changes which will necessarily happen by the shrinking of timber as it dries, and will consider what dimensions of his framings will be affected by this, and what will not; and will then dispose the pieces which are less essential to the strength of the whole, in such a manner that their tendency to shrink shall be in the same direction with the shrinking of the whole framing. If he do otherwise, the seams will widen, and parts will be split asunder. He will dispose his boardings in such a manner as to contribute to the stiffness of the whole, avoiding at the same time the giving them positions which will produce lateral strains on truss-beams which bear great pressures: recollecting, that although a single board has little force, yet many united have a great deal, and may frequently perform the office of very powerful struts.

Our limits confine us to the joinings which are most essential for connecting the parts of a single piece of a frame when it cannot be formed of one beam, either for want of the necessary thickness or length; and the joints for connecting the different sides of a trussed frame.

Much ingenuity and contrivance has been bestowed on the manner of building up a great beam of many thicknesses, and many singular methods are practised, as great nostrums, by different artists; but when we consider the manner in which the cohesion of the fibres performs its office, we shall clearly see that the simplest are equally effectual with the most refined, and that they are less apt to lead us into false notions of the strength of the assemblage.

Thus, were it required to build up a beam for a great lever or a girder, so that it may act nearly as a beam of the same size of one log; it may either be done by plain joggling, as in *Figure* 27, A, or by scarfing, as at B or C. If it is to act as a lever, having the gudgeon on the lower side, we believe that most artists will prefer the form B and C: at least this has been the case with nine-tenths of those to whom we have proposed the question. The best informed only hesitated; but the ordinary artists were all confident in its superiority: and we found their views of the matter very coincident. They considered the upper piece as grasping the lower in its hooks; and several imagined that, by driving the one very tight on the other, the beam would be stronger than an entire log: but if we attend carefully to the internal procedure in the loaded lever, we shall find the upper one clearly the strongest. If they are formed of equal logs, the upper one is thicker than the other by the depth of the joggling or scarfing, which we suppose to be the same in both; consequently, if the cohesion

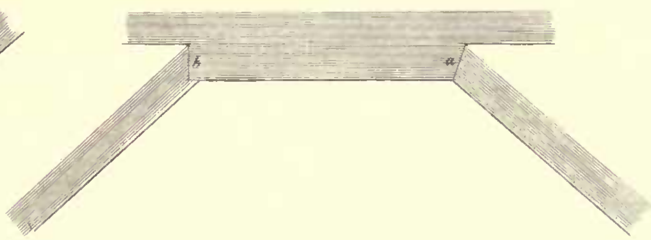

Fig. 43.

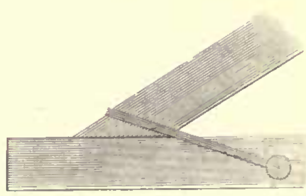

of the fibres in the intervals is able to bring the uppermost filaments into full action, the form A is stronger than B, in the proportion of the greater distance of the upper filaments from the axis of the fracture: this may be greater than the difference of the thickness, if the wood is very compressible. If the gudgeon be in the middle, the effect, both of the joggles and the scarfings, is considerably diminished; and if it is on the upper side, the scarfings act in a very different way. In this situation, if the loads on the arms are also applied to the upper side, the joggled beam is still more superior to the scarfed one. This will be best understood by resolving it in imagination into a trussed frame. But when a gudgeon is thus put on that side of the lever which grows convex by the strain, it is usual to connect it with the rest by a powerful strap, which embraces the beam, and causes the opposite point to become the resisting point. This greatly changes the internal actions of the filaments, and, in some measure, brings it into the same state as the first, with the gudgeon below. Were it possible to have the gudgeon on the upper side, and to bring the whole into action without a strap, it would be the strongest of all; because, in general, the resistance to compression is greater than to extension. In every situation the joggled beam has the advantage; and it is the easiest executed. We may frequently gain a considerable accession of strength by this building up of a beam; especially if the part which is stretched by the strain be of oak, and the other part of fir. Fir being so much superior to oak as a pillar (if Musschenbroek's experiments may be confided in), and oak so much preferable as a tie, this construction seems to unite both advantages. But we shall see much better methods of making powerful levers, girders, &c. by trussing.

Observe, that the efficacy of both methods depends entirely on the difficulty of causing the piece between the cross joints to slide along the timber to which it adheres. Therefore, if this be moderate, it is wrong to make the notches deep; for as soon as they are so deep that their ends have a force sufficient to push the slice along the line of junction, nothing is gained by making them deeper; and this requires a greater expenditure of timber.

Scarfings are frequently made oblique, as in *Figure* 28, but we imagine that this is a bad practice. It begins to yield at the point, where the wood is *crippled* and *splintered* off, or at least bruised out a little: as the pressure increases, this part, by squeezing broader, causes the solid parts to rise a little upwards, and gives them some tendency, not only to push their antagonists along the base, but even to tear them up a little. For similar reasons, we disapprove of the favourite practice of many artists, to make the angles of their scarfings acute, as in *Figure* 29. This often causes the two pieces to tear each other up. The abutments should always be perpendicular to the directions of the pressures. Lest it should be forgotten in its proper place, we may extend this injunction also to the abutments of different pieces of a frame, and recommend it to the artist even to attend to the shrinking of the timbers by drying. When two timbers abut obliquely, the joint should be most full at the obtuse angle of the end; because, by drying, that angle grows more obtuse, and the beam would then be in danger of splintering off at the acute angle.

It is evident, that the nicest work is indispensably necessary in building up a beam. The parts must abut on each other completely, and the smallest play, or void, takes away the whole efficacy. It is usual to give the butting joints a small taper to one side of the beam, so that they may require moderate blows of a maul to force them in, and the joints may be perfectly close when the external surfaces are even on each side of the beam. But we must not exceed in the least degree; for a very taper wedge has great force; and if we have driven the pieces together by very heavy blows, we leave the whole in a state of violent strain, and the abutments are perhaps ready to splinter off by a small addition of pressure.

The most general reason for piecing a beam is to increase its length. This is frequently necessary, in order to procure tie-beams for very wide roofs. Two pieces must be scarfed together. Numberless are the modes of doing this; and almost every master carpenter has his favourite nostrum. Some of them are very ingenious: but here, as in other cases, the most simple are commonly the strongest. We do not imagine that any, the most ingenious, is equally strong with a tie consisting of two pieces of the same scantling laid over each other for a certain length, and firmly bolted together. We acknowledge that this will appear an artless and clumsy tie-beam; but we only say that it will be stronger than any that is more artificially made up of the same thickness of timber. This, we imagine, will appear sufficiently certain. The simplest and most obvious scarfing (after the one now mentioned) is that represented in *Figure* 30, No. 1 and 2. If considered merely as two pieces of wood joined, it is plain that, as a tie, it has but half the strength of an entire piece, supposing that the bolts (which are the only connections) are fast in their holes. No. 2 requires a bolt in the middle of the scarf, to give it that strength; and, in every other part, is weaker on one side or the other.

But the bolts are very apt to bend by the violent strain, and require to be strengthened by uniting their ends by iron plates; in which case it is no longer a wooden tie. The form of No. 1 is better adapted to the office of a pillar than No. 2; especially if its ends be formed in the manner shown in the elevation, No. 3. By the sally given to the ends, the scarf resists an effort to bend it in that direction. Besides, the form of No. 2 is unsuitable for a post; because the pieces, by sliding on each other by the pressure, are apt to splinter off the tongue which confines their extremity.

Figures 31 and 32, exhibit the most approved form of a scarf, whether for a tie or a post. The key represented in the middle is not essentially necessary: the two pieces might simply meet square there. This form, without a key, needs no bolts (although they strengthen it greatly); but if worked very true and close, and with square abutments, will hold together, and will resist bending in any direction. But the key is an ingenious and a very great improvement, and will force the parts together with perfect tightness. The same precaution must be observed that we mentioned on another occasion, not to produce a constant internal strain on the parts by over-driving the key. The form of *Figure* 31 is by far the best; because the triangle of 32 is much easier splintered off by the strain, or by the key, than the square wood of 31. It is far preferable for a post, for the reason given when speaking of *Figure* 30, No. 1 and 2. Both may be formed with a sally at the ends equal to the breadth of the key. In this shape, *Figure* 31 is vastly well suited for joining the parts of the long corner posts of spires and other wooden towers. *Figure* 31, No. 2, differs from No. 1 only by having three keys. The principle and longitudinal strength are the same. The long scarf of No. 2, tightened by the three keys, enables it to resist a bending much better.

None of these scarfed tie-beams can have more than one-third of the strength of an entire piece, unless with the assistance of iron plates; for if the key be made thinner than one-third, it has less than one-third of the fibres to pull by.

We are confident, therefore, that when the heads of the bolts are connected by plates, the simple form of *Figure* 30, No. 1, is stronger than those more ingenious scarfings. It may be strengthened against lateral bendings by a little tongue, or by a sally; but it cannot have both.

The strongest of all methods of piecing a tie-beam would be to set the parts end to end, and grasp them between other pieces on each side, as in *Figure* 33. This is what the ship-carpenter calls *fishing* a beam; and is a frequent practice for occasional repairs. M. Perronet used it for the tie-beams, or stretchers, by which he connected the opposite feet of a centre, which was yielding to its load, and had pushed aside one of the piers above four inches. Six of these not only withstood a strain of 1,800 tons, but, by wedging behind them, he brought the feet of the truss 2½ inches nearer. The stretchers were 14 inches by 11, of sound oak, and could have withstood three times that strain. M. Perronet, fearing that the great length of the bolts employed to connect the beams of these stretchers would expose them to the risk of bending, scarfed the two side pieces into the middle piece. The scarfing was of the triangular kind (*trait de Jupiter*), and only an inch deep, each face being two feet long, and the bolt passed through close to the angle.

In piecing the pump rods, and other wooden stretchers of great engines, no dependence is had on scarfing; and the engineer connects everything by iron straps. But we doubt the propriety of this, at least in cases where the bulk of the wooden connection is not inconvenient.

These observations must suffice for the methods employed for connecting the parts of a beam; and we now proceed to consider what are more usually called *the joints* of a piece of carpentry.

Where the beams stand square with each other, and the strains are also square with the beams, and in the plane of the frame, the common mortise and tenon is the most perfect junction. A pin is generally put through both, in order to keep the pieces united, in opposition to any force which tends to part them. Every carpenter knows how to bore the hole for this pin, so that it shall draw the tenon tight into the mortise, and cause the shoulder to butt close, and make neat work; and he knows the risk of tearing out the bit of the tenon beyond the pin, if he draw it too much. We may just observe, that square holes and pins are much preferable to round ones for this purpose, bringing more of the wood into action, with less tendency to split it. The ship-carpenters have an ingenious method of making long wooden bolts, which do not pass completely through, take a very fast hold, though not nicely fitted to their holes, which they must not be, lest they should be crippled in driving. They call it *fox-tail wedging.* They stick into the point of the bolt a very thin wedge of hard wood, so as to project a proper distance: when this reaches the bottom of the hole by driving the bolt, it splits the end of it, and squeezes it hard to the side. This may be practised with advantage in carpentry. If the ends of the mortise are widened inwards, and a thin wedge be put into the head of the tenon, it will have the same effect, and make the joint equal to a dovetail. But this risks the splitting of the piece beyond the shoulder of the tenon, which would be unsightly. This may be avoided as follows:—Let the tenon, T, *Figure* 34, have two very thin wedges, *a* and *c*, stuck in near its angles, projecting equally: at a very small distance within these, put in two shorter wedges, *b*, *d*, and more within these, if necessary. In driving this tenon, the wedges *a* and *c* will take first, and split off a thin slice, which will easily bend without breaking. The wedges *b*, *d*, will act next, and have a similar effect, and the others in succession. The thickness of all the wedges taken together must be equal to the enlargement of the mortise toward the bottom.

The mortise in a girder for receiving the tenon of a binding joist of a floor should be as near the upper side as possible, because the girder becomes concave on that side by the strain. But as this exposes the tenon of the binding-joist to the risk of being torn off, we are obliged to mortise farther down. The form (*Figure* 35) generally given to this joint is extremely judicious. The sloping part *a b*, gives a very firm support to the additional bearing *c d*, without much weakening of the girder. This form should be copied in every case where the strain has a similar direction.

The joint that most of all demands the careful attention of the artist, is that which connects the ends of beams, one of which pushes the other very obliquely, putting it into a state of extension. The most familiar instance of this is the foot of a rafter pressing on the tie-beam, and thereby drawing it away from the other wall. When the direction is very oblique (in which case the extending strain is the greatest), it is difficult to give the foot of the rafter such a hold of the tie-beam as to bring many of its fibres into the proper action. There would be little difficulty if we could allow the end of the tie-beam to project to a small distance beyond the foot of the rafter; but, indeed, the dimensions which are given to tie-beams, for other reasons, are always sufficient to give enough of abutment when judiciously employed. Unfortunately, this joint is much exposed to failure by the effects of the weather. It is much exposed, and frequently perishes by rot, or becomes so soft and friable, that a very small force is sufficient, either for pulling the filaments out of the tie-beam, or for crushing them together. We are therefore obliged to secure it with particular attention, and to avail ourselves of every circumstance of construction.

One is naturally disposed to give the rafter a deep hold by a long tenon; but it has been frequently observed, in old roofs, that such tenons break off. Frequently they are observed to tear up the wood that is above them, and push their way through the end of the tie-beam. This, in all probability, arises from the first sagging of the roof, by the compression of the rafters and of the head of the king-post. The head of the rafter descends; the angle, with the tie-beam, is diminished by the rafter revolving round its step in the tie-beam. By this motion the heel, or inner angle of the rafter, becomes a fulcrum to a very long and powerful lever much loaded. The tenon is the other arm, very short, and being still fresh, it is therefore very powerful. It therefore forces up the wood that is above it, tearing it out from between the cheeks of the mortise, and then pushes it along. Carpenters have therefore given up long tenons, and give to the toe of the tenon a shape which abuts firmly, in the direction of the thrust, on the solid bottom of the mortise, which is well supported on the under side by the wall-plate. This form has the farther advantage of having no tendency to tear up the end of the mortise; and is represented in *Figure* 36. The tenon has a small portion, *a b*, cut perpendicular to the surface of the tie-beam, and the rest, *b c*, is perpendicular to the rafter.

But if the tenon be not sufficiently strong (and it is not so strong as the rafter, which is thought not to be stronger than is necessary), it will be crushed, and then the rafter will slide out along the surface of the beam. It is therefore necessary to call in the assistance of the whole rafter. It is in this distribution of the strain among the various abutting parts, that the varieties of joints and their merits chiefly consist. It would be endless to describe every nostrum, and we shall only mention a few that are most generally approved of.

The aim, in *Figure* 37, is to make the abutments exactly perpendicular to the thrusts. It does this very precisely; and the share which the tenon and the shoulder have of the whole

may be what we please, by the portion of the beam that we notch down. If the wall plate lie duly before the heel of the rafter, there is no risk of straining the tie across, or breaking it, because the thrust is made direct to that point where the beam is supported. The action is the same as against the joggle on the head or foot of a king-post. We have no doubt but that this is a very effectual joint. It is not, however, much practised. It is said that the sloping seam at the shoulder lodges water; but the great reason seems to be a secret notion that it weakens the tie-beam. If we consider the direction in which it acts as a tie, we must acknowledge that this form takes the best method for bringing the whole of it into action.

Figure 38 exhibits a form that is more general, but certainly worse. The part of the thrust that is not borne by the tenon acts obliquely on the joint of the shoulder, and gives the whole a tendency to rise up and slide outward.

The shoulder joint is sometimes formed like the dotted line, *a b c d e f g*, of *Figure* 38. This is much more agreeable to the true principle, and would be a very perfect method, were it not that the intervals, *b d* and *d f*, are so short that the little wooden triangles, *b c d*, *d e f*, will be easily pushed off their bases, *b d*, *d f*.

Figure 39 seems to have the most general approbation. It is the joint recommended by Price, (p. 7), and copied into all books of carpentry, as the true joint for a rafter foot. The visible shoulder-joint is flush with the upper surface of the tie-beam. The angle of the tenon at the tie nearly bisects the obtuse angle formed by the rafter and the beam, and is therefore somewhat oblique to the thrust. The inner shoulder, *a c*, is nearly perpendicular to *b d*. The lower angle of the tenon is cut off horizontally, as at *e d*.

Figure 40 is a section of the beam and rafter foot, showing the different shoulders.

We do not perceive the peculiar merit of this joint. The effect of the three oblique abutments *a b*, *a c*, *e d*, is undoubtedly to make the whole bear on the outer end of the mortise, and there is no other part of the tie-beam that makes immediate resistance. Its only advantage over a tenon extending in the direction of the thrust, is, that it will not tear up the wood above it. Had the inner shoulder had the form *e c i*, having its face, *i c*, perpendicular, it certainly would have acted more powerfully in stretching many filaments of the tie-beam, and would have had much less tendency to force out the end of the mortise. The little bit, *c i*, would have prevented the sliding upwards along *e c*. At any rate, the joint, *a b*, being flush with the beam, prevents any sensible abutment on the shoulder, *a c*.

Figure 39, No 2. is a simpler, and in our opinion a preferable, joint. We observe it practised by the most eminent carpenters, for all oblique thrusts; but it surely employs less of the cohesion of the tie-beam than might be used without weakening it, at least when it is supported on the other side by the wall-plate.

Figure 39, No. 3, is also much practised by the first carpenters.

Figure 41 is proposed by Mr. Nicholson, as preferable to *Figure* 39, No. 3, because the abutment of the inner part is better supported. This is certainly the case; but it supposes the whole rather to go to the bottom of the socket, and the beam to be thicker than the rafter. Some may think that this will weaken the beam too much, when it is no broader than the rafter is thick: in which case they think that it requires a deeper socket than Nicholson has given it. Perhaps the advantages of Nicholson's oonstruction may be had by a joint like *Figure* 41, No. 2.

Whatever be the form of these butting joints, great care should be taken that all parts bear alike, and the artist will attend to the magnitude of the different surfaces. In the general compression, the greater surfaces will be less compressed, and the smaller will therefore change most. When all has settled, every part should be equally close. Because great logs are moved with difficulty, it is very troublesome to try the joint frequently, to see how the parts fit; therefore we must expect less accuracy in the interior parts. This should make us prefer those joints whose efficacy depends chiefly on the visible joint.

It appears from all that we have said on this subject, that a very small part of the cohesion of the tie-beams is sufficient for withstanding the horizontal thrust of a roof, even though very low pitched. If therefore no other use be made of the tie-beam, one much slenderer may be used, and blocks may be firmly fixed to the ends, on which the rafters might abut, as they do on the joggles on the head and foot of a king-post. Although a tie-beam has commonly floors or ceilings to carry, and sometimes the workshops and store-rooms of a theatre, and therefore requires a great scantling, yet there frequently occur in machines and engines very oblique stretches, which have no other office, and are generally made of dimensions quite inadequate to their situation, often containing ten times the necessary quantity of timber. It is therefore of importance to ascertain the most perfect manner of executing such a joint. We have directed the attention to the principles that are really concerned in the effect. In all hazardous cases, the carpenter calls in the assistance of iron straps; and they are frequently necessary, even in roofs, notwithstanding this superabundant strength of the tie-beams. But this is generally owing to the bad construction of the wooden joint, or to the failure of it by time. Straps will be considered in their place.

There need but little to be said of the joints at a joggle worked out of solid timber; they are not near so difficult as the last. When the size of a log will allow the joggle to receive the whole breadth of the abutting brace, it ought certainly to be made with a square shoulder; or, which is still better, an arch of a circle, having the other end of the brace for its centre. Indeed, this in general will not sensibly differ from a straight line perpendicular to the brace. By this circular form, the setting of the roof makes no change in the abutment; but when there is not sufficient stuff for this, we must avoid bevel joists at the shoulders, because these always tend to make the brace slide off. The brace, in *Figure* 42, must not be joined as at *a*, but as at *b*, or some equivalent manner.

When the very oblique action of one side of a frame of carpentry does not extend, but compress the piece on which it abuts, as in *Figure* 21, there is no difficulty in the joint. Indeed, a joining is unnecessary, and it is enough that the pieces abut on each other; and we have only to take care that the mutual pressure be equally borne by all the parts, and that it do not produce lateral pressures, which may cause one of the pieces to slide on the butting joint. A very slight mortise and tenon is sufficient at the joggle of a king-post, with a rafter or straining beam. It is best, in general, to make the butting plain, bisecting the angle formed by the sides, or else perpendicular to one of the pieces. In *Figure* 42, No. 2, where the straining beam, *a b*, cannot slip away from the pressure, the joint *a* is preferable to *b*, or indeed to any uneven joint, which never fails to produce very unequal pressures on the different parts, by which some are crippled, others are splintered off, &c.

When it is necessary to employ iron steps for strengthening a joint, a considerable attention is necessary, that we may place them properly. The first thing to be determined is the direction of the strain. We must then resolve this strain into a strain parallel to each piece, and another perpendicular to it. Then the strap, which is to be made fast to any of the pieces, must be so fixed, that it shall resist in the direction parallel to the piece. Frequently this cannot be done; but we must come as near to it as we can. In such cases, we must suppose that the assemblage yields a little to the pressures which act on it. We must examine what change of shape a small yielding will produce. We must now see how this will affect the iron strap, which we have already supposed attached to the joint in some manner that we thought suitable. This settling will perhaps draw the pieces away from it, leaving it loose and unserviceable; (this frequently happens to the plates which are put to secure the obtuse angles of butting timbers, when their bolts are at some distance from the angles, especially when these plates are laid on the inside of the angles); or it may cause it to compress the pieces harder than before; in which case it is answering our intention. But it may be producing cross strains, which may break them; or it may be crippling them. We can hardly give any general rules; he will see the nature of the strap or stirrup by which the king-post carries the tie-beam. The strap that we observe most generally ill-placed is that which connects the foot of the rafter with the beam. It only binds down the rafter, but does not act against its horizontal thrust. It should be placed farther back on the beam, with a bolt through it, which will allow it to turn round. It should embrace the rafter almost horizontally near the foot, and should be notched square with the back of the rafter. Such a construction is represented in *Figure* 43. By moving round the eye-bolt it follows the rafter, and cannot pinch and cripple it, which it always does in its ordinary form. We are of opinion that straps which have eye-bolts in the very angles, and allow all motion round them, are, of all, the most perfect. A branched strap, such as may at once bind the king-post and the two braces which butt on its foot, will be more serviceable if it have a joint. When a roof warps, those branched steps frequently break the tenons, by affording a fulcrum in one of their bolts. An attentive and judicious artist will consider how the beams will act on such occasions, and will avoid giving rise to these great strains by levers. A skilful carpenter never employs many straps, considering them as auxiliaries foreign to his art, and subject to imperfections in workmanship, which he cannot discern nor amend.—*Supplement to the article Carpentry of the Encyclopædia Britannica, by Professor Robinson.*

The following part was written by Mr. Nicholson for the *Edinburgh Cyclopædia*, and is here inserted by permission of the editor.

A circular roof may be executed with timbers disposed in vertical planes, whether the ribs or rafters are convex, concave, or straight, without any tie between the rafters or ribs, even though the wall were ever so thin; provided that it be only sufficient to sustain the weight of the roof pressing vertically, by joining the wall-plate so as to form a complete ring, and by strutting the rafters in one or more horizontal courses, without danger of lateral pressure, or of the timbers being bent by the weight of the covering. The same cannot be done with the roof of a rectangular building, for single parallel rafters would not only obtain a concave curvature, but would thrust the walls outwards: hence the means of executing circular roofs with safety are simple; but those for straight-sided buildings are complex, and require much skill in contriving, according to the use that is to be made of the space between the rafters, which may be found necessary in rendering more lofty, or more elegant apartments, as in concave, or coved ceilings.

A polygonal roof, with a great number of sides, approaching very nearly to a circle, is stronger than one of fewer sides; the less the number of sides, the weaker will the roof be, and more liable to get out of order. A roof executed upon an equilateral and equiangular polygonal plan, is much stronger than one that is elongated. All circular roofs, for the same reason, are stronger than elliptical ones; the pressure in the former case being equally distributed round the wall-plate, which is therefore kept in an equal state of tension.

Trusses are strong frames of carpentry, resolved into two or a series of triangles, so as to make the truss act as a solid body, and thereby support certain weights, each at a given immoveable point, the truss itself being suspended from two such immoveable points. The trusses of roofs are constructed generally of a triangular form, and disposed equidistantly on the wall-plates, in parallel vertical planes, at right angles to the walls; the top of the opposite walls are the two points of suspension, and the weights supported by the truss at the immoveable points are horizontal pieces of timber, running transversely to the planes of the trusses: these horizontal pieces of timber support other equidistant pieces parallel to the upper sides of the trusses, and these last timbers support the covering, or the covering and timber-work, to which the covering is fixed. In a truss, some pieces of timber are in a state of tension, and some are in a state of compression; but a piece of timber which is neither extended nor compressed, is useless. A quadrilateral frame, so constructed that each two adjoining timbers, made moveable round a point at their intersection, may be put into an infinite number of forms, because the whole frame will be revolvable about the angles: but if any one of the angles be immoveable, the whole frame will also be so. Two pieces of timber forming an angle, and revolving round a point at their intersection, may be made immoveable by fastening each end of a bar to each leg, or by taking any two points in the bar, and fastening each point to each leg. Now, if a force be applied at any of the three angular points, the frame will be immoveable, but of the two legs which form the angle, the one will be in a state of tension, and the other in a state of compression, provided that the direction of the force applied does not fall within the angle if produced; but if the line of direction of the force applied fall within the angle of the triangle, then both legs are either in a state of tension or in a state of compression, according as the force applied is pulling or pressing; if one of the sides of the triangle be lengthened without the boundary, and a force be applied transversely to the part so lengthened, this force will bend the side of the figure which is in the straight line with the side to which the force is applied: therefore, suppose again a quadrangle, or quadrilateral, revolvable about the angles, and a bar be fixed to any two sides forming an angle, viz., a point in the bar to a point in one of the legs, and another point in the bar to a point in the other leg, and suppose the two points not to be in two of the angles, or one of the points to be in the side, at some distance from either end, the figure will be divided into two parts, one will always be a triangle; then, if it be supported at two of its angles, and a force be applied to the angle opposite, the angle which has the bar fixed to its legs, so that the direction of the force thus applied does not tend to the fixed point, which is the farther extremity of the one leg, where the force is applied to the angular point at the other extremity, all the sides of this figure will be bent, and the bar thus fixed will occasion transverse strains to the sides. But if the bar be fixed to two opposite angles, and if the frame be held immoveable at one of the angular points where the bar is fixed, and also at one of the other angles at the extremity of one of the legs of the said angle, and a force in any direction in the plane of the figure be applied to the angle where the frame is unsupported, and where the bar is not fixed, the frame will be by this means rendered immoveable, and the force by this disposition will not occasion any transverse strain on the sides of the frame. Suppose the frame to be pentagonal, and a bar fixed in like manner to two angles, at the ends of two adjoining sides, these two adjoining sides and the bar will form a triangular compartment in the figure; if the frame be suspended by two of the angles of the triangle, the three remaining sides will be moveable at the extremities of the bar, and at the remaining angles; but if another bar be fixed to any one of the three angles of the triangle at one end, to one of the angles of the other three sides, to form another triangle, three of the sides of the pentagonal frame will be made immoveable, and the two remaining sides will be so likewise. In like manner, in whatever number of sides the frame consists, by first forming a triangle of two of the sides, and fixing a second bar from any angle of the triangle to one of the other angles of the figure, at the remote ends of two adjoining sides of this frame, will form another immoveable side, and give another immoveable point at the next angle of the frame; if, from this fixed point, or any of the other three points, which are the angles of the triangle, the end of a third bar be fixed, and the other end of the bar to one of the remaining angles of the frame, so as to form a triangle with the second bar and one of the adjoining moveable sides of the frame, or a triangle with one of the fixed sides of the frame and the adjoining moveable side; and by proceeding in this manner successively, until all the sides are fixed, the frame will be made immoveable; so that if any two angles of this frame be supported, and a force or forces be applied at one or each of the angles in the plane of the figure, the whole figure will be immoveable.

Frames of a triangular form, which have to resist only a single force, or support one weight, are most simply and best constructed of three sides; the frame being suspended from two angles, and the force or weight from the other. A triangular frame, supporting only one weight, has no occasion for any subdivision to compart the internal space, provided the compressed timber or timbers were inflexible, so as to support their own weight without bending, and the tensile timbers incapable of extension. Though a frame should have to support several weights, the external figure may be of any form whatever, provided that the points from which the weights are hung, and the two points from which the frame is suspended, be all immoveably supported by comparting the figure with timber divisions, and thereby forming a succession of adjoining triangles, of which each two contiguous have a common side; that is, when two of the angles of each of the adjacent triangles are coincident. It may be proper to observe here, that though it may not be at all times eligible to divide a frame, so that all the compartments will be triangles, yet the succession must not by any means be discontinued by the intervention of quadrilateral or polygonal figures, for these compartments may adjoin without injury to the truss. The triangle is the most simple of all rectilinear figures; it is also easier constructed, and better adapted to the discharge of rain or moisture in a roof, than any other figure; but, in its adoption to large buildings, as several weights must be supported, and as there is only one point from which this weight can be suspended, it becomes necessary to take other equidistant points in the sides, in order to support the covering equally: these points may be made stationary, by the former means of dividing the interior space into a succession of triangular compartments. But if the two upper sides of the frame be of equal lengths, and equally inclined to the horizon, the opposite points may be made to counteract each other without a concatenation of triangles, by introducing timbers from point to point, parallel to the horizon; in this the compartments will all be trapezoids, except the upper one, which will be a triangle. These beams may be supported by vertical bolts passing transversely through them from the points where the weights are supported, and the bolts may be nutted below the beams. This mode of securing the points of support depends entirely upon the doctrine of equilibrium, and thus a very little difference from the equality of forces might easily occasion a change of figure, to which the other method by a series of triangles is not liable. The securing of the points of support by beams is not confined to triangular frames, but may be applied to roofs having two or several rafters upon each side, so that their lengths and inclinations are equal, and their junctions on the same level. The beauty of every truss is to dispose the timbers in positions as direct to each other as possible: oblique directions require timbers of large scantlings, and exert prodigious thrusts on the abutments, so as to compress the joggle-pieces, and render the truss in danger of sagging. Trusses are variously constructed, according to the width of the building, and contour of the roof, and the circumstances of walling below.

The general principle of construction is a series of triangles, of which every two are connected by a common side.

Let A B C D E F G (see Plate I., Centering, *Figure* 1,) be the curve of the arch which requires a centre. Let the points A B C, &c., be connected, so as to form the equilateral polygon A B C D E F G, and join A C, C E, and E G; the timbers thus disposed will form three triangles, which may be looked upon as so many solids revolvable about the angular points, A, C, E, G; suppose now these to be in equilibrium, the smallest force on either side would throw it down; and therefore, without other connecting timbers, it would be unfit for the purpose of a centre.

Let A B C D E F G (Plate I., Centering, *Figure* 2,) be the curve of an arch which requires a centre. First, from the equilateral polygon, A B C D E F G, with the timbers, A B, C D, G D, &c., and fix the timbers A C, C E, E G, as before, which will form three triangles, moveable round A C E G; let the timbers B D and D F be fastened, and thus the whole will be immutable, so that if supported at the points A and G, and a force be applied at any other of the angles, B, C, D, or F, the timbers will be all in a state of tension, or in a state of compression, and the whole may be looked upon as a solid body. For since the sides and angular points of a triangle are fixed, when the triangle is supported at two of the angles, and a force applied to the other, let us suppose the triangle, A B C, to be supported at the points A and B, and the point C, and the other two sides, B C, C A, will be fixed; and, because B C D is a triangle, and the points B and C are fixed, the point D, and consequently the sides C D and D B, are fixed. In like manner, since C D E is a triangle, and the points C and D fixed, the point E will also be fixed, and also the sides D E and E C. The same may be shown in like manner for the points F and G. Suppose, then, two equal and opposite forces applied at the points A and G, in the plane of the figure, the figure can neither be extended out nor compressed together. The pieces A H, H B, and G I, I F, are of no other use than to make the centre stand firmly on its base. This disposition of the timbers will cause them to occupy the least possible space.

If the timbers are fixed at the points *k*, *l*, *m*, *n*, *o*, *p*, the same immutability of figure may be demonstrated; for suppose the points A and H to be fixed, the point *k* will also be fixed; the points A and k being fixed, the point B, of the triangle A k B, will likewise be fixed. Again, the points B and k being fixed, the point l will also be fixed: in the same manner, all the remaining points, C, m, D, n, o, F, p, G, L, may be proved to be stationary in respect of the points A, H; and the whole figure being kept in equilibrio by any three forces, acting in the plane of the figure at any three angles, the action of the forces will only tend to compress or extend the timbers in the direction of their length.

In the construction of this truss, the triangular parts may be constructed all in the same plane, and the pieces, B D and D F, may be halved upon the pieces C A and E G; but the utmost care must be taken to secure the several pieces concurring at each of the angles, by bolting, or iron straps, as no dependence can be put in any such joint without iron; but perhaps the best method of any is to halve the thicknesses of the pieces A C, C E, E G, at the points C and E, and also the pieces A B, B C, C D, D E, E F, F G, at the points B, D, F: then bolting the ends, A and C, of the pieces B A, D C, the end C and E, of the pieces D C and D E, and the ends E and G of the pieces F E and F G, and then fixing double braces, B D, D F; that is, fixing B D upon one side of the truss, and another upon the other side of the truss, opposite to it; also fixing D F upon one side, and another opposite to it.

Figure 6, of the same plate, represents the manner of constructing a centre according to the principles of Perronet, the celebrated French engineer; but the disposition of the timbers, forming only a series of quadrilaterals, gives nothing but immutability of figure; and can, therefore, only derive its stiffness from the resistance of the joints.

Having thus given a general account of the principles of centering, as connected with the article Carpentry, we must refer our readers to the article STONE BRIDGE for its application, and other practical remarks in the construction.

MECHANICAL POWERS, such machines as are used for raising greater weights, or overcoming greater resistances, than could be effected by the natural strength without them; the power or strength being applied to one part of the machine, and another part of the machine applied to the weight or resistance. In treating of each of which, two principal problems ought to be resolved.

The first is, to determine the proportion which the power and weight ought to have to each other, that they may just sustain one another, or be in equilibrio.

The second is, to determine what ought to be the proportion of the power and weight to each other in a given machine, that it may produce the greatest effect possible, in a given time.

As to the first problem, this general rule holds in all powers: suppose the engine to move, and reduce the velocities of the power and weight to the respective directions in which they act; find the proportions of these velocities; then, if the power be to the weight as the velocity of the weight is to the velocity of the power,—or, which amounts to the same thing, if the power multiplied by its velocity, gives the same product as the weight multiplied by its velocity,—this is the case wherein the power and weight sustain each other, and are in equilibrio; so that in this case the one would not prevail over the other, if the engine were at rest; and if in motion, it would continue to proceed uniformly, were it not for the friction of its parts, and other resistances.

The second general problem in mechanics is, to determine the proportion which the power and weight ought to bear to each other, that when the power prevails, and the machine is in motion, the greatest effect possible may be produced by it in a given time. It is manifest, that this is an inquiry of the greatest importance, though few have treated of it. When the power is only a little greater than that which is sufficient to sustain the weight, the motion is too slow; and though a greater weight is raised in this case, it is not sufficient to compensate the loss of time. When the weight is much less than that which the power is able to sustain, it is raised in less time; and this may happen not to be sufficient to compensate the loss arising from the smallness of the load. It ought, therefore, to be determined when the product of the weight, multiplied by its velocity, is the greatest possible; for this product measures the effect of the engine in a given time, which is always the greater in proportion as the weight which is raised is greater, and as the velocity with which it is raised is greater.

The simple machines by which power is gained are six in number, viz., the *lever*, the *wheel and axle*, or *axis in peritrochio*, the *pulley* (or rather system of pulleys), the *inclined plane*, the *wedge*, and the *screw*. Of these, all sorts of mechanical engines consist; and in treating of them, so as to settle their theory, we must consider them as mechanically exact, and moving without friction. For the properties and applications of the mechanical powers, see LEVER, PLANE (INCLINED), PULLEY, WEDGE, and WHEEL.

MEDALLION (from the French), in architecture, a circular tablet, on which are embossed figures, bustos, or other ornaments.

MEDIÆVAL ARCHITECTURE, comprises all those styles which were prevalent during what are commonly, though unfairly, styled the dark ages, viz., from the fall of the Roman empire to the revival of classic art. It includes those styles which may be peculiarly termed Christian, amongst which may be enumerated the Romanesque, the Byzantine, and Lombardic, and more especially the Gothic style. These are treated of under their distinctive titles.

MEDIANÆ, in Vitruvius, the columns in the middle of the portico, where the intercolumniation is enlarged.

MEMBER (from the French) any part of an edifice; or any moulding in a collection.

MENSURATION (from the Latin *mensura*, measurement) that branch of mathematics which is employed in ascertaining the extension, solidities, and capacities of bodies; and in consequence of its very extensive application to the various purposes of life, it may be considered as one of the most useful and important of all the mathematical sciences: in fact, mensuration, or geometry, which were anciently nearly synonymous terms, seem to have been the root whence all the other exact sciences, with the exception of arithmetic, have derived their origin.

As soon as men began to form themselves into society, and direct their attention towards the cultivation of the earth, it became as necessary to have some means of distinguishing one person's allotment from another, both as to position and quantity, as it did to enumerate the number of their flocks and herds; and hence, in all probability, the former gave rise to the science of mensuration, as the latter did to that of arithmetic; and though we may easily imagine that each of them remained for ages in a rude uncultivated state, yet it is from this period that we must date their commencement; and therefore, to state the precise time when they were discovered, or by whom they were first introduced, would be to trace out the origin of society itself: on this head, therefore, we shall barely observe, that in all probability they first arose from the humblest efforts of unassisted genius, called forth by the great mother of invention, necessity; and that they have since grown up by slow and imperceptible degrees, till they have at length acquired the dignity of the most perfect sciences; as the acorn which is first accidentally sown in a field, is in due course of time converted into the majestic oak

But notwithstanding we cannot attribute the invention of the science of mensuration to any particular person or nation, yet we may discover it in an infant state, rising, as it were, into a scientific form, amongst the ancient Egyptians; and hence the honour of the discovery has frequently been given to this people, and to the circumstance of the overflowing of the Nile, which takes place about the middle of June, and ends in September. It is, however, to the Greeks that we must consider ourselves indebted for having first embodied the leading principles of this art into a regular system. Euclid's *Elements of Geometry* were probably first wholly directed to this subject; and many of those beautiful and elegant geometrical properties, which are so much and so justly admired, it is not unlikely, arose out of simple investigations directed solely to the theory and practical application of mensuration. These collateral properties, when once discovered, soon gave rise to others of a similar kind; and thus geometry, which was first instituted for a particular and limited purpose, became itself an independent and important science, which has perhaps done more towards harmonizing and expanding the human faculties, than all the other sciences united.

But notwithstanding the perfection which Euclid attained in geometry, the theory of mensuration was not in his time advanced beyond what related to right-lined figures; and this, so far as regards surfaces, might all be reduced to that of measuring a triangle; for as all right-lined figures may be reduced to a number of trilaterals, it was only necessary to know how to measure these, in order to find the surface of any other figure whatever bounded only by right lines. The mensuration of solid bodies, however, was of a more varied and complex nature, and gave this celebrated geometrician a greater scope for the exercise of his superior talents, and, still confining himself to bodies bounded by the right-lined plane superficies, he was able to perform all that can be done even at this day. With regard to curvilinear figures, he attempted only the circle and the sphere, and if he did not succeed in those, he failed only where there was no possibility of success; but the ratio that such surfaces and solids have to each other he accurately determined.

After Euclid, Archimedes took up the theory of mensuration, and carried it to a much greater extent. He first found the area of a curvilinear space, unless, indeed, we except the lunules of Hippocrates, which required no other aid than that of the geometrical elements. Archimedes found the area of the parabola to be two-thirds of its circumscribing rectangle, which, with the exception above stated, was the first instance of the quadrature of a curvilinear space. The conic sections were at this time but lately introduced into geometry, and they did not fail to attract the particular attention of this celebrated mathematician, who discovered many of their very curious properties and analogies. He likewise determined the ratio of spheres, spheroids, and conoids, to their circumscribing cylinders, and has left us his attempt at the quadrature of the circle. He demonstrated that the area of a circle is equal to the area of a right-angled triangle, of which one of its sides about the right angle is equal to the radius, and the other equal to the circumference, and thus reduced the quadrature of the circle to that of determining the ratio of the circumference to the diameter, a problem which has engaged the particular attention of the most celebrated mathematicians of all ages, but which remains at present, and in all probability ever will remain, the desideratum of geometricians, and, at the same time, a convincing and humiliating proof of the limited powers of the human mind.

But, notwithstanding Archimedes failed in establishing the real quadrature of the circle, it is to him we are indebted for the first approximation towards it. He found the ratio between the diameter of a circle, and the periphery of a circumscribed polygon of 96 sides, to be less than 7 to 22, or less than 1 to $3\frac{10}{70}$; but the ratio between the diameter, and periphery of an inscribed polygon of the same number of sides, he found to be greater than 1 to $3\frac{10}{71}$; whence *à fortiori*, the diameter of a circle is to its circumference in a less ratio than 1 to $3\frac{1}{7}$, or less than 7 to 22. Having thus established this approximate ratio between the circumference and diameter, that of the area of the circle to its circumscribed square, is found to be nearly as 11 to 14. Archimedes, however, makes the latter the leading proposition. These, it is true, are but rude approximations, compared with those that have been since discovered; but, considering the state of science at this period, particularly of arithmetic, we cannot but admire the genius and perseverance of the man, who, notwithstanding the difficulties that were opposed to him, succeeded in deducing this result, which may be considered as having led the way to the other more accurate approximations which followed, most of which, till the invention of fluxions, were obtained upon similar principles to those employed by this eminent geometrician. Archimedes also determined the relation between the circle and ellipsis, as well as that of their similar parts; besides which figures, he has left us a treatise on the spiral, a description of which will be given under that article. See SPIRAL.

Some advances were successively made in geometry and mensuration, though but little novelty was introduced into the mode of investigation till the time of Cavalerius. Till his time, the regular figures circumscribed about the circle, as well as those inscribed, were always considered as being limited, both as to the number of their sides, and the length of each. He first introduced the idea of a circle being a polygon of an infinite number of sides, each of which was, of course, indefinitely small; solids were supposed to be made up of an indefinite number of sections indefinitely thin, &c. This was called *the doctrine of indivisibles*, which was very general in its application to a variety of difficult problems, and by means of it many new and interesting properties were discovered: but it unfortunately wanted that distinguishing characteristic which places geometry so pre-eminent amongst the other exact sciences. In pure elementary geometry, we proceed from step to step, with such order and logical precision, that not the slightest doubt can rest upon the mind with regard to any result deduced from those principles; but in the new method of considering the subject, the greatest possible care was necessary in order to avoid error, and frequently this was not sufficient to guard against erroneous conclusions. But the facility and generality which it possessed, when compared with any other method then discovered, led many eminent mathematicians to adopt its principles, and of these, Huygens, Dr. Wallis, and James Gregory, were the most conspicuous, being all very fortunate in their application of the theory of indivisibles. Huygens, in particular, must always be admired for his solid, accurate, and masterly performances in this branch of geometry. The theory of indivisibles was, however, disapproved of by many mathematicians, and particularly by Newton, who, amongst his numerous and brilliant discoveries, has given us that of the method of fluxions, the excellency and generality of which immediately superseded that of indivisibles, and revived some hopes of squaring the circle, and accordingly its quadrature was again attempted with the greatest eagerness. The quadrature of a space, and the rectification of a curve, was now reduced to that of finding the fluent of a given fluxion; but still the problem was found to be incapable of a general solution in finite terms. The fluxion of every fluent was found to be always assignable, but the converse proposition, viz., of finding the fluent of a given fluxion, could only be effected in particular cases, and amongst these exceptions, to the great disappointment and regret of geometricians, was included the case of the circle, with regard to all the forms of fluxions under which it could be obtained.

At length, all hopes of accurately squaring the circle and some other curves being abandoned, mathematicians began to apply themselves to finding the most convenient series for approximating towards their true length and quadrature; and the theory of mensuration now began to make rapid progress towards perfection. Many of the rules, however, were given in the transactions of learned societies, or in separate and detached works, till at length Dr. Hutton formed them into a complete treatise, intitled, *A Treatise on Mensuration*, in which the several rules are all demonstrated, and some new ones introduced. Mr. Bonnycastle also published a very neat work on this subject, intitled *An Introduction to Mensuration*. Several books on the subject have been published since the above, which, notwithstanding, still maintain their high reputation.

Particular rules for measuring the various kinds of geometrical figures and solids will be found under their respective heads; but as a collection of examples of the mensuration of distances capable of application to the purposes of enginery and architecture is a desideratum in science, the following, likely to occur in general practice, are here inserted.

Mensuration of Lines.

Problem I.—*Any two sides of a right-angled triangle being given, to find the third.*

Case I.—When the two legs are given, to find the hypothenuse.

Rule.—Add the squares of the two legs together, and the square root of the sum will give the hypothenuse.

Example 1.—In the right-angled triangle, A B C, are given the base, A B, equal to 195 feet, and the perpendicular, B C, = 28 feet: what is the length of the hypothenuse, A C?

```
     195            28
     195            28
    ----           ----
     975           224
    1755           56
    195            ----
    ----           784
(A B)² = 38025
(B C)² =   784
    ----------
    3,88,09 (197 = A C
    1
   ----
29 ) 288
     261
    -----
387 ) 2709
      2709
```

Example 2.—If the span, A B, of a roof, be 24 feet, and the height, D C, 5 feet, what should be the length of the rafters, A C and C B.

This is resolved into two equal and similar right-angled triangles, as follows:—

$24 \div 2 = 12$, the half base.

$(12^2 + 5^2)^{\frac{1}{2}} = 13$, the answer.

Case II.—When the hypothenuse and one of the legs are given, to find the other leg.

Rule.—From the square of the hypothenuse take that of the given leg; and the square root of the difference will be the leg required.

Example 1.—In the right-angled triangle, A B C, are given the hypothenuse D C, 601, the perpendicular A C, 240; required the base.

$(601^2 - 240^2)^{\frac{1}{2}} = 551$, the answer.

Example 2.—In a roof, whose span, A B, is 45 feet 6 inches, and the rafters, A C or B C, 25 feet 5 inches; required the height, D C, of the roof.

```
  45 .. 6         25 .. 5
  12              12
  ----            ----
2 ) 546        Rafter, 305 inches.
```

Base of each triangle, 273 inches.

Then will $(305^2 - 273^2)^{\frac{1}{2}} = 136$ Inches $= 11$ Feet .. 4 Inches the answer.

Example 3.—In a roof, whose rafters are each 26 feet, and the perpendicular height 10 feet, what is the span or distance between the feet of the rafters?

$(26^2 - 10^2)^{\frac{1}{2}} = 24$ feet, half the span.

Consequently, 48 feet is the distance between the feet of the rafters.

Examples for Practice.

1. Given the hypothenuse, 1625 yards, and the perpendicular, 400; required the base.—*Answer*, 1575 yards.

2. Wanted to prop a building with raking-shores at the height of 25 feet from the ground, having several pieces of wood of equal length which might be used for the purpose, each 30 feet long; how far must the bottom of the shores be placed from the base of the building?—*Answer*, 16,583.

The following rule for the construction of right-angled triangles, the sides of which shall be commensurable with each other, may be found useful in the practice of constructing roofs.

Rule.—Take any two square numbers at pleasure; then their sum, their difference, and the double product of their roots, will give the sides of a right-angled triangle, which shall be commensurable with each other.

Example 1.—Let the two square numbers 1 and 4 be taken: the roots of which are 1 and 2.

Then $4 + 1 = 5$, the hypothenuse.
$4 - 1 = 3$, one of the legs,
and $2 \times 2 \times 1 = 4$, the other leg, equal to double the product of the roots; consequently, 3, 4, 5, are the numbers required, and are the least numbers by which a right-angled triangle can be constructed.

Example 2.—Let the two square numbers be 144 and 25.
Then $144 + 25 = 169$, the hypothenuse.
$144 - 25 = 119$, one of the legs.
$2 \times 12 \times 5 = 120$, the other leg.
In this manner an infinite variety of ratios may be found for the sides of right-angled triangles.

The above rule may be found in some books of arithmetic; but having obtained the three sides, suppose 169, 119, 120, the following progressive table of ratios may be constructed, by adding 10 continually to the fourth column, and the opposite number of the vertical arithmetical progressive column on the left hand to each horizontal number in the second and third columns, which will generate those immediately below.

Example.—To generate the numbers 194, 144, 130: Add 25 to 169, and the sum will be 194, the hypothenuse of the triangle. In like manner, $25 + 119 = 144$, one of the legs;

and by adding 10 to 120, we have 130, the other leg. And thus, in every instance, each horizontal number will be generated by adding the number in the vertical left-hand column to each of the two adjacent numbers in the second and third columns of the same horizontal line, and by adding 10 to the number expressed in the fourth.

Generating numbers.	Sides of a right-angled triangle, expressed by any three of the horizontal numbers.			Ratio of the two legs.
25	169	119	120	$1\frac{1}{119}$
27	194	144	130	$1\frac{7}{65}$
29	221	171	140	$1\frac{31}{140}$
31	250	200	150	$1\frac{1}{3}$

75	1394	1344	370	$3\frac{117}{185}$
77	1469	1419	380	$3\frac{279}{380}$
79	1546	1496	390	$3\frac{326}{390}$
81	1625	1575	400	$3\frac{15}{16}$
83	1706	1656	410	$4\frac{8}{205}$

Problem II.—*To find the length of a cylindrical helix.*

Rule.—Multiply the circumference of the base by the number of revolutions; to the square of the product add the square of the height of the spiral, or the square of the distance of the axis from the beginning to the end; and the square root of the sum will be the length of the spiral.

The form of the cylindric helix is a right-angled triangle, the base of which is the number of revolutions, and the height that of the spiral: *i. e.*, if the whole were unwound and stretched upon a plane, the development would be a right-angled triangle.

Example 1.—Required the length of a screw twisting round a cylinder 22 inches in circumference, $3\frac{1}{2}$ times, and extending along the axis 16 inches.

22	16
$3\frac{1}{2}$	16

Example 2.—Required the number of feet of hand-railing for a semicircular stair, consisting of 9 winders, each $6\frac{1}{2}$ inches high, the diameter of the well-hole being 18 inches.

Problem III.—*The chord and versed sine of an arc of a circle being given, to find the diameter.*

Rule 1.—Divide the sum of the squares of the sine and the versed sine by the versed sine itself, and the quotient is the diameter.

Example 1.—Given, the chord, A B = 48 feet, and the versed sine, D E = 18 feet; required the diameter.

$$\frac{48}{2} = 24, \text{ the sine, or half chord.}$$

Then $\frac{24^2 + 18^2}{18} = 50$, the diameter required.

This arithmetical operation of finding the radius is much preferable to the geometrical construction, the calculation being so easy, and performed in a very small compass; whereas the other mode requires a floor, or flat surface, to describe it upon, which cannot at all times be obtained; recourse must therefore be had to a temporary floor of rough boarding, which requires an immense time in the preparation, and when done is not much to be depended upon.

Examples for Practice.

A room is to be constructed with a cylindric bow, the plan being the segment of a circle, whose chord is 18 feet, and the height of the segment 6 feet; what length of a rod will be necessary to describe the arc?

A bridge is to be constructed of a cylindric intrados, the section of which is to be the segment of a circle, to span 100 feet, and to rise 33 feet; what length of a line, or wire, will be necessary to describe the arc?

Rule 2.—As the versed sine is to the half chord, so is the half chord to a fourth proportional; add this fourth proportional to the versed sine, and the sum is the diameter: thus, take the dimensions in the preceding example; we have

$$18 : 24 :: 24 : \frac{24 \times 24}{18} = 32;$$

then 32 + 18 = 50, the diameter.

Problem IV.—*In the segment of a circle are given the chord, and its distance from the centre; to find the radius of the circle.*

Rule.—Add the square of the half chord to the square of the distance; and the square root of the sum will be the radius of the circle.

Example 1.—Let the chord, A B, be 8 feet, and the distance of A B from the centre, C D, 3 feet; required the radius of the circle.

Here $\frac{8}{2} = 4$ the half chord.

Then $(4^2 + 3^2)^{\frac{1}{2}} = 5$, the answer.

Or thus, at full length.

4	3
4	3
—	—
16	9
9	
—	
25 (5, the answer.	

Example 2.—In Stewart's *Ruins of Athens*, vol. II. pl. vi. ch. 1, are given, in a section of the columns of the portico of the temple of Minerva at Athens, the distance between the chords of two opposite equal and parallel flutes, 6 feet 1.8 inches, and the chord of each flute 11.688 inches; required the diameter of the column, which he has omitted.

6 1.8
12
———
2) 73.8 diameter reduced to inches.
———
36.9

2) 11.688
———
5.844 half chord.

Inches.

$(36.9^2 + 5.844^2)\ \frac{1}{2} = 37.36$ the radius nearly.

Problem V.—*The radius of a circle being given, and the chord of a segment of that circle: to find the versed sine of the lesser segment.*

Rule.—*Method* 1.—Subtract the square of the half chord from the square of the radius, and the square root of the difference will be the cosine; subtract the cosine from the radius, and their difference will be the versed sine of the lesser segment; that is, $v = r - (r^2 - y^2)^{\frac{1}{2}}$.

Example.—A weir is to be constructed across a river, in the arc of a circle of 250 feet radius; the span of the river, or chord, to be 200 feet; what is the versed sine of the lesser segment?

$250 - (250^2 - 100^2)^{\frac{1}{2}} = 20\ 87122$, the versed sine required.

N. B. If the versed sine of the greater segment is required, add the cosine to the radius, and the sum will be the versed sine.

Method 2.—When the chord is very small, and the diameter large.

As the diameter of the circle is to the half chord, so is the half chord to the versed sine, nearly.

Example 1.—Suppose a bridge is to be executed, 56 feet in diameter, the breadth or chord of each stone on the face and on the intrados of the arch being 12 inches; what is the versed sine, or height of the arc of a single stone?

56
12
———
672 : 6 : : 6
6
———
672) 36.000(.053 inches nearly.
33 60
———
2 400
2 016
———
384

Example 2.—Supposing the diameter of the earth to be 7957 miles, how much does the curvature rise in a chord of 2 miles?

We have 7957 : 1 : : 1 : .000125 of a mile, which reduced gives 7.92 inches nearly for the rise of the arc.

This would also be the distance that the curvature of the earth would fall from the tangent in one mile.

N. B. The deflection of the arc from the level is as the square of the distance from the point of contact nearly. This proportion would give the same result as the method by which this example is wrought.

Problem VI.—*Given the distance between the two parallel sides of a trapezoid, and the breadth of the lesser end; to find the breadth of the greater end, so that the sides may tend to a point at any given distance.*

Note.—The distance from the lesser end to the given point is here termed *the distance of the point of convergence.*

Rule.—As the given distance is to the sum of that distance, and the distance to the point of convergence; so is the breadth of the lesser end to that of the greater.

Example 1.—Given the distance, E F, between the parallel sides, A B and D C, of a trapezoid A B C D, equal to 3 feet; the breadth of the lesser end, D C, 2 feet; and the distance, E G, from the lesser end, D C, to the point, G, of the meeting of the inclined sides, A D and B C, 58 feet; required the breadth, A B, of the greater end.

$58 : 58 + 3 : : 2 : \frac{(58 + 3) \times 2}{58} = 2.103$, the breadth of the greater end.

Example 2.—A stone weir is to be constructed across a river, in the form of the segment of a circle, with the convex side of the arc towards the stream; the joints of the stones being all to tend to the centre: now the length of each stone in the direction of a radial is 4 feet, the radius 250 feet, and the breadth of the lesser end of the stone 1 foot; required the breadth of the upper end of the stones.

	Foot.	In.	Sec.
Answer, 1.016 feet, or,	1	0	2

This problem is also useful in perspective, in the drawing of two lines towards a vanishing point.

Example 3.—A bridge is to be constructed of a cylindric intrados, the section of which is the segment of a circle of 28 feet radius, the length of the archstones are to be 2 feet, and their breadth in front of the arch and on the intrados 1 foot; required the breadth of the thick end of the stone.

28 : 28 + 2 : : 1 to the answer.

Or,
28 : 30 : : 1
1
—
28)30(1.0714 the breadth of the greater end, as required.
28
———
200
196
———
40
28
———
120
112
———
8

Or, the answer may be reduced to the workman's rule for taking his dimensions, thus:

1.0714
12
.8568
8
6.8544
4
3.4176

This gives one foot and very nearly seven-eighths of an inch, the foot being divided into twelve equal parts, called *inches*, and each inch into eight equal parts; the workmen seldom regard anything less than the sixteenth part of an inch.

This example corresponds to Problem V. Method 2, which ascertains the versed sine of the arc of the stone of a bridge, weir, or the like, of a given radius and given chord: it likewise ascertains the taper that the stones should have in the direction of a radius. The mould of the section of the stones may therefore be found by calculation, and the arc described by Problem LII. of the article GEOMETRY, almost within the compass of the section itself, without having recourse to the long distance of a centre, which not only requires an inconvenient degree of space, but occasions great loss of time in the preparation.

PROBLEM VII.—*To find any point in the arc of the segment of a circle at the extremity of an ordinate; the radius of the circle, the chord of the arc, and the distance of the ordinate from the middle of the chord, being given.*

RULE.—Find the versed sine by Problem V. subtract it from the radius, and the remainder will be the cosine; subtract this cosine from the square root of the difference of the squares of the radius and of the distance from the middle of the chord to the ordinate, and the difference will give the length of the ordinate.

Example.—Suppose the radius, A D, of the segment, G E H, to be 250 feet, the chord, G H, 200 feet, and the distance from the middle B, of the chord to the ordinate, C D, 50 feet; required the ordinate, C D.

The versed sine I E, will be found to be 20.871, by Problem V., consequently, $250 - 20.871 = 229.129$ the cosine; therefore $(250^2 - 50^2)^{\frac{1}{2}} - 229.129 = 15.820$ feet, the answer.

In the following examples, the radius and chord are the same as in the last; but the variation is in the distance of the ordinate from the middle of the chord.

EXAMPLES FOR PRACTICE, TO BE ANSWERED.

Let the distance from the middle of the chord to the ordinate be 10; required the ordinate.—*Answer.*

Let the distance from the middle of the chord to the ordinate be 20; required the ordinate.—*Answer.*

Let the distance from the middle of the chord to the ordinate be 30; required the ordinate.—*Answer.*

Another rule, without finding the versed sine, is as follows:

First.—Find the cosine of G E, the half arc, thus: from $(250)^2$ viz. the square of the radius, subtract $(100)^2$ viz. the square of the sine, or half chord, 200; and the square root, 229.129, of the remainder gives A B, the cosine of the arc G E.

Secondly.—Find the cosine of the arc D E in the same manner, thus; from $(250)^2$ viz. the square of the radius, subtract $(50)^2$, viz. the square of the sine, or half chord, of 100, that is, the distance from B to C; and the square root, 244.949, of the remainder gives A I the cosine of the arc D E.

Thirdly.—Subtract the cosine, A B = 229.129, of the greater arc G E, from the cosine A I = 244.949 of the lesser arc, D E; and the remainder, B I = 15.82, is equal to the ordinate C D.

PROBLEM VIII.—*Given the chord of a very large segment of a circle, and the radius of the circle; to find any number of points in the arc, and thence to describe it.*

RULE.—Divide the chord into any number of convenient equal parts each way from the middle, and erect ordinates upon the points of division; calculate the length of each ordinate by the last problem; find the versed sine to a chord not less than the distance between the two most remote adjacent points in the ends of the arc; describe an arc to this chord and versed sine by Problem LII. of the article GEOMETRY; then procure a board equal to the length of the chord, and curve its edge to the arc; with the curved edge draw an arc between every two points of the extended arc, and the entire arc will be formed.

N. B. There are several methods of describing segments of circles, as shown under the article GEOMETRY; but none so eligible, upon a large scale, where accuracy is required, as the above. It will be found convenient to erect the ordinates ten feet apart on each side of the middle of the chord, though the last distance at each end, between the extreme ordinate and the extreme of the curve, should be less than the intermediate 10 feet distances. Boards in general do not exceed 10 or 12 feet; but a twelve-foot board will be sufficient for ten-foot distances on the chord, in most cases, even when the versed sine rises high in proportion to the chord.

Example.—An engineer intending to construct a stone weir over a river, in the arc, A L M, of a circle; the chord, A M, of which being 200 feet, and the radius 250 feet; required the length of the ordinates at 10 feet distance from each other, and the versed sine to a chord of 12 feet, for completing the arc.

N L, the versed sine	20.871	Problem V.
O K, the first ordinate . . .	20.671	Problem VII.
P I, the second ditto	20.07	ditto.
Q H, the third ditto	19.065	ditto.
R G, the fourth ditto	17.651	ditto.
S F, the fifth ditto	15.82	ditto.
T E, the sixth ditto	13.565	ditto.
U D, the seventh ditto . . .	10.872	ditto.
V C, the eighth ditto	7.726	ditto.
W B, the ninth ditto	4.11	ditto.

These ordinates are respectively calculated at 10, 20, 30, 40, 50, 60, 70, 80, 90 feet distance from the middle of the chord to each ordinate.

It now remains to calculate the versed sine corresponding to a chord of 12 feet of the same arc as that of the weir: This will be found by Problem V. to be .072 of a foot, or very nearly seven-eighths of an inch, being, as workmen say, bare measure. Curve the edge of a twelve-foot board to a versed sine of seven-eighths of an inch; then lay the curved edge, with the concave side towards the chord, successively between every two points, A, B; B, C; C, D, &c., drawing each part until the whole arc is completed to the chord A M.

N. B.—A boarding is generally fixed to a timber grating or framing, supported by piles, for the foundation of the stone-work.

PROBLEM IV.—*In a parabola having two abscissas and an ordinate to one of them, to find the ordinate of the other.*

RULE.—As the abscissa of the given ordinate is to the abscissa of the required ordinate, so is the square of the ordinate of the former abscissa to the square of the ordinate of the latter. Then the root of the fourth term so found will be the ordinate required.

Example.—In the parabola, A B C A, are given the base, or double ordinate, A C, 18 feet, the height, or abscissa, B D, 16 feet, and the abscissa, B E, 8 feet; required the ordinate, E F.

$\frac{18}{2} = 9$, the ordinate.

and $9^2 = 81$.

$16 : 8 :: 81 : \frac{81 \times 8}{16} = 40.5$ the square of E F.

Therefore, $40.5^{\frac{1}{2}} = 6.364 =$ E F, the ordinate required.

In this manner any number of ordinates, and consequently of points, may be found in the curve, so as to construct the figure. This method is the most appropriate for use in the formation of the curve, when the abscissa is greater than the ordinate, or equal to it.

PROBLEM V.—*To find any point in the curve of a parabola by means of an abscissal parallel, or transverse ordinate; the height, or abscissa, the ordinate, and the distance of the transverse ordinate from the abscissa, being given.*

Note.—A transverse ordinate, or abscissal parallel, is a right line terminated by the curve and by the base parallel to the abscissa, commonly called a *diameter*, in this particular curve.

RULE.—Multiply the difference of the squares of the ordinate and of the distance of the abscissal parallel, or transverse ordinate, from the abscissa, by the height; divide the product by the square of the ordinate, and the quotient will give the height of the transverse ordinate.

Or, thus: Take any two numbers, in the proportion of the ordinate, or half base, and the distance between the abscissa and transverse ordinate; call these numbers respectively A and B: multiply the difference of the squares of A and B by the height; divide the product by the square of A; and the quotient will give the transverse ordinate.

Example.—In the parabola, A B C, are given the abscissa, B D, 8 feet, the ordinate, A D, 40 feet, and the distance, D E, 16 feet; to find the abscissal parallel, or the transverse ordinate, E F.

$$\frac{(40^2 - 16^2) \times 8}{40^2} = 6.72 \text{ feet, the answer.}$$

Or, because 5 and 2 are in the same proportion as 40 and 16, we have $\frac{(5^2 - 2^2) \times 8}{5^2} = 6.72$ feet, as before.

This method, as it avoids the square root, will not only be easier than the last, of finding a point in the curve of the parabola, but will be much more accurate when the abscissa is less than the ordinate.

PROBLEM XI.—*Given the abscissa and ordinate of a parabola, to find any number of equidistant diameters, or abscissal parallels, and consequently points, in the curve, at the extremities.*

Take the simple arithmetical progression of the numerical scale 1, 2, 3, 4, 5, &c. till the last contain as many units as the number of equal parts intended to be contained in the ordinate. Then if the last number represent the ordinate, the preceding numbers, 1, 2, 3, &c., will represent the respective distances that each transverse ordinate is from the abscissa. Proceed with these numbers as distances, and calculate as in the last Problem, and the several results will give the ordinates.

Or thus: If a double ordinate be given, and the number of transverse ordinates be even, or the equal parts of the double ordinate odd, take the odd numbers of the arithmetical progression 1, 3, 5, 7, &c., and proceed as above: and having found the transverse ordinates, let the real base, or double ordinate, be divided into the equal parts required, and perpendiculars erected at the points of division, and made respectively equal to the results on each side of the abscissa, will give the transverse ordinates, and consequently as many points in the curve.

This method applies to the construction of a parabola of very great extent, as the extrados of a bridge, not for one arch only, but for the upper line of a series of arches. The parabolic curve is well adapted to bridges, as it gets quicker towards the middle, and therefore the contrast with the land is not so violent as the circular arc, which has the same curvature at the ends as in the middle. The use of transverse ordinates in constructing the curve, is not only more expeditious in calculation, but more accurate in ascertaining the curve at the vertex.

SYNOPSIS OF THE PRINCIPAL RULES OF MENSURATION.

THEOREM I. RULE 1.—The circumference, c, of a circle being given, to find the diameter, d.

$$d = \frac{c}{3.1416}.$$

THEOREM II. RULE 2.

$$d = \frac{7c}{22}.$$

THE RECTIFICATION OR DEVELOPMENT OF CURVES.

THEOREM I. RULE 1.—To rectify or develop the circumference of a circle.

$$c = 3.1416\, d.$$

THEOREM II. RULE 2.

$$c = \frac{22\,d}{7}.$$

THEOREM III. RULE 1.—To rectify the arc of a circle, the radius, r, and the sine, s, of half the arc, being given.

Let z be the length of the arc required, in all the following cases; then

$$z = 2\,s + \frac{1.1\,q}{2.3}\text{A} + \frac{3.3\,q}{4.5}\text{B} + \frac{5.5\,q}{6.7}\text{C}, \text{ \&c. where } q = \frac{s^2}{r^2},$$

and A, B, C, the preceding terms.

THEOREM IV. RULE 2.—Let h equal the chord of the half arc, and c equal the chord of the whole arc.

$$z = \frac{8\,h - c}{3}, \text{ by Huygens.}$$

THEOREM V. RULE 3.—The diameter, d, the versed sine, v, and the chord, c, being given:

$$z = c + \frac{4\,v\,c}{6\,d - 5\,v} = c \times \frac{6\,d - v}{6\,d - 5\,v} = 2 \times (dv - v^2)^{\frac{1}{2}} \times \frac{6\,d - v}{6\,d - 5\,d}.$$

THEOREM VI. RULE 4.—The chord, c, and the versed sine, v, being given:

$$z = c + \frac{8\,v^2\,c}{3\,c^2 + 2\,v^2}, \text{ or } c\,\frac{3\,c^2 + 10\,v^2}{3\,c^2 + 2\,v^2}.$$

THEOREM VII. RULE 5.—The sine, s, and versed sine, v, of half the arc being given:

$$z = 2s + \frac{8v^2 s}{6s^2 + v^2}, \text{ or } 2s\,\frac{6s^2 + 5v^2}{6s^2 + v^2}.$$

THEOREM VIII. RULE 6.—The diameter, d, the sine, s, and versed sine, v, of half the arc, being given:

$$z = \frac{22ds}{11d - 8v}, \text{ or } 22s\,\frac{s^2 + v^2}{11s^2 + 3v^2}.$$

THEOREM IX. RULE 7.—The radius, r, the chord, c, and versed sine, v, being given:

$$z = c + \frac{cv}{3r} + \frac{v^3}{cr}.$$

THEOREM X. RULE 1.—To rectify the curve of an ellipsis, the major axis, t, and the minor axis, c, being given:

$$z = A - \frac{d}{2.2}A - \frac{3d}{4.4}B - \frac{3.5d}{6.6}C - \frac{5.7d}{8.8}, \text{ \&c., where}$$

$d = \frac{t^2 - c^2}{t^2}$; and A, B, C, &c., are the preceding terms.

THEOREM XI. RULE 2.

$$z = \frac{23t + 21c}{14}.$$

AREAS OF PLANE SURFACES.

In the following theorems, let A be the proposed area.

THEOREM I.—To find the area of a parallelogram; the length, l, and the breadth, b, at right angles to the length, being given:

$$= l\,b.$$

THEOREM II. RULE 1.—To find the area of a triangle; the base, b, and the perpendicular height, h, from the opposite angle, being given:

$$A = \frac{bh}{2}.$$

THEOREM III. RULE 2.—The three sides, a, b, c, being given, let s be the half sum of the three sides, then

$$A = (s \times \overline{s-a} \times \overline{s-b} \times \overline{s-c})^{\frac{1}{2}}.$$

THEOREM IV. RULE 3.—Given, b, the base, and s, the half sum of the two opposite sides:

$$A = \tfrac{1}{4}\,(\overline{s^2 - b^2} \times \overline{b^2 - d^2})^{\frac{1}{2}}.$$

THEOREM V.—To find the area of a polygon; the side, s, the number, n, of the sides of the polygon, and the radius, r, of the inscribed circle, being given:

$$A = \frac{rsn}{2}.$$

THEOREM VI. RULE 1.—To find the area of a circle; the diameter, d, and circumference, c, being given:

$$\frac{d}{2} \times \frac{c}{2}, \text{ or } \frac{dc}{4}.$$

THEOREM VII. RULE 2.—The diameter, d, being given:

$$.7854\,d^2.$$

THEOREM VIII. RULE 3.—The circumference, c, being given;

$$.0796\,c^2.$$

THEOREM IX.—To find the area of the sector of a circle, the radius, r, and the arc, a, being given:

$$A = r \times \frac{a}{2}, \text{ or } \frac{ra}{2}.$$

THEOREM X.—To find the area of a frustum sector, or part of a circular ring, contained between two radii; the breadth, b, the exterior arc, e, and interior arc, a, of the ring, being given:

$$A = b \times \frac{a + e}{2}.$$

THEOREM XI. RULE 1.—To find the area of the segment of a circle; the diameter, d, and the versed sine, v, being given:

$$A = 2v\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{2}{3} - \frac{v}{5d} - \frac{v^2}{28d^2} - \frac{v^3}{72d^3}\right), \text{ \&c.}$$

Or thus, RULE 2.

$$2v\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{2}{3} - \frac{3v}{5.2d}A - \frac{5v}{7.4d}B - \frac{7.3v}{9.6d}C - \frac{9.5v}{11.8d}D, \text{ \&c.}\right)$$

A, B, C, &c. being the first, second, third, &c. terms.

Or thus, RULE 3.

V being the supplemental versed sine, and $V = d - v$, therefore $d = V + v$; therefore

$$A = 2v\,V^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{1}{1.1.3} + \frac{v}{1.3.5\,V} + \frac{v^2}{3.5.7\,V^2} + \frac{v^3}{5.7.9\,V^3}, \text{ \&c.}\right)$$

Or thus, RULE 4.—Where A, B, C, denote the preceding terms:

$$A = \frac{4}{3}v\,v^{\frac{1}{2}}\,V^{\frac{1}{2}} + \frac{v}{5V}A - \frac{1v}{7V}B + \frac{3v}{9V}C - \frac{5v}{11V}D, \text{ \&c.}$$

THEOREM XII. RULE 5.—The chord, c, and versed sine, v, being given:

$$A = \frac{2cv}{3} + \frac{v^3}{2c}, \text{ or } v\left(\frac{2c}{3} + \frac{v^2}{2c}\right) \text{ or}$$

$$A = \frac{2cv}{3} + \frac{v^3}{2c} - \frac{v^6}{20c^4}, \text{ still nearer.}$$

THEOREM XIII. RULE 6.—The chord, c, of the half arc, and the versed sine, v, of the same, being given:

$$A = \left(c + \frac{4c}{3}\right) \times \frac{4}{10}v, \text{ or } c + \frac{4}{3}d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \frac{4}{10}v,$$ by Sir Isaac Newton.

THEOREM XIV. RULE 7.—The radius, r, tne sine, s, and the versed sine, v, of half the arc, being given:

$$A = 11rs \times \frac{s^2 + v^2}{11s^2 + 3v^2}.$$

THEOREM XV.—To find the area of an ellipsis; the major axis, M, and the minor, m, being given:

$$A = .7854\,M\,m.$$

THEOREM XVI.—To find the area of an elliptic segment; the length, l, and the altitude, a, being given: also the breadth, b, of the segment of a circle of the same altitude and of the same diameter as the axis of the ellipsis, perpendicular to b.

$$A = \frac{l}{b} \times \left(\frac{2ab}{3} + \frac{a^3}{2c}\right).$$

THEOREM XVII.—To find the area of a parabola; the base, b, and the altitude, a, being given:

$$A = \frac{2ab}{3}.$$

THEOREM XVIII.—To find the area of the sinical curve; the radius, r, and the versed sine, v, of the segment, being given:

$$A = rv.$$

AREAS OF CURVED SURFACES.

THEOREM I.—To find the area of a cylindric surface; the axis, a, and the diameter, d, being given:

$A = 3.1416\,d\,a$ in a right cylinder.

Or $A = p\,a$ in an oblique cylinder, where p is the perimeter.

THEOREM II.—To find the curved surface of a cylindric ungula, $A = \frac{ds - ac}{v}\,h$; where h is the length of the part that is cut, and v the versed sine of the segment which forms the base, and d the diameter.

THEOREM III.—To find the area of the curved surface of a right cone; the side, s, and the circumference, c, of the circumference, being given:

$$A = \frac{sc}{2}.$$

THEOREM IV.—To find the area of the segment of a square dome.

$A = 4\,(s^2 + v^2)$, or $4\,d\,v$; where s is the sine, and v the versed sine of the circular segment which forms the vertical section, or d the diameter of the circle which forms the vertical section.

THEOREM V.—To find the area of a segment of a hemisphere; given the radius, s, of the base, the versed sine, v, and the diameter, d, of the axal section:

$A = 3.1416\,(s^2 + v^2)$, or $3.1416\,d\,v$.

THEOREM VI.—To find the area of the frustum of the segment of a hemisphere; the circumference, c, of the great circle, and the distance, d, of the parallel planes, being given:

$$A = c\,d.$$

THEOREM VII. RULE 1.—To find the surface of a spheroid; given the axis, a, and the diameter, d, of the great circle:

$A = .5236 \times (4\,a\,d + 2\,d^2)$.
Or, $A = 1.0472\,(2\,a\,d + d^2)$.

This is a near approximation.

THEOREM VIII. RULE 2.

$A = .8805\,(2\,a\,d + d^2) + \frac{a^2 + 2\,d^2}{6}$; still nearer to the truth than Rules 1 and 2.

THEOREM IX. RULE 1.—To find the surface of an ellipsoid; the length, a, the breath, b, and the thickness, c, being given:

$$2 \times .5236\,(a\,b + a\,c + b\,c).$$

This rule is a near approximation.

THEOREM X. RULE 2.

$A - 8805\,(a\,b + a\,c + b\,c) + \frac{a^2 + b^2 + c^2}{6}$; it is a nearer approximation than Rule 1.

THEOREM XI.—To find the surface of a semi-circular groin; given the side b.

$$A = 1.1416\,b^2.$$

SOLIDITIES OF BODIES.

THEOREM I.—To find the solidity of a cube.

$S = s^3$, where s is the linear dimension.

THEOREM II.—To find the solidity of a prism.

$S = a\,h$; where a is the area of the base, and h the perpendicular height. This also includes cylinders.

THEOREM III.—To find the solidity of a pyramid.

$S = \frac{ah}{3}$, or $\frac{h}{3} \times a$, or $\frac{a}{3} \times h$; where a is the area of the base, and h the perpendicular height. This also includes cones.

THEOREM IV.—To find the solidity of a wedge, or pyramoid; the two adjoining edges, a and b, of the base, the edge, c, in the same plane with a, and the height, being given:

$$S = \frac{2\,a\,b + c\,b}{6}\,h.$$

THEOREM V.—To find the solidity of the frustum of a pyramoid.

$S = \frac{a\,b + c\,d + 4\,e\,f}{6}\,h$; where a and c are the opposite terminations of a plane of one of the sides; b and d the opposite terminations of the plane of one of the adjoining sides; a and b being adjoining sides of the base, c and d those of the top, e the half sum of a and c, and f the half sum of b and d.

THEOREM VI.—To find the solidity of a cuneoid.

$S = \frac{2\,a\,b + c\,b}{6} \times .7854 \times h$. This formula is the same as that of Theorem V. except the additional multiplier .7854; this solid only differing in construction from the pyramoid in having elliptic sections instead of rectangular ones.

THEOREM VII.—To find the solidity of the frustum of a cuneoid.

$S = \frac{a\,b + c\,d + 4\,e\,f}{6} \times .7854 \times h$; where a and c are the two axes of the elliptic base, and c and d the axes of the elliptic top; c being opposite to a, and d opposite to b. This solid only differs from the frustum of a pyramoid in being circular.

THEOREM VIII.—To find the solidity of the segment of a cylinder.

RULE 1.—$S = a\,l\left(\frac{2\,b}{3} + \frac{a^2}{2\,b}\right)$; where a is the versed sine, b the chord of the base, and l the length of the cylinder.

RULE 2.—$S' = l \times \left(\frac{a\,b + a^2}{2} + \frac{b^2}{56}\right)$; still nearer than Rule 1. when the segment is nearly a semi-cylinder.

THEOREM IX.—To find the solidity of the segment of a square dome.

RULE 1.—$S = 4\,r\,x^2 - \frac{4\,x^3}{3}$; where x is the height, and r the radius of the circle, of which the segment forming the vertical section is a part. *See* vol. i. p. 284 of this Work.

RULE 2.—$S = \frac{a\,s^2}{2} + \frac{2\,a^3}{3}$; where s is the side of the square base, and a the altitude of the dome. *See* vol. i. p. 286 of this Work.

THEOREM X.—To find the solidity of the segment of a hemisphere.

RULE 1.—$s' = p\left(r x^2 - \frac{x^3}{3}\right)$; where p is equal to $4 \times .7854 = 3.1416$; and x and r, as in the preceding Theorem.

RULE 2.—$s = .7854\left(\frac{a s^2}{2} + \frac{2 a^3}{3}\right)$.

This only differs from RULE 2. THEOREM IX. in the base being circular. It gives the contents independent of the diameter of the great circle.

THEOREM XI.—To find the solidity of a truncated square dome, independent of the radius, or diameter, of the vertical section.

$s = a s^2 - \frac{4 a^3}{3}$; where a is the altitude, and s the side, of the square base.

THEOREM XII.—To find the solidity of the frustum of a hemisphere.

$s = .7854\left(a s^2 - \frac{4 a^3}{3}\right)$; being the same as in the last Theorem, except the multiplier .7854.

THEOREM XIII.—To find the solidity of a hollow truncated square dome.

$s = a\,(D^2 - d^2)$; where D is the side of the square base, between the opposite external surfaces, d the side of the square base between the opposite internal surfaces, and a the altitude; supposing the heel to be equally thick.

THEOREM XIV.—To find the solidity of a hollow hemispheric frustum.

$.7854\ a\,(D^2 - d^2)$; being the same as Theorem XIII., excepting the multiplier .7854.

THEOREM XV.—To find the solidity of a paraboloid.

$s = \frac{b\,h}{2}$; where h is the height, and b the area of the base.

THEOREM XVI.—To find the solidity of the frustum of a paraboloid.

$s = \frac{a + b}{2}\,h$; where a and b are the areas of the two ends.

THEOREM XVII.—To find the solidity of an hyperboloid.

$s = \frac{a + b + 4\,m}{6}\,h$; where a and b are the areas of the two ends, and m the area of the middle section. This theorem will also serve to measure a sphere, spheroid, paraboloid, cone, pyramid, pyramoid, or any segment, or frustum of these bodies.

Notes on the preceding Theorems.

RECTIFICATION OF CURVES.

RULE 2, of THEOREM VII. by Huygens, is very neatly expressed by $\frac{8\,h - c}{3}$; but the half chord must either be found geometrically, by bisecting the chord by a perpendicular, and drawing the half chord, or by a very operose arithmetical operation. If $d = 2\,h - c$, then will $c + d + \frac{d}{3}$ be the length of the arc: this affords a very easy geometrical construction; viz., *if to the chord of the whole arc be added the difference of twice the chord of the half arc and the chord of the whole arc, and one-third of the said difference, the sum will be nearly the length of the arc, for* $c + d + \frac{d}{3} = c + (2\,h - c) + \frac{2\,h - c}{3} = \frac{8\,h - c}{3}$.

RULES 3, 4, 5, 6. THEOREMS VII. VIII. IX. and X. were invented by Mr. Nicholson. The circumstance which gave rise to them was a stone weir, or dam, which he had designed and superintended at Denton Holm Head, over the river Caldew, near Carlisle. The form of the weir was that of the segment of a circle, of which the chord was 200 feet, and the versed sine 22 feet; when the work was completed, the contractor for the mason's work was very desirous to have it measured, but at that time, being early in the spring of 1810, the river was flooded so high, that the water ran two feet above the top of the weir; now having the true dimensions, as above, and an exact section of the work, it was only necessary to find the length of the arc, and then the solid contents were easily computed: but, in order to obtain this end, he found that the calculations by the rule of Huygens would require too much trouble for common business, and therefore, as well for present convenience as for anything that might happen in future of a like nature, the following formulas were invented: $L = c\,\frac{6\,d - v}{6\,d - 5\,v}$,

$$\text{or } L = c + \frac{4\,v\,c}{6\,d - 5\,v}, = c\,\frac{3\,c^2 + 10\,v^2}{3\,c^2 + 2\,v^2},$$

$$\text{or } L = c + \frac{8\,v^2\,c}{3\,c^2 + 2\,v^2}, = c\,\frac{6\,s^2 + 5\,v^2}{6\,s^2 + v^2},$$

$$\text{or } L = c + \frac{4\,v^2\,c}{6\,s^2 + v^2}.$$

The second formula, or Rule 4, is derived from the first, by substituting the value of d in terms of c and v; and Rule 5 is also derived from Rule 3, by substituting the value of d in terms of s and v; so that, being derived from each other, they will all give the very same result; and to show how near this is to the truth, the investigation is as follows:

For $c\,\frac{6\,d - v}{6\,d - 5\,v} = 2\,(d\,v - v^2)^{\frac{1}{2}} \times \frac{6\,d - v}{6\,d - 5\,v}$, the quantity $2\,(d\,v - v^2)^{\frac{1}{2}}$, being the value of c, in terms of d and v:

but $2\,(d\,v - v^2)^{\frac{1}{2}} = 2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 - \frac{v}{2\,d} - \frac{v^2}{8\,d^2}, \text{ \&c.}\right)$

and $\frac{6\,d - v}{6\,d - 5\,v} = 1 + \frac{2\,v}{5\,d} + \frac{5\,v^2}{9\,d^2}$, &c.

Hence $2\,(d\,v - v^2)^{\frac{1}{2}} \times \frac{6\,d - v}{6\,d - 5\,v} = 2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times$

$$\left(1 - \frac{v}{2\,d} - \frac{v^2}{8\,d^2}, \text{ \&c.}\right) \times \left(1 + \frac{2\,v}{3\,d} + \frac{5\,v^2}{9\,d^2}, \text{ \&c.}\right)$$

$$= 2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 + \frac{v}{6\,d} + \frac{7\,v^2}{72\,d^2}, \text{ \&c.}\right)$$

but $2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 + \frac{v}{6\,d} + \frac{3\,v}{40\,d^2}, \text{ \&c.}\right)$ is known to express the arc of a circle, whose diameter is d, and its versed sine v; now this last series only differs from the former in the third term, in being less; the excess being $\frac{v}{45\,d^2}$.

Now, to show how far these rules may be depended upon in practice, Mr. Nicholson calculated the following table, where the numbers found answer to segments of different proportions. The results found, both by Huygens' rule and by that of Nicholson, are compared with the result found by an infinite series, which is the criterion; because, by such an infinite series the answer may be found, which can be depended upon, to any number of figures. The result found by the series in the table is therefore true to the last figure, or to the last but one when the next figure would be above 5. In this case, the last figure of the decimal is augmented by unity.

In the table, the first vertical column contains the chords, and is marked C; the second column contains the versed sines of the several segments, and is marked V; the third column contains the lengths of the arcs, according to the dimensions stated in columns C and V in the same horizontal row, and is marked L; and the last column, marked R, shows the ratio, or number of times that the versed sine is contained in the chord. In each cell under L are the three results; the upper one being that of Huygens, the middle one that of the series, and the lower one that of Nicholson.

C	V	L	R
936	155	1002.666 1002.959 1002.9	$6\frac{6}{155}$
24	5	26.666 26.687 26.69	$4\frac{4}{5}$
556	136	631.333 632.252 632.5	$4\frac{1}{68}$
8	3	10.666 10.724 10.743	$2\frac{2}{3}$
240	119	370.666 374.960 375.24	$2\frac{2}{119}$
14	7	21.73 21.991 22.	2

From this table it appears, that in low segments the result is nearly the same by each rule, but that Nicholson's is nearer to the series than that of Huygens; and it becomes much more so in proportion as the segment approaches towards a semicircle: thus, in a semicircle, the length of the arc found by the series is 21.991; the length found by Huygens is 21.73; the difference .261. Now, the length of the arc found by Nicholson's rule is 22, which is ultimately the Archimedean proportion, and the difference between this result and that found by the series is only .009.

In the first horizontal row, both methods agree with the series to four places of figures; in the second, they agree in three places; in the third, fourth, and fifth, they agree in two places; and in the sixth they agree in one. In the first horizontal column, Nicholson's method agrees in five places with the series; in the second, third, and fourth, with three figures of the series; in the fifth, with two figures of the series, and in the last with one figure of the series; but only differs in five figures from the truth by .009.

The length of the arc found by the two approximating rules in low segments, is exceedingly near the true value; but when the result is found by Huygens' rule in high segments, it is very considerably below it, and cannot well be employed in large dimensions.

There is still another rule to be found in books of mensuration, which will give the length of the arc to any exactness, either by finding the number of degrees by means of an instrument, or by trigonometry; the former is not very eligible in practice, and the latter would require too much time to be of real utility amid the hurry of business.

The investigation of Rule 6, Theorem X., from the geometrical division of the arc of the circle into equal parts, by the diameter being divided also into equal parts, is as follows:

Let A D B C be a circle; A B and C D two diameters, intersecting each other in E at right angles; let the diameter, D C, be produced to F, so that the part, C F, without the circle may be three-quarters of the radius, E C, or three-eighths of the diameter, D C; draw D G parallel to A B; take any portion, D I, of the arc D A; join F I; and produce F I to G:

Let D C be denoted by d; then will $\text{F D} = d + \frac{3\,d}{8} = \frac{11\,d}{8}$;

and $\text{F K} = \text{F D} - \text{K D} = \frac{11\,d}{8} - v = \frac{11\,d - 8\,v}{8}$.

Now, the triangles F K I and F D G are similar; therefore F K : F D : : K I : D G;

that is, $\frac{11\,d - 8\,v}{8} : \frac{11\,d}{8} :: s : \text{D G} = \frac{11\,d\,s}{11\,d - 8\,v}$; which is the value of the tangent.

Then, to show how nearly this value is to that of the arc, we have $\frac{11\,d\,s}{11\,d - 8\,v} = \frac{s}{1 - \frac{8\,v}{11\,d}}$;

but $s = (d\,v - v^2)^{\frac{1}{2}} = d^{\frac{1}{2}}\,v^{\frac{1}{2}}\left(1 - \frac{v}{2\,d} - \frac{v^2}{8\,d^2}, \text{\&c.}\right)$

therefore $\frac{s}{1 - \frac{8\,v}{11\,d}} = d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \frac{1 - \frac{v}{2\,d} - \frac{v^2}{8\,d^2}, \text{\&c.}}{1 - \frac{8\,v}{11\,d}} = d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 + \frac{5\,v}{22\,d} + \frac{39\,v^2}{968\,d^2}, \text{\&c.}\right)$ the value of the tangent, which should be equal to that of the arc; but the series expressed in the same terms for the value of the arc, is $d^{\frac{1}{2}} v^{\frac{1}{2}} \times \left(1 + \frac{v}{6\,d} + \frac{3\,v^2}{40\,d^2}, \&c.\right)$ it therefore appears that the value of the tangent is too great to express the value of the arc.

The length of the arc may be ascertained with tolerable exactness by Theorems XII. and XIII., which are thus expressed :—$z = c + \frac{c\,v}{3} + \frac{v^3}{c\,r}$, or $2\,s + \frac{c\,v}{3} + \frac{2\,v^4}{s^3 + v^3}$, by substituting $\frac{s^2 + v^2}{2\,v}$ for r, and $2\,s$ for c, in the first formula.

This rule gives the length of the arc 10.73, when the chord is 8 and the versed sine 3; and the series gives 10.724; and in a semicircle, where the chord is 14 and the versed sine 7, the length of the arc will be 22.16; the proportion of Archimedes would give 22. As this rule depends upon the area of the segment, the investigation will be given under that of Rule 7, Theorem XI, of the areas of plane figures, which follows.

Areas of Plane Figures.

Theorem XII. Rule 5, is a very near approximation to the quadrature of the segment of a circle. It is much easier than any other rule yet shown for the same purpose. It was invented, and first published in the article Mensuration, of *The principles of Architecture*, by Nicholson; since that time, it has been copied into the new edition of Hawney's *Mensuration*. The rule was first given without a demonstration; but it is now supplied with the following investigation.

The expression for the area is $\frac{2\,c\,v}{3} + \frac{v^3}{2\,c}$, where c is the chord, and v the versed sine.

$$\text{Now, } c = 2\,(d\,v - v^2)^{\frac{1}{2}} = 2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 - \frac{v}{d}\right)^{\frac{1}{2}} = 2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(1 - \frac{v}{2\,d} - \frac{v^2}{8\,d^2}, \&c.\right)$$

$$\text{therefore } \frac{2\,c\,v}{3} = \frac{4\,d^{\frac{1}{2}}\,v^{\frac{1}{2}}}{3} \times \left(1\,v - \frac{v^2}{2\,d} - \frac{v^3}{8\,d^2}, \&c.\right)$$

$$\frac{1}{c} = \frac{1}{2\,d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times \left(1 - + \frac{v}{2\,d} + \frac{3\,v^2}{8\,d^2}, \&c.\right)$$

$$\text{Therefore } \frac{v^3}{2\,c} = \frac{v^3}{4\,d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times 1 + \frac{v}{2\,d} + \frac{3\,v^2}{8\,d^2}, \&c.$$

$$\text{Hence } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = \frac{4\,d^{\frac{1}{2}}\,v^{\frac{1}{2}}}{3} \times v - \frac{v^2}{2\,d} - \frac{3\,v^3}{8\,d^2}, \&c. + \frac{v^3}{4\,d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times 1 + \frac{v}{2\,d} + \frac{3\,v^2}{8\,d^2}, \&c.$$

Now let the last equation be meltiplied by $d^{\frac{1}{2}}\,v^{\frac{1}{2}}$.

$$\text{Then } d^{\frac{1}{2}}\,v^{\frac{1}{2}}\left(\frac{2\,c\,v}{3} + \frac{v^3}{2\,c}\right) = \frac{4\,d\,v}{3} \times \left(v - \frac{v^2}{2\,d} - \frac{v^3}{8\,d^2}, \&c.\right) + \frac{v^3}{4} \times \left(1 + \frac{v}{2\,d} + \frac{3\,v^2}{8\,d^2}, \&c.\right)$$

$$= \frac{4\,d\,v^2}{3} - \frac{4\,v^3}{6} - \frac{4\,v^4}{24\,d}, \&c. + \frac{v^3}{4} + \frac{v^4}{8\,d} + \frac{3\,v^5}{32\,d^2}, \&c.$$

$$= \frac{4\,d\,v^2}{3} - \frac{5\,v^3}{12} - \frac{v^4}{24\,d}, \&c.$$

Now let this last equation be divided by $d^{\frac{1}{2}}\,v^{\frac{1}{2}}$,

$$\text{and we obtain } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = \frac{1}{d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times \left(\frac{4\,d\,v^2}{3} - \frac{5\,v^3}{12} - \frac{v^4}{24\,d}, \&c.\right)$$

$$\text{or } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = \frac{1}{d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times \frac{d^{\frac{1}{2}}\,v^{\frac{1}{2}}}{d^{\frac{1}{2}}\,v^{\frac{1}{2}}} \times \left(\frac{4\,d\,v^2}{3} - \frac{5\,v^3}{12} - \frac{v^4}{24\,d}, \&c.\right)$$

$$\text{or } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = \frac{d^{\frac{1}{2}}\,v^{\frac{1}{2}}}{d\,v} \times \left(\frac{4\,d\,v^2}{3} - \frac{5\,v^3}{12} - \frac{v^4}{24\,d}, \&c.\right)$$

$$\text{or } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{4\,v}{3} - \frac{5\,v^2}{12\,d} - \frac{v^3}{24\,d^2}, \&c.\right)$$

$$\text{or } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{4\,v}{3} - \frac{10\,v^2}{24\,d} - \frac{2\,v^3}{48\,d^2}, \&c.\right)$$

$$\text{or } \frac{2\,c\,v}{3} + \frac{v^3}{2\,c} = 2\,v \times d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{2}{3} - \frac{5\,v}{24\,d} - \frac{v^2}{48\,d^2}, \&c.\right)$$

But $2\,v \times d^{\frac{1}{2}}\,v^{\frac{1}{2}} \times \left(\frac{2}{3} - \frac{v}{5\,d} - \frac{v^2}{28\,d^2}, \&c.\right)$ is known to be the value of the segment, the diameter of which is d, and its versed sine v; then by comparing these two series they will be found to be nearly equal, the former being the greater;

for the first term is $\frac{2}{3}$ in both, and the second term in the approximation only differs from that of the proper series by a quantity less than $\frac{v}{120\,d}$.

From this Theorem, $\frac{2\,c\,v}{3} + \frac{v^3}{2\,c}$, we may derive $c + \frac{c\,v}{3} + \frac{v^3}{c\,r}$, as in Theorem XI. Rule 7, for the rectification of curves.

In the sector A D C E A draw the chord A C and E D perpendicular to A C, cutting A C at B; let A C′ $= c$, and B D $= v$; then B E = D E − D B $= r - v$; consequently the area of the triangle A C E $= \frac{r - v}{2} \times c = \frac{c\,r - c\,v}{2}$; but the area of the segment A D C is $\frac{2\,c\,v}{3} + \frac{v^3}{2\,c}$; therefore the area of the sector A D C E A is equal to $\frac{2\,c\,v}{3} + \frac{v^3}{2\,c} + \frac{c\,r - c\,v}{2} = \frac{c\,v}{6} + \frac{v^3}{2\,c} + \frac{c\,r}{2}$; and if this area be divided by the radius, we obtain $\frac{c\,v}{6\,r} + \frac{v^3}{2\,c\,r} + \frac{c}{2}$, or $\frac{c}{2} + \frac{c\,v}{6\,r} + \frac{v^3}{2\,c\,r}$ for the half arc, or $c + \frac{c\,v}{3\,r} + \frac{v^3}{c\,r}$, for the whole arc. And if $\frac{c^2 + 4\,v^2}{8\,v}$ be substituted for r, we obtain $c + \frac{8\,c\,v^2}{3\,c^2 + 12\,v^2} + \frac{8\,v^4}{c^3 + 4\,c\,v^2}$ for the value of the arc in terms of c and v.

Theorem XIV. Rule 7, of the areas of plane figures, $11\,r\,s \times \frac{s^2 + v^2}{11\,s^2 + 3\,v^2}$, being the area of the segment, the sine of the half arc of which is s, the versed sine v, and the radius r, evidently follows from Theorem X. Rule 6, by multiplying half the arc, $\frac{11\,s}{2} \times \frac{s^2 + v^2}{11\,s^2 + 3\,v^2}$, by the radius r.

Theorem XVI. being $\frac{l}{b} \times \left(\frac{2\,a\,b}{3} + \frac{a^3}{2\,b}\right)$ will easily be obtained from the following consideration, viz., suppose the ellipsis to be completed, and a circle to be described upon the axis, which bisects the base of the elliptic segment; then let the base of the elliptic segment, to be continued, if necessary, meet the circumference of the circle on each side; then it will be as the base of the circular segment is to the base of the elliptic segment, so is the area of the circular segment to the area of the elliptic segment; therefore, if the area of the circular segment be known, that of the elliptic segment will follow; now the area of the circular segment is $\frac{2\,a\,b}{3} + \frac{a^3}{2\,b}$; therefore, $b : l :: \frac{2\,a\,b}{3} + \frac{a^3}{2\,b} : \frac{l}{b} \times \left(\frac{2\,a\,b}{3} \times \frac{a^3}{2\,b}\right)$ the area of the elliptic segment.

Areas of Curved Surfaces.

Theorem VII. Rule 1, is an approximation; and the following will show what dependence is to be placed in the result obtained by calculation.

Let $a =$ the axis of the spheroid;
$b =$ the diameter of the great circle;
and $x =$ an indefinitely small distance, compared with a or d.

Now $.5236\,a\,d^2$ is the expression for the solidity of the spheroid, being two-thirds of its circumscribing cylinder;

then $(d + x)^2 \times (a + x) = a\,d^2 + 2\,a\,d\,x + a\,x^2 + d^2\,x + 2\,d\,x^2 + x^3 = a\,d^2$ nearly, being in excess;
and $(d - x) \times (a - x)$ $\quad a\,d^2 - 2\,a\,d\,x + a\,x^2 - d^2\,x + 2\,d\,x^2 - x^3 = a\,d^2$ nearly, being in defect;
therefore $\quad 4\,a\,d\,x \quad + 2\,d^2\,x \quad + 2\,x^3$ will be the solidity of a thin shell, the thickness of which is x; therefore $4\,a\,d + 2\,d^2 + 2\,x^2$ will be the area of such a shell, or $4\,a\,d + 2\,d^2$, by leaving out the quantity $2\,x^2$, which is indefinitely small: therefore $.5236\,(4\,a\,d + 2\,d^2)$ is the area of a spheroid nearly; it is exactly so when a and d are equal; for then $.5236\,(4\,a\,d + 2\,d^2)$ becomes $.5236 \times 6\,d^2 = 4 \times .7854\,d^2$, but the greater the difference between a and d, the more will the error be; because the thin shell varies more in its thickness.

Corollary 1.—Hence the surface of every rectangular prism with a square base is $4\,a\,d + 2\,d^2$.

Corollary 2.—When $a =$ nothing, then $.5236\,(4\,a\,d + 2\,d^2)$ becomes $.5236 \times 2\,d^2 = 1.0472\,d^2$, instead of $.7854\,d^2$, the area of the base.

Example for the Oblong Spheroid.

50 $= a$	40 $= d$
40 $= d$	40 $= d$
2000 $= a\,d$	1600 $= d^2$
4	2
8000 $= 4\,a\,d$	3200
3200	
11200 $= 4\,a\,d + 2\,d^2$	

.5236
11200
1047200
5236
5236
5864.3200 $= .5236\,(4\,a\,d + 2\,d^2)$.

The true answer is 5882.6385, the difference is therefore only 18.3185, which is not worth regarding in so large a number. In a dome which is the half of an oblong spheroid, the error would only be 9.1592 less than the truth.

Example for an Oblate Spheroid.

40 $= a$	50
50 $= d$	50
2000 $= a\,d$	2500 $= d^2$
4	2
8000 $= 4\,a\,d$	5000
5000	
13000 $= a\,d + 2\,d^2$	

.5236
    13000

15708000
5236

6806.8000 $= .5236\ (4\,a\,d + 2\,d^2)$

The answer ought to be 6830.4507; the error being about 24 less than the truth, which is very trifling in so great a number.

In architecture, we very seldom have domes of such large dimensions; and the value of a foot of plaster, or painting, can never be of any great consequence. This rule will therefore be sufficient for every practical purpose.

The following table contains the areas of the curved surfaces of spheroids of various proportions, according to the formula $.5236 \times (4\,a\,d + d^2)$ and to the real series; the comparison of the results will enable us to judge of the truth of the answer as found by the formula.

Rules.	A	D	Area.	Difference.
Series......	40	40	5026.56	none, being equal.
Formula....	40	40	5026.56	
Series......	50	40	5882.63	18.31 defective.
Formula....	50	40	5864.32	
Series......	60	40	6867.30	65.22 defective.
Formula....	60	40	6702.08	

Let us now try if any addition can be made to amend the above formula, which always gives the result less than the truth. We know, that the quantity to be added must be equal to nothing, when a is equal to d; we also know that the sum of the squares of two quantities is greater than twice their product; and when these quantities are equal, that the sum of their squares and twice their product will be equal: therefore $a^2 + d^2$ is greater than $2\,a\,d$; and the greater the difference between a and d, the more the sum of the squares of a and d will exceed twice the product, $2\,a\,d$, of a and d: thus, when one of the quantities, as d, is nothing in the sum, $a^2 + d^2$, of the squares, the quantity a^2 only remains, and in twice the product $2\,a\,d$, the whole vanishes. Therefore the value of $a^2 + d^2 - 2\,a\,d$ will be greater, as the difference between a and d is greater.

But to show what this difference is, by finding the value of these quantities in the same terms:

Let the greater, $d = a + x$;
then $d^2 = a^2 + 2\,a\,x + x^2$;
and $a^2 + d^2 = 2\,a^2 + 2\,a\,x + x^2$.
Again, $2\,a\,d = 2\,a\,(a + x) = 2\,a^2 + 2\,a\,x$:
now $2\,a^2 + 2\,a\,x + x^2$ is greater than $2\,a^2 + 2\,a\,x$ by x^2; that is, the sum of the squares, $a^2 + d^2$, of a and d, is greater than $2\,a\,d$ by the square of the difference of a and d; therefore the value of $a^2 + d^2 - 2\,a\,d$ will be greater, as a is greater than d. But to show that the square of the difference will not be very great in common cases, let $a = 4$, and $d = 3$, then the square of the difference is only 1; that is, when the difference is 1, the square of the difference will also be 1.

Let us now return to the subject, by adding the quantity proposed to $.5236\ (4\,a\,d + 2\,d^2)$; it will be found by adding $a^2 + d^2 - 2\,a\,d$ to $.5236\ (4\,a\,d + 2\,d^2)$ that the sum will be too great; therefore let the quantity $a^2 + d^2 - 2\,a\,d$ be divided by some number: on trial it appears that the addition of $\frac{a^2 + d^2 - 2\,a\,d}{6}$ to $.5236\ (4\,a\,d + 2\,d^2)$ will give a result very near to the truth, at the same time that it furnishes a very easy formula for architectural purposes, in the mensuration of domes, as will be seen in the following table.

This formula will therefore now stand $.5236\ (4\,a\,d + 2\,d^2) + \frac{a^2 + d^2 - 2\,a\,d}{6} = 1.0472\ (4\,a\,d + 2\,d^2) + \frac{a^2 + d^2 - 2\,a\,d}{6}$, which may again be reduced to this form $.8805\ (2\,a\,d + d^2) + \frac{a^2 + 2\,d^2}{6}$.

Rules.	A	D	Areas.	Difference.
Series......	40	40	5026.56	nothing.
Formula....	40	40	5026.56	
Series......	50	40	5882.63	1.83 in defect
Formula....	50	40	5880.8	
Series......	60	40	6767.30	1.44 in excess.
Formula....	60	40	6768.74	

This table shows the formula sufficiently exact for any practical purpose, at least in all useful propositions of architecture; and therefore confirms Theorem VIII. Rule 2. If a dome upon an elliptic plan, rising half the minor axis, be required to be measured, then the rule for such a dome will be $.4402\ (2\,a\,d + d^2) + \frac{a^2 + 2\,d^2}{12}$.

The approximating formula $2 \times .5236\ (a\,b + a\,c + b\,c)$, Theorem IX. Rule 1, may be thus confirmed: let the three dimensions of the ellipsoid be a, b, c, and let x be a very small increment to be added to a, b, and c, respectively; also a very small decrement to be taken from a, b, and c, respectively; now the solidity of an ellipsoid is $.5236\ a\,b\,c$; then

$$a\,b\,c = (a + x) \times (b + x) \times (c + x) = a\,b\,c + b\,c\,x + a\,c\,x + c\,x^2 + a\,b\,x + b\,x^2 + a\,x^2 + x^3, \text{ nearly;}$$
$$\text{and } a\,b\,c = (a - x) \times (b - x) \times (c - x) = a\,b\,c - b\,c\,x - a\,c\,x + c\,x^2 - a\,b\,x + b\,x^2 + a\,x^2 - x^3, \text{ nearly;}$$
$$\text{therefore } \quad 2\,b\,c\,x + 2\,a\,c\,x \quad + 2\,a\,b\,x \quad + 2\,x^3 \text{ is the}$$

increment of the solid, or the solidity of a shell, the thickness of which is x; consequently, if the increment, $2\,b\,c\,x + 2\,a\,c\,x + 2\,a\,b\,x$, of the solid be divided by x, we shall then obtain $2\,b\,c + 2\,a\,c + 2\,a\,b + 2\,x^2$ for the surface of the solid; but the quantity $2\,x^2$ is indefinitely small, and appears as nothing in comparison of $2\,b\,c + 2\,a\,c + 2\,a\,b$; therefore $2\,b\,c + 2\,a\,c + 2\,a\,b$, or $2\,a\,b + 2\,a\,c + 2\,b\,c$ is nearly equal to the surface of the solid; and consequently, $.5236\ (2\,a\,b + 2\,a\,c + 2\,b\,c)$, or $1.0472\ (a\,b + a\,c + b\,c)$ will be nearly equal to the surface of the ellipsoid.

Corollary 1.—Hence $2\,a\,b + 2\,a\,c + 2\,b\,c$ will be the surface of a rectangular prism, exactly.

Corollary 2.—Let a, b, and c, be each equal to d; then $1.0472\ (a\,b + a\,c + b\,c)$ becomes $1.0472 \times 3\,d^2 = 3.1416\,d^2 = 4 \times .7854\,d^2$, as it ought to be: but the greater the difference between a, b, and c, the more will the error be.

This rule may be corrected in the same manner as Theorem VII. Rule 1; by adding $\frac{a^2 + b^2 + c^2 - a\,b - a\,c - b\,c}{6}$; which being done, the formula may be reduced to .8805 $(ab+ac+bc)+\frac{a^2+b^2+c^2}{6}$, which gives Theorem X. Rule 2.

Notes on the Solidities of Bodies.

The method of the middle section has never been noticed by any writer in a practical way. There can be little doubt but this method took its rise from that of equidistant ordinates, first given by Sir Isaac Newton, as we are informed by Shirtcliffe, in his *Art of Gauging*, in the following words:

"I shall lay down a proposition for measuring planes or solids by approximation, a thing of the greatest importance to this part of science, of any that was ever brought for that purpose, since it may be said to contain the whole art of gauging, and that of coppers, stills, tuns, as well as all kinds of casks, whether full or partly empty, either standing or lying.

"*Of measuring curvilinear planes and solids, by approximation.*

"Proposition.—If MQ $= y'$, NR $= y''$, PS $= y'''$ represent three equidistant perpendicular ordinates to the axis of a curve, MNP, whose equation is $y = a + bx + cx^2$, where x stands for any abscissa, QT, and y its ordinate, TO; then, calling QS the distance of the extreme ordinates, l, the measure of the space, QMPS, will be thus expressed:

"Theorem. QMPS $= \overline{y' + y''' + 4y''} \times \frac{l}{6}$.

"For by the preceding principles, the quadrature of the curve, whose abscissa is x, and ordinate $a + bx + cx^2$, will be found $a + \overline{\frac{bx}{2}} + \overline{\frac{cx^2}{3}} \times x$; and this, when x becomes l, is

$$\overline{a + \frac{bl}{2} + \frac{cl^2}{3}} \times l = \overline{6a + 3bl + 2c^2} \times \frac{l}{6}, = \text{QMPS}.$$

But from the equation of the curve we have these three equations,

$$y' = a;$$
$$y'' = a + \frac{bl}{2} + \frac{cl^2}{4};$$
$$y''' = a + bl + cl^2.$$

And by taking the difference of those above, we have

$$y - a = \frac{bl}{2} + \frac{cl^2}{4};$$
$$y''' - y'' = \frac{bl}{2} + \frac{3cl^2}{4}.$$

And the difference of the last gives

$$y''' - 2y'' + a = \frac{cl}{2}.$$

Whence $2cl^2 = 4 \times \underline{y''' - 2y' + a}$; and by the third equation above, $bl = \underline{y''' - a - cl^2}$; therefore $3bl = 3y''' - 3a - 6 \times \overline{y''' - 2y'' + a} = -3y''' + 12y'' - 9a$; put these for $2cl^2$ and $3bl$, in the above expression of the area, and then we have, QMPS, $= \overline{6a + 3bl + 2cl^2} \times \frac{l}{6} = y' + 4y'' + y''' + \frac{l}{6}$. Q. E. D.

"Corollary 1.—The same method of demonstration extends to any number of equidistant ordinates; so if A denotes the sum of the extreme ordinates, B the sum of those next to them, C the sum of the two next following the last, and so on; then we shall have the following tables of areas, for the several numbers of ordinates prefixed to them, viz., for

2. $A \times \frac{l}{2}$;

3. $\overline{A + 4B} \times \frac{l}{6}$;

4. $\overline{A + 3B} \times \frac{l}{8}$;

5. $\overline{7A + 32B + 12C} \times \frac{l}{90}$;

6. $\overline{19A + 75B + 50C} \times \frac{l}{288}$;

7. $\overline{41A + 216B + 27C + 272D} \times \frac{l}{840}$;

8. $\overline{751A + 3577B + 1323C + 2989D} \times \frac{l}{17280}$ &c. &c.

"This method was invented by Sir Isaac Newton, and published by Mr. Jones in 1711; and since prosecuted by Mr. Coats, Mr. De Moivre, and by Mr. Stirling, in a whole treatise entirely built thereon, where such as desire a farther insight into this matter, may find it sufficiently explained, and applied to some of the most intricate parts of mathematics."

This table errs in the last term of the areas corresponding to the ordinates 3, 5, 7, &c., viz., 4 B should only be 2 B, and 12 C should only be 6 C, and so of the rest; that is, they are double what they ought to be.

This error has also escaped the notice of that great mathematician, Mr. Emerson, see p. 29 of his *Differential Method*, published with his *Conic Sections*, 1767, where he has the same table as in *Shirtcliffe's Gauging*; but it has been corrected by Dr. Hutton. *See* his *Mensuration*, large copy, printed in 1770.

To show how this rule may be derived in the simplest manner, in order to approximate any curvilinear surface, of which the ends are parallel, let AEDBA be bounded on one side by a parabolic curve, BCD; and let AB and ED be two diameters, or straight lines, parallel to its axis; and let AE be perpendicular to AD and ED; also let AE be bisected in F; and let FC be drawn parallel to AB or ED; and let BD be drawn cutting FC in G;

and let AB $= q$,
FC $= b$,
and ED $= c$;
also, AF, or FE $= m$:

now FG will be equal to $\frac{a+c}{2}$,

and the part GO will be $b - \frac{a+c}{2}$;

but the space BCDB is equal to a parabola, of which the base is AE, or $2m$, and the height GC, or $b - \frac{a+c}{2} = \frac{2b-a-c}{2}$;

therefore $\frac{2}{3}$ + G C × A E = $\frac{2}{3} \times \frac{2b - a - c}{2} \times 2m = \frac{2m}{3} \times (2b - a - c)$ the area B C D B; but the area of the trapezoid A B D E is equal $\frac{1}{2} \times (a + c) \times 2m = (a + b) \times m$; therefore the area A B C D E A = $(a + c) \times m + (2b - a - c) \times \frac{2m}{3} = \left(a + c + \frac{4b - 2a - 2c}{3}\right) \times m = \frac{3a + 3c + 4b - 2a - 2c}{3} \times m = \frac{a + c + 4b}{3} \times m$, or $\frac{a + 4b + c}{3} \times m$.

Now, let A B C D E F G, &c. be the abscissa of a curve, H I J K L M N, &c. and let A H, B I, C J, be any number of even equidistant ordinates, and let these ordinates be denoted by a, b, c, d, e, f, g, &c. Let us suppose a parabolic curve to pass through every adjoining three; that is, taking in every two adjoining spaces; and let m be the common breadth of every space; then the area of the first two spaces will be $\frac{a + 4b + c}{3} \times m$; the area of the two next spaces will be $\frac{c + 4d + e}{3} \times m$; the area of the two next spaces will be $\frac{e + 4f + g}{3} \times m$, and so on, as far as we please. Now the sum of all these areas will be the area of the whole curve; therefore, $\frac{a + 4b + c}{3} \times m + \frac{c + 4d + e}{3} \times m + \frac{e + 4f + g}{3} \times m$, &c. $= \frac{4b + 4d + 4f + 2c + 2e + a + g}{3} \times m = \frac{4 \times (b + d + f) + 2 \times (c + e) + a + g}{3} \times m$ equal to the area of the curve.

This not only holds true in superficies, but also in solids.

Then, if the intermediate ordinates be called sections, and be numbered 1, 2, 3, &c., the first being called odd, the next even, and so on alternately; the last section will always be odd; then to four times the sum of the odd sections add twice the sum of the even sections, and the two ends; then one-third of the sum being multiplied by the common distance gives the area, which is a near approximation for any curvilinear figure whatever.

Observations on Averaging Surfaces, bounded on one or on two opposite sides by a Curve.

In the mensuration of superficies bounded by curves, the common method of taking the average, or mean, of any number of ordinates, by adding all the ordinates together, and dividing by their number, and multiplying the quotient by the length, is extremely vague.

For let the figure proposed to be measured be A E F H K A, divided by the equidistant ordinates B I, C H, D G. Let A K be denoted by a, B I by b, C H by c, D h by d, E F by e; and let the common distance, A B, or B C, &c., be denoted by m; and let each of the areas, A B I K A, B C H I B, C D G H C, D E F G D, be computed according to the method of measuring a trapezoid; then the sum of the contents will be the area of the whole space, A E F H K A, provided that the lines, K I, I H, H G, G F, be straight, and very nearly equal to the true area, when the figure is bounded on one side by a curve; being in excess when K I H G F is concave, and in defect when convex: then will

$$\frac{a + b}{2} \times m = \text{A B I K A},$$

$$\frac{b + c}{2} \times m = \text{B C H I B},$$

$$\frac{c + d}{2} \times m = \text{C D G H C},$$

$$\text{and } \frac{d + e}{2} \times m = \text{D E F G D}.$$

The sum of these areas is $\left(\frac{a + e}{2} + b + c + d\right) m$; that is, if the half sum of the extreme ordinates be added to the intermediate ones, and the sum multiplied by the common distance, the product will give the area: and it is evident that this will always be the case, whatever be the number of ordinates.

Therefore, let a, b, c, d, &c., to p and q, be any series of ordinates whatever, whereof a is the first term, and p and q the two last; then the area of the curvo-rectilinear space will be generally expressed by $\left(\frac{a + q}{2} + b + c + d, \text{ \&c. to } p\right) \times m$; now, let l = the length; then if n be equal to the number of ordinates, $n - 1$ will be the number of spaces, or areas; therefore $\left(\frac{a + q}{2} + b + c + d, \text{ \&c. to } p\right) \times m = \frac{\left(\frac{a + q}{2} + b + c + d, \text{ \&c. to } p\right) \times l}{n - 1} = \frac{a + q + 2b + 2c + 2d, \text{ \&c. to } 2p}{2n - 2}$, and the value of the average method, viz. $\frac{a + b + c + d, \text{ \&c. to } p + q}{n} \times m \times (n - 1) = \frac{a + b + c + d, \text{ \&c. to } p + q}{n} \times l$; then putting one of these equal to the other, there will result $n \times \frac{a + q}{2} = a + b + c + d$, &c. to $p + q$.

It appears, therefore, that there can be no equality except when the half sum of the extreme ordinates, multiplied by the whole number of terms, is equal to the sum of all the ordinates; which, therefore, must be in arithmetical progression, or amount to such.

The method of averaging will therefore be very uncertain; as the half sum of the two extreme terms, multiplied by the number of ordinates, can be taken in any ratio, with respect to the sum of the ordinates.

The difference between the average method and the true method, would be the very same as the difference between $l \times \frac{a + q}{2 \times (n - 1)}$ and $l \times \frac{a + b + c + d, \text{ \&c. to } p + q}{n \times (n - 1)}$; for if from two unequal quantities equal quantities be taken away, their difference will still be the same; and if to two unequal quantities equal quantities be added, the difference between the sums will still be the same.

If equimultiples be taken of unequal quantities, the difference between the products will be the same multiple of the difference; and if any aliquot part, or equisubmultiple, be taken of two unequal quantities, the difference will be equal to the same submultiple of the former difference; now because the equation $n \times \frac{a+q}{2} = a + b + c + d$, &c., to $p + q$, was obtained by dividing each side of the equation $l \times \frac{a + q + 2b + 2c + 2d, \text{ \&c. to } 2p}{2n - 2} = l \times \frac{a + b + c + d, \text{ \&c. to } p + q}{n}$ by l, and multiply each side respectively by n, $n - 1$, and then adding, or taking away the common parts; by making the divisor l a multiplier, and the multipliers n, $n - 1$, divisors; then multiplying the equation $n \times \frac{a+q}{2} = a + b + c + d$, &c. to $p + q$ by l, and dividing it by n and $n - 1$, there will arise $l \times \frac{a+q}{2 \times (n-1)} = l \times \frac{a + b + c + d, \text{ \&c. to } p + q}{n \times (n-1)}$.

Example.—Let $a = 4$, $b = 12$, $c = 16$, $d = 18$, $p = 19$, $q = 18$, and $l = 10$;

then $l \times \frac{a+q}{2(n-1)} = 10 \times \frac{4 + 18}{2 \times (6 - 1)} = 22$,

and $l \times \frac{a + b + c + d, \text{ \&c. to } p + q}{n + (n-1)} = 10 \times \frac{4 + 12 + 16 + 18 + 19 + 18}{6 \times (6-1)} = 29$; the difference is therefore 7, the same as between $\dfrac{\left(\frac{a+q}{2} + b + c + d, \text{\&c. to } p + q\right)}{n - 1} \times l$, and $\frac{a + b + c + d, \text{ \&c. to } p + q}{n} \times l$.

Mensuration of Artificers' Works. All such works, whether superficial or solid, are computed by the rules proper for the figure of them.

The most common instruments for taking the measures are, a five-feet rod, divided into feet and quarters of a foot; and a rule, either divided into inches, or twelfth parts, and each twelfth part into twelve others; a fractional part beyond this division, measurers seldom, or never, take any account of.

When the dimensions are taken by a rule divided in this manner, the best methods to square the dimensions will then be by duodecimals, by the rule of practice, or by the multiplication of vulgar fractions; but, in the opinion of some, the best method of taking dimensions is with a rule, when each foot is divided into ten parts, and each part into ten other parts, or seconds, because the dimensions may be then squared by the rules of multiplication of decimals, which is by far the shortest and readiest method. Those who contend that duodecimals, or cross multiplication, is the easiest method of squaring dimensions, as well as the most exact, are very much mistaken; for if the dimensions are taken in duodecimals, and reduced to decimals, and then squared, the operation, in this case, will certainly be much longer than if it had been done at once by duodecimals, and sometimes not so exact: but if the dimensions are taken in feet, tenths, &c. the operation will not only be easier and shorter, but in many cases will be much more exact than by duodecimals: the reason is obvious to those who consider that there are many cases in which it will be impossible to express, truly, a decimal scale equal to a duodecimal one; neither will it, in many cases, be possible to express accurately, a duodecimal scale equal to a decimal one; duodecimals have the same property with regard to twelfth parts, as decimals have to tenth parts; therefore, in many cases, duodecimals will sometimes circulate and run on, *ad infinitum*, when reduced from decimals, as decimals will, when reduced from duodecimals; and farther, since duodecimals are expressed by a series of twelfth parts, and decimals by a series of tenth parts, in multiplying each of the parts of the former, the trouble of dividing by twelve will then be unavoidable, and more burdensome to the mind than if the operation had been done by the latter, where there is no such division to be made, but merely to multiply as in common mutiplication, and point off the decimal places in the product.

This last method is always to be preferred, as the most natural, as well as the most easy of the two.

Bricklayers' Work.

The mensuration of brickwork has already been treated of at considerable length under that head, but in order to complete the article, we shall give a few more problems and examples.

Problem I.—*To measure the vacuity of a window.*

Find the area of the outside of the window, and multiply that by the number of half bricks thick, from the face of the sash-frame on the outside, to the face of the wall on the same side; to the area so found, at half a brick thick, add the area of the inside vacuity multiplied by the number of half bricks thick, from the face of the sash-frame on the outside, to the face of the brick-work within the building; also add the area of the vacuity of the recess, the height being taken from the bottom of the sash-frame to the floor, and its width the same as the inside vacuity above; multiply this also by the number of half bricks thick, then the sum of these will be the whole vacuity, or void space in the whole window, at half a brick thick; and if required to be reduced to the standard, divide the area so found by 3, and the area of the contents will be reduced to $1\frac{1}{2}$ brick thick.

Example.—Let the height of the outside vacuity be 8 feet, its breadth 4 feet, and half a brick thick; the height of the inside vacuity 8 feet, and its breadth 4 feet 9 inches, and two bricks thick; the recess is 2 feet 9 inches high, 4 feet 9 inches wide, and half a brick thick; required the area of the whole vacuity, at half a brick thick.

Ft.	In.		
8	0		height of the outside vacuity.
4	0		width of the outside vacuity.
32	0		area of the outside vacuity, half a brick thick.
4	9		width of the inside vacuity.
8	0		height of the inside vacuity.
38	0		
4	0		number of half bricks.
152	0		area of the inside vacuity, half a brick thick.
4	9		width of the inside vacuity.
2	9		height of the recess from the floor to the side of the sash.
9	6		
3	6	9	
13	0	9	area at $1\frac{1}{2}$ brick thick.
3	0	0	
39	2	3	area of the recess, half a brick thick.
32	0	0	
152	0	0	
223	2	3	area of the whole vacuity, half a brick thick.

PROBLEM II.—*To measure any angle chimney, standing equally distant each way from the angle of the room.*

Multiply the breadth, A B, by the height of the story, and the product by the number of half bricks contained in the half breadth, A B, and it will give the solidity at half a brick thick, after deducting the vacuity, or opening of the chimney.

PROBLEM III.—*To measure an angle chimney, when the plane of its breast intersects the two sides of the room unequally distant from the angle.*

From the points A and B, where the plane of the breast intersects the sides of the room, draw two lines, A E, E B, parallel to the two sides of the room; then multiply either of the lines, A E or E B, suppose E B, by the height of the room, and multiply that product by the number of half bricks contained in the other line, A E, and deduct the vacuity as before, and the remainder will be the content, at half a brick thick.

PROBLEM IV.—*To measure an angle chimney, when the plane of the breast projects out from each wall, and unequally distant from the angle of the room.*

Draw the two lines, G F and F H, parallel to the two sides of the room, as before; then multiply the breadth, F H, by the height of the story, and the product contained in the half of the other side, F G; from this product deduct F D, multiplied by the height of the story, and by the number of half bricks contained in the half of F C, and also the vacuity of the chimney.

PROBLEM V.—*To find the area of an arched operture.*

To twice the height at the middle add the height of the jambs; and one-third of the sum multiplied by the breadth of the aperture will give the superficial content, sufficiently near for practice.

Example.—Let the height of the arch be 12 feet, each jamb 10 feet, and the breadth of the aperture 5 feet; what is the superficial content?

Feet.
12
2
24
10
3) 34
$11\frac{1}{3}$
5
$56\frac{2}{3}$ feet, the answer.

But if greater accuracy be required, add the quotient arising from the division of the cube of the altitude by twice the breadth of the aperture, and the sum will be exceedingly near the truth.

Example.—In the foregoing example, the height of the arch is 2 feet, and the chord of the arch, or twice the breadth of the aperture, is 5 feet; then the cube of 2 is 8; and 8 divided by 10, or twice five, gives .8 of a foot for the quantity to be added to the above.

Now the above $56\frac{2}{3}$ = 56.666, &c.
.8

57.466, the area, exceedingly near the truth.

PROBLEM VI.—*To find the area of a wall, or of the foundation of a building, placed upon a curved surface, supposing it to be built upon uneven ground.*

Divide the length into any number of even parts (the more the truer) by parallel vertical sections; call the first of these sections *odd*, the next *even*, the next *odd*, and so on alternately; and thus the first and last sections will always be odd. Then add together four times the sum of the odd sections, twice the sum of the even sections, and the two ends: divide the sum by three times the number of parts that the length is divided into; then multiply the quotient by the length of the wall, and the product will be the superficial content.

Example.—Suppose a brick wall, 32 feet long, to be divided into eight equal parts, by seven sections of the following heights, taken in successive order, 5 feet, 6 feet, 6 feet 2 inches, 6 feet 3 inches, 5 feet 5 inches, 4 feet, 3 feet, the one end 3 feet and the other 2 feet 6 inches; required the area of the wall.

Now, 5 feet, 6 feet 2 inches, 5 feet 5 inches, and 3 feet, are the odd ordinates; and 6 feet, 6 feet 3 inches, 4 feet, are the even ordinates; therefore,

Feet.	In.		Feet.	In.
5	0		6	0
6	2		6	3
5	5		4	0
3	0		16	3
19	7			2
	4		32	6

78	4		= four times the sum of the odd sections.
32	6		= twice the sum of the even sections.
3	0		= the one end.
2	6		= the other end.
3) 116	4		
8) 38	9	4	
4	10	2	
32			
155	1	4	

The following erroneous method is usually practised by measurers and workmen:—

Add all the heights together, and divide the sum by their number; then the quotient, multiplied by the length, is supposed to give the area.

Let us therefore resume the same example by this method:

Feet.	In.		
3	0		
5	0		
6	0		
6	2		
6	3		
5	5		
4	0		
3	0		
2	6		
9) 41	4		the sum of all the heights.
4	7	$1\frac{1}{3}$	
32			
146	11	$6\frac{1}{3}$	the answer, considerably below the truth.

Where the foundation would consist of several straight lines, forming trapezoids, the best method is to find the content of each trapezoid separately; and then adding all the trapezoids together, their sum will be the area of the whole; but if the figure of the ground on which the building is raised be a curve, the measurer will be grossly deceived as to the true contents of the work, unless he divide the length into equal parts, as already recommended.

The contents in brickwork may be found by multiplying the area by 3, and dividing by the number of half bricks.

The following example is added, in order to show the use of the method of equidistant ordinates.

Example.—Let E F G H be a wall of brickwork, or the back of a house, to be built over a public road, or valley, H L G; the under part of the wall is built from the foundation, H L G, up to the level at I K, three bricks thick, and from I K to the top, E F, parallel to it, two bricks and a half thick, to the height of 15 feet, having five windows in it; the vacuities on the outside of each window are 8 feet by 4 feet, and half a brick thick; the vacuities on the inside are 8 feet by 4 feet 9 inches, two bricks thick; the recess on the inside for the finishing of the backs in each window, one and a half brick thick; the height 2 feet 6 inches, from the top of the floor to the sill of the window; the width is that of the vacuity on the inside of the window, viz., 4 feet 9 inches. There is an arched way underneath for carriages, &c. to pass through, whose opening is 12 feet, and its height from the level of the pavement to the crown or top of the arch 11 feet, and the height, from the pavement to the springing of the arch, 9 feet; the under wall is divided into an even number of equidistant spaces, whose ordinates are respectively as follow:—6 feet, 10 feet, 13 feet, 14 feet, 10 feet, 4 feet 6 inches, and 1 foot; the whole length of the building is 50 feet; required the number of bricks, and the quantity of sand and lime to build the said wall.

Explanation.—The under part of the building being an irregular figure, it is measured according to the method of equidistant ordinates, Problem VI.; the upper part is found as in the foregoing examples. The arched way is measured by Problem V. The contents of the windows are obtained by Problem I. Then deduct all the vacuities at half a brick thick from the area of the whole, found as if it were solid, at half a brick thick, as before: the remainder being divided by 3, will reduce it to the standard thickness of one brick and a half.

3) 310 0
———
103 4 area of the vacuity of the archway, 3 bricks thick.
6 number of ½ bricks thick.
———
620 0 area of the vacuity of the archway, ½ a brick thick.
———
160 0
791 8
178 1
620 0
———
1749 9 areas of all the vacuities, ½ a brick thick.

Feet.	Inches.	
2666	8	
3750	0	
6416	8	area of the whole $\frac{1}{2}$ a brick thick, as if solid.
deduct 1749	9	
3) 4666	11	true area of the whole, $\frac{1}{2}$ a brick thick.
272) 1555	7	(5 rods 195 feet, reduced to the standard thickness.
1360		
195		

Thus $5.195 \times 4500 = 25726$ number of bricks nearly.
$5.195 \times 1\frac{1}{4} = 7\frac{211}{372}$ cwt. of lime nearly.
$5.195 \times 2\frac{1}{2} = 14\frac{79}{272}$ loads of sand nearly.

To persons, to whom the saving of time is an object, the following tables will be found of great utility in the calculation of brickwork, as well as in the examination of the several operations wrought without them. The explanations and examples of their use will follow.

Table I.

Showing the number of rods contained on the superficies or face of the wall or building, from half a brick to five bricks in thickness, and reduced to the standard measure of one brick and a half thick, being already cast up.

A general Explanation of the Tables and their Construction.

In Tables, which may be calculated by a proportion, in which one of the terms is constantly the same, and consequently the other two only variable, the given data, or numbers, are always of two kinds; one of the kinds is placed in one row, and the other in another row, at a right angle therewith; the former being parallel to the edges of the page, and upon the left hand, and the other perpendicular to the said edges, and at the top of the page: we shall call the former, the given vertical column; and the latter, the given horizontal row; the first part of the given horizontal row over the given vertical column, contains the title of this column; and the given numbers of this horizontal row follow each other in succession, having each a separate cell with the title at the top; then other rows are made in a line with each cell, parallel to the given vertical column, so that the respective numbers which form the said columns may also line with the numbers in the left-hand vertical column: then each of these numbers, so disposed, are to be the answers of the two numbers at the extremity of the legs in each given row. From this it appears, that the answer is in the concourse of the given column and row, traced from each given datum parallel to the given columns in which the data are inserted. All the useful variations of one of the given species, or kinds, are expressed by one or several arithmetical progressions, in the given vertical column, and the other species in an arithmetical progression in the given horizontal row. If the given vertical column consist only of one arithmetical progression, the answer for any number in the said column, between the first and the last, may be obtained at once: but if the given vertical column consist of several arithmetical progressions, *viz.* from 1 to 10, from 10 to 100, from 100 to 1000, &c., the common difference of the following progression being 10 times greater than that which precedes it, then the given number belonging to the vertical column must be divided into component parts, so as to correspond with as many of the numbers to be found in the progressions; each of the answers are to be taken out separately, and added together, and the sum will be the answer in full. Where the given vertical column consists of one or more arithmetical progressions, so will each vertical column of answers consist of as many arithmetical progressions, and each horizontal row of answers will also form an arithmetical progression; therefore in the construction of the Table, there is no necessity for calculating by the rule of proportion, nor even by plain division or multiplication, except in the first or uppermost two numbers in the first and second vertical columns of answers; the difference of each of these numbers, so found, is the common difference of the progression in the first horizontal row of answers; then this common difference being added to that at the head of the second column gives the next towards the right hand, or the uppermost answer at the head of the third vertical column; the common difference being added to this sum, again gives the next succeeding answer, and so on to the end of the horizontal progression: proceed with each vertical column by adding the common difference in the same way throughout each progression, if more than one; observing, that whatever number of times the common difference of any following progression in the given vertical column contains the common difference in the preceding progression, so must the common difference of any following corresponding progression, in any vertical column of answers, contain the common difference of the arithmetical progression immediately preceding in the same column.

One thing may be observed in each vertical column, where the answers consist of integers only, and where there are several arithmetical progressions, from 1 to 10, from 10 to 100, from 100 to 1000, and where each progression is formed of 10 terms, all the numbers of the first progression are to be found respectively in as many of the first figures of the second progression, and all the figures of each number in the second progression are to be respectively found in as many of the first figures of each of the numbers in the third progression, and so on, whatever be the number of progressions: therefore, if the last progression be constructed, the whole of the progressions upwards may also be constructed: for whatever number of figures each number of the lower progression consists of, each number of the progression immediately above will respectively consist of the same, wanting the right-hand figure; likewise the third progression will have the same number of figures in each number, wanting one, that each respective number has in the second progression, or wanting two that each respective number in the undermost progression has. So that, by proper attention, one small Table, consisting only of 10 horizontal rows, will give the answer for any number whatever.

In Tables where the given columns consist of different denominations, the answers may be first obtained in one denomination, and afterwards each of the answers may be divided into the several denominations it will resolve into, in order to facilitate the construction of the Tables.

TABLE I.

Explanation.—At the head of this table, over each vertical column, is the thickness of the wall in bricks and half bricks, *viz.* from $\frac{1}{2}$ a brick to 5 bricks; the first vertical column, or that on the left hand, contains the number of rods, from $\frac{1}{4}$ to 21, and each succeeding column towards the right shows the number of rods, quarters, and feet, reduced to a brick and a half, according to the thickness expressed at the top of the column, and to the number of rods to be found in the same horizontal line in the first column.

Use.—Suppose a wall, $2\frac{1}{2}$ bricks thick, contained 8 rods, how many standard rods does the wall contain? Look for 8 rods in the first column, carry your eye horizontally to the $2\frac{1}{2}$ brick column, in which you will find 13 1 22; that is, 13 rods, 1 quarter, and 22 feet; and so proceed for any other quantity and thickness.

Construction of the Table.—Multiply the number of superficial rods expressed in any number of the first column, by the number of half bricks that the wall is in thickness, divide the product by 3, and the quotient will exhibit the number of reduced rods: multiply the remainder, if any, by 272, and $\frac{1}{3}$ of the product will be reduced feet; the inches not being noticed. Now, as 68 feet are the quarter of a rod, the quotient, if it equal or exceeds 68, must be divided thereby, and the last quotient will give the quarters of a rod, and the remainder, if any, will be feet.

Example.—Let it be required to find to the quantity of reduced work in a wall $2\frac{1}{2}$ bricks thick, the superficial measure being 8 rods:

```
      8
      5  half bricks           Then 68) 90 (1
   ----                                 68
3) 40                                   --
   ------                               22
   13   90
```

	Rds.	Ft.		R.	Qt.	Ft.
That is	13	90	=	13	1	22

And thus for any other number of superficial rods. A Table, similar to the above, may be found in Leadbeater's *Gentleman's and Tradesman's Assistant*, second edition; and also in Crosby's *Builder's Price Book.*

TABLE II.

Explanation and Use.—The first column contains the number of superficial feet, from 1 to 10 inclusive, the common difference being 1; from 10 to 100 inclusive, the common difference being 10; from 100 to 1000 inclusive, the common difference being 100; from 1000 to 10,000 inclusive, the common difference being 1000; and from 10,000 to 90,000 inclusive, the common difference being 10,000. The adjacent vertical columns, towards the right, show the number of bricks respectively required to build a wall at the thickness of $\frac{1}{2}$, 1, $1\frac{1}{2}$, 2, $2\frac{1}{2}$ bricks, according to the superficial feet expressed by the number in the first vertical column, in the same horizontal line.

Let it be required to find the number of bricks necessary to build a wall half a brick thick, containing an area of 4850 feet: Divide the number into its component parts thus, 4850 = 4000 + 800 + 50, then look for each of these parts separately, and you will find, that

	4000	will require	22058	add these together,
	800	„ „	4411	
	50	„ „	275	
and the whole	4850	„ „	26744	

Again, let it be required to find the number of bricks that will build a wall two bricks thick, containing an area of 35,864 feet: then say, 35,864 = 30000 + 5,000 + 800 + 60 + 4, and you will find that—

30000	will require	661764
5000	„ „	110294
800	„ „	17647
60	„ „	1323
4	„ „	88
35864	„ „	791116

Construction.—Reduce the standard rod of 272 feet, and the given area, into walls of half a brick thick; then say, as the number of feet in the standard, thus reduced, is to the area reduced to the same thickness, so is 4,500 bricks, the quantity required to build the former, to the quantity required to build the latter.

Example I.—How many bricks will be required to build a wall containing an area of 35,864 feet, two bricks thick?

```
Then 272          35864
       3              4
     ---          ------

                    ----
                     528
```

The answer is within one of what is obtained from the Tables; the difference arises from the fractions being lost, in adding the several parts together.

Example II.—How many bricks will be required to build a partition wall, half a brick thick, containing an area of 4850 feet?

```
      272          4850
        3             1

                    ----
                     264
```

which is rather more than the aggregate found by the Tables, the remainders being omitted in adding the component parts together.

In this manner, by the rule of proportion, every number in the Table may be found. Or if the solidity of the wall be divided by the solidity of a brick, both of the same dimension, the quotient will give the number of bricks; but this operation will not be shorter than the above.

In Salmon's *Architect's Assistant*, is a Table similar to that above described, showing the number of bricks necessary to build a wall, from half a brick to two bricks and a half thick inclusive, and from one foot on the surface, to 27,000 inclusive. The column of feet goes on from unity to 100 inclusive, the common difference being one; then from 100 to 1,000 inclusive, the common difference being 100; and lastly from 1,000 to 27,000 inclusive, the common difference being 1,000.

But there is no advantage in a long table, unless the number could be found at once without addition, which is not generally the case. The short Table here introduced, is extended farther than Salmon's, and is much more handy.

Another Table, of the same description, was published by Mr. J. Leadbeater, and assistants, in his *Gentleman's and Tradesman's Complete Assistant.* The progression of the numbers expressing the area is exactly the same as in Salmon's, except that the latter author's work contains two horizontal lines more than the former; the one ending in 27,000, the other in 25,000; and with the exception of the following numbers, all the others correspond:

In the one-brick column, opposite 35, Salmon has 381, and Leadbeater 386, the difference is 5, but Leadbeater is right.

In the same column, opposite 45, Salmon has 502, and Leadbeater 503: but the number ought to be 496.

In the brick-and-half column, opposite 53, Salmon has 876, and Leadbeater 878; the true number is 876, or more nearly 877: in this instance they differ but little from the truth.

In the one-brick column, opposite 62, Salmon has 689, and Leadbeater 696; which are both in excess; the true number being 683, or very nearly 684. The greatest difference is 12 or 13 that Leadbeater is beyond the truth.

In the brick-and-half column, opposite 84, Salmon has 1389, and Leadbeater 1380; which are both in excess; the true number being 1356. Salmon, who has the greatest, exceeds the truth by 33.

In the same column, opposite 97, Salmon has 1604, and Leadbeater 1614: Salmon is right.

And lastly, in the two-and-a-half brick column, opposite 12,000, Salmon has 343,087, and Leadbeater 353,087, which are both vastly beyond the truth, which is 330,882. Salmon is therefore 12,205 in excess, and Leadbeater 22,205.

These differences are so great, and the nearest so wide of the truth, that one must suppose, either that these gentlemen were governed by no regular rule, or that they were very careless; for indeed they might have come nearer to the required number at a mere guess.

But if in the few numbers here examined, such enormous differences appear, what may not be expected from the far greater part of them?

It may perhaps happen that these differences, as they are few, are typographical errors; and should this be the case, it is most probable that one has copied from the other. The quotations from these works are from the second edition; Salmon's is dated 1748, and Leadbeater's 1769.

In Crosby's *Builder's Price Book*, by Phillips, for 1811, is a similar Table; and I am sorry to find, in a book of so much reputation, that the same numbers are to be found as in Salmon's and Leadbeater's, except in the four following:

In the one-brick column, opposite 20, Crosby has 223, and Salmon and Leadbeater, each, 220, the true number.

In the two-brick column, opposite 300, Crosby has 6626, and Salmon and Leadbeater, 6616, the true number.

In the two-and-a-half brick column, first, opposite 50, Crosby has 1476, and Salmon and Leadbeater, 1478; but the true number is 1378: Secondly, opposite 5000, Crosby has 145,953, and Salmon and Leadbeater, 142,953; whereas the true number is 137,867.

These numbers are so nearly alike in the three books here mentioned, that the differences appear to be no more than typographical errors; whence we may conclude that Leadbeater's *Assistant* has been copied from Salmon's, and the Table in Crosby's from one of them; for though it is much contracted, the errors in the numbers are the same.

If compilers in general would be at the necessary pains of examining what they intend to adopt, three-fourths of the books that are published on scientific subjects would never have appeared; the far greater part of them are made from scraps of others, and many are exactly the same in substance, only slightly varied in the arrangement, or in a single word now and then; and even whole paragraphs or sections are frequently to be met with, and sometimes whole works are copied, without any acknowledgment of the original author. Such is the case with the three authors alluded to; neither of the latter two takes any notice of the first; but taking it for granted that he is right, and depending upon this, they each make the part thus adopted their own, little suspecting that these antiquated works would ever undergo re-examination. But happy it is for scientific subjects, and for original writers, that there are still some few men of principle who will pry to the bottom of the greatest difficulties, and undergo the most laborious calculations; and though such authors as those referred to, may have credit in the mean time for what they have done, they must be ultimately exposed to that censure which their works so justly deserve.

There is hardly a number in the latter part of these Tables but is wrong, in some instances even to thousands: but as I have put the reader in possession of a method by which to examine them, he may do it at his leisure; or he may compare any of the other numbers with those here inserted.

When such errors arising from carelessness, are to be found in a single Table of a Price Book, is there not reason to suppose that in other parts, not examined, they abound equally, and therefore create a doubt as to the degree of dependence to be placed in any one article? There is no man perfect; and when different ideas crowd upon the mind of a writer at the same time, in treating of subjects that have not been before investigated, he may inadvertently insert a wrong word, or a typographical error may escape his notice; but in most cases this will be easily detected, as other parts of the subject will readily ascertain the author's meaning, or otherwise it may be deduced from a palpable contradiction in terms, where only one idea could be meant.

Table III.

Explanation.—The first vertical column contains the contents of the wall in superficial feet, the given row the thickness in bricks and half-bricks, and the other vertical columns the answers.

Use.—What is the quantity of reduced brickwork in a wall containing 5,348 feet superficial and $2\frac{1}{2}$ bricks thick?

Say, $5,348 = 5,000 + 300 + 48$: then we have by the Table,

	R.	Qr.	Ft.	In.
5000 will require	30	2	37	4
300 " "	1	3	24	0
48 " "	0	1	12	0
consequently 5348 " "	32	3	5	4

The same found by the rule thus:

```
         5348
            5
      -------
      3)26740
      -------     R. Qr. Ft. In.
   272)8913 4 (32  3   5  4, the answer, as
       816                         before.
       ----
        753
        544
       ----
    68)209(3
       204
       ----
         5
```

The rule here applied is the same as Rule I. p. 50, vol 1. As the first progression goes on from 1 to 50 inclusive, and two adjacent numbers differing by unity, any number from 50 to 1 may be taken at once.

Example.—In a wall of two bricks thick, containing an area of 47 feet, what is the standard measure?

In the meeting of the 2-brick column and the horizontal row from 47, you have 62 feet 8 inches, the answer required.

In constructing a table, such as this, with different denominations, it will be much more ready to find the whole numbers, as in the last Table, in the least denomination, and afterwards to divide each respective number by as many as will make one of the next denomination; then the quotient is so many of this denomination, and the remainder, if any, so many of the first; and if the quotient exceed the number that makes one of the third denomination, divide it by this number, and the second quotient is so many of the third denomination, and the remainder, if any, so many of the second; and so on, as long as division can be made.

Table IV.

Explanation and Use.—As the prices of bricks and of labour may vary in any ratio in respect of each other, it is convenient to have a price at once agreeable to these variations, which can be easily obtained from this Table. The given price of bricks per thousand is arranged in the first vertical column, the price of mortar and labour in the given horizontal row, and the required price per rod is found, as in the other Tables, in the point or place of intersection of the horizontal row and vertical column, carried from each of the given prices.

Example.—What is the price of a rod of brickwork, when the rate of bricks is £1 18s. per thousand, and the price of mortar and labour £3 10s. per rod?

Carry your eye horizontally from £1 18s. in the given column of bricks, until you come to the vertical column under £3 10s. the given price of labour and mortar; and you will find £12 1s. the price of the rod, as required.

Construction.—Multiply the price of bricks per thousand by $4\frac{1}{2}$, and add the product to the price of labour at the top, and you will have the price per rod, as in the Table. Let us take the above as an example: then (£1 18s.) $\times$ $4\frac{1}{2}$ = £8 11s. the price of bricks in a rod, to the product; add £3 10s. the price of labour and mortar, and you will have £12 1s. as before.

This Table might be otherwise constructed, by giving a Table of the variations of lime and sand, but then it would be much longer. The articles of labour, lime, and sand, are classed together, upon the supposition or probability, that the increase or decrease of either of the two is nearly in the same ratio; but should it prove otherwise, and the disparity be great, a Table must be constructed upon different principles.

Table V.

Explanation and Use.—This Table consists of only two vertical columns; the price per foot is contained in the first and the price per rod in the second column. So that if the price per foot be given, you have the price per rod in the same horizontal line; or the very reverse is sometimes necessary, when the price per rod is given, to know the price per foot.

Example.—What will 3r. 258ft. of reduced brickwork come to, at £2 16s. 8d. per rod? First multiply £2 16s. 8d. by 3; look for £2 16s. 8d. under the column per rod, on the left hand of it, you have $0\frac{1}{2}$d. for the price per foot; therefore multiply 258 feet by $\frac{1}{2}$, that is, divide it by 2, and you will have the number of pence, which divided by 12 will give the shillings. Thus:

```
 £.   s.   d.          Feet.
 2   16    8          2)258
           3          -----
 -----------        12)129
 8   10    0          -----
     10    9            10 9
 -----------
 9    0    9
```

To perform such operations entirely by rule is sometimes very tedious.

Construction.—The quantity of superficial feet in a rod is 272; this being multiplied by the price per foot, gives evidently the price per rod: Suppose $0\frac{3}{4}$d. per foot, what is the price per rod?

```
Thus:            272
multiplied by      3
                 ---
               4)816
                 ---
              12)204 pence per rod.
                 ---
                  17 shillings.
```

Table VI.

Explanation.—The different gauges are contained in the top row, the given areas in the first vertical column, and the answers in the succeeding vertical columns.

Example.—How many tiles are sufficient, at a 7-inch gauge, to cover an area of 5.349 feet?

Here 5349 = 5000 + 300 + 40 + 9.

```
          Now,  5000  will require  32,500
                 300    "     "      1,950
                  40    "     "        260
                   9    "     "         58½
                ----                ------
     therefore  5349    "     "     34,768½
```

Or thus, by calculation:—It is evident that the numbers are as the areas: suppose it is ascertained that 52 plain tiles will cover 8 feet superficial, at a 7-inch gauge, we shall then have, as the area of 8 feet, is to the area of 5,349 feet, so is 8 tiles, the number required for 8 feet, to the number of tiles required, $34{,}768\frac{1}{2}$.

```
Thus 8  :  5349  : :  52
             52
         ------
          10698
         26745
         ------
       8)278148
         ------                [by the Table.
         34768½ the answer, as above found
```

It may be observed in this, as all the foregoing Tables, that any two numbers in any vertical column, are in the same ratio as any other two opposite numbers in any other vertical column; that is, as any number in any vertical column is to any other number in the same column, so is any number opposite the former in any other column to the number opposite the latter in this last column.

The following memoranda, extracted principally from an useful little work entitled the Student's Guide to Measuring and Vaulting Artificers' work, may prove useful.

Size and Weight of Various Articles.

	Length.		Breadth.		Thickness.		Weight.	
	Ft.	In.	Ft.	In.	Ft.	In.	lbs.	oz.
Stock bricks........... each	0	8¾	0	4½	0	2½	5	0
Paving " .... ditto	0	9	0	4½	0	1¾	4	0
Dutch clinkers......... ditto	0	6¼	0	3	0	1½	1	8
12-Inch paving tiles .... ditto	0	11¾	0	11¾	0	1½	13	0
10-Inch " " .... ditto	0	9¾	0	9¾	0	1	8	9
Pan-tiles.............. ditto	1	1½	0	9½	0	0½	5	4
Plain tiles .... ditto	0	10½	0	6½	0	0⅝	2	5
Pan-tile laths, per 10-feet bundle	120	0	0	1½	0	1	4	6
Ditto, per 12-feet bundle ..... (A bundle contains 12 laths.)	144	0	0	1½	0	1	5	0
Plain tile laths, per bundle.... (Thirty bundles of laths make a load.)	500	0	0	1	0	0¼	3	0

A bricklayer's hod measures 1 foot, 4 inches, × 9 inches × 9 inches, and contains 20 bricks.

A single load of sand is 27 cubic feet, or 1 cubic yard, and contains 18 heaped or 21 striked bushels, and 23½ cubic feet equal one ton.

A double load of sand is 54 cubic feet, or 2 cubic yards.

A measure of lime is 27 cubic feet, or 1 cubic yard, and contains from 16 to 18 bushels.

Quantities.

A rod of brickwork measures 16 feet, 6 inches × 16 feet, 6 inches, or 272 feet, 3 inches superficial, 1½ brick, or 13½ inches thick, called the standard thickness, or 306 cubic feet, or 11½ cubic yards; and weighs 13 tons.

A rod of brickwork, laid to a 12-inch gauge, *i. e.* four courses to measure 1 foot in height, requires 4353 stock bricks.

Ditto, laid to 11½-inch gauge, requires 4533 stock bricks.

A foot of reduced brickwork requires 16 bricks.

These calculations are made without allowance for waste, and indeed there is very little, as nearly every part is worked in, and much space is occupied by timbers, flues, &c., for which no deduction is made in measurement; and therefore, in the erection of dwelling houses, containing flues and bond timbers, 4300 stocks is quite sufficient, and this is the usual number allowed for a rod of brickwork.

5370 stocks to the rod, if laid dry; 4900 ditto, in wells and circular cess-pools.

A rod of brickwork, laid four courses to gauge 12 inches, contains 235 feet cube of bricks, and 71 feet cube of mortar, and the average weight is about 15 tons.

A rod of brickwork requires 1½ cube of chalk lime, and 3 loads of sand, or 36 bushels of cement and 36 bushels of sharp sand.

A cubic yard, or load of mortar, requires 9 bushels of lime and one load of sand.

The proportion of mortar or cement, when made up to the materials in their unmixed state, is as two to three.

Facing requires 7 bricks per foot superficial.

Gauged arches, 10 ditto ditto.

Brick-nogging, per yard superficial, requires 30 bricks on edge, or 45 laid flat.

Paving.

Description.		Number required.
Stock bricks, laid flat .	. per yard	36
Ditto, on edge . .	—	52
Paving bricks, laid flat .	—	36
Ditto, on edge . .	—	82
Dutch clinkers, ditto . .	—	140
12-inch paving tiles . .	—	9
10-inch ditto.	—	13

Tiling.

	Gauge—Inches.	Number required.
Pan-tiles per square . . .	12	150
Ditto ditto	11	164
Ditto ditto	10	180

A square of pan-tiling requires 1 bundle of laths, and 1½ hundred of 6d. nails.

Plain tiles, per square . .	4	600
Ditto ditto . . .	3½	700
Ditto ditto . . .	3	800
Ditto ditto . . .	laid flat	210

A square of plain tilling requires one bundle of laths and nails, one peck of tile-pins, and 3 hods of mortar.

The laths are sold in bundles of 3, 4, and 5 feet lengths; a bundle of 3 feet contains 8 score; 4 feet, 6 score; and 5 feet, 5 score. The nails used are fourpenny; and the number required for a bundle of 5 feet and 6 feet laths, are 500 and 600 respectively.

Calculation of Labour.

Digger.—The amount of digging which a man can perform in a day depends so much on the nature of the soil on which he has to operate, that it is almost impossible to fix a Constant for this description of labour. The following data may, however, serve as a slight guide:

In loose ground a man will throw up about 10 cubic yards per day, but in hard or gravelly soil, where hacking is necessary, from 3 to 5 cubic yards, according to the hardness of the ground, will be a fair day's work.

Wheeling is estimated by the run of 20 yards. A gang of 3 men, 2 for filling and 1 for wheeling, will remove about 30 yards per day to this distance; and the labour for removing earth may be calculated according to the distance, allowing 3 men to the first run, and an additional man for every 20 yards of distance. [17½ cubic feet of clay weighs one ton. 18 cubic feet of common earth weighs one ton.]

The following table, though far from complete, contains Constants for all the principal descriptions of bricklayer's work.

Concrete.—Labour in mixing, wheeling, throwing in from a stage, and puddling (when required to be done), including erection of scaffolding, per yard cube . . .335
(The Constant to be multiplied by the rate of wages for a labourer per day.)

Brickwork, per rod 4.941
(To be multiplied by the rate of wages of a bricklayer and labourer per day.)

Extra labour to malm facings 014
(To be multiplied by the rate of wages for a bricklayer per day.)

Paving.

Brick paving, laid flat in sand .	. per yard	.046
on edge in sand . .	—	.075
flat in mortar . . .	—	.056
edge in mortar . . .	—	.084
Paving brick laid flat in sand . .	—	.046
on edge in sand . .	—	.106
laid flat in mortar . .	—	.175
on edge in mortar . .	—	.121
Clinker paving on edge in sand .	—	.132
10 or 12-inch tile paving . . .	—	.010

Tiling.

Pan-tiling, laid dry	per square	.422
pointed outside	—	.685
inside	—	.790
Plain tiling laid to a 4-inch gauge	—	.739
to a $3\frac{1}{2}$-inch gauge	—	.764
to a 3-inch gauge	—	.790

The above Constants all to be multiplied by the rate of wages for a bricklayer and labourer per day.

Masons' Work.

Masons' work is measured in the same manner as bricklayers', so far as the superficial content is concerned.

The joints of the plane surface of an ashlar wall are measured in breath, according to the thickness of the ashlar work, which is generally about six inches; and the two surfaces which are supposed to come in contact, or to be cemented, both of the vertical and horizontal joints, are accounted as only one surface, as in cornices; and are supposed to be equivalent to that of the vertical facing of the wall after being rubbed smooth.

In brick walls, stone strings must correspond to the thickness of the bricks. Strings are generally bevelled, or weathered, upon the upper side, and grooved on the under side: the weathering is denominated *sunk work*, and the grooving, *throating*. Stone sills in common use are about $4\frac{3}{4}$ inches thick, and 8 inches broad; they are weathered at the top, which reduces the front, or vertical face, to about 4 inches, and the horizontal surface at top to about $1\frac{1}{2}$ inch on the inside; so that the part taken away is $6\frac{1}{2}$ inches broad, and three-quarters of an inch deep. Sills of windows, when inserted in the wall, most commonly project about $2\frac{1}{2}$ inches. The horizontal plane part, left on the inside of the top, the vertical part, or face, and the horizontal part on the lower side without the wall, are denominated *plain work*; the sloping part is the *sunk work*. Plain and sunk work are measured by the foot superficial; throating by the foot run; and are thus entered in the measurer's book:

$$\text{adding}\begin{cases}1\frac{1}{2}\\4\\2\frac{1}{2}\end{cases}$$

the sum is 8 inches for the breadth of the plain work in the sill, according to the dimensions stated.

Ft.	In.	
4	0	Plain work.
0	8	
4	0	Sunk work.
0	$6\frac{1}{2}$	
2 { 0	8	Plain to end.
0	$4\frac{1}{2}$	
4	0	Run of throating.

The sawing is not taken into account.

Cornices are measured by girting round the mouldings; that is, round all the vertical and under sides: this is denominated *moulded work*.

Thus, suppose a cornice to project one foot, and to girt two feet, and to be 40 feet in length; then the dimensions are entered as below:

Ft.	
40	Moulded work.
2	
40	Sunk work at top.
1	

To this must be added all the vertical joints.

All cylindrical work is measured in the girt, and the surface is acounted equivalent to plane work taken twice.

Thus, suppose a cylinder girts 4 feet 9 inches, and is in height 12 feet, then the dimensions are written as follow:

Ft.	In.	
12	0	Super plain work.
4	9	Double measure.

Rough stone, or marble, is measured by the foot cube; but for workmanship, the superficies are measured before it is sunk, for plain work; one bed, and one upright joint, are also accounted plain work, as before stated; then to take the plain sunk work, or circular, if any, and the straight moulded work, or circular moulded work, if there be any such. In taking the dimensions, particular care is required to distinguish these different species of work in the progressive state of preparing the stone. Throatings, and all narrow sinkings, are measured by the foot running measure. In taking the dimensions of moulded work, the mouldings must be girt with a string.

The contents of pavements, slabs, and chimney-pieces, are found by superficial measure; as also stones under two inches thick are valued according to the same measure; but those that are solid by the foot cube.

The construction of rubble-walls is not known in London, from the want of stone; but in many countries such erections are very general.

The standard thickness of rubble-wall is 2 feet; the content is first found in feet and inches, then divided by 9, which reduces it to superficial yards; and the yards are again divided by 36, which reduces it to roods, should the superficial content in yards admit of such division: when the wall is above 2 feet, it is reduced to that standard by adding one-eighth, one-fourth, one-half, according as the additional thickness may be 3 or 6 inches, or a foot.

Weight of Stone.

Purbeck stone,	14	cubic feet, weight	one ton.
Portland —	16	ditto	ditto
Bath —	17	ditto	ditto
Yorkshire —	15	ditto	ditto
Granite	$13\frac{1}{2}$	ditto	ditto
Marble	13	ditto	ditto
Purbeck paving	50	feet superficial	ditto
Ditto step 13 by $6\frac{1}{2}$	25	feet run	ditto

Valuation of Labour.

Table of Constants for the different descriptions of mason's work.

N.B.—The factor to be applied is the rate of wages for a mason per day.

Labour.—Squaring and laying new York or Purbeck.

		Days.
Paving, per foot superficial		.021
If in courses, add		.010

Labour on Portland or similar, per foot superficial.

N.B.—Sawing to be taken as half plain work.

Plain work, to bond stones	per foot superficial	.140
to beds and joints	ditto	.181
rubbed face	ditto	.209
ditto circular	ditto	.291
Sunk work, rubbed	ditto	.250
circular	ditto	.313
Moulded work, rubbed	ditto	.292
circular	ditto	.417

	Per foot superficial.	Days.
Circular work to shafts of columns, having the neck moulding, or part of the base, worked in the same stone	ditto	.334
Circular or spherical work to domes or balls	ditto	.500
If rubbed add extra	ditto	.049
Taking up, squaring, and re-laying old paving	ditto	.042
Add, if in courses,	ditto	.015

Labour on statuary or vein marble, including sawing, working, and polishing

	Per foot superficial.	Days.
Plain work	ditto	.875
Circular ditto	ditto	1.250
Sunk ditto	ditto	1.667
Moulded ditto	ditto	2.334
Circular sunk ditto	ditto	2.334
Circular moulded ditto	ditto	3.000
On Old Work.		
Old vein marble chimney re-set	ditto	.125
Ditto square and re-set	ditto	.167
Ditto sanded, grounded, and squared	ditto	.209
Ditto and re-set	ditto	.250
Ditto cleaned and re-set	ditto	.250
Ditto sanded, polished, and re-set	ditto	.350
Ditto sawed, sanded, polished, squared, and re-set	ditto	.626

Carpenters' Work.

Definition.—By carpenters' work is meant the measuring of common centres, groined centres, floors, partitions, centering, bond-timbers, lintels, wall-plates, and roofs.

For the general customs see the article Carpenters' work.

Problem I.—*To measure the centering of a cylindrical vault.*

Rule.—Multiply the length of the vault in feet, by the circumference of the arch, for the breadth; and divide the product by 100, if greater than the same, and the quotient will give the number of squares and feet.

Example I.—How many squares of centering are there in a vault, whose length is 18 feet 6 inches, and circumference 31 feet 6 inches?

By duodecimals.		By vulgar fractions.
Feet.	In.	
31	6	31½
18	6	18½
		15½+¼

582 9 or 5 squares, 82 feet, 9 inches.

By decimals.

```
 31.5
 18.5
 ----
 1575
2520
315
 -------
5,82.75
```

Problem II.—*To measure naked floors, whether for materials, or workmanship.*

Rule I.—If there be any number of pieces of timber of the same scantlings and length, and the solidity of one of them; and that solidity multiplied by the number of pieces will give the solidity of the whole.

Rule 2.—If the pieces be of the same scantling, but of different lengths, add all the different lengths together, multiply the sum by the area of the end of one of the pieces, and the product will give the solidity of the whole.

Rule 3.—If the pieces be of different scantlings, but of the same length, find the areas of the ends of all the pieces, and the sum of these areas being multiplied by the common length, will give the solidity of the whole number.

Rule 4.—If some of the pieces be of one scantling, equal among themselves, and others of the pieces of another scantling, equal among themselves, but all of the same length; multiply the area of the ends of each, by the number of such as are of the same seantling, add the products together, and their sum, multiplied by the common length, will give the solidity.

Rule 5.—If the lengths vary, as well as the scantlings, find the solidity of each piece separately, and the sum will give the solidity of the whole.

Note.—Wherever a tenon is made, the length of the piece must be taken from the ends of the tenons, and not from the shoulders.

If the floors be fixed in the building, the distance the timber goes into the wall, which is about one-third of the thickness of the wall, must be added to the length of the respective pieces that are clear of the walls.

The best method of finding the solidity of a joist, where the length is given in feet, inches, &c., and the dimension of the section in inches, is to multiply the inches together, and throw the twelves out of the product; also throw the twelves out of the length, and multiply these together.

Example.—Suppose a joist 15 feet long, 3 inches by 9; the product is 27, which divided by 12 gives 2 feet 3 inches; also 15 divided by 12 gives 1 foot 3 inches; then

```
1 3

45

72 feet, sum of all the solidities in the whole floor.

Problem III.—*To measure roofing, or partitions, either for materials or workmanship.*

All timbers in a roof, or partition, are measured in the same manner as floors, excepting king-posts and queen-posts, &c., when there is a necessity for cutting out parallel pieces of wood from their sides, in order that the ends of such braces as come against them may have, what is called by workmen, a *square butment.* To measure the workmanship of such pieces, or posts, take their breadth and depth, at the widest part, multiply them by the length, and the product will give the solidity for workmanship. To find the quantity of materials, if the pieces sawn out are 2½ inches thick, or more, they are esteemed pieces of timber fit for use; when more than two feet long, their lengths should not be esteemed so long by 5 or 6 inches, because the saw cannot enter the wood with much less waste, and consequently the pieces must be deducted from the whole solidity, and the remainder will give the quantity of materials; but if the pieces cut out be less than 2½ inches, the whole post must be measured as solid for the materials, because pieces cut out are of little use.

Example.—Let the tie-beam be 36 feet long, 9 inches wide, by 1 foot 2 inches deep; the king-post, is 11 feet 6 inches high, 1 foot broad at the bottom, by 5 inches thick: out of this are sawn two pieces from the sides, 3 inches thick and 7 feet long; the braces, are 7 feet 6 inches long, 5 inches by 5 inches; the rafters are 19 feet long, 10 inches by 5 inches each; the struts are 3 feet 6 inches long, and 4 inches by 5 inches; required the measurement for workmanship, and also for materials.

1 2
9

10 6

2	7	3	braces.
18	2	4	rafters.
4	9	6	king-post.
	11	8	solidity of the struts.
53	0	9	solidity of the roof for workmanship.
	8	9	
52	4	0	solidity for materials.

Valuation of Carpenters' and Joiners' Work.

Memoranda.

50 cubic feet of timber equal one load.
100 feet superficial, equal one square.
120 deals are called one hundred.
A reduced deal is 1½ in. thick, 11 inches wide, and 12 ft. long.
120 12 feet 3 inch deals, equal 5¾ loads of timber.
400 feet superficial of 1½ in. plank or deals, equal one load.
Planks are 11 inches wide, deals 9 inches; and battens 7 inches.

A square of flooring requires—	Number of 12 feet boards.
Laid rough	12¼
Ditto edges shot	12½
Wrought and laid folding	13
— straight joint	13½
— — and ploughed and tongued	14
	Number of 12 feet battens.
One square of wrought folding floors requires	17
Ditto straight joint	18

Weight of Timber.

39 cubic feet of	oak	equal	1 ton.
65 —	fir	—	do.
66 —	deals	—	do.
60 —	elm	—	do.
51 —	beech	—	do.
45 —	ash	—	do.
35 —	mahogany	—	do.

JOINERS' WORK.

In boarded flooring, the dimensions must be taken to the very extreme parts, and from thence the squares are to be computed; out of which deductions are to be made for staircases, chimneys, &c.

Weather-boarding is done by the yard square, and sometimes by the square, containing 100 superficial feet.

Boarded partitions are measured by the square; out of which must be deducted the doors and windows, except they are agreed to be included.

Windows are generally made and valued by the foot superficial, and sometimes by the window. When they are measured, the dimensions must be taken in feet and inches, from the under side of the sill to the upper side of the top rail, for the height; and for the breadth, from outside to outside of the jambs; the product of these is the superficial content. For farther particulars, see the article JOINERY.

Example.—How many feet does a piece of dwarf wainscoting contain, that is 18 feet 7 inches long, and 5 feet 3 inches high?

By cross multiplication.	By decimals.
18 6	18.5
5 3	5.25
1 6	925
54	370
30	925
12) 85	97.125
7 1	
90	
97 1 6	

PAINTERS' WORK.

This work is measured by the yard square, and the dimensions are taken in feet, inches, and tenths.

In painters' work, every part that is coloured is measured; consequently the dimensions must be taken with a line girt over the mouldings. Ornamental work must be paid double measure; and if carved, at per value, according to the time.

Iron or wood railings, balusters, &c., to be measured on both sides as solid work, at per yard superficial. The following contracts may be used for common work—

First coat, including stopping	.027
Second, and following coats	.019

PLASTERERS' WORK.

This is done by the yard square, and the dimensions are taken in feet and inches.

When a room consists of more than four quoins, the additional corners must be allowed at per foot run.

In measuring ceilings with ribs, the superficies must first be taken for the plain work; then an allowance must be made for each mitre, and the ribs must be valued at so much per foot run, according to the girt, or by the foot superficial, allowing moulded work.

In measuring common work, the principal things to be observed are as follow:

1. To make deductions for chimneys, windows, and doors.
2. To make deductions for rendering upon brickwork, for doors and windows.
3. If the workman find materials for rendering between quarters, one-fifth must be deducted for quarters; but if workmanship only is found, the whole must be measured as whole work, because the workman could have performed the whole much sooner, if there had been no quarters.
4. All mouldings in plaster work are done by the foot superficial, as joiners do, by girting over the mouldings with a line.

When rooms have cornices, measure the ceiling or walls, including half the width or height of the cornice respectively, except when the cornices are bracketed, and then only measure up to them. In measuring the length of cornices, take the size of the room, taking one projection in and one out, and girt the cornices. Enriched friezes, &c., must be measured first as plain work, and the enrichments taken separately afterwards.

Valuation of Plasterers' Work.—Calculation of Materials.

1 hundred of lime = 25 striked bushels (old measure).

	Materials.	Labour.
100 yards of render set require	$1\frac{1}{2}$ hod. of lime. 1 double load of sand. 4 bushels of hair.	Plasterer, Labourer and Boy, 3 days each.
130 yards of lath plaster, and set require	1 load of laths. 10,000 nails. $2\frac{1}{2}$ hds. of lime. $1\frac{1}{2}$ dble. lds. of sand. 7 bushels of hair.	Plasterer, Labourer, and Boy, 6 days each.

Lathing.

1 bundle of laths and 384 nails will cover 5 yards.

Render only.

$187\frac{1}{2}$ yards require . . . . . $1\frac{1}{2}$ hod. of lime. 2 double loads of sand. 5 bushels of hair.

Floating requires more labour, but not more than half the quantity of stuff as rendering.

Setting only.

375 yards require . . . . $1\frac{1}{2}$ hod. of lime. 5 bushels of hair.

20 per cent. is always allowed on the prime cost of the materials.

Calculation of Labour.

The decimal is to be multiplied by the rate of wages for plasterer, labourer, and boy, per day.

	Days.
Rough render	.019
Floating render	.021
Setting	.016
Lathing	.019
If circular work, add on the lathing, and also on each coat of plastering	.008
If to groins, add as before	.001

GLAZIERS' WORK.

Glaziers' work is measured by the foot superficial, and the dimensions are taken in feet, tenths, hundredths, &c. For this purpose, their rules are generally divided into decimal parts, and their dimensions squared according to decimals.

Circular, or oval windows, are measured as if they were rectangular; because in cutting the squares of glass there is a very great waste, and more time is expended than if the windows had been of a rectangular form.

Example.—How many feet superficial of glazing does a window contain, that is 7.25 high and 3.75 wide?

```
   7.25
   3.75
   ----
   3625
  5075
 2175
 -------
 27.1875 feet, the answer.
```

Plumbers' Work.

This is generally done by the pound, or hundredweight.

Sheet lead, used in roofing, for guttering and valleys, is in weight from 7lb. to 12lb. per foot; and for ridges from 6lb. to 8lb.

The following table will show the weight of a foot, according to several thicknesses.

The thickness is set in tenths and hundredths of an inch, in the first vertical column; and the weight opposite, in the same horizontal line, in the second vertical column on the right hand: the integers show the number of pounds avoirdupois, and the decimals the number of thousandth parts above the integer: so that the weight of a square foot of $\frac{1}{10}$ or .10 of an inch thick is 5lb. and 899 thousandth-parts.

Thickness.	lbs. to a sq. foot.
.10	5.899
.11	6.489
$\frac{1}{9}$ = .11 &c.	6.554
.12	7.078
$\frac{1}{8}$ = .125	7.373
.13	7.668
.14	8.258
$\frac{1}{7}$ = .14 &c.	8.427
.15	8.848
.16	9.438
$\frac{1}{6}$ = .16 &c.	9.831
.17	10.028
.18	10.618
.19	11.207
$\frac{1}{5}$ = .20	11.797
.21	12.387

Example.—What is the weight of a sheet of lead, 25 feet 6 inches long, and 3 feet 3 inches broad; at 8½lb. to the square foot?

```
   3.25
   25.5
   ----
   1625
  1625
  650
  ------
  82.875
     8.5
  ------
  414375
 663000
 -----------
 704.4375lbs., as required.
```

Lead-headed nails, wall-hooks, and hold-fasts, are charged at per piece; clout-nails by the hundred: all kinds of pipes are charged at per foot run according to size of bore. Washers, plugs, valves, &c., at so much each. Joints are charged separately.

Paviors' Work.

Paviors' work is done by the square yard.

Example.—Suppose a pathway to be 45 feet 6 inches long, and the breadth 12 feet 3 inches; how many square yards does it contain?

```
     45.5 length.
    12.25 breadth.
    -----
     2275
     910
    910
   455
   -------
9) 557.375
   -------
   61.930 the number of yards required.
```

The decimals will be reduced to feet by multiplying them by 9; thus,

```
  .930
     9
 -----
 8.370 feet.
```

It is not necessary to go any farther, as the value of the next denomination is not worth the trouble.

Slaters' Work.

If the roof be equally hipped on all sides with a flat at top, and the plan of the building be rectangular, add the length and breadth of two adjoining sides at the eaves, and the length and breadth of two adjoining sides of the flat together; multiply the sum by the breadth of the slope, and the product will give the area of the space that is covered.

Add the number of square feet produced by multiplying the girt of the roof by the length of a slate at the eaves, to the area, for the trouble of putting on the double row of slates; also add the number of square feet produced by multiplying the length of the hips by one foot in breadth, for the trouble of cutting the slates where they meet, to the said area; and the sum will be the whole contents, so as to make a compensation for the trouble and waste of materials.

Example.—Suppose a house 40 feet 6 inches in width and 60 feet 3 inches in length; the breadth of the slope 15 feet 9 inches, the breadth of the flat 12 feet, and the length 31 feet 9 inches.

```
     Ft.  In.
     40   6
     60   3
     12   0
     31   9
    -------
    144   6
     15   9
    ----------
          4   6
   1296
     90
    -----
12) 1390
    ---------
    115  10
    720
    144
    -------------
   2275  10   6 the area.
```

To this area add the allowances for workmanship and waste.

If there be no flat, add the two adjoining sides and twice the length of the ridge, for the length; multiply the sum by the breadth of the slope, for the area of the space covered; then add the allowances as before.

Mensuration of Timber.

The following rules are from Dr. Hutton's Mensuration.

"Problem I.—*To find the area or superficial feet in a board or plank.*

"Rule.—Multiply the length by the mean breadth.

"*Note.*—When the board is tapering, add the breadth at the two ends together, and take half the sum for the mean breadth.

By the sliding rule.—Set 12 on B to the breadth in inches on B; then against the length in feet on B, is the content on A, in feet and fractional parts.

"*Example* 1.—What is the value of a plank, whose length is 12 feet 6 inches, and mean breadth 11 inches; at 1½*d.* per square foot?

	By decimals.		By duodecimals.
	12.5		12 6
	11		11
12	137.5	1½*d.* is ⅛	11 5 6
1½*d.* is ⅛	11.46		1*s.* 4½*d.*
	1*s.* 5*d.* ans.	5 in. is	0 ½
			1*s.* 5d.

"*By the sliding rule.*

"As 12B : 11A : : 12½B : 11½A.

"That is, as 12 on B is to 11 on A, so is 12½ on B to 11½ on A.

"*Example* 2.—Required the content of a board, whose length is 11 feet 2 inches, and breadth 1 foot 10 inches.—Answer, 20 feet, 5 inches, and 8 seconds.

"*Example* 3.—What is the value of a plank, which is 12 feet 9 inches long, and 1 foot 3 inches broad, at 2½*d.* a foot—Answer, 3*s.* 3¾*d.*

"*Example* 4.—Required the value of five oaken planks, at 3*d.* per foot, each of them being 17½ feet long; and their several breadths as follow, namely, two of 13½ inches in the middle; one of 14¼ inches in the middle, and the two remaining ones, each 18 inches at the broader end, and 11¼ at the narrower.—Answer, £1 5*s.* 8¼*d.*

"Problem II.—*To find the solid content of squared or four-sided timber.*

Rule.—Multiply the mean breadth by the mean thickness, and the product again by the length, and the last product will give the content.

"*By the sliding rule.*

	C		D		D		C
"As	length	:	12 or 10	: :	quarter girt	:	solidity.

"That is, as the length in feet on C, is to 12 on D when the quarter girt is in inches, or to 10 on D when it is in tenths of feet; so is the quarter girt on D, to the content on C.

"*Note* 1.—If the tree taper regularly from the one end to the other, either take the mean breadth and thickness in the middle, or take the dimensions at the two ends, and then half their sum for the mean dimensions.

"2. If the piece do not taper regularly, but is unequally thick in some parts, and small in others, take several different dimensions, add them all together, and divide their sum by the number of them, for the mean dimensions.

"3. The quarter-girt is a geometrical mean proportional between the mean breadth and thickness; that is, the square root of their product. Sometimes unskilful measurers use the arithmetical mean instead of it, that is, half their sum; but this is always attended with error, and the more so as the breadth and depth differ the more from each other.

"*Example* 1.—The length of a piece of timber is 18 feet 6 inches, the breadth at the greater and less end 1 foot 6 inches and 1 foot 3 inches, and the thickness at the greater and less end 1 foot 3 inches and 1 foot: required the solid content.

Decimals.		Duodecimals.
1.5		1 6
1.25		1 3
2) 2.75		2) 2 9
1.375	mean breadth	1 4 6

12375000		9 3 4
1546875		
28.6171875	content	28 7 4 10

"*By the sliding rule.*

	B		A		B		A
"As	1	:	13½	: :	16½	:	223, the mean square.
	C		D		C		D
"As	1	:	1	: :	223	:	14.9, quarter-girt.
	C		D		D		C
"As	18½	:	12	: :	14.9	:	28.6, the content.

"*Example* 2.—What is the content of the piece of timber, whose length is 24½ feet, and the mean breadth and thickness each 1.04 feet?—Answer, 26½ feet.

"*Example* 3.—Required the content of a piece of timber, whose length is 20.38 feet, and its ends unequal squares, the side of the greater being 19½ inches, and the side of the less 9¾ inches.—Answer, 29.7562 feet.

"*Example* 4.—Required the content of a piece of timber, whose length is 27.36 feet; at the greater end the breadth is 1.78, and thickness 1.23; and at the less end the breadth is 1.04, and thickness 0.91?—Answer, 41.278 feet.

"Problem III.—*To find the solidity of round or unsquared timber.*

"Rule 1, or Common Rule.—Multiply the square of the quarter-girt, or of one-fourth of the mean circumference, by the length, for the content.

"*By the sliding rule.*—As the length upon C : 12 or 10 upon D : : quarter girt, in 12ths or 10ths, on D : content on C.

"*Note* 1.—When the tree is tapering, take the mean dimensions, as in the former Problems, either by girting it in the middle for the mean girt, or at the two ends, and take half the sum of the two. But when the tree is very irregular divide it into several lengths, and find the content of each part separately.

"2. This rule, which is commonly used, gives the answer about one-fourth less than the true quantity in the tree, or nearly what the quantity would be after the tree is hewed square in the usual way; so that it seems intended to make an allowance for the squaring of the tree. When the true quantity is desired, use the second rule given below.

"*Example* 1.—A piece of round timber being 9 feet 6 inches long, and its mean quarter-girt 42 inches; what is the content?

Decimals.		Duodecimals.
3.5	quarter girt	3 6
3.5		3 6
175		10 6
105		1 9
12.25		12 3
9.5	length	9 6
6125		110 3
11025		6 1 6
116.375	content	116 4 6

"*By the sliding rule.*

	C		D		D		C
As	9.5	:	10	: :	35	:	116⅓
Or	9.5	:	12	: :	42	:	116⅓

"*Example* 2.—The length of a tree is 24 feet, its girt at the thicker end 14 feet, and at the smaller end 2 feet; required the content.—Answer 96 feet.

"*Example* 3.—What is the content of a tree, whose mean girt is 3.15 feet, and length 14 feet 6 inches?—Answer, 8.9922 feet.

"*Example* 4.—Required the content of a tree, whose length is 17¼ feet, and which girts in five different places as follows, namely, in the first place 9.43 feet, in the second 7.92, in the third 6.15, in the fourth 4.74, and in the fifth 3.16.—Answer, 42,5195.

"Rule 2.—Multiply the square of one-fifth of the mean girt by double the length, and the product will be the content, very near the truth.

"*By the sliding rule.*—As the double length on C : 12 or 10 on D : : ⅕ of the girt, in 12ths or 10ths, on D : content on C.

"*Example* 1.—What is the content of a tree, its length being 9 feet 6 inches, and its mean girt 14 feet?

Decimals.		Duodecimals.
2.8	⅕ of girt	2 9 7

7056		7 10 1
784		19
148.96	content	148 11 7

"*By the sliding rule.*

	C		D		D		C
As	19	:	10	: :	28	:	149.
Or	19	:	12	: :	$33\frac{6}{16}$	:	149.

"*Example* 2.—Required the content of a tree, which is 24 feet long, and mean girt 8 feet.—Answer, 122.88 feet.

"*Example* 3.—The length of a tree is 14½ feet, and mean girt 3.15 feet; what is the content?—Answer, 11.51 feet.

"*Example* 4.—The length of a tree is 17¼ feet, and its mean girt 6.28; what is the content?—Answer, 54.4065 feet.

"*Note* 1.—That part of a tree, or of the branches, which is less than 2 feet in circumference, or 6 inches quarter-girt, is cut off; not being accounted timber.

"2.—Fifty cubic feet of timber make a load; and therefore, to reduce feet to loads, divide them by 50."

Example.—How many loads of timber are there in 248 feet?

5,0) 24,8

4 48

So that this quantity contains four loads and 48 feet.

It is customary, however, to make a difference between square and round timber, in many places. The load of round timber containing 50 cubic feet, while that of square timber contains only 40. This allowance is reasonable, on account of the waste.

"A Table,

"*For readily finding the Content of Trees, according to the common Method of Measuring Timber.*

"Rule.—Seek the quarter-girt in the first column towards the left-hand, and take out the number opposite. Multiply that number by the length of the tree in feet, &c., and the product will be the content in solid feet, &c.

Scholium.—In measuring squared timber, unskilful measurers usually take one-fourth of the circumference, or girt, for the side of a mean square; which quarter girt therefore multiplied by itself, and the product multiplied by the length, they account the solidity, or content: when the breadth and thickness are nearly equal, this method will give the solidity pretty near the truth; but if the breadth and thickness differ considerably, the error will be so great, that it ought by no means to be neglected.

"Thus, suppose we take a balk, 24 feet long, and a foot square throughout; and consequently its solidity 24 cubic feet: if this balk be slit exactly in two, from end to end, making each piece 6 inches broad, and 12 inches thick, the true solidity of each will be 12 feet; but, by the quarter-girt method, they would amount to much more; for the false quarter girt, being equal to half the sum of the breadth and thickness, in this case will be 9 inches, the square of which is 81, which being divided by 144, and the quotient multiplied by 24. the length, we obtain $13\frac{1}{2}$ feet for the solidity of each part; and consequently the two solidities together make 27 feet, instead of 24.

"Again, suppose the balk to be so cut, that the breadth of one piece may be 4 inches, and that of the other 8 inches. Here the true content of the less piece will be 8 feet, and that of the greater 16 feet. But, proceeding by the other method, the quarter-girt of the less piece will be 8, whose square, 64, multiplied by 24, and the product divided by 144, gives $10\frac{2}{3}$ feet instead of 8. And by the same method, the content of the greater piece will be $16\frac{2}{3}$ feet, instead of 16. And the sum of both is $27\frac{1}{3}$ feet, instead of 24 feet.

"Farther, if the less piece be cut only 2 inches broad, and the greater 10 inches; the true content of the less piece would be 4 feet, and that of the greater 20. But, by the other method, the quarter-girt of the less piece would be 7 inches, whose square, 49, being divided by 6, gives $8\frac{1}{6}$ feet, instead of 4, for the content. And, by the same method, the content of the greater piece would be $20\frac{1}{6}$, instead of 20 feet. So that their sum would be $28\frac{1}{3}$, instead of 24 feet.

"Hence it is evident, that the greater the proportion between the breadth and depth, the greater will the error be, by using the false method; that the sum of the two parts, by the same method, is greater, as the difference of the same two parts is greater, and consequently the sum is least when the two parts are equal to each other, or when the balk is cut equally in two; and lastly, that when the sides of a balk differ not above an inch or two from each other, the quarter-girt method may then be used, without inducing an error that will be of any material consequence.

"Problem IV.—*To find where a piece of round tapering timber must be cut, so that the two parts, measured separately, according to the common method of measuring, shall produce a greater solidity than when cut in any other part, and greater than the whole.*

"Rule.—Cut it through exactly in the middle, or at half of the length, and the two parts will measure to the most possible, by the common method.

"*Example.*—Supposing a tree to girt 14 feet at the greater end, 2 feet at the less, and consequently 8 feet in the middle; and that the length is 32 feet.

"Then, by the common method, the whole tree measures to only 128 feet; but when cut through at the middle, the greater part measures 121, and the less part to 25 feet; whose sum is 146 feet; which exceeds the whole by 18 feet, and is the most that it can be made to measure to by cutting it into two parts.

"Demonstration.—Put G = the greatest girt, g = the least, and x = the girt at the section; also L = the whole length, and z = the length to be cut off the less end.

"Then, by similar figures, $L : z :: G - g : x - g$. Hence $x = \frac{Gz - gz}{L} + g$. But $(g + x)^2 . z + (G + x)^2 . (L - z)$ = a maximum; whose fluxion being put equal to nothing, and the value of x substituted instead of it, there results $z = \frac{1}{2} L$. Q. E. D.

"Corollary.—By thus bisecting the length of a tree, and then each of the parts, and so on, continually bisecting the lengths of the several parts, the measure of the whole will be continually increased.

"Problem V.—*To find where a tree should be cut, so that the part next the greater end may measure to the most possible.*

"Rule.—From the greater girt take 3 times the less; then, as the difference of the girts is to the remainder, so is one-third of the whole length, to the length from the less end to be cut off.

"Or, cut it where the girt is one-third of the greatest girt.

"*Note.*—If the greatest girt do not exceed three times the least, the tree cannot be cut as is required by this problem. For, when the least girt is exactly equal to one-third of the greater, the tree already measures to the greatest possible; that is, none can be cut off, nor indeed added to it, continuing the same taper, that the remainder or sum may measure to so much as the whole: and when the least girt exceeds one third of the greater, the result by the rule shows how much in length must be added, that the result may measure to the most possible.

"*Example.*—Taking here the same example as before, we shall have, as $12 : 8 :: \frac{3}{32} : 7\frac{1}{9}$ = the length to be cut off; and consequently the length of the remaining part is $24\frac{8}{9}$; also $\frac{14}{3} = 4\frac{2}{3}$ is the girt of the section. Hence the content of the remaining part is $135\frac{41}{81}$ feet; whereas the whole tree, by the same method, measures only to 128 feet.

"Demonstration.—Using the same notation as in the last demonstration; we have here also $x = \frac{Gz - gz}{L} + g$, and $(G + x)^2 . (L - x)$ = a maximum; which, treated as before, gives $z = \frac{G - 3g}{G - g} \times \frac{1}{3} L$. And $x = \frac{G - g}{L} z + g \frac{1}{3} G$, by substituting the above value of z. Q. E. D.

"Problem VI.—*To cut a tree so as that the part next the greater end may measure, by the common method, to exactly the same quantity as the whole measures to.*

Rule.—Call the sum of the girts of the two ends s, and their difference d, then multiply by the sum of d and $4s$, thus:

$$d \times (d + 4s).$$

From the root of the product take the difference between d and $2s$, thus:

$$\sqrt{(d^2 + 4ds)} - 2s + d.$$

Then, As twice d—is to the remainder,
So is the whole length—to the length to be cut off;

Thus calling the whole length L, and the part to be cut off l, we have:

$$2d : \sqrt{(d^2 + 4ds)} - 2s + d :: L : l = \frac{L}{2d}$$
$$\times (\sqrt{(d^2 + 4ds)} - 2s + d).$$

Example.—Using still the same numbers as in the preceding examples, we have, $s = 16$, $d = 12$, and $L = 32$.

$$l = \frac{L}{2d} \times (\sqrt{(d^2 + 4ds)} - 2s + d) = \frac{32}{2 \times 12} \times$$
$$(\sqrt{(12^2 + 4 \times 12 \times 16)} - 2 \times 16 + 12) = \frac{4}{3} \times$$
$$(\sqrt{(144 + 768)} - 20)\frac{4}{3} \times (\sqrt{(912)} - 20) = \frac{4}{3} \times$$
$$(30.1993377 - 20) = \frac{4}{3} \times 10.199337 = 13.5991198$$ the length to be cut off.

Therefore the length of the remaining part is 32 — 13.5991168 = 18.4008832.

And if s be taken from the root, viz. $\sqrt{(d^2 + 4ds)}$ half the remainder will be the girt of the section. Therefore, according to the numbers given, the girt of the section $\frac{\sqrt{(d^2 + 4ds)} - s}{2} = \frac{30.1993377 - 16}{2} = 7.0996688.$

Hence the girt in the middle of the greater part is $\frac{14 + 7.099669}{2} = 10.549834$, whose fourth part is 2.637458;

and consequently the content of the same part is $2.637458^2 \times 18.40083 = 128$, the very same as the whole tree measures to, notwithstanding above one-third part is cut off the true length.

"*Note.*—The principles of these last three Problems are also applicable to the new, or second rule, in page 361, and indeed to any other approximate rule, or such as is not founded on the rule for the frustum of a cone.

"DEMONSTRATION.—Using still the same notation, we shall have $s^2 L = (L - 2) \times (G + x)^2$; hence, instead of x, substituting its value $\frac{dz}{L} + g$, we obtain $z = \frac{L}{2d} \times (\sqrt{(4s + d).d}) - (2s + d)$.

"And hence $x = \frac{1}{2}(\sqrt{(4s + d).d}) - \frac{1}{2}s$. Q. E. D."

Rules have already been given for measuring the areas of circular segments, which may at least be depended upon to three places of figures, and which we have thought sufficiently correct for most practical purposes; but where greater accuracy is required, the following Table will carry the approximation to five or six figures.

The construction which comes after the Table depends upon the following series for the segment of a circle.

The area of the segment is $A + \frac{Av}{5V} - \frac{1Bv}{7V} + \frac{3Cv}{9V} - \frac{5Dv}{11V} + \frac{7Ev}{13V}$, &c. where $A = \frac{4v}{3}\sqrt{vV}$, B, the second, C the third, &c. *See* also Rules 3 and 4, Theorem XI., page 171, which are the same in principle as this.

A TABLE

Of the Areas of the Segments of a Circle, whose diameter is Unity, and supposed to be divided into 1000 *equal Parts.*

To find the Area of the Segment of a circle by the preceding Table.

Divide the height of the segment by the diameter of the circle, so that the quotient may contain three places of decimals; look for the corresponding number to the quotient in the column height, then take out the number in the same horizontal row in the vertical column, intitled *Area Seg.* at the top; multiply the square of the diameter by the number thus taken out, and the product will be the area of the segment.

Example.—Required the area of the segment of a circle, the height of which is two, and the diameter of the circle 52.

```
52)2.000(.038
    156
    ---
    440
    416
    ---
     24
```

There remains 24, which is $\frac{24}{52} = \frac{6}{13}$.

The area of the segment corresponding to .038, is .009763, but since there is a fraction over and above .038 of $\frac{6}{13}$, find the next greater area .010148; take the difference between these two areas, which is .000385, multiply this difference by the fraction $\frac{6}{13}$, and it gives, .000177, which being added to .009763, gives .009940 for the area of the segment, answering to $.038\frac{6}{13}$.

The table is founded upon the following principle: Let the diameter of a circle be 1, which suppose divided into 1,000 equal parts, through every one of which imagine perpendiculars drawn and continued both ways to the circumference.

Then, since the versed sine is .001, we have $v = .001$ and $\frac{v}{\text{V}} = \frac{.001}{999} = \frac{.1}{999}$; therefore $\text{A} = \frac{4\,v}{3}\sqrt{v\,\text{V}} = \frac{4}{3000}\sqrt{.000999} = .00004214$, and $\text{B} = \frac{\text{A}\,v}{5\,\text{V}} = \frac{.00004215}{999 \times 5} = .00000001$, whence the first number of the table is .00004215.

The second versed sine is $.002 = v$, therefore $\text{V} = .998$ and $\frac{v}{\text{V}} = \frac{2}{998} = \frac{1}{199}$, whence $\text{A} = \frac{8}{3000}\sqrt{.001996} = .00011914$, and $\text{B} = \frac{\text{A}\,v}{5\,\text{V}} = \frac{.00011914}{499 \times 5} = .00000005$; therefore the second number is .00011919.

The third versed sine is $.003 = v$, therefore $\text{V} = 1 - .003 = .997$, whence $\frac{v}{\text{V}} = \frac{4}{997}$, and $\text{A} = \frac{12}{3000}\sqrt{0002991} = .00021876$: also $\text{B} = \frac{\text{A}\,v}{5\,\text{V}} = \frac{.00021876 \times 3}{5 \times 997} = .00000013$; thence the third number of the Table is .00021889.

And by this method the whole might be computed; but after a sufficient number of terms are found at the beginning of the table, the rest may be had (to seven or eight places of decimals) by this rule: let a, β, γ, δ, denote any four terms succeeding in the order of the letters, then $\delta = a + \overline{\beta \times \gamma - \beta}$.

And if any term of this Table be divided by 78539816, or multiplied by its reciprocal, it will produce the common table of segments, when the area is unity.

MERIDIAN, in astronomy, a great circle of the sphere, passing through the zenith, nadir, and poles of the world, crossing the equinoctial at right angles, and dividing the sphere into two hemispheres, the one eastern and the other western.

It is called meridian, from the Latin *meridies*, *noon*, or *mid-day*, because when the sun is in this circle, it is noon in all places situated under it.

MERIDIAN, in geography, a great circle, as PAQD, passing through the poles of the earth P and Q. and any given place at Z. So that the plane of the terrestrial meridian is in the plane of the celestial one.

Hence, 1. As the meridian invests the whole earth, there are several places situated under the same meridian. And, 2. As it is noon-tide whenever the centre of the sun is in the meridian of the heavens, and as the meridian of the earth is in the plane of the former, it follows, that it is noon at the same time, in all places situate under the same meridian. 3. There are as many meridians on the earth as there are points conceived in the equator. In effect, the meridians always change, as the longitude of the place is varied; and may be said to be infinite; each respective place, from east to west, having its respective meridian.

Meridian, *First*, is that from which the rest are accounted, reckoning from west to east. The first meridian is the beginning of longitude.

The fixing of the first meridian is merely arbitrary; and hence different persons, nations, and ages, have fixed it differently; whence some confusion has arisen in geography. The rule among the ancients was, to make it pass through the place farthest to the west that was known. But the moderns, knowing that there is no such place in the earth as can be esteemed the most westerly, the way of computing the longitudes of places from one fixed point is much laid aside.

But without much regard to any of these rules, our geographers and map-makers frequently assume the meridian of the place where they live, or the capital of their country, for a first meridian; and thence reckon the longitudes of their places.

The astronomers, in their calculations, usually choose the meridian of the place where their observations are made, for their first meridian; as Ptolemy, at Alexandria; Tycho Brahe, at Uranibourg; Riccioli, at Bologna; Mr. Flamsteed, at the Royal Observatory at Greenwich; and the French, at the Observatory at Paris.

Meridian Line, an arc, or part of the meridian of the place, terminated each way by the horizon. Or, a meridian line is the intersection of the plane of the meridian of the place with the plane of the horizon, vulgarly called a *north and south line*, because its direction is from one pole towards the other.

The use of a meridian line in astronomy, geography, dialing, &c., is very great, and on its exactness all depends; whence infinite pains have been taken by divers astronomers to fix it with the utmost precision. M. Cassini has distinguished himself by a meridian line drawn on the pavement of the church of S. Petronio, at Bologna, the largest and most accurate in the world; being 120 feet in length. In the roof of this church, 1,000 inches above the pavement, is a little hole, through which the sun's rays, when in the meridian, falling upon the line, mark his progress all the year. When finished, M. Cassini, by a public writing, informed the mathematicians of Europe of a new oracle of Apollo, or the Sun established in a temple, which might be consulted, with entire confidence, as to all difficulties in astronomy.

To draw a meridian line.

On the horizontal plane, from the same centre, c, draw several arcs of circles, B A, *b a*, &c., and on the same centre, c, erect a style, or gnomon, perpendicular to the plane A C B, a foot, or half a foot long. About the 21st of June, between the hours of nine and eleven in the morning, and between one and three in the afternoon, observe the points B, *b*, &c., A, *a*, wherein the shadow of the style terminates. Bisect the arcs A B, *a b*, &c., in D, *d*, &c. If then the same right line, D E, bisect all the arcs, A B, *a b*, &c., it will be the meridian line sought.

As it is difficult to determine the extremity of the shadow exactly, it is best to have the style flat at top, and to drill a little hole, noting the lucid spot projected by it on the arcs A B and *a b*, instead of the extremity of the shadow. Otherwise the circles may be made with yellow, instead of black, &c.

If the meridian line be bisected by a right line, O V, drawn perpendicularly through the point C, O V will be the intersection of the meridian, and first vertical; and, consequently, O will show the east point, and V the west.

Lastly,—If a style be erected perpendicularly in any other horizontal plane, and a signal be given when the shadow of the style covers the meridian line drawn in another plane, noting the apex, or extremity, of the shadow projected by the style, a line drawn from that point through that wherein the style is raised, will be a meridian line.

Meridian Line, on a dial, is a right line arising from the intersection of the meridian of the place with the plane of the dial. This is the line of twelve o'clock, and from hence the division of the hour-line begins.

MERLON, the elevated or solid portion of a battlement which alternates with the embrasures.

MEROS, (Greek,) the middle part of the triglyph. The breadth of the triglyph is divided into six parts; of which five are placed in the middle, two and a half being on either side. The middle one makes the regula, or femur, which the Greeks call *meros*. On either side of this are the channels, sunk as if imprinted with the elbow of a square. To the right and left of these another femur is formed, and at the extremities semi-channels are slanted.

MESAULÆ, in Grecian architecture, passages between the peristylium and hospitalium; the same as the audionas of the Romans. *See* House.

META, the goal in the Roman circus to which the chariots ran.

METAGENAS, a Grecian architect, who wrote a description of the temple of Diana at Ephesus; he also jointly conducted this edifice with his father Ctesiphontes, the Gnossian.

METALS. *See* Materials, Iron, &c.

METATOME, the interval between two dentals.

METEZAU, CLEMENT, a celebrated French architect, who flourished in the former part of the seventeenth century, was a native of Dreux, but settled at Paris, became architect to Louis XIII., and acquired much fame by carrying into execution, with Tiriot, a Parisian mason, the plan suggested by Cardinal Richelieu, for reducing Rochelle by means of an immense dyke, in imitation of what Cæsar had done at Durazzo, and Alexander the Great at Tyre. This scheme was to run a solid wall across a gulf upwards of 740 fathoms, or more than three-quarters of a mile broad, into which the sea rolled with great force, and, when the wind was high, with an impetuosity which seemed to set at defiance the art of man. Those who had undertaken the business were not to be turned aside by any obstacles: they began by throwing in huge rocks, to lay a kind of foundation; upon these were placed vast stones, cemented by the mud thrown up by the sea. These were supported by immense beams, driven into the bottom with incredible labour. It was raised so high that the soldiers were not incommoded by the water even at spring-tides. The platform was nearly 30 feet wide, and 90 feet at the foundation. At each extremity there was a strong fort, in the middle there was an open passage of 150 paces, several vessels being sunk immediately before it, together with high stakes in a double row, and before these thirty-five vessels linked together, so as to form a kind of floating palisade. This amazing dyke was completed in somewhat less than six months, and proved the principal means of occasioning the surrender of the city. So honourable were the exertions of M. Metezau in this business, that his portrait was circulated widely through France, to which were attached the following lines:

> "Dicitur Archimedes Terram potuisse movere;
> Æquora qui potuit sistere, non minor est."

METOCHE, (from the Greek μετοχε), in ancient architecture, a term used by Vitruvius, to signify the space or interval between the dentils of the Ionic, or triglyphs of the Doric orders.

Baldus observes, that, in an ancient MS. copy of that author, the word *metatome* is found for *metoche.* Hence Daviler takes occasion to suspect that the common text of Vitruvius is corrupted, and concludes that it should not be *metoche*, but *metatome*, q. d. *section.*

METOPE, or Metopa, (from μετα, *inter*, *between*, and οπη, *an aperture*), in architecture, the square piece or interval between the triglyphs, in the Doric frieze. In the original Greek the word signifies the distance between one aperture, or hole, and another, or between one triglyph and another; the triglyphs being supposed to be solives, or joists, that fill the apertures.

Vitruvius having shown that the Doric order took its rise from the disposition of the timberwork in the construction of the original hut, proceeds as follows:

"From this imitation, therefore, arose the use of triglyphs and mutules in Doric work: for it cannot be, as some erroneously assert, that the triglyphs represent windows; because triglyphs are disposed in the angles, and over the quarters of the columns, in which places windows are not permitted; for if windows were there left, the union of the angles of buildings would be dissolved; also, if the triglyphs are supposed to be situated in the place of the windows, by the same reason the dentils in Ionic work may be thought to occupy the places of the windows; for the intervals between the dentils, as well as between the triglyphs, are called *metopæ*; the Greeks calling the bed of the joists and assers *opas*, (as we call it *cava*, *columbaria*;) so because the inter-joist is between two opæ, it is by them called *met-opæ*."

As some difficulty arises in disposing the triglyphs and metopes in that just symmetry which the Doric order requires, many architects use this order only in temples.

In the Doric order, it is not the space between the mutules, but the space between the triglyphs, that forms the metope.

From the authority of Stewart, in his *Ruins of Athens*, the following proportions are taken; where observe, that feet are distinguished by the mark (′) being placed over them, and inches thus (″); the numbers following the latter are decimals.

In the Doric portico at Athens, the breadth of the metope, or space between the triglyphs, is 3′ 3″ and 3′ 3″.6, (*see* Chap. I. Plate IV.); the height is 3′ 0″.7, including the band or capital over it, (*see* Plate V.): or without the band, 2′ 9″.05, (*see* Plate VI).

In the temple of Minerva, at Athens, (Vol. ii. Chap. I.) the height of the metope, without its capital, or band, is 3′ 11″.15, (*see* Plate VI.); and the breadth of the metope is 4′ 3″.35.

In the Propylæa, (Vol. II. Chap. V. Plate VI.) the breadth of the metope is 3′ 8″.25, and the height 3′ 9″.85, including the band and the bead over it; and in the entablature of the antæ (Plate IX.) the breadth of the metope is 2′ 8″.734, and the height 2′ 5″, without the band.

In the temple of Theseus, (Vol. III. Chap. I. Plate VI.) the breadth of the metope is 2′ 6″.475, and its height 2′ 8″.55, including a very broad band. So that the height of the tympan, or panel, is universally less than the breadth.

MEXICAN ARCHITECTURE, is remarkable chiefly as forming a specimen of the style and mode of building adopted by the aborigines of the New World. Their resemblance to some of the ancient edifices and forms of building prevalent in the eastern continent is curious, and worthy of comment. The only Mexican buildings of which we have any remains are the teocallis, or houses of God, which are almost universally of the pyramidal form, resembling the pyramids of Egypt, but bearing, it would seem, even a more striking similarity to the famous tower of Babel, as described by Herodotus and modern travellers. *See* Babylonian Architecture. This resemblance is especially pointed out by Humboldt, to whom we are indebted for the greater part of our information on the subject.

These teocallis were solid masses of earth raised up in a pyramidal form, having the shape of a truncated pyramid, and faced either entirely or partially with masonry. In the interior were small cavities similar to those discovered in the Egyptian pyramids, and which were evidently intended for places of sepulture. The sides of the pyramid often face the cardinal points, and are divided into steps or stories on the exterior, in both which particulars they resemble those of Egypt. Their similarity to the tower of Babel is noticed further in the temple at the top of the pyramid, and, the use to which both erections were put as observatories for astronomical purposes.

The largest temple in Mexico is the great pyramid of Cholula, which is constructed of alternate layers of unburnt bricks and clay, and consists of four stories. In the interior are cavities of considerable size, one of which, upon being laid open was found to contain skeletons and a number of curiously painted and varnished vases, thus proving their sepulchral character. The height of the pyramid is 177 feet, the length of a side of the base 1,423 feet, the area on the top 3,500 yards, and the number of steps to the top 120.

At Papantla, in the northern part of Vera Cruz, is a small pyramid, 80 feet square at the base and 60 feet high, divided into seven stories, and ascended by a flight of 57 steps. It is constructed of immense blocks of stone laid in mortar, the faces of which are covered with hieroglyphics, amongst which are to be seen serpents and crocodiles. There are also a number of niches regularly disposed round each story.

A mass of ruins known as the Casa Grande are situated in the gulph of California, on the banks of the Rio Gila: the sides facing the cardinal points are of irregular size, those from north to south measuring 445 feet, while those from east to west are only 276 feet. They are composed of unburnt bricks of irregular size, the walls being 4 feet in thickness, and divided into three stories.

"In the district of Oaxaca, south of Mexico, stands the palace of Mitla, contracted from Mignitlan, signifying, in Aztec, the *place of woe*. By the Tzapotec Indians the ruins are called *leoba* or *luiva* (burial or tomb), alluding to the excavations found beneath the walls. It is conjectured to have been a palace constructed over the tombs of the kings, for retirement, on the death of a relation. The tombs of Mitla are three edifices, placed symmetrically in a very romantic situation. That in the best preservation, and, at the same time the principal one, is nearly 130 feet long. A staircase formed in a pit, leads to a subterranean apartment 88 feet in length and twenty-six in width. This, as well as the exterior part of the edifice, is decorated with fret and other ornaments of similar character. But the most singular feature in these ruins, as compared with other Mexican architecture, was the discovery of six porphyry columns, placed for the support of a ceiling in the midst of a vast hall. They are almost the only ones which have been found in the new continent, and exhibit strong marks of the infancy of the art, having neither base nor capital. The upper part slightly diminishes. Their total height is 19 feet in single blocks of porphyry. The ceiling under which they were placed was formed by beams of sabine wood, and three of them are still in good preservation. The roof is of very large slabs. The number of separate buildings was originally five, and they were disposed with great regularity. The gate, whereof some vestiges are still discernible, led to a court 150 feet square, which, from the rubbish and remains of subterranean apartments, it is supposed was surrounded by four oblong edifices. That on the right is tolerably preserved, the remains of two columns being still in existence. The principal building had a terrace, raised between three and four feet above the level of the court, and serving as a base to the walls it surrounnds. In the wall is a niche with pillars four or five feet above the level of the floor. The stone lintel over the principal door of the hall is in a single block 12 feet long and 3 feet deep. The excavation is reached by a very wide staircase, and is in the form of a cross, supported by columns. The two portions of it which intersect each other at right angles are each 82 feet long by 25 feet wide. The inner court is surrounded by three small apartments having no communication with the fourth, which is behind the niche. The interiors of the apartments are decorated with paintings of weapons, sacrifices, and trophies. Of windows there are no traces. Humboldt was struck with the resemblance of some of the ornaments to those on Etruscan vases of Lower Italy. In the neighbourhood of these ruins are the remains of a large pyramid and other buildings."

The only remarkable monuments in the valley of Mexico, Mr. Humboldt tells us, are the remains of the two pyramids of San Juan de Teotihuacan, on the north-east of the lake Tezcuco, consecrated to the sun and moon, and called by the Indians Tonatiuh Ytzaqual, (house of the sun,) and Metzli Ytzaqual, (house of the moon.) Mr. Bullock visited this site on his return from Themasceltepec. For some time before he reaches the gate of Tezcuco, the traveller is apprised of his approach to a place of ancient importance by a large aqueduct still in use, and the ruins of several stone buildings. The Spanish quarters, built for Cortes, are still entire. Several tumuli are seen on entering the gates, which are supposed to have been teocallis. The most important ruin is what Mr. Bullock calls the site of the palace of the ancient caziques of Tezcuco, which, though in ruins, far surpassed every idea he had formed of ancient Mexican architecture. It extended 300 feet, forming one side of the great square, and was placed on sloping terraces, raised one above another by small steps. Some of these terraces are still entire, and are covered with cement, very hard, and equal in beauty to that found in ancient Roman buildings. From what is known of the extensive foundations of this palace, it must have occupied some acres of ground. It was composed of large blocks of basaltic stone, of about 4 or 5 feet long and 2½ or 3 feet thick, cut and polished with the utmost exactness. The sculptured stones from these ruins have been used in building the modern churches and houses. Heaps of ruins surround it on every side, and Tezcuco, the Athens of Anahuac, as it is called by a Spanish historian, would seem to invite, above all others in Mexico, the attention of the antiquary.

At about two leagues from Tezcuco, is a spot called Bano de Montezuma, Montezuma's Bath, on the summit of a conical hill called Tescosingo. "We scrambled with great difficulty," observes Mr. Bullock, "through bushes and over loose stones, which were in great quantities on all sides, and at last perceived that we were on the ruins of a very large building, the cemented stones remaining in some places covered with stucco, and forming walks and terraces, but much encumbered with earth fallen from above, and overgrown with a wood of nopal, which made it difficult to ascend." He discovered the bath on one of the sides of the hill. "It was cut in the solid rock, and standing out like a martin's nest from the side of a house. It is not only an extraordinary bath, but still more extraordinarily placed. It is a beautiful basin, about 12 feet long by 8 wide, having a well about 5 feet by 4 deep in the centre, surrounded by a parapet or ruin 2 feet 6 inches high, with a throne or chair such as is represented in ancient pictures to have been used by the kings. There are steps to descend into the basin or bath, the whole cut out of living porphyry rock, with the utmost mathematical precision, and polished in the most beautiful manner." The mountains appear to have been covered with palaces, temples, baths, hanging gardens, &c.; and Mr. Bullock was informed that he had seen but the commencement of the wonders of the place.

About two miles from Tezcuco, is the Indian village of Huexotla. Mr. Bullock observed, on his approach, several small pyramids of alternate layers of clay and unburnt brick, one of them had evidently an entrance in the centre, which was discovered by part of it having fallen in; within the town were the foundations of a palace, and two large reservoirs, with which it was supplied with water, remain entire. The ancient wall of the town, almost 30 feet high and very thick, extends to a considerable distance. It is singularly constructed, being divided into five unequal parts. The broadest division is built of large oval stones, with ends standing out, so as to give it the appearance of having been formed of human sculls. and it is divided from the rest by a projecting cornice. Beyond the walls, on the road to Tezcuco, a broad covered-way runs between two huge walls terminating near a river, which appears to have been one of the entrances to the town. Over the bed of the river, which is now dry, there is a remarkable bridge, with a pointed arch nearly 40 feet high, supported on one side by a mass of masonry in a pyramidal shape. It is ascribed to the ancient Mexicans; but if constructed on the principle of the arch, it must have been the work of European architects.

Mr. Bullock visited the celebrated pyramids of San Juan di Teotihuacan. "As we approached them," he says, "the square and perfect form of the largest became at every step more and more visibly distinct, and the terraces could now be counted. We rode first to the lesser, which is the most dilapidated of the two, and ascended to the top, over masses of fallen stone and ruins of masonry, with less difficulty than we expected. On the summit are the remains of an ancient building, 47 feet long and 14 wide; the walls are principally of unhewn stone, 3 feet thick and 8 feet high; the entrance at the south end, with three windows on each side, and on the north end it appears to have been divided at about a third of its length; we soon arrived at the foot of the largest pyramid, and began to ascend. It was less difficult than we expected, though, the whole way up, lime and cement are mixed with fallen stones. The terraces are perfectly visible, particularly the second, which is about 38 feet wide, covered with a coat of red cement 8 or 10 inches thick, composed of small pebble-stones and lime. In many places as you ascend, the nopal trees have destroyed the regularity of the steps, but nowhere injured the general figure of the square, which is as perfect in this respect as the great pyramid of Egypt. We everywhere observed broken pieces of instruments like knives, arrows, spear-heads, &c., of obsidian, the same as those found on the small hills of Cholula; and on reaching the summit, we found a flat surface of considerable size, but which has been much broken and disturbed. On it was probably a temple or some other building; report says, a statue covered with gold. We rested some time on the summit, enjoying one of the finest prospects imaginable, in which the city of Mexico is included. Here I found fragments of small statues and earthenware, and what surprised me more, oyster-shells, the first I had seen in Mexico. In descending, I also found some ornamental pieces of earthenware. The pattern, one of which is in relief, much resembling those of China, the other has a grotesque human face. On the north-east side, about half way down, at some remote period an opening has been attempted. This should have been from the south to the north, and on a level with the ground, or only a few feet above it, as all the remains of similar buildings have been found to have their entrances in that direction. According to the measurements made by Dr. Oteyza, a young Mexican savant, in 1803, the base of the larger pyramid is 682 feet long, and its elevation 180 feet perpendicular; Mr. Bullock thinks its height to be nearly half the base. The other pyramid, that of the moon, is 36 feet lower, and its base much smaller. They are constructed of clay mixed with small stones, covered with a thick facing of porous amygdaloid, over which was a coating of cement. There are four stages subdivided into smaller steps; a stair of hewn stone formerly led to their summits. Early travellers all mention the prevailing tradition, that their interior was hollow. Around them in the plain, there are several hundred smaller ones, in general about 30 feet high; which, according to the tradition, were dedicated to the stars. It is probable, however, that the whole plain was a vast burial-place, its Aztec name was Micaotl, the road of the dead; which the Spaniards, borrowing a word from the language of the island of Cuba, have rendered Llano de los Cues. They are supposed to be the most ancient of all the Mexican monuments."

MEZANINE, or Mezzanine, a word borrowed from the Italians, who call *mezzanini* those little windows, less in height than breadth, which serve to illuminate an attic, or entresole. It is used by some architects, to signify an intermediate apartment, frequently introduced into the principal story when all the rooms are not required to be of the same height; so that where mezanines are introduced, the principal story is divided into two heights, in order to make store-rooms, or lodging-rooms for servants. *See* Apartment.

MEZZO-RELIEVO, a piece of sculpture in half relief. *See* Bas-Relief.

MIDDLE-POST, in a roof, the same as King-Post; which see.

MIDDLE-QUARTERS OF COLUMNS. When the plan or horizontal section of a column is divided into four quadrants, by lines not at right angles to the front, but at an angle of 45 degrees therewith, the four quarters are called the *middle quarters*.

MILE (from the Latin, *mille*, a thousand) a long measure, whereby the English, Italians, and some other nations, express the distance between places. *See* Measure.

In this sense *mile* is used to the same purpose with league, by the French and other nations. The mile is of various extent in different countries. The geographical, or Italian mile, contains a thousand geometrical paces, *mille passus*, whence the term *mile* is derived.

The English mile consists of eight furlongs, each furlong of 40 poles, and each pole of $16\frac{1}{2}$ feet: so that it is equal to 1760 yards, or 5280 feet.

The mile employed by the Romans in Great Britain, and restored by Henry VII., is our present English mile. A degree of the meridian in England, north latitude 52, according to the measurement of Colonel Mudge, is 121,640 yards, or 69.114 miles. A geographical, or sea mile, is the 60th part of such a degree, *i. e.* $2{,}027\frac{1}{3}$ yards; and three sea-miles make a league. A degree of the meridian, in north latitude 45, as measured in France in 1796, is 57,008 toises = 121,512 yards = 69.092 English miles.

Casimir has made a curious reduction of the miles, or leagues, of the several countries in Europe into Roman feet, which are equal to the Rhinland feet generally used throughout the north.

	Feet.
The mile of Italy	50,000
" of England	5,454
" of Scotland	6,000
" of Sweden	30,000
" of Muscovy	3,750
" of Lithuania	18,500
" of Poland	19,850
" of Germany, the small	20,000
" " the middle	22,500
" " the largest	25,000
" of France	15,750
" of Spain	21,270
" of Burgundy	18,000

A Table of the Length of Miles, Leagues, &c. ancient and modern, in English yards.

	Eng. Yards.
Ancient Roman mile	1610.348
Olympic stadium = $\frac{1}{8}$th of an ancient Roman mile	201.2935
Stadium = $\frac{1}{10}$th of an ancient Roman mile	161.0348
Stadium = 1100th part of a degree	111.2
Jewish risin, of which $7\frac{1}{2}$ = an ancient Roman mile	214.713
Gallic leuca = $1\frac{1}{2}$ ancient Roman mile	2415.522
German rast, or common league in France = 2 Gallic leuca	4831.044
Persian parasanga = 2 Gallic leagues	4831.044
Egyptian schœnos = 4 ancient Roman miles	0441.392
German league, or that of Scandinavia = 2 rasts	9662.088
The mile, or league of Germany = 200 Rhenish yards	8239.846
Great Arabian mile, used in Palestine in the time of the Crusades, rated at $1\frac{1}{2}$ ancient Roman mile	2415.713
Modern Roman mile	1628.466
Modern Greek mile of 7 Olympic stadia	1409.0545
Modern French league = 2,500 toises	5328.75
Mile of Turkey, and the common werst of Russia, supposing it seven Olympic stadia	1409.0545
League of Spain = 4 ancient Roman miles	6441.392
Large league of Spain = 5 ditto	8051.74

MILITARY ARCHITECTURE, denotes the art of fortification. *See* Architecture.

MILLSTONE-GRIT, a coarse-grained quartzy sandstone. It is found between the mountain-limestone and the superincumbent coal formations.

MILK-HOUSE, or ROOM, an apartment for keeping milk sweet and good; this apartment ought to be as cool as possible, and on no account exposed to the rays of the sun; consequently a northern situation, when it can be obtained, will be the most eligible for this purpose. *See* Dairy.

MINARET, or Minneret, a Turkish steeple with a balcony, from which a person calls the people to prayers; no bells being permitted in Turkey.

MINION, an iron ore, useful in the composition of mortar; when mixed with a proper quantity of lime, it makes an excellent water-cement. *See* Cement and Mortar.

MINOTAUR, or Minotaurus, a fabulous monster much talked of by the poets; feigned to be half a man and half a bull.

MINSTER, the church belonging to a monastery.

MINSTREL GALLERY, a gallery in old halls, in which the minstrels sat during the feast. There is a gallery so termed near the centre of the choir of Exeter cathedral.

MINUTE, (from the Latin, *minutus*, small) in architecture, usually denotes the sixtieth, but sometimes only the thirtieth, part or division of a module.

MISERERE, a term applied to a seat of peculiar form, found in some of our larger churches and cathedrals. It is in shape like a bracket, and turns up on a hinge. When down, it forms a seat of the usual height and size, and the front beneath the seat is usually carved into a knop of foliage, or otherwise; but when turned up, this front presents a small high seat, which was used to recline against. It falls back out of the perpendicular, so as to retain itself in its position, but will fall forward with the least motion of the occupant.

MITCHELS, among builders, are Purbeck stones, from 15 inches square to 2 feet, squared and hewed ready for building.

MITRE, or Mitra, (from Μιτρα, a head-dress) a pontifical ornament, worn on the head by bishops, and certain abbots, on solemn occasions.

The mitre is a round cap, pointed, and cleft at top, with pendants hanging down on the shoulders, and fringed at both ends. The bishop's is only surrounded with a fillet of gold, set with precious stones; the archbishop's issues out of a ducal coronet. These are never used otherwise than on their coats of arms. Abbots wear the mitre turned in profile, and bear the crosier inwards, to show that they have no spiritual jurisdiction without their own cloisters.

The pope has also granted to some canons of cathedrals the privilege of wearing the mitre. The counts of Lyons are also said to have assisted at church in mitres.

Mitre, in joinery: when two pieces of wood contain equal angles, and one side of the one piece is joined to one side of the other, so that their vertices may coincide, the common seam, or joint, is called a *mitre*, and the pieces themselves are said to be *mitred*.

The whole angle thus joined is generally a right angle, and when this is the case, each of the pieces joined will be forty-five degrees.

Mitering is also employed in dovetail joints, in order to conceal the dovetailing.

Mitre-Box, a trough for cutting mitres, having three sides, open at the ends.

MIXED ANGLE, an angle of which one side is a curve, and the other a straight line.

Mixed Figure, one that is composed of straight lines and curves, being neither entirely the sector nor the segment of a circle; nor the sector or segment of an ellipsis; nor a parabola nor an hyperbola.

MOAT, (from the Latin, *mota*, a ditch) in fortification, a deep trench dug round a town, or fortress, to be defended on the outside of the wall or rampart.

The depth and breadth of a moat often depend on the nature of the soil; according as it is marshy, rocky, or the like. The brink of the moat next the rampart, in any fortification, is called the *scarp*, and the opposite one the *counter-scarp*.

MODEL, (from the Latin, *modulus*, a copy) an original, or pattern, proposed for any one to copy or imitate. St. Paul's cathedral is said to be built after the model of St. Peter's at Rome.

Model is particularly used, in building, for an artificial pattern, made of wood, stone, plaster, or other matter, with all its parts and proportions; for the better guidance of the artificers in executing some great work, and to give an idea of the effect it will have when complete.

In all great buildings it is much the surest way to make a model in relievo; and not to trust to a bare design, or draught. There are also models for the building of ships &c., and for extraordinary staircases, &c.

Model, in painting and sculpture, anything proposed to be imitated.

Hence, in the academies, they give the term *model* to a naked man, disposed in several postures, to afford an opportunity to the scholars of designing him in various views and attitudes.

The sculptors have little models of clay, or wax, to assist them in their design of others that are larger, in marble, &c., and to judge of the attitude and correctness of a figure.

Statuaries likewise give the name *model* to certain figures of clay, or wax, which are but just fashioned, to serve by way of guide in the making of larger, whether of marble or other matter.

MODILLIONS, (French,) in architecture, mutules carved into consoles, placed under the soffit or bottom of the drip of the corona in the Corinthian and Roman orders, for supporting the larmier and sima, or appearing to perform the office of support.

In Grecian architecture, the Ionic order is without modillions in the cornice, as are also the Roman examples of the same order, except the temple of Concord, at Rome, which has both dentils and modillions.

A singular and curious example of a modillion cornice, but contrary to the principles of architecture, is to be found in the interior cornices of the Tower of the Winds, at Athens, in which the projecting part is much thicker than the interior, where the stress seems to lie, and, consequently, gives the idea of weakness.

A singular example of modillions is to be found in the frontispiece of Nero, at Rome, where they consist of two plain faces, separated by a small sima-reversa, and crowned with an ovolo and bead. Another very extraordinary form of modillions is that placed in the frieze of the fourth order of the Coliseum, cut on the outside, or projecting part, of a sima-reversa form.

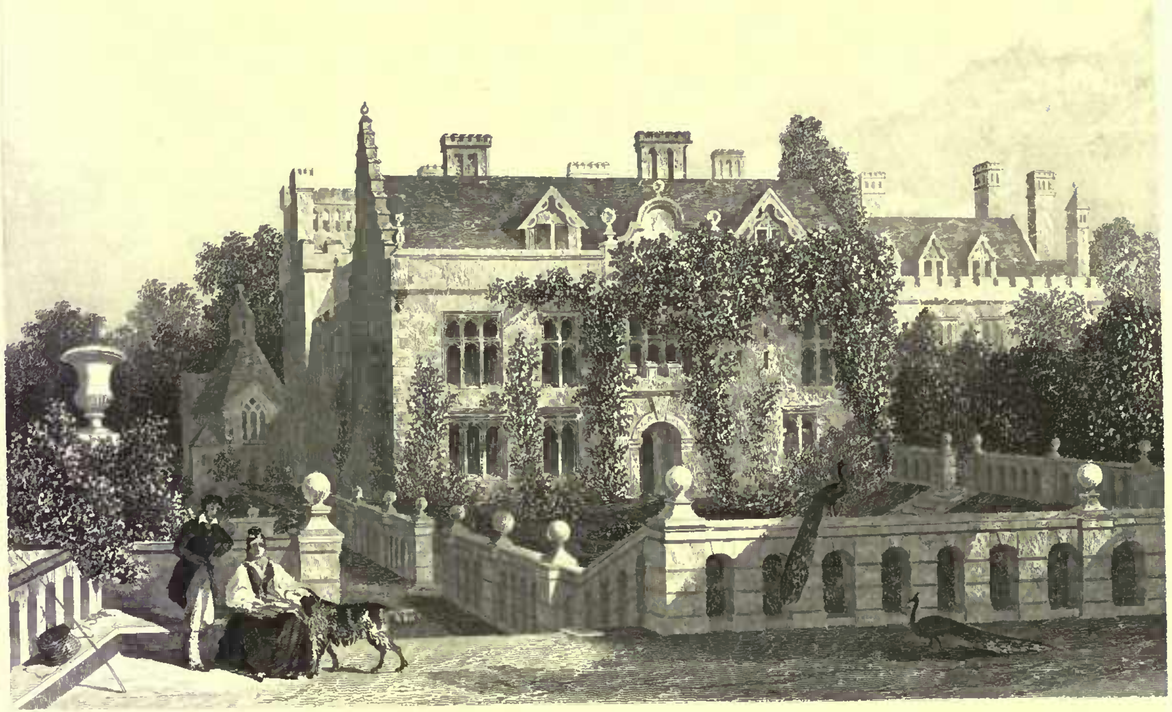
In most examples of the Corinthian and Roman orders, the cornices have both dentils and modillions; but, if the two are used together, in good proportion to the other parts, so as to appear distinctly at a reasonable distance, the cornice will be overcharged, both in proportion and weight, to the other principal members of the entablature, or the entablature to the whole order; the one or the other ought, therefore, to be omitted in the same cornice.

In the general disposition of modillions, if each one is conceived to be divided into two equal parts by a vertical plane at right angles to the surface of the frieze, one of the modillions is so disposed, that its dividing vertical surface will be entirely in a plane passing through the axis of the column, and in the column next the angle of the building there is generally only one modillion between that through which the plane along the axis passes, and the angle of the cornice.

The vertical sides of modillions at right angles to the face, are generally finished with volutes of different sizes, and turned on different sides of the same line; the greater being that next to the vertical surface, to which they are attached, and the lesser at the extremity.

The soffits of the modillions, so constructed, follow the under line of the volutes, and the connecting undulated line which joins them. The upper part of each volute is on the same level, and is attached to a moulding of the sima-inversa form, which returns round it; and this moulding is again attached to the corona, which hangs over the modillion.

In some of the Roman buildings, the modillions are not placed over the axes of the columns, neither upon those at



Newstead Abbey.

THROUGH THY BATTLEMENTS, NEWSTEAD, THE HOLLOW WINDS WHISTLE;
THOU, THE HALL OF MY FATHERS, ART GONE TO DECAY;

IN THY ONCE SMILING GARDEN, THE HEMLOCK AND THISTLE
HAVE CHOKED UP THE ROSE WHICH LATE BLOOM'D IN THE WAY.

the extremes, or over the axes of the intermediate shafts. In the Pantheon, the modillion next each angle of the building has its vertical side, which is opposed to the next modillion, nearer to the central plane of the portico, over the axis of the column, and consequently the whole breadth of the modillion on one side of the axis entirely, and on that side next to the angle of the building. In the whole portico are 47 modillions, including those at each extreme; the intervals are, therefore, 46 in number, and 44 between the columns that are between their axis. The portico is octostyle, and, consequently, the intercolumns are seven in number: from this it will be found, that if the columns were placed equidistantly, the number of intermodillions would be $6\frac{2}{7}$ in number. In this temple the corresponding intervals are very irregular. The two extreme ones are, according to Desgodetz, 9′ $4\frac{1}{2}$″, and 9′ $2\frac{3}{4}$″; the next two, nearer the centre, are 9′ $5\frac{1}{6}$″, and 9′ $1\frac{7}{8}$″; the next two, still nearer to the centre, are exactly equal, being 9′ 5″ each; and the central intercolumniation is 10′ $4\frac{3}{4}$″: so that the modillions appear to be equally divided, without any regard to the axis of the columns. The same irregularity in the disposition of the modillions may be observed in the temple of Concord, and in that of Jupiter the Thunderer. In the three remaining columns of the temple of Jupiter Stator, each column has a modillion placed over its axis, and each intercolumn has three modillions regularly disposed: the distance between the lower ends of the shafts are 3 modules, $4\frac{1}{2}$ parts, and the columns are in height 20 modules, $6\frac{5}{6}$ parts.

In the Pantheon, the modillions are placed in the pediment, contrary to the authority of Vitruvius.

MODULAR PROPORTION, that which is regulated by a module. *See* Module.

MODULATION, (from the Latin, *modulor*, to regulate,) the proportion of the parts of an order.

MODULE, (from the Latin, *modulus*, a pattern,) in architecture, a certain measure taken at pleasure, for regulating the proportions of columns, and the symmetry or distribution of the whole building.

Architects usually choose the diameter, or semi-diameter, of the bottom of the column, for their module; and this they subdivide into parts or minutes.

Vignola divides his module, which is a semi-diameter, into twelve parts, for the Tuscan and Doric; and into eighteen, for the other orders.

The module of Palladio, Scammozzi, M. Cambray, Desgodetz, Le Clerc, &c., which is also the semi-diameter, is divided into 30 parts or minutes, in all the orders.

Some divide the whole height of the column into 20 parts for the Doric, $22\frac{1}{2}$ for the Ionic, 25 for the Roman, &c., and one of these parts they make a module, by which to regulate the rest of the building.

There are two ways of determining the measures, or proportions of buildings: the first by a fixed standard measure, which is usually the diameter of the lower part of the column, called a *module*, subdivided into 60 parts, called *minutes*. In the second there are no minutes, nor any certain and stated division of the module; but it is divided occasionally into as many parts as are judged necessary. Thus the height of the Attic base, which is half the module, is divided either into three, to have the height of the plinth; or into four, for that of the greater torus; or into six, for that of the lesser.

Both these manners have been practised by the ancient as well as the modern architects; but the second, which was that chiefly used among the ancients, is, in the opinion of Perrault, preferable.

As Vitruvius, in the Doric order, has lessened his module, which, in the other orders, is the diameter of the lower part of the column, and has reduced that great module to a mean one, which is a semi-diameter; M. Perrault reduces the module to a third part, for the same reason, viz., to determine the several measures without a fraction. For in the Doric order, beside that the height of the base, as in the other orders, is determined by one of these mean modules; the same module gives likewise the heights of the capital, architrave, triglyphs, and metopes. But our little module, taken from the third of the diameter of the lower part of the column, has uses much more extensive: for, by this, the heights of pedestals of columns, and entablatures, in all orders, are determined without a fraction.

As then the great module, or diameter of the column, has 60 minutes; and the mean module, or half the diameter 30 minutes; our little module has 20. *See* Column.

MOILON, a name given by the French to a kind of stone, that forms the upper crust, and lies round the free-stone, in most quarries. It is an excellent substance for forming the body of fluxes, or soft enamel.

MOINEAU, (French,) in fortification, a flat bastion raised before a curtain when it is too long, and the bastions of the angles too remote to be able to defend each other.

Sometimes the moineau is joined to the curtain, and sometimes it is divided from it by a moat. Here musqueteers are placed, to fire each way.

MOLDING. *See* Moulding.

MOLE, (from the Latin, *moles*,) a massive work of large stones laid in the sea by means of coffer-dams, extending either in a right line, or in the arc of a circle, before a port, which it serves to close, to defend the vessels in it from the impetuosity of the waves, and to prevent the passage of ships without leave.

Mole is sometimes also used to signify the harbour itself.

Mole, among the Romans, was also used for a kind of mausoleum, built in the manner of a round tower on a square base, insulated, encompassed with columns, and covered with a dome.

The mole of the emperor Adrian, now the castle of St. Angelo, was the greatest and most stately of all the moles. It was crowned with a brazen pine-apple, in which was a golden urn containing the ashes of the emperor.

MOMENT or Momentum, (from the Latin,) the impetus, force, or quantity of motion in a moving body; or the word is sometimes used simply for the motion itself. Moment is frequently defined by the *vis insita*, or power by which moving bodies continually change place. In comparing the motion of bodies, the ratio of their momenta is always compounded of the quantity of matter, and the celerity of the moving body; so that the moment of any such body may be considered as a rectangle under the quantity of matter, and the celerity.

And since it is certain, that all equal rectangles have their sides reciprocally proportionable; therefore, if the momenta of any moving bodies be equal, the quantity of matter in one to that of the other, will be reciprocally as the celerity of the latter to that of the former; and, on the contrary, if the quantities of matter be reciprocally proportionable to the celerities, the momenta or quantities in each will be equal.

The moment, also, of any moving body may be considered as the aggregate or sum of all the momenta of the parts of that body; and, therefore, where the magnitudes and number of particles are the same, and where they are moved with the same celerity, there will be the same momenta of the whole. *See* Force.

MONASTERY, a convent, or house, built for the reception of religious devotees; whether it be abbey, priory, nunnery, or the like. The term is only properly applied to the houses of monks, friars, and nuns. The rest are more properly called *religious houses. See* ABBEY.

The houses belonging to the several religious orders, which obtained in England and Wales, were cathedrals, colleges, abbeys, priories, preceptories, commanderies, hospitals, friaries, hermitages, chantries, and free chapels. These were under the direction and management of several officers. The dissolution of houses of this kind began so early as the year 1312, when the Templars were suppressed; and in 1323, their lands, churches, advowsons, and liberties, here in England, were given, by 17 Edw. II. stat. 3, to the priory and brethren of the hospital of St. John of Jerusalem. In the years 1390, 1437, 1441, 1459, 1497, 1505, 1508, and 1515, several other houses were dissolved, and their revenues settled on different colleges in Oxford and Cambridge. Soon after the last period, Cardinal Wolsey, by license of the king and pope, obtained a dissolution of above thirty religious houses, for the founding and endowing his colleges at Oxford and Ipswich. About the same time, a bull was granted by the same pope to Cardinal Wolsey, to suppress monasteries, where there were not above six monks, to the value of 8,000 ducats a year, for endowing Windsor, and King's College, in Cambridge; and two other bulls were granted to Cardinals Wolsey and Campeius, where there were less than twelve monks, and to annex them to the greater monasteries; and another bull to the same cardinals, to inquire about abbeys to be suppressed, in order to be made cathedrals. Although nothing appears to have been done in consequence of these bulls, the motive which induced Wolsey, and many others, to suppress these houses, was the desire of promoting learning; and Archbishop Cranmer engaged in it with a view of carrying on the Reformation. There were other causes that concurred to bring on their ruin: many of the devotees were loose and vicious; the monks were generally thought to be, in their hearts, attached to the pope's supremacy; their revenues were not employed according to the intent of the donors; many cheats in images, feigned miracles, and counterfeit relics, had been discovered, which brought the monks into disgrace; the Observant friars had opposed the king's divorce from Queen Catharine; and these circumstances operated, in concurrence with the king's want of a large supply, and the people's desire to save their money, to forward a motion in parliament, that, in order to support the king's state, and supply his wants, all the religious houses might be conferred upon the crown, which were not able to spend above £200 a year; and an act was passed for that purpose, 27 Hen. VIII. c. 28. By this about 380 houses were dissolved, and a revenue of £30,000 or £32,000 a year came to the crown; besides about £100,000 in plate and jewels. The suppression of these houses occasioned great discontent, and at length an open rebellion: when this was appeased, the king resolved te suppress the rest of the monasteries, and appointed a new visitation; which caused the greater abbeys to be surrendered apace; and it was enacted by 31 Hen. VIII. c. 13, that all monasteries, which have been surrendered since the 4th of February, in the twenty-seventh year of his majesty's reign, and which hereafter shall be surrendered, shall be vested in the king. The knights of St. John of Jerusalem were also suppressed by the 32 Henry VIII., c. 24. The suppression of these greater houses by these two acts, produced a revenue to the king of above £100,000 a year, besides a large sum in plate and jewels. The last act of dissolution, in this king's reign, was the act of 37 Hen. VIII., c. 4, for dissolving colleges, free chapels, chantries, &c., which act was farther enforced by 1 Ed. VI., c. 14. By this act were suppressed 90 colleges, 110 hospitals, and 2,374 chantries and free chapels. The number of houses and places suppressed, from first to last, so far as any calculations appear to have been made, seems to be as follows:

Of lesser monasteries, of which we have the valuation	374
Of greater monasteries	186
Belonging to the hospitallers	48
Colleges	90
Hospitals	110
Chantries and free chapels	2374
Total	3182

Besides the friars' houses, and those suppressed by Wolsey, and many small houses, of which we have no particular account.

The sum total of the clear yearly revenue of the several houses, at the time of their dissolution, of which we have any account, seems to be as follows:

	£.	s.	d.
Of the greater monasteries	104,919	13	3½
Of all those of the lesser monasteries, of which we have the valuation	29,702	1	10½
Knights hospitallers' head house in London	2,385	12	8
We have the valuation of only twenty-eight of their houses in the country	3,026	9	5
Friars' houses, of which we have the valuation	751	2	0¾
Total	140,784	19	3¾

If proper allowances are made for the lesser monasteries, and houses not included in this estimate, and for the plate, &c., which came into the hands of the king by the dissolution, and for the value of money at that time, which was at least six times as much as at present, and we also consider that the estimate of the lands was generally supposed to be much under the real worth, we must conclude their whole revenues to have been immense.

It doth not appear that any computation hath been made of the number of persons contained in the religious houses.

Those of the lesser monasteries dissolved by 27 Hen. VIII. were reckoned at about	10,000
If we suppose the colleges and hospitals to have contained a proportionable number, these will make about	5,347
If we reckon the number in the greater monasteries, according to the proportion of their revenues, they will be about 35,000; but as probably they had larger allowances in proportion to their number than those of the lesser monasteries, if we abate upon that account 5,000, they will then be	30,000
One for each chantry and free chapel	2,374
Total	47,721

But as there were probably more than one person to officiate in several of the free chapels, and there were other houses which are not included within this calculation, perhaps they may be computed in one general estimate at about 50,000. As there were pensions paid to almost all those of the greater monasteries, the king did not immediately come into the full enjoyment of their whole revenues: however, by means of what he did receive, he founded six new bishoprics, viz., those of Westminster, (which was changed by Queen Elizabeth into a deanery, with twelve prebends and a school,) Peterborough, Chester, Gloucester, Bristol, and Oxford. And in eight other sees he founded deaneries and chapters.

by converting the friars and monks into deans and prebendaries, viz., Canterbury, Winchester, Durham, Worcester, Rochester, Norwich, Ely, and Carlisle. He founded also the colleges of Christ-Church in Oxford, and Trinity in Cambridge, and finished King's College Chapel there. He likewise founded professorships of divinity, law, physic, and of the Hebrew and Greek tongues, in both the said universities. He gave the house of Gray Friars, and St. Bartholomew's Hospital, to the City of London; and a perpetual pension to the poor knights of Windsor; and laid out great sums in building and fortifying many ports in the Channel. It is observable, upon the whole, that the dissolution of their houses was an act, not of the church, but of the state, in the period preceding the Reformation, by a king and parliament of the Roman Catholic communion in all points except the king's supremacy; to which the pope himself, by his bulls and licenses, had led the way.

Although few will now be found entirely to approve either the original establishment or continued subsistence of monasteries, yet the destruction of them was felt and lamented, for a considerable time, as a great evil; and with good reason. One inconvenience that attended their dissolution was the loss of many valuable books, which their several libraries contained: for, during the middle ages, religious houses were the repositories of literature and science. Besides, they were schools of education and learning; for every convent had one person or more appointed for this purpose; and all the neighbours that desired it, might have their children taught grammar and church music there, without any expense. In the nunneries also, young females were taught to work and read; and not only people of the lower rank, but most of the noblemen's and gentlemen's daughters, were instructed in those places. All the monasteries were also in effect great hospitals, and were most of them obliged to relieve many poor people every day. They were likewise houses of entertainment for all travellers. And the nobility and gentry provided not only for their old servants in these houses, by corrodies, but for their younger children, and impoverished friends, by making them first monks and nuns, and in time priors and prioresses, abbots and abbesses. On the other hand, they were very injurious to the secular and parochial clergy, by taking on themselves many prebends and benefices, by getting many churches appropriated to them, and pensions out of many others; and by the exemptions they got from the episcopal jurisdiction, and from the payment of tithes. We say nothing now of the laxity of discipline, and acts of moral turpitude, which have been attributed to the inmates of such establishments; which, however greatly they have been exaggerated, did unquestionably prevail in some instances. Such faults, however, are chargeable rather upon individuals, than upon the system, against which the previous objections are of greater weight.

MONKEY, the weight used in pile-driving, which is raised to the top of the machine, and then allowed to fall on the head of the pile.

MONOGRAM, (Greek *εν μονω γραφειν*,) the combination or interlacing of several letters, so as to produce a single cipher or device, employed for the purpose of abbreviation.

MONOLITH, (*μονος*, *single*, and *λιθος*, *a stone*,) a structure consisting of a single colossal stone. The term is applied to such structures found in Celtic remains. *See* Celtic Architecture.

MONOPTERON, or Monoptral Temple (from *μονος*, *single*, and *πτερον*, *a wing*) in architecture, an edifice, consisting of a circular colonnade supporting a dome, without any enclosing wall, and consequently without a cell, as in other temples.

MONOTRIGLYPH, (from *μονος*, *single*, and *τριγλυφος*, *a triglyph*) having only one triglyph between two adjoining columns. The monotriglyph intercolumniation was the general practice in the Grecian Doric; as in the temple of Theseus, and in that of Minerva, at Athens.

Mr. Rively, in his preface to the third volume of Stewart's *Athens*, says, "There is a certain appearance of eternal duration in this species of edifice (meaning a Grecian Doric temple) that gives a solemn and majestic feeling, while every part is perceived to contribute its share to this character of durability. From this rapid sketch, it will readily be seen that no other intercolumniation than that of the monotriglyph can succeed in this dignified order. The Propylæa, indeed, as well as the temple of Augustus, or Agora, has one interval of the space of two triglyphs; but it is easy to perceive, that this deviation from the general principle was merely an accommodation to circumstances; both these buildings requiring a wide opening in the middle of the front. Accordingly, these are the only instances of this deviation to be found at Athens."

In the island of Delos, the portico of Philip, king of Macedon, is another instance.

MONSTRANCE, the vessel in which the consecrated wafer is placed during the benediction; it is usually made of a metal frame, to contain a glass vessel, through which the wafer is seen. Some of them are of very beautiful and rich design.

MONUMENT, (from the Latin, *monumentum*, a memorial) a structure raised to preserve the memory of some eminent person, or to perpetuate some remarkable event.

Monuments at first consisted of stones erected over the tombs of the deceased, on which were engraved the name, and frequently the actions, of the person to whose memory they were reared.

Monuments received different names among the ancients, according to their figure. When the base was square, and the solid erected thereon a prism, the monument was called *steles*; whence square pilasters, or attic columns, are supposed to be derived. When the base was circular, and the solid erected thereon a cone, the monument was called *stylos*. Those monuments that were square at the foot, and tapering therefrom in planes to a point in which the planes ended, were called *pyramids*. Others, which had triangular bases, and their sides ending in a point, were called *obelisks*; being constructed in imitation of the instruments or spits used in roasting the sacrifices.

Monument of Lysicrates. The choragic monument of Lysicrates, commonly called the *Lantern of Demosthenes*, is the most beautiful edifice of antiquity of its size.

This monument, which is exquisitely wrought, stands near the eastern end of the Acropolis. It is composed of three distinct parts. First, a quadrangular basement; secondly, a circular colonnade, the intercolumniations of which are entirely closed up; and, thirdly, a *tholus*, or cupola, with a beautiful ornament upon it.

The quadrangular basement is entirely closed on every side, so as to exclude entrance. On breaking through one of the sides, it was found not to be quite solid; but the void is so small, and irregular, that a man can hardly stand upright in it.

This basement supports the circular colonnade, which was constructed in the following manner: six equal panels of white marble, placed contiguous to each other, on a circular plan, formed a continued cylindrical wall; which of course was divided, from top to bottom, into six equal parts, by the junctures of the panels. On the whole length of each juncture was cut a semicircular groove, in which a Corinthian column was fitted with great exactness, and effectually concealed the junctures of the panels. These columns projected somewhat more than half their diameters from the surface of the cylindrical wall, and the wall entirely closed up the intercolumniation. Over this was placed the entablature, and the cupola, in neither of which any aperture was made, so that there was no admission to the inside of this monument, and it was quite dark. It is, besides, only 5 feet 11¼ inches in the clear, and, therefore, was never intended for a habitation, or even a repository of any kind.

An entrance, however, has been since forced into it, by breaking through one of the panels; probably in expectation of finding treasures here. For in these countries such barbarism reigns at present, every ancient building which is beautiful, or great, beyond the conception of the present inhabitants, is always supposed by them to be the work of magic, and the repository of hidden treasures. At present three of the marble panels are destroyed; their places are supplied by a door, and two brick walls, and it is converted into a closet.

It should be observed, that two tripods with handles to them, are wrought in basso-relievo on each of the three panels which still remain. They are perhaps of the species which Homer and Hesiod describe by the name of *τρίποδες ὠτώεντες*, or *eared tripods.*

The architrave and frieze of this circular colonnade are both formed of only one block of marble. On the architrave is cut the following inscription:

ΛΥΣΙΚΡΑΤΗΣ ΛΥΣΙΘΕΙΔΟΥ ΚΙΚΥΝΕΥΣ ΕΧΟΡΗΓΗΙ
ΑΚΑΜΑΝΤΙΣ ΠΑΙΔΩΝ ΕΝΙΚΑ ΘΕΩΝ ΗΥΛΕΙ
ΛΥΣΙΑΔΗΣ ΑΘΗΝΑΙΟΣ ΕΔΙΔΑΣΚΕ ΕΥΑΙΝΕΤΟΣΗΡΧΕ

From this we may conclude, that on some solemn festival which was celebrated with games and plays, Lysicrates of Kikyna, a demos or borough-town of the tribe of Akamantis, did on behalf of his tribe, but at his own expense, exhibit a musical or theatrical entertainment; in which the boys of the tribe of Akamantis obtained the victory; that in memory of their victory, this monument was erected; and the name of the person at whose expense the entertainment was exhibited, of the tribe that gained the prize, of the musician who accompanied the performers, and of the composer of the piece, are all recorded on it; to these the name of the annual archon is likewise added, in whose year of magistracy all this was transacted. From which last circumstance it appears, that this building was erected above 330 years before the Christian æra; in the time of Demosthenes, Apelles, Lysippus, and Alexander the Great.

Round the frieze is represented the story of Bacchus and the Tyrrhenian pirates. The figure of Bacchus himself, the fauns and satyrs who attend him on the manifestation of his divinity, the chastisement of the pirates, their terror, and their transformation into dolphins, are expressed in this basso-relievo with the greatest spirit and elegance. The cornice, which is otherwise very simple, is crowned with a sort of Vitruvian scroll, instead of a cymatium. It is remarkable, that no cornice of an ancient building, actually existing, and decorated in this manner, has hitherto been published; yet temples, crowned with this ornament, are frequently represented on medals; and there is an example much resembling it, among those ancient paintings which adorn a celebrated manuscript of Virgil, preserved in the Vatican library. This cornice is composed of several pieces of marble, bound together by the cupola, which is of one entire piece.

The outside of the cupola is wrought with much delicacy; it imitates a thatch, or covering, of laurel leaves; edged with a Vitruvian scroll, and enriched with other ornaments. In certain cavities on its upper surface, some ornament, now lost, probably a tripod, was originally placed.

It was the form of the upper surface of the flower, and principally, indeed, the disposition of four remarkable cavities in it, which first led to this discovery. Three of them are cut on the three principal projections of the upper surface; their disposition is that of the angles of an equilateral triangle; in these the feet of the tripod were probably fixed. In the fourth cavity, which is much the largest, and is in the centre of this upper surface, a baluster was in all likelihood inserted; its use was to support the tripod.

It is well known that the games and plays which the ancient Grecians exhibited at the celebration of their greater festivals, were chiefly athletic exercises, and theatric or musical performances; and that these made a very considerable, essential, and splendid part of the solemnity. In order, therefore, to engage a greater number of competitors, and to excite their emulation more effectually, prizes were allotted to the victors; and these prizes were generally exhibited to public view during the time in which these games were celebrated.

Monument, *The*, absolutely so called among us, denotes a magnificent pillar, designed by Sir C. Wren, and erected by order of parliament, in memory of the burning of the city of London, anno 1666, near the place where the fire began. This pillar, begun in 1671 and finished in 1677, is of the Doric order, fluted, 202 feet high from the ground, and 15 feet in diameter, of solid Portland stone, with a staircase in the middle, of black marble, containing 365 steps. The lowest part of the pedestal is 28 feet square, and its altitude 40 feet; the front being enriched with curious basso-relievos. It has a balcony within 32 feet of the top, and the whole is surmounted with a curious and spacious blazing urn of gilt brass.

MOORISH, Moresque, Arabian, or Saracenic Architecture.—The style of building indifferently designated by any one of the above titles, is that which was practised by the Arabs, or Moors, and which, owing to the migratory condition of that race, and to their widely-spread influence, prevailed in many parts of the eastern continent. It is sometimes styled Mohammedan, for under the auspices of that faith it chiefly flourished; and amongst the edifices which Islamism gave rise to, are to be found some of the most magnificent and characteristic examples of the style. Previous to the time of Mohammed the Arabs seem to have possessed but little knowledge of the arts, and to have made little progress in the art of building until the commencement of the Ommiad dynasty. They would appear to have acquired a great portion of their knowledge of the arts from the various nations they subdued, during the reign of Omar, who died A. D. 644. It was this prince who founded a mosque, still called after his name, on the site of the ancient temple at Jerusalem, and which, by the additions and embellishments of succeeding kaliphs, has been reared into a large and magnificent pile. With the commencement of the Ommiad dynasty, was introduced a taste for the cultivation of the fine arts, and after the first kaliph of that house had removed the seat of empire from Medina to Damascus, the Moors began to assume the refined manners and the magnificence of the more polished Asiatic empires. During this and the following reigns, Damascus was adorned with numerous and splendid public buildings, amongst which the great mosque, founded by Alwalid I. is particularly celebrated. This prince was the first to introduce the minaret, an appendage which, although an innovation at the time, has now become a marked characteristic of Mohammedan buildings. He likewise made considerable additions to the mosque of Medina, and enlarged and adorned that built by Omar at Jerusalem to which we have referred above; in short, he expended a great portion of his revenues in the promotion of architecture, an example which was followed by his subjects generally.

The zeal of this race, however, in the promotion of the fine arts was surpassed by the house of El Abbas. The second kaliph of the Abassides removed the seat of empire from Damascus to Bagdad, which was founded by Almansur, A. D. 762, and continued in affluence and splendour for the space of five hundred years. "In the structure and decoration of this city, neither labour nor expense were spared, and the details of the gorgeous magnificence of the kaliph's palace would almost exceed the ordinary limits of belief, were they not authenticated by contemporary and ocular testimony."

Egypt and Africa were at an early period in possession of the Arabs, and the seat of empire was placed at Cairo, which was founded by the victorious general, Akbah, and flourished chiefly under the Fatimite line of kaliphs, who in the tenth century founded the new city of Cairo, and affected to rival the kaliphs of Asia in the splendour and magnificence of their buildings. Numerous vestiges of their edifices still remain, and amongst the most stately must be enumerated the great mosque, which is accounted the most magnificent in Barbary, and is said to be supported by five hundred columns of granite, porphyry, and Numidian marble.

But of all the Moors, those of Spain were surpassed by none in the magnificence and grandeur of their buildings, which rivalled, if they did not excel, those of Damascus, Bagdad, and Cairo, even in their most palmy days. The exceeding splendour of the mosque at Cordova, and of the palaces of the Alhamra and El Genaraliffe, places those buildings on an equal footing with the most celebrated cities of antiquity; and as the remains here are more numerous, and withal better known and more readily accessible, than those of Asia or Africa, they are usually made to form the groundwork of an examination of the general style, and to afford examples of its application;—a practice which we shall adopt in the present article.

It is remarkable that while the Arabs were diffused so widely over the earth's surface, the style of architecture adopted by them retained in every place a striking identity. It is true that differences of detail may be found in different places, as well as variety of application, yet in every country their buildings retain a very close general resemblance. This similarity is to be accounted for probably by the peculiarity of their religious creed, which, wherever it is professed, diffuses a close uniformity of habits, manners, and opinions. Notwithstanding, however, this general resemblance, which is amply sufficient to identify all buildings of this race as belonging to the same style, it must not be understood that, as a style, the Moorish was at any given period exactly the same in different countries under their dominion, or in one country at different periods, or even at the same period, for such was not the case. Indeed, if we may judge from the remains of some edifices in Asia and Egypt, of apparently the same date, we shall perceive many distinctions not only in the minutiæ of the ornamental and apparently characteristic ornaments, but also in their distribution. It is to be regretted that we have but little knowledge of the Asiatic and African remains of this style, for we are thereby prevented instituting a satisfactory comparison between the example of different localities and dates. The edifices of Spain, of which we have no inconsiderable information, must suffice as a type of the style, for which purpose they will probably serve better than those of any other country.

Various opinions as to the merits of this style have been entertained by various writers, some speaking of it in a very disparaging manner, as fanciful and capricious, whilst others extol it as elegant and poetical. It is in truth eminently fanciful, but this we judge to be rather to its praise than otherwise, as evidencing a lively and fertile imagination on the part of their architects: their buildings are indeed the embodiment of a luxuriant fancy, tempered, however, in most cases with taste and judgment. It is true that this style may not rank amongst the higher examples of the art, for it is notably deficient in constructive science; and in this feature it falls immeasurably below its rival in variety and luxuriance—the Gothic or Pointed style. In the latter the construction is paramount; in the former it is made entirely subservient to ornamentation.

Nevertheless, although Arabian architecture does not present that appearance of strength and security which is to be looked for in the perfection of the art, it never fails to gratify the eye as well as the imagination, by the richness of its picturesque and fantastic decoration; for all its parts are perfectly symmetrical, and never degenerate into heaviness or incoherence. Neither do we mean to assert that the Arabians erected their buildings without any reference to the principles of construction, for we know that they had attained great proficiency in the mathematics, and we can scarcely suppose that they neglected to apply them to such a purpose; indeed, we have very satisfactory proof to the contrary in the durability of their buildings. We are equally unacquainted with the rules by which they were guided, or the proportions which they observed in the art, and yet we know that they worked by well-defined rules, and that numerous treatises were written upon the subject, as we learn from the Arabian MSS. in the Escurial. Their ideas of design in this art must have been borrowed from a great variety of sources, amongst which may be enumerated the edifices of Egypt, Syria, India, Greece, Rome, and Byzantium, and out of all these they eliminated a style which is perfectly distinct from every one of them. All these styles, diverse as they are, were blended together with such taste and skill, and the borrowed forms so moulded and adapted, as to form one harmonious and perfect whole. The style, which is eminently peculiar, would seem to have been a development of their religious creed; it breathes the very spirit of Islamism; it is sensual and voluptuous, and appeals to the gratification of the senses rather than to the higher and nobler faculties of the mind: the Egyptian awes by its grandeur; the Grecian elevates by its purity; the Gothic humbles by its solemnity; but the Moorish gratifies only by its luxury. Of all the Mohammedans, the Turks seem to have deviated most widely from the general character of this style, by giving a preponderance to the Byzantine peculiarities by which they were surrounded in their chief city, Constantinople.

Amongst the characteristics of Moorish architecture the *horse-shoe* arch stands conspicuous. This is sometimes called the *crescent* arch, a name which may probably give us some clue to the reasons for the adoption of this form, which is indeed that of a crescent, the peculiar symbol of the Mohammedan faith; in imitation of which, it is reasonable to suppose it was introduced in a prominent position in their buildings. We shall the more readily concur in this suggestion, when we consider that such a form could not have been dictated by any principles of construction; against which it offends not a little. We must therefore look for some other reason, and that not a weak one, which could induce the Arabians to disregard the ordinary and simple axioms of construction; and we think we find a sufficient one in the idea just broached, that it was to symbolize their religious faith. The fact that it was named by the Mohammedans, the sacred arch, will tend to corroborate this statement. The shape was first introduced into architecture by Muavia, the first of the Ommiad dynasty, who adopted it in all the buildings he erected, and it afterwards became common in all countries into which the Moors had penetrated. The same outline is found in the bulbous dome, which is so peculiar a feature of the Mohammedan mosque; and there can be no doubt but that this dome was suggested by the crescent arch, no more indeed than that the semicircular or segmental domes were derived from the corresponding arches. We might say that the probability in the former case is the stronger, inasmuch as that form of dome is scarcely natural, and not to be accounted for by requirements of construction. The profile of the bulbous dome is precisely that of the horse-shoe arch. Another instance in which the crescent-shape appears, is the cusping or scalloping of the soffit, or sometimes of both outlines of the arch, which is a common practice, and may have given rise to the use of cusps in Gothic architecture.

The profile of the horse-shoe arch is that of a segment of a circle greater than a semicircle, or, in other words, it is a circular segmental arch, which is struck from a centre above the springing line. A modification of the same form is used, which may be termed the *pointed-crescent* or *horse-shoe* arch. This form consists of two segments meeting in a point at the apex, and is struck from two centres, both, as before, above the springing line.

The *semicircular* arch was borrowed by them, and used occasionally in conjunction with the others. The *pointed* arch is by some supposed to be invented by the Arabians, and to have been copied from them by the Gothic architects; be this, however, as it may, it is certain that it was extensively in use amongst them, and is found in Persia, Egypt, and Arabia, but was most prevalent at Bagdad and in the East. It is said to have been introduced by the house of El Abbas, who adopted it in opposition to the crescent form which had been employed by the rival house of the Ommiades; but even by them the old form was not entirely discarded, being retained in the principal entrances, and also in the form of the domes.

Another variety of arch is the *stilted*, which is of semicircular form, the centre from which it is struck being taken, as in the case of the horse-shoe arch, somewhat above the springing line; but instead of the circle being continued downwards, and contracted in width towards the impost line, the ends of the semicircle are carried down straight or perpendicularly, so as to give an appearance of elevation and lightness to the arch, which it would not otherwise possess.

The last form which we shall notice is the *cusped* or *scalloped* arch, the outline of which is similar to the polyfoil-headed compartments in Gothic apertures, being produced by three or more intersecting semicircles. There is this difference, however, that whereas the Gothic examples are merely ornamental accessories, the Moorish form main parts of the construction; the scallops are large and form the outline of their main arches, the extrados as well as the intrados following the same profile.

All the above forms of arches are treated in various ways, both as to their impost and decoration. Sometimes the arch springs directly from the solid wall, at other times it is made to rest upon columns. In the case of the horse-shoe arch, when the former arrangement takes place, the whole of the arch rests upon the wall, or, in other words, the wall projects as far as the most prominent part of the arch, so that the arch does not overhang the impost; but in the other arrangement, the columns are recessed back so as to range with the extremity of the diameter with which the arch is struck, thus leaving a space between the columns as wide as the diameter or extreme width of the arch; the capital of the column, or an impost moulding above it, projects forward so as to sustain the extremities of the arch. Sometimes, but more especially when *stilted*, the arch is supported by corbels projecting from the walls, and serving as imposts. This practice of corbelling is very prevalent. In some cases the face of the arch, that is, the width between the intrados and extrados, is continued down the impost-jambs, but in others it stops at the springing. This face again varies considerably in breadth, and sometimes is not shown at all on the face of the wall; it is generally, however, a wide band or archivolt following the outline of the arch, sometimes plain, showing only the joints, sometimes plain with the addition of a moulding round the extrados, and at others both moulded and otherwise decorated. The decoration is usually in compartments formed by the joints, and frequently the alternate voussoirs are contrasted by a difference of ornamentation. The depth of the archivolt was sometimes so great as to equal the radius. Cusping in the direction of the outline of the arch is a common mode of decoration, being sometimes applied in the shape of a moulding round the extrados, and sometimes the intrados or soffit only being so cut or serrated. Occasionally the arches of apertures are left blank, being filled up with walling, and having a square-headed aperture underneath: this is especially the case with the crescent arch. Arches of whatever kind are generally placed within a square-headed panel or compartment, which is frequently surrounded by a border or plat-band, somewhat similar to the square hood-mould of the perpendicular period of Gothic architecture. This band, as well as the spandrels intercepted between it and the arch, are usually covered with ornamentation of various descriptions. Sometimes two plat-bands are introduced, with a space between them, which is commonly filled up with inscriptions or other decoration. This last method, however, is not common except in large apertures, or in principal entrances.

The columns are of slender proportions, and remarkable for extraordinary lightness and variety of form. Their shafts are sometimes plain, but often ornamented with carving, being sometimes surrounded with a spiral groove twisting round the shaft, at others grooved perpendicularly. The capitals are of various forms, usually carved into clustered foliage, being sometimes imitations of the classic orders, and sometimes designs of their own; the cap is covered with a plain abacus. Columns were very frequent in Arabian edifices, disposed in clusters or rows, and supporting low arcades; they add considerably to the light appearance of their buildings.

Corbelling, which consists in the projection of stones or bricks at regular distances from the main wall, is of extensive use in Arabian architecture, and was probably introduced into Europe by them. The practice seems to have originated in the East, for it is seen in Eastern edifices of very early date, and prevails to a great extent in the architecture both of India and China. The Arabians employed corbels in all their structures, but more especially in their fortresses, to throw out the parapets for machicolations.

Amongst the many peculiarities of Arabian art, perhaps none is more worthy of mention than that method of ornamentation which has been designated under the title of *arabesques*, although the term, as applied by the moderns, does not exactly describe the peculiar ornament alluded to; with us, the term includes a wider range of decoration. The law of the Mohammedan faith prohibited all representations of human or animal figures, as bordering too closely on the practices of Christianity and paganism, and this precept was at first very strictly adhered to. Their arabesques therefore, excluding all forms of animal life, consisted entirely of representations of fanciful plants, stalks, and foliage, treated in an artistic manner, and gracefully entwined in an endless variety of form; these were introduced on the walls, sometimes in colour only, but very often in stucco, the pattern standing out from the wall in high relief.

Another style of decoration, very similar to the last, consists of panels or compartments filled with lines or bands, disposed in an infinite diversity of geometrical figures, and interlacing one with another in such a manner as to form a sort of labyrinth, whose arrangement and combination was unintelligible, except by close observation. Of this method of decoration, a writer on the subject very justly observes—"Their geometrical patterns exhibit singular beauty and complexity, inexhaustible variety of combinations, and a wonderful degree of harmonious intricacy, arising out of very simple elements; to which must be added the variety produced by colour also, whereby the same arrangements of lines and figures could be greatly diversified. Hence, though apparently quite unmeaning, and intended only to gratify the eye, such embellishment must have powerfully recommended itself to a people both imaginative and contemplative, and whose fancy would find occupation in patiently tracing and unravelling the manifold intricacies and involvements, the mazes of what at first sight looks like a mere labyrinth, until its scheme unfolds itself; but merely momentarily, as it were, being again lost when attention is diverted from it to particular parts.

Another method of decoration, which was very prevalent, and is to some extent a characteristic, consists in the application of inscriptions as a means of enrichment. This custom was in all probability borrowed from the Egyptian practice of inscribing hieroglyphics on their walls; although the idea is somewhat differently applied. A nearer approach to the Arabian system, is seen in that adopted by the Gothic architects, the application in both instances being almost identical. The most usual position for such inscriptions was round their doors and windows, or on the surface of bands, architraves, and friezes; they were usually raised in relief from the surface of the wall, and oftentimes inlaid similarly to mosaic work, and richly illuminated with precious stones; in almost all cases, they were enriched with gilding and colour, and the characters rendered as calligraphic as possible. The inscriptions which mostly prevailed, were sentences from the Koran, sometimes other moral and religious precepts, and occasionally passages of Oriental poetry, the nature of the inscription varying in accordance with the requirements of the place or building they enriched.

Another addition to the decorative character of the style, is seen in the open trellis-work employed to close apertures—a happy contrivance for excluding the rays of the sun at the same time that it admitted freely both light and air; a matter of great importance in a warm climate. The idea is supposed to have been derived from network, suspended before apertures for the same purposes, as well as for the exclusion of insects; it is decidedly of Oriental origin. This fret-work is composed of bands interlaced, and forming an infinite variety of figures, and is very similar to the geometrical patterns we alluded to above.

The designs are often very elegant; and although they appear somewhat intricate at first, upon closer examination it will be found that they are composed of simple parts as simply put together, and yet they produce a great variety of tasteful patterns, in which the star is not unfrequently a prominent figure. The same eulogy will apply to this lattice-work, as to the geometrical arabesques. A similar method of interlaced work, is not unfrequently to be seen in their pierced parapets, which were common in the edifices of the East.

The floors, and sometimes a portion of their walls, were inlaid with mosaic work, disposed in various patterns, in which the interlacing band again makes its appearance, and with like success. The roofs are often coffered or recessed in panels in a very peculiar manner, which gives to them very much the appearance of a honeycomb; sometimes also they are covered with pendants, in such a way as to realize the idea of stalactite caverns. A very beautiful method of lighting their baths from the roof, has been noticed and extolled by almost every traveller; small star-shaped apertures are cut in a sloping direction through the roof, and while their form delights by its beauty and propriety, they admit only a subdued degree of light.

On the whole, when we consider the fantastic form of the arches, the slender proportions of their columns, the infinite variety and profuseness of their decorations, and remember that the entire edifice was enriched with the most brilliant colouring, it must be confessed that it would be difficult to picture a more vivid realization of our notions of fairy-land, than is presented to us by such a description.

Notwithstanding, however, the gorgeousness of their interiors, the Arabs, of Spain especially, paid little attention to external decoration. The exterior of their edifices is decidedly plain, sometimes approaching to rudeness, frequently composed of irregular masses of scattered buildings, without symmetry, or any attempt at ornament, and to be admired only for their bold outline and picturesque effect. One circumstance which adds to their heavy, massive appearance, arises from their custom of lighting their halls from the interior courts, so as to escape as much as possible the heat of the sun.

Their mosques and other buildings in the East presented a less rude exterior, the outline being broken up and varied by the numerous domes and minarets, the lofty and slender forms of the latter forming a picturesque contrast with the swelling curves of the former. These minarets are light circular towers, elevated above the rest of the building, with projecting galleries round the upper part, whence the imaum called to prayer; they are usually enriched with a profusion of delicate fret-work. Many mosques were covered with a multitude of domes, one principal one being larger than the others which surrounded it. The walls too are more enriched than those of the buildings in the West, and altogether the exteriors were of a much lighter and elegant description. *See* Mosque.

M. Laborde, in his voyage "Pittoresque de l'Espagne," divides Arabian architecture of Spain into three distinct chronological periods: the first of which dates from the establishment of Islamism to the ninth century; the second from the ninth to the thirteenth century; and the last, from that period to the decline of Mohammedan influence in Spain. The mosque of Cordova has been selected as the most apt type of the first period: a building which bears a close resemblance to the later works of the Romans, the plan corresponding in many respects with the oldest churches in Rome, and the materials being either procured or coarsely imitated from the Baselaine, which had been previously erected in Spain by the Romans.

In the second period, we see a considerable advance in elegance, of which the palace of the Alhambra presents a favourable example. In this period, most of the traces of the Byzantine style disappear, and the new style is seen in a state of perfect development; indeed, the examples of this date are of greater beauty, and more correct taste, than those either preceding or following it.

The third period shows a decline in art, and its examples exhibit a mixture with the style then prevalent in Italy, and which was spreading itself throughout Europe. M. Laborde found specimens of this style in the fortresses of Benevente, Pennafiel, Cordesillas, Segovia, and Seville. At this date the plans continued much the same as before, but Greek ornaments began to be employed, and Corinthian columns are frequently seen supporting Moorish arches. The restrictions also respecting the representation of living figures began to be less strictly adhered to.

We forthwith proceed to give a description of some of the more noted Spanish structures of this style, at the head of which in point of date, if not of importance, stands the mosque of Cordova.

This place is stated to have contained no less than 600 mosques, 900 baths, and 2,000 houses. Of these buildings the mosque to which we allude was one of the most important; it was commenced by Abdurrahman in the eighth century, and completed by his son and successor, Hisham, in the same century, since which period it has been frequently enlarged and enriched by subsequent kaliphs. The plan of the building is a rectangle or oblong, whose longest side from north to south is 620 feet, and that from east to west 440 feet; the whole space being enclosed by a wall with counterforts, both of which are embattled, and surrounded by four streets, which renders it isolated from all other buildings. The wall is 8 feet thick, and varies in height from 35 to 60 feet. The entire space enclosed by it, is divided into two parts, the first of which, at the northern extremity, was the court in which the Moslems performed the requisite ablutions ere entering the mosque. This quadrangle measured 210 feet in depth, and was surrounded by a colonnade of 72 columns enclosing three fountains. The remaining space is occupied by the mosque, which is divided internally into 19 naves, running from north to south, and extending in length about 400 feet, and into 32 from east to west. Each of the naves from south to north is about 16 feet wide, and those in the cross direction somewhat less, and are separated from each other in both directions by rows of columns, whose number amounted in all to 850, to which, if we add the 72 in the external colonnade, we shall have a total of 922 columns. They were composed of jasper and the richest marbles, measuring 18 inches in diameter, and on an average 15 feet in height: their capitals are of various designs, but all approaching the Corinthian or Composite in form, and upon these spring the arches. There were no less than 21 entrances, the doors of which were all covered with the best Andalusian brass. The cupola was 72 cubits, or 108 feet in height, and was surmounted by three apples, two of which were of pure gold, and the central one of silver, each measuring three spans and a half in circumference. The ceilings were of wood painted, each range forming on the exterior a small-roof, separated from the adjoining one by a gutter. The chief entrance that led into the Maksura or sanctuary, is said to have been formed of gold, as were also the walls of the Mibhra or chancel: the floor of the Maksura was of pure silver, and in it, on a throne of wood of aloes, with nails of pure gold, was preserved, in a case of the same metal set with pearls and rubies, the principal copy of the koran. The pulpit was formed of the most precious woods, such as ebony, sandal, brazil, citron, and wood of aloes, and occupied a period of seven years in its manufacture. The interior of the edifice was lighted by 280 chandeliers of brass and silver, containing 11,000 lamps.

Cordova once possessed a palace, which, according to the accounts of Mohammedan writers, was of the greatest magnificence; of this, however, although of more recent erection than the mosque by two centuries, we have no remains: it is said to have been adorned with 4,000 pillars of marble, and to have had floors of the same material.

The Alhambra is the most perfect and beautiful building of this style with which we are acquainted, and one of which we have more detailed information than of any other. It is situated on the northern brow of one of the steep hills of Granada, and is approached from the city through a narrow street, which leads to the entrance, called the Gate of Judgment, so named from the ancient practice of holding the courts of justice at the entrance of cities. This gate is a square tower, with an entrance under a large horse-shoe arch, which reaches half-way up the tower, and has an open hand sculptured on the key-stone, emblematical of the omnipotence of the Deity. The gate is of white marble, which, however, has become much discoloured through age and exposure; it is decorated above with mosaic tiling, about 3 feet 4 inches in height, beneath which is an inscription in Cufic characters, of the motto "There is no conqueror but God," and beneath this again on the keystone of the arch is sculptured a key, one of the principal symbols of the followers of Mohammed.

The entire plan of the building measures 2,300 feet, by 600 feet, and is divided into several courts, all upon the same plane. The first of these is the court of cisterns, so named from the cisterns which it contains, and which supplied the palace with water. The largest cistern is 102 feet long, and 56 feet wide, the whole being enclosed by a wall 6 feet thick, and covered over with an arch 47 feet 6 inches in the centre, and 17 feet 6 inches below the surface of the ground. There are two circular apertures 25 feet 6 inches apart, and 3 feet 6 inches in diameter, strongly built, and carried up 3 feet 6 inches above the level of the ground. The water is by this means kept in a constant state of coolness; in warm climates, a matter of some importance.

On the north side of the Court of Cisterns, is the Mesuar, or common bathing-court, which is an oblong of 150 feet by 56 feet. This hall is more enriched than the last, which leads us to notice a common practice of the Moors, that of increasing the luxury and magnificence of their decorations towards the interior of their buildings. In this hall there is an arcade springing from very light marble columns, of which material the floor also is composed; the walls are covered with mosaic tiling up to the ceiling, in which are small apertures in the shape of stars, lined with green-glazed tiles, to assist ventilation, and diffuse a refreshing coolness throughout the building. The bath-rooms of the kaliph and sultana are very richly finished, ornamented with gilding and porcelain: the basins are of white marble, and the walls are covered to the height of the cornices with black and white mosaics. The roof is of stone, vaulted, and is perforated for ventilation, as above.

At the lower end of the Mesuar is the Court of Lions, which is considered one of the most splendid examples of Moorish architecture still existing. It is, like the others, an oblong court, measuring 100 feet in length by 50 in breadth, and is surrounded with a corridor or arcade, supported by 128 columns of white marble, 9 feet high, and 8½ inches in circumference. The capitals vary in design; each design being frequently repeated, but similar designs being placed without any regard to regularity. The columns also are disposed irregularly, sometimes singly, at others coupled, and occasionally in groups of three.

The arches are of different sizes, the larger being 4 feet 2 inches wide, the smaller about 3 feet. They are enriched with a profusion of highly finished arabesques, and surmounted with an inscription; a rich cornice runs round the entire court. The floor of the colonnade is laid with white marble, and the dado of the walls is formed of a lining 5 feet high, of brilliant yellow and blue mosaic tiling, with a border containing the inscription. "There is no conqueror but God," in blue and gold. At each end of this court projects a kind of portico, supported, like the colonnade, with light marble columns and arches, and having a fine stuccoed ceiling. In the centre of the court stands the celebrated Fountain of Lions, which consists of an alabaster basin, richly decorated, supported on the backs of twelve lions, and carrying another smaller basin above. from which the water fell into the larger one, and thence through the lions' mouths into a large reservoir of black marble.

From the right-hand side of the Court of Lions, is a passage to the Hall of the Two Sisters, so named, from the two beautiful slabs of white marble forming part of the pavement on each side of the fountain, and which measure 15 feet by $7\frac{1}{2}$ feet, the entire surface being perfectly free from crack or stain. "The walls are decorated from the pavement to the rise of the arches, with the usual elegant mosaics; the panels between them are filled with a delicate ornament, which, at a little distance, has the appearance of a plain face; the ceiling is composed of stalactites, in stucco, and finished in a style of great elegance. The four balconies of this sumptuous apartment were appropriated to musicians; the women of the harem sat below, and a jet d'eau in the middle diffused a refreshing coolness through the hall. The windows look into a little myrtle garden."

On the other side of the Court of Lions, and opposite that of the Two Sisters, is the Hall of the Abencerrages, said to be so called, from the circumstance of some noble Arabs having been put to death there by one of the kings of Granada. "It appears to have been a central saloon, opening a communication to the other parts of the palace. Every possible variety of combination which can be devised by ingenuity and patience, are formed on the walls and ceiling; the lines regularly cross each other in a variety of directions, and return again to the point from which they were first projected. The extraordinary designs are thought to have been produced by pouring prepared gypsum into moulds, and, after it was applied to the walls, painting them with gold, azure, and purple.

"The concert-room of the baths is a lofty saloon, in which the royal family listened to the concerts of musicians, stationed in an elevated tribune, while the audience sat below on rich carpets. The columns are of white marble, and the mosaics between the columns are black, green, yellow, and white, set in a green border; the roof is covered with tiles, and the woodwork richly ornamented, especially the three lattices or windows."

The Hall of the Ambassadors is a square court, the sides of which measure 36 feet, and the height 64 feet. It is entered through an arched door, decorated profusely with arabesques in stucco, coloured in blue and gold. The walls are covered with mosaics of various patterns, interspersed with inscriptions formed in porcelain, and made to form a most harmonious combination with the stucco arabesques; the cornices are enriched with the same inscription as in the other halls. The ceiling is arched and decorated with great variety of chiligon mosaics, knots, and other ornaments; and gold, silver, and azure purple, are the colours covering the coloured facets; the floor is inlaid with mosaics. The walls of this hall are of an immense thickness, no less than 15 feet on three sides, and 9 feet thick on the fourth; they are composed of a mixture of pebbles and red clay. "The ceiling is composed of strong pieces of larch, in admirable preservation, which are keyed and fastened together in such a manner, that, on pressing the feet on the centre of the ceiling, the whole vibrates like a tight rope. The roof is formed of a scantling of 10 inches square deal, and laid close together, with cross-braces at the angles. Bricks are laid on these rafters, and upon them is a coating of lime; on these are placed the bricks and tiles forming the exterior covering of the roof.

"The walls of this splendid building are formed throughout of a sort of rubble-work mixed with clay, and were, on an average, 7 feet in thickness, flanked with solid towers 18 feet thick; bond-timbers of pine were inserted in the walls, and at other times, strands or twists made of rush were inserted for the same purpose; nails were driven into the walls to receive the plaster, being first coated with gypsum to prevent corrosion, but when timbers were to be plastered, they twisted Esparta cords round them to bind the plaster. The bricks with which the open courts are paved. are 14 inches long by $7\frac{1}{2}$ wide, and 3 inches deep; the underside had a groove sunk in it about $2\frac{1}{2}$ inches wide and 1 inch deep, and extending the length of the brick, for the purpose of forming a good bond with the cement. When these bricks were laid over boarding, a layer of potters' clay, or of bricks laid dry, was placed between the timber and the paving.

"The durability of the woodwork throughout this building is surprising, it is mostly of pine, and has withstood the attacks of dry-rot, worm, and every other insect, without injury; it seems now perfectly sound, and free from every sign of decay, and it is even stated, that, in the Court of Lions, the ancient woodwork is perfect, whilst that of later date is rapidly decaying." The Spaniards attribute this durability to the timber being coated with a composition consisting of Safne glue and garlic well pounded in a mortar; these being mixed together, with the addition of vermilion, are boiled over a gentle fire, until the glue becomes as thin as water; too much or too little boiling deprives it of its viscous property. Planks cemented with this composition are said to adhere so firmly, as to break at any other part except at the joint. Garlic being noxious to worms, the Moors evidently mixed it with their cement, in order to prevent their depredations; it is not improbable that it was mixed with the gypsum used in the Alhambra, which may account for the stucco work remaining uninjured either by spiders or insects. Some suppose that this durability arises from the trees having been lanced or deprived of their sap when felled.

The durability of the Arabian buildings of Spain will appear more marvellous when contrasted with other buildings. The wooden gate of Cyprus, belonging to the celebrated temple of Diana, is said to have existed for four centuries, and that of the old church of S. Peter at Rome, which was composed of the same material lined with sheets of silver, continued undecayed for 550 years, but the beams employed in the construction of the roof of the mosque of Cordova manifest no symptoms of decay after a lapse of 1,000 years.

The arabesques, paintings, and mosaics, which give so great a charm to this building, are very highly and carefully preserved. The former appear to have been cast in moulds, and fixed to the walls in pieces so accurately connected, that no sign of juncture is visible. The ornaments which recede from the eye are coloured in gold, pink, light blue, and dusky purple, the first colour being nearest to the eye, and the last farthest from it, the general surface being white, which is remarkably pure and splendid. All the colours are fresh and bright, and, if the dust be removed, appear in all their pristine beauty.

The domes and arcades are formed of artificial casts, which are almost as light as wood, and as hard as marble, having endured the test of ten centuries.

A house built during the third period still exists at Seville, which was the residence of a Moorish Arab chieftain; the whole is most voluptuously contrived for a warm climate, and is in the most perfect state of preservation, though upwards of 500 years old; one of the apartments is almost perfect of its kind. The form resembles a double cube, the one placed above the other, its height about 60, and its length and breadth about 30 feet. The ornaments begin at about 10 feet from the floor, and are continued to the top of the room: they consist of a kind of variegated network of stucco, designed with the most perfect regularity, and yet most admirable variety in the patterns and the interlacings of each. This edifice has often been adduced as an instance of the wonderful superiority of the Arabs over the modern Spaniards in the art of building.

There is one very ancient and remarkable building which we have not here described, but which may not be passed over without notice; we allude to the CAABA, of which a description will be found under that head.

For further and more detailed descriptions of this style of building, we refer the reader to the elaborate works of Jones and Murphy.

MOOR-STONE, a very remarkable stone, found in Cornwall, and some other parts of England, used in the coarser works of modern builders. It is, in fact, a white granite, and is a very valuable stone. It is very coarse and rude, but has beautiful congeries of variously constructed and differently figured particles, not diffused among, or running into one another, but each pure and distinct, though firmly cohering with whatever it comes in contact. Its colours are principally black and white: the white are of a soft marble texture, and opaque, formed into larger congeries, and emulating a sort of tabulated structure; among these are many of a pure crystalline splendour and transparence; and in some are lodged, in different directions, many small flaky masses of pure talcs, of several colours; some are wholly pellucid, others of an opaque white, others of the colour of brown crystal, and a vast number perfectly black. It is found in immense strata in some parts of Ireland, but is disregarded there.

It is found with us in Devonshire, Cornwall and some other counties; and brought thence in vast quantities, to London. It never forms any whole strata there, but is found on the surface of the earth, in immense and unmanageable masses; to separate these, and render them portable, a hole is dug in some part of the mass, which being surrounded with a ridge of clay, is filled up with water; this by degrees soaks in, and finding its way into the imperceptible cracks, so far loosens the cohesion of the particles, that the day after, on driving a large wedge into the hole, the stone breaks into two or more pieces. It is used in London for the steps of public buildings, and on other occasions, where great strength and hardness are required.

MOOT-HALL. MOOT-HOUSE, a town-hall; hall of judgment. In the *moot-halls*, formerly connected with the inns of court, imaginary or moot-cases were argued by the students at law.

MORESK, or MORESQUE, (from the Spanish *morisco*,) a kind of painting, carving, &c., done after the manner of the Moors, consisting of several grotesque pieces and compartments promiscuously intermingled, not containing any perfect figure of a man or other animal, but a wild resemblance of birds, beasts, trees, &c.

They are also called *arabesques*, and are particularly used in embroideries, damask-work, &c.

MORTAR (from the Dutch *morter*, cement) in architecture, a composition of lime, sand, &c. mixed with water.

In the construction of works in masonry, some kinds of cementitious matter is generally employed for connecting the stones together, and rendering them firm and compact. When the works are to be exposed to the action of water immediately after being built, this cementitious matter must be of such a nature, that it will harden under water. Hence it is, that we have occasion for two kinds of mortar, one that will set and harden under water, called by Smeaton a *water-mortar*, or cement; and *common mortar*, for ordinary buildings. *See* MORTAR, HYDRAULIC.

Common mortar is the substance placed between the stones or bricks of a building, to cement them together, and thus cause them to retain their places, and give strength and stability to the edifice. Mortar is essentially composed of lime and silicious sand, the first being in the state of hydrate or slacked lime: the sand is used of different degrees of fineness. The hardness of mortar is owing to the gradual conversion of the hydrate of lime into carbonate of lime, which takes place very slowly by the absorption of carbonic acid gas from the atmosphere; in this state it adheres very firmly to the particles of silica diffused through it, and both are strongly united with the material employed in the building.

In order that this change may occur with advantage, certain conditions are requisite: if the mortar dries too quickly, the carbonate formed will remain much divided, and will not acquire the necessary adhesive property; if on the other hand, the mortar be placed under water, a portion of the lime will gradually dissolve, what remains will become carbonate with great difficulty, and the particles of sand will be isolated. If, on the contrary, the mortar be long kept moist and exposed to the air, the carbonic acid gas acts slowly but incessantly on the lime, the water of which becomes gradually saturated with it, and this being transferred to the lime, it is converted into almost a crystalline carbonate, in successive portions or layers, and these adhere with great force to the particles of sand. It follows, from what has been stated, that buildings erected when the weather is too hot are less stable than those which are constructed later in the year; but it is to be observed, that during frost, owing to the freezing of the water, the absorption of carbonic acid is not only stopped, but the solidity of the mortar is destroyed by the freezing or crystallization of the water.

Much has been said as to the extreme hardness of ancient mortar, and it is supposed that some secret method was adopted in its preparation; but the fact may probably be accounted for by merely referring to the circumstance, that the long exposure which it has undergone in considerable masses has given it the opportunity of slowly acquiring the carbonic acid from the air, upon which its hardness and durability depend. It is to be observed, that lime which is not sufficiently burnt, or lime which has been slacked by the moisture which it has acquired by exposure to the atmosphere, cannot form good mortar: the first has not been deprived of the carbonic acid which it is requisite to regain slowly from the air; and the latter has re-acquired it under circumstances which diminish instead of increase the solidity of the mortar.

Other materials, such as limestone, marble, chalk or shells, may be used to burn for lime or common mortar, all these substances being composed chiefly of lime and carbonic acid; and if a piece of one of them be slowly burnt or calcined, so as to expel the whole, or nearly the whole, of its carbonic acid, it loses about 44 per cent. of its weight; and when a small quantity of water is added to the calcined matter, it swells, gives out heat, and falls into a finely-divided powder called *slack lime*. The bulk of the powder is about double that of limestone. If this powder be rapidly formed into a stiff paste with water, it sets or solidifies as a hydrate of lime, and ultimately hardens by the absorption of carbonic acid from the air. This constitutes common building-mortar. Hydrate of lime consists of 100 parts of lime, and 31 parts of water. Common limestone consists of carbonate of lime, with very little of any other substance; it produces a white lime, which slakes freely when well burnt; it dissolves in diluted muriatic acid, with only a small portion of residue, and never contains more than a trace of iron. It differs much in external characters, as chalk, marble, common compact limestone, &c.

These limestones do not form cements to set in water, without the addition of other kinds of cementing matter; hence they are usually employed only for common mortar. The hardest marble and the softest chalk make equally good lime when well burnt; but chalk-lime will slake when not perfectly burnt, and therefore seldom has a sufficient quantity of fire; whereas stone-lime does not re-absorb carbonic acid so rapidly as chalk-lime.

Lime made from common limestone, sustains very little injury from being kept after it has been formed into mortar, provided the air be effectually excluded; indeed, Alberti mentions an instance of some which had been covered up in a ditch for a very long time, and yet was found to be of an excellent quality.

To employ lime alone in the composition of mortar would render it expensive; besides, it would be of inferior quality. The material commonly used to mix with lime is sand, and this sand should be of a hard nature, not very fine, but angular; also, the more irregular it is in size, the better. It should be free from any mixture of soft or earthy matter, if it can be procured without. The reason is obvious; for mortar, composed of soft sand, cannot be harder than that sand. Sea-sand makes good mortar, particularly water-mortar. Very hard-burnt brick, or tile, reduced to a coarse powder, also makes an excellent substance to mix with lime, for many purposes. It may be observed, although generally supposed otherwise, that there is really no chemical affinity between lime and sand, it is only a mechanical mixture.

De Lorme observes, that the best mortar is made of puzzolana instead of sand; adding, that this penetrates black flints, and turns them white. Mr. Worledge observes, that fine sand makes weak mortar, and that the larger the sand the stronger the mortar. He therefore advises, that the sand be washed before it is mixed; and adds, that dirty water weakens the mortar considerably. Wolfius recommends that the sand be dry and sharp, so as to prick the hands when rubbed; yet not so earthy as to foul the water in which it is washed.

Vitruvius observes, that fossil sands dry sooner than those taken out of rivers. Whence, he adds, the latter is fitted for the insides, the former for the outsides of a building. But fossil sand lying long in the air, becomes earthy.

Palladio takes notice, that of all sands the white are the worst, from their want of asperity.

The proportion of lime and sand in our common mortar is extremely variable: Vitruvius prescribes three parts of pit-sand, and two of river-sand, to one of lime; but the quantity of sand here seems to be too great.

The best proportion of sand for common mortar, is easily ascertained by trial; enough should be added to render the mortar rather short than tough under the trowel. The proportion varies from 4 parts of sand to 1 of lime, or $1\frac{1}{4}$ parts of sand to 1 of lime, by measure, the proportion differing according to the coarseness of the sand, the nature of the limestone, and the precautions used in burning it; all set proportions being universally adhered to only by those who are utterly ignorant of the subject. In many situations, it is impossible to procure good sand, except at an enormous expense.

Mr. Dossie, in the second volume of the *Memoirs of Agriculture*, p. 20, &c., gives the following method of making mortar—impenetrable to moisture, acquiring great hardness, and exceedingly durable—discovered by a gentleman of Neufchatel: Take of unslaked lime and of fine sand, in the proportion of one part of the lime to three parts of the sand, as much as a labourer can well manage at once; and then adding water gradually, mix the whole well together with a trowel, till it is reduced to the consistence of mortar. Apply it, while hot, to the purpose, either of mortar, as a cement to brick or stone, or of plaster to the surface of any building. It will then ferment for some days in dry places, and afterwards gradually concrete or set, and become hard; but in a moist place it will continue soft for three weeks or more; though it will, at length, attain a firm consistence, even if water have such access to it as to keep the surface wet the whole time. The lime for this mortar must be made of lime-stone, shells, or marl; and the stronger it is, the better the mortar will be. It is proper also to exclude the sun and wind from the mortar, for some days after it is applied; that the drying too fast may not prevent the due continuance of the fermentation, which is necessary for the action of the lime on the sand. When a very great hardness and firmness are required in this mortar, the using of skimmed milk instead of water, either wholly or in part, will produce the desired effect, and render the mortar extremely tenacious and durable.

Dr. Higgins, who made a variety of experiments for the purpose of improving mortar, says, the perfection of lime, prepared for the purpose of making mortar, consists chiefly in its being deprived of its fixed air. On examining several specimens of the lime commonly used in building, he found that it is seldom or never sufficiently burned; for they all effervesced, and yielded more or less fixed air, on the addition of an acid, and slaked slowly, in comparison with well-burned lime. He also recommends that, as lime owes its excellence to the expulsion of fixed air from it in the burning, it should be used as soon as possible after it is made, and guarded from exposure to the air, as much as possible, before it is used.

From other experiments, made with the view of ascertaining the best relative proportions of lime, sand, and water, in the making of mortar, it appeared that those specimens were the best which contained one part of lime in seven of the sand. Also, that mortar, which is to be used where it must dry quickly, ought to be made as stiff as the purpose will admit, or, with the smallest practicable quantity of water; and that mortar will not crack, although the lime be used in excessive quantity, provided it be made stiffer, or to a thicker consistence, than mortar usually is.

In order to the greatest induration of mortar, it must be suffered to dry gently, and set; the exsiccation must be effected by temperate air, and not accelerated by the heat of the sun or fire; it must not be wetted soon after it sets; and afterwards it ought to be protected from wet as much as possible, until it is completely indurated; the entry of acidulous gas must be prevented as much as possible, until the mortar is finally placed and quiescent; and then it must be as freely exposed to the open air as the work will admit, in order to supply acidulous gas, and enable it sooner to sustain the trials to which mortar is exposed in cementitious buildings, and incrustations.

Dr. Higgins also inquired into the nature of the best sand or gravel for mortar, and into the effects produced by bone ashes, plaster-powder, charcoal, sulphur, &c., and he deduces great advantages from the addition of bone-ashes, in various proportions, according to the nature of the work for which the composition is intended.

This author describes an invention of his own for a superior kind of mortar, or stucco, applicable to ornamental work in imitation of stone. As the same general principles ought to be followed in making even the commonest kinds of mortar, we shall insert here the instructions given by Dr. Higgins.

Of sand, the following kinds are to be preferred; first, *drift-sand*, or *pit-sand*, which consists chiefly of hard quartose flat-faced grains, with sharp angles; secondly, that which is the freest, or may be most easily freed by washing, from clay, salts, and calcareous, gypseous, or other grains less hard and durable than quartz; thirdly, that which contains the smallest quantity of pyrites, or heavy metallic matter, inseparable by washing; and fourthly, that which suffers the smallest diminution of its bulk in washing. Where a coarse and fine sand of this kind, and corresponding in the size of their grains with the coarse and fine sands hereafter described, cannot be easily procured, let such sand of the foregoing quality be chosen, as may be sorted and cleansed in the following manner:—

Let the sand be sifted in streaming, clear water, through a sieve which shall give passage to all such grains as do not exceed one-sixteenth of an inch in diameter; and let the stream of water, and the sifting, be regulated so that all the sand which is much finer than the Lynn-sand, commonly used in the London glass-houses, together with clay, and every matter specifically lighter than sand, may be washed away with the stream; whilst the purer and coarser sand, which passes through the sieve, subsides in a convenient receptacle, and the coarse rubbish and rubble remain on the sieve to be rejected.

Let the sand which thus subsides in the receptacle, be washed in clean streaming water through a fine sieve, so as to be further cleansed, and sorted into two parcels; a coarser, which will remain in the sieve which is to give passage to such grains of sand only, as are less than one-thirteenth of an inch in diameter, and which is to be saved apart under the name of *coarse sand*, and a finer, which will pass through the sieve, and subside in the water, and which is to be saved apart under the name of *fine sand*. Let the coarse and the fine sand be dried separately, either in the sun, or on a clean iron-plate, set on a convenient surface, in the manner of a sand-heat.

Let the *stone lime* be chosen, which heats the most in slaking, and slakes the quickest when duly watered; that which is the freshest made and closest kept; that which dissolves in distilled vinegar with the least effervescence, and leaves the smallest residue insoluble, and in the residue the smallest quantity of clay, gypsum, or material matter. Let the lime, chosen according to these rules, be put in a brass wired sieve, to the quantity of fourteen pounds. Let the sieve be finer than either of the foregoing; the finer the better it will be; let the lime be slaked, by plunging it into a butt filled with soft water, and raising it out quickly, and suffering it to heat and fume; and by repeating this plunging and raising alternately, and agitating the lime until it be made to pass through the sieve into the water; and let the part of the lime which does not easily pass through the sieve be rejected; and let fresh portions of the lime be thus used, until as many ounces of lime have passed through the sieve as there are quarts of water in the butt.

Let the water thus impregnated stand in the butt, closely covered, until it becomes clear; and through wooden cocks, placed at different heights in the butt, let the clear liquor be drawn off, as fast and as low as the lime subsides, for use. This clear liquor is called *lime-water*. The freer the water is from saline matter, the better will be the cementing liquor made with it.

Let fifty-six pounds of the aforesaid chosen lime be slaked, by gradually sprinkling the lime-water on it, and especially on the unslacked pieces, in a close clean place. Let the slaked part be immediately sifted through the last-mentioned fine brass-wire sieve: let the lime which passes be used instantly, or kept in air-tight vessels; and let the part of the lime which does not pass through the sieve be rejected. This finer and richer part of the lime which passes through the sieve, may be called *purified-lime*. Let bone-ash be prepared in the usual manner, by grinding the whitest burnt bones; but let it be sifted, so as to be much finer than the bone-ash commonly sold for making cupels.

The best materials for making the cement being thus prepared, take fifty-six pounds of the coarse sand, and forty-two pounds of the fine sand; mix them on a large plank of hard wood placed horizontally, then spread the sand so that it may stand to the height of six inches with a flat surface on the plank, wet it with the lime-water, and let any superfluous quantity of the liquor, which the sand in the condition described cannot retain, flow away off the plank. To the wetted sand add fourteen pounds of the purified lime, in several successive portions; mixing and beating them up together, in the mean time, with the instruments generally used in making fine mortar; then add fourteen pounds of the bone-ash, in successive portions, mixing and beating all together.

The quicker and more perfectly these materials are mixed and beaten together, and the sooner the cement thus formed is used, the better it will be. This may be called *cross-grained cement*, which is to be applied in building, pointing, plastering, stuccoing, or other work, as mortar and stucco generally are; with this difference chiefly, that, as this cement is shorter than mortar, or common stucco, and dries sooner, it ought to be worked expeditiously in all cases; and, in stuccoing, it ought to be laid on by sliding the trowel upwards on it. The materials used along with this cement in building, or the ground on which it is to be laid in stuccoing, ought to be well wetted with the lime-water in the instant of laying on the cement. The lime-water is also to be used when it is necessary to moisten the cement, or when a liquid is required to facilitate the floating of the cement.

When such cement is required to be of a still finer texture, take 98 pounds of the fine sand, wet it with the lime-water, and mix it with the purified lime and the bone-ash, in the quantities and in the manner above described, with this difference only, that 15 pounds of lime, or thereabouts, are to be used instead of 14 pounds, if the greater part of the sand be as fine as Lynn sand. This may be called *fine-grained cement*. It is used in giving the last coating, or the finish, to any work intended to imitate the finer-grained stones or stucco. But it may be applied to all the uses of the *coarse-grained cement*, and in the same manner.

When, for any of the foregoing purposes of pointing, building, &c., a cement is required much cheaper and coarse-grained than either of the foregoing, then, much coarser clean sand than the foregoing coarse sand, or well washed fine rubble, is to be provided. Of this coarse sand, or rubble, take 56 pounds; of the foregoing coarse sand, 28 pounds; and of the fine sand, 14 pounds; and, after mixing these, and wetting them with the cementing liquor, in the foregoing manner, add 14 pounds, or somewhat less, of the bone-ash, mixing them together in the manner already described. When the cement is required to be white, white sand, white lime, and the whitest bone-ash, are to be chosen. Gray sand, and gray bone-ash formed of half-burnt bones, are to be chosen to make cement gray; and any other colour of the cement is obtained, either by choosing coloured sand, or by the admixture of the necessary quantity of coloured talc in powder; or of coloured, vitreous, or metallic powders, or other durable colouring ingredients, commonly used in paint.

This cement, whether the coarse or fine-grained, is applicable in forming artificial stone, by making alternate layers of the cement and of flint, hard stone, or bricks, in moulds of the figure of the intended stone, and by exposing the masses so formed to the open air, to harden.

When such cement is required for water-fences, two-thirds of the prescribed quantity of bone-ashes are to be omitted; and, in the place thereof, an equal measure of powdered terras is to be used; and, if the sand employed be not of the coarsest sort, more terras must be added, so that the terras shall be one-sixth part of the weight of the sand.

When such a cement is required of the finest grain, or in a fluid form, so that it may be applied with a brush; flint powder, or the powder of any quartzy or hard earthy substance, may be used in the place of sand; but in a quantity smaller, in proportion as the flint or other powder is finer; so that the flint-powder, or other such powder, shall not be more than six times the weight of the lime, nor less than four times its weight. The greater the quantity of lime within these limits, the more will the cement be liable to crack by quick drying, and vice-versâ.

Where the above described sand cannot be conveniently procured, or where the sand cannot be conveniently washed and sorted, that sand which most resembles the mixture of coarse and fine sand above prescribed, may be used as directed, provided due attention be paid to the quantity of the lime, which is to be greater as the quality is finer, and vice-versâ.

Where sand cannot be easily procured, any durable stony body, or baked earth, grossly powdered, and sorted nearly to the sizes above prescribed for sand, may be used in the place of sand, measure for measure, but not weight for weight, unless such gross powder be specifically as heavy as sand.

Sand may be cleansed from every softer, lighter, and less durable matter, and from that part of the sand which is too fine, by various methods, preferable in certain circumstances to that which has been already described.

Water may be found naturally free from fixable gas, selenite, or clay; such water may, without any great inconvenience, be used in the place of the lime-water; or a lime-water sufficiently useful, may be made by various methods of mixing lime and water in the described proportions, or nearly so.

When stone-lime cannot be procured, chalk lime, or shell lime, which best resembles stone-lime in the foregoing characters of lime, may be used in the manner described, excepting that fourteen pounds and a half of chalk-lime will be required in the place of fourteen pounds of stone-lime. The proportion of lime, as prescribed above, may be increased without inconvenience, when a cement or stucco is to be applied where it is not liable to dry quickly; and, in the contrary case, this proportion may be diminished. The defect of lime, in quantity or quality, may be very advantageously supplied, by causing a considerable quantity of lime-water to soak into the work, in successive portions, and at distant intervals of time; so that the calcareous matter of the lime-water, and the matter attracted from the open air, may fill and strengthen the work.

The powder of almost every well-dried or burnt animal substance, may be used instead of bone-ash; and several earthy powders, especially the micaceous and the metallic; and the elixated ashes of divers vegetables whose earth will not burn to lime, as well as the ashes of mineral fuel, which are of the calcareous kind, but will not burn to lime, will answer the ends of bone-ash in some degree.

The quantity of bone-ash described, may be lessened without injuring the cement; in those circumstances especially, which admit the quantity of lime to be lessened, and in those wherein the cement is not liable to dry quickly. The art of remedying the defects of lime, may be advantageously practised to supply the deficiency of bone-ash, especially in building, and in making artificial stone with this cement.

As the preceding method of making mortar differs, in many particulars, from the common process, it may be useful to inquire into the causes on which this difference is founded.

When the sand contains much clay, the workmen find that the best mortar they can make must contain about one-half lime; and hence they lay it down as certain, that the best mortar is made by the composition of half sand and half lime.

But with sand requiring so great a proportion of lime as this, it will be impossible to make good cement; for it is universally allowed, that the hardness of mortar depends on the crystallization of the lime round the other materials which are mixed with it; and thus uniting the whole mass into one solid substance. But if a portion of the materials used be clay, or any other friable substance, it must be evident that, as these friable substances are not changed in one single particular by the process of being mixed up with lime and water, the mortar, of which they form a proportion, will consequently be more or less of a friable nature, in proportion to the quantity of friable substances used in the composition of the mortar. On the other hand, if mortar be composed of lime and good sand only, as the sand is a stony substance, and not in the least friable, and as the lime by perfect crystallization, becomes likewise of a stony nature, it must follow that a mass of mortar, composed of these two stony substances, will itself be a hard, solid, unfriable substance. This may account for one of the essential variations in the preceding method from that in common use, and point out the necessity of never using, in the place of sand, which is a durable stone body, the scrapings of roads, old mortar, and other rubbish, from ancient buildings, which are frequently made use of; as all of them consist more or less of muddy, soft, and minutely divided particles.

Another essential point is the nature and quality of the lime. Now, experience proves that, when lime has been long kept in heaps, or untight casks, it is reduced to the state of chalk, and becomes every day less capable of being made into good mortar; because as the goodness and durability of the mortar depends on the crystallization of the lime, and, as experiments have proved, that lime, when reduced to this chalk-like state, is always incapable of perfect crystallization, it must follow, that, as lime in this state never becomes crystallized, the mortar, of which it forms the most indispensable part, will necessarily be very imperfect; that is to say, it will never become a solid stony substance; a circumstance absolutely required in the formation of good durable mortar. These are the two principal ingredients in the formation of mortar; but, as water is also necessary, it may be useful to point out that which is the fittest for this purpose; the best is rain-water, river-water the second, land-water the next, and spring-water last.

The ruins of the ancient Roman buildings are found to cohere so strongly, as to have caused an opinion, that their constructors were acquainted with some kind of mortar, which, in comparison with ours, might justly be called *cement:* and that, to our want of knowledge of the materials they used, is owing the great inferiority of modern buildings in their durability. But a proper attention to the above particulars would soon show, that the durability of the ancient edifices depended on the manner of preparing their mortar more than on the nature of the materials used. The following observations will, we think, prove this beyond a possibility of doubt.

Lime, which has been slaked and mixed with sand, becomes hard and consistent when dry, by a process similar to that which produces natural *stalactites* in caverns. These are always formed by water dropping from the roof. But, when the small drop of water comes to be exposed to the air, the calcareous matter contained in it begins to attract carbonic acid from the atmosphere. In proportion as it does so, it also begins to separate from the water, and to re-assume its native form of lime-stone or marble. When the calcareous matter is perfectly crystallized in this manner, it is to all intents and purposes lime-stone, or marble of the same consistence as before. If lime, in a caustic state, be mixed with water, part of the lime will be dissolved, and will also begin to crystallize. The water which parted with the crystallized lime will then begin to act upon the remainder, which it could not dissolve before; and thus the process will continue, either till the lime be all reduced to an *effete* or crystalline state, or something hinders the action of the water upon it. It is this crystallization which is observed by the workmen when a heap of lime is mixed with water, and left for some time to macerate. A hard crust is formed upon the surface, which is ignorantly called *frosting*, though it takes place in summer as well as in winter. If, therefore, the hardness of the lime, or its becoming a cement, depends entirely upon the formation of its crystals, it is evident that the perfection of the cement must depend upon the perfection of the crystals, and the hardness of the matters which are entangled among them.

The additional substances used in the making of mortar, such as sand, brick-dust, or the like, serve only for a purpose similar to what is answered by sticks put into a vessel full of any saline solution; namely, to afford the crystals an opportunity of fastening themselves upon a nucleus. If, therefore, the matter interposed between the crystals of the lime is of a friable, brittle nature, such as brick-dust or chalk, the mortar will be of a weak and imperfect kind; but, when the particles are hard, angular, and very difficult to be broken, such as those of river or pit sand, the mortar turns out exceedingly good and strong. That the crystallization may be the more perfect, a large quantity of water should be used, the ingredients be perfectly mixed together, and the drying be as slow as possible. An attention to these particulars, and to the quality of bricks and stones, would make the buildings of the moderns equally durable with those of the ancients. In the Roman works, the great thickness of the walls necessarily required a vast length of time to dry. The middle of them was composed of pebbles thrown in at random, and which evidently had thin mortar poured in among them. Thus a great quantity of the lime would be dissolved, and the crystallization performed in the most perfect manner. The indefatigable pains and perseverance for which the Romans were so remarkable in all their undertakings, leave no room to doubt that they would take care to have the ingredients mixed together as well as possible. The consequence of all this is, that the buildings formed in this manner are all as firm as if cut out of a solid rock; the mortar being equally hard, if not more so, than the stones themselves. See Cement, Concrete, Grout.

Mortar, Hydraulic, sometimes also called Roman cement is the composition used in walls under, or exposed to, the action of water, such as those of harbours, docks, &c. The material best adapted to the manufacture of hydraulic mortar is the poorer sorts of limestone, such as contain from 8 to 25 per cent. of foreign matter, in silica, magnesia, alumina, &c. These, when pulverized, absorb water without swelling up, or heating, as a richer lime does, and though calcined, do not slake when moistened, but makes a paste which hardens in a few days *under* water, though in the air it never acquires much solidity. These facts were discovered by Smeaton.

The following analyses of different hydraulic limestones, by Berthier, is given by Dr. Ure in his Dict. of Arts and Manufactures.

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.
A. *Analyses of limestones.*					
Carbonate of lime	97·0	98·5	74·5	76·5	80·0
Carbonate of magnesia	2·0	—	23·0	3·0	1·5
Carbonate of protoxide of iron	—	—	—	3·0	—
Carbonate of manganese	—	—	—	1·5	—
Silica and alumina				15.2	18.0
Oxide of iron	1·0	1·5	1·2		
	100·0	100·0	100·0	100·0	100·0
B. *Analyses of the burnt lime.*					
Lime	96·4	97·2	78·0	68·3	70·0
Magnesia	1·8	—	20·0	2·0	1·0
Alumina	1·8	2·8	2·0	24·0	29·0
Oxide of Iron	—	—	—	5·7	—
	100·0	100.0	100·0	100·0	100·0

"No. 1, is from the fresh-water lime formation of Chateau-Landon, near Nemours; No. 2, the large-grained limestone of Paris; both of these afford a fat lime when burnt. Delormite affords a pretty fat lime, though it contains 42 per cent. of carbonate of magnesia; No. 3, is a limestone from the neighbourhood of Paris, which yields a poor lime, possessing no hydraulic property; No 4, is the secondary limestone of Metz; No. 5, is the lime marl of Senonches, near Dreux; both the latter have the property of hardening under water, particularly the last, which is much used at Paris on this account."

All good hydraulic mortars must contain alumina and silica; the oxides of iron and manganese, at one time considered essential, are rather prejudicial ingredients. By adding silica and alumina, or merely the former, in certain circumstances, to fat lime, a water-cement may be artificially formed; as also adding to lime any of the following native productions, which contain silicates; puzzolana, trass or tarras, pumice-stone, basalt-tuff, slate-clay. Puzzolana is a volcanic product, which forms hills of considerable extent to the south-west of the Appenines, in the district of Rome, the Pontine marshes, Viterbo, Bolsena, and in the Neapolitan region of Puzzuola, whence the name. A similar volcanic tufar is found in many other parts of the world. According to Berthier, the Italian puzzolana consists of 44·5 silica; 15·0 alumina; 8·8 lime; 4·7 magnesia; 1·4 potash; 4·1 soda; 12 oxides of iron and titanium; 9·2 water; in 100 parts.

The tufa stone, which when ground forms trass, is composed of 57·0 silica, 16·0 clay, 2·6 lime, 1·0 magnesia, 7·0 potash, 1·0 soda, 5 oxides of iron and titanium, 9·6 water. This tuff is found abundantly filling up valleys in beds of 10 or 20 feet deep, in the north of Ireland, among the schistose formations upon the banks of the Rhine, and at Manheim in Bavaria.

The fatter the lime, the less of it must be added to the ground puzzolana or trass, to form an hydraulic mortar; the nixture should be made extemporaneously, and must at any ate be kept dry till about to be applied. Sometimes a pro-portion of common sand mortar instead of lime is mixed with he trass. When the hydraulic cement hardens too soon, as in 12 hours, it is apt to crack; it is better when it takes 8 days o concrete. Through the agency of water, silicates of lime, alumina, (magnesia,) and oxide of iron, are formed, which assume a stony hardness.

Beside the above two volcanic products, other native earthy compounds are used in making water cements. To his head belong all limestones which contain from 20 to 30 per cent. of clay and silica. By gentle calcination, a portion of the carbonic acid is expelled, and a little lime is combined with the clay, while a silicate of clay and lime results, asso-iated with lime in a subcarbonated state. A lime-marl con-aining less clay will bear a stronger calcining heat without rejudice to its qualities as a hydraulic cement; but much lso depends upon the proportions of silica present, and the hysical structure of all the constituents."

In England, what is commonly called *cement-stone*, is the ubstance generally used for making this kind of mortar. ; is found in great abundance on the coasts of Kent, in the sles of Sheppey and Thanet, and various other places. The tones vary in size from that of a fist to a man's head, are of yellow-gray or brown colour, interspersed with veins f talc spar. Their specific gravity is 2.59.

The following analyses of several cement-stones, and of ie cement made with them, is taken from the works f Berthier, Davy, and others—

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.
Constituents of the cement stones.					
arbonate of lime	65.7	61.6	—	82.9	63.8

The stones are in this country calcined in kilns, ground, ted, and packed in casks. The colour of the powder is a rk brown, with a tinge of red. It absorbs very little ater when made into paste, and soon hardens. Immediately fore using, it is mixed with sharp sand in various oportions.

This composition is employed in all marine and river-nbankments, in the footings of walls in damp situations, d in various other purposes to which common mortar is suited.

Mortar, *Mixing*, *Blending*, *and Beating of;* M. Felibien serves, that the ancient masons were so very scrupulous the process of properly mixing and blending the materials the making of mortar, that the Greeks kept ten men con-ntly employed, for a long space of time, to each bason; s rendered the mortar of such prodigious hardness, that truvius tells us the pieces of plaster falling off from old lls, served to make tables. Felibien adds, that it was a xim among old masons to their labourers, that they should ute it with the sweat of their brow, i. e., labour at it a long time instead of drowning it with water to have done the sooner.

In modern practice, when the buildings are of considerable magnitude, the mortar is usually ground in a mill; but which-ever way made, it may be laid down as a fixed rule, that the more labour there is bestowed on the mixing and thoroughly blending the mortar, the harder and better will it be, and, as a necessary consequence also, so much more perfect will be the work in which it is used.

The following excellent observations on the advantages of *beating* mortar, are taken from Mr. Weale's useful little work, "Dictionary of Terms of Arts."

"Mortar contained in a mould may be beaten or rammed in the manner of pisé, 'a mode of building formerly in use, whereby walls were formed by ramming and beating down earth, clay, &c., between upright planks,' and acquires by that means great compactness; but an increase of resistance does not always result from it.

"In order that any material be beaten with effect, it is necessary that it should possess a certain degree of consis-tency, which is a mean between complete pulverulence and that state of ductility which constitutes a firm paste. No compression is possible, when the material escapes from under the rammer; and this is still practised by the builders in pisé, who never employ any but earth slightly moistened. Mortar may always be prepared in this way, leaving it, after it has been worked in the ordinary manner, to undergo desiccation to a proper extent.

"The successive approximation of the particles of the compressed material to one another, necessarily determines a foliated structure, which, though it may not be perceived, is nevertheless real. Analogy will lead to the conclusion, that in every possible case, a body thus formed ought to oppose a greater resistance to a tractile force, in proportion as its direction forms a smaller angle with the plane of the laminæ; however, experience shows that this in general does not take place. The following has been determined in this respect:—

"1st. Beating has the effect of augmenting the absolute resistance of mortars of rich limes and pure sand in every case, but in an unequal manner. The greatest resistance assumes a direction perpendicular to the planes of the laminæ, when the mortars are buried in a damp soil immediately after their fabrication. It remains parallel to these same planes, when the mortars have been exposed to the atmospheric influence.

"2nd. The effect of beating is not constantly useful to mortars of hydraulic or eminently hydraulic limes, and cal-careous or quartose sands or powders, except in the case when these mortars are used under a damp soil. The greatest resistance is then in a direction perpendicular to the planes of these laminæ, as with the mortars of rich limes; but in the air the superiority of the mortars which have been beaten, over those which have not, is only exhibited in one direction, and that is parallel to the plane of the laminæ.

"3rd. Beating becomes injurious in every case, when the hydrates of the hydraulic or eminently hydraulic limes are employed without admixture, and subjected to the influence of a damp soil; and is favourable to it only in the direction parallel to the laminæ, when the stuff dries in the air."

Mortar, White, used in plastering the walls and ceilings, is made of ox or cow's hair mixed with lime and water, without any sand. The common method of making this mortar, is one bushel of hair to six bushels of lime.

Mortar, used in making water-courses, cisterns, &c., is made of lime and hogs' grease, sometimes mixed with the juice of figs, and sometimes with liquid pitch; after application, it is washed over with linseed oil.

For this purpose, mortar made of terras, puzzolana, tile-dust, or cinders, is mixed and prepared in the same manner as common mortar: only that these ingredients are mixed with lime instead of sand, in a due proportion, which is about half and half. The lime should be made of shells, or marble; and in works which are sometimes dry and sometimes wet, instead of terras, which is very dear, tile-dust or cinder-dust may be used.

MORTAR, for sun-dials on walls, or for tablets to write on, may be made of lime and sand, tempered with linseed oil; or, for want of that, with skimmed milk. This will grow to the hardness of stone. For buildings, one part of washed soap-ashes, mixed with another of lime and sand make a very durable mortar.

MORTAR MILL, a machine contrived by Mr. Supple, but since much improved by others, for the purpose of saving labour, and more effectually mixing the ingredients in making mortar.

MORTISE, or MORTICE, (from the French, *mortoise*, perhaps derived from *mordeo*, to bite, or pinch,) in carpentry and joinery, an excavation recessed within the surface of a piece of timber, to receive a projection called *a tenon*, left on the end of another piece, in order to fix the two together at a given angle. The sides of the mortise are generally four planes at right angles to each other, and to the surface whence the excavation is made. *See* CARPENTRY and JOINERY.

MORTISE LOCK, a lock made to fit into a mortise cut in the style and rail to receive it.

MORTUARY, a term sometimes used to signify a burial-place.

MOSAIC, or MOSAIC-WORK, (from *mosaicum*, a corruption of *musaicum*, as that is of *musivum*, as it was called among the Romans: but Scaliger derives it from the Greek, *μουσα*, and imagines the name was given to this sort of work, as being very fine and ingenious; and Nebricensis is of opinion it was so called, because *ex illis picturis ornabanter musea*.) an assemblage of little pieces of glass, marble, shells, precious stones, woods, or the like, of various colours, cut square, and cemented on a ground of stucco, &c., imitating the natural colours and gradations of painting. In this sense, mosaic work includes marquetry, or inlaid work, veneering, &c. But, in its more proper and restrained sense, mosaic only takes in works of stone, metals, and glass; those of wood being distinguished by the name of *marquetry* or *inlaying*. (*See* those words.)

Others distinguish differently between mosaic and marquetry. In that properly called *mosaic*, they say the several stones are all of the same colour; and the changes and diminutions of colours and shades are made by applying different stones, one on another, but all of the same colour. Marquetry, on the contrary, consists of stones of different colours; and by these the several colours, shades, gradations, &c., are expressed.

Mosaic seems to have taken its origin from paving: the fine effect and use of pavements composed of pieces of marble of different colours,—so well joined together, as that, when dried, they might be polished, and the whole make a very beautiful and solid body, which, continually trodden upon, and washed with water, was not at all damaged,—gave the painter the hint, who soon carried the art to a much greater perfection, so as to represent foliages, masques, and other grotesque pieces, of various colours, on a ground of black or white marble. But nature not producing variety of colours enough for them in marbles, to paint all kinds of objects, they thought of counterfeiting them with glass and metals coloured.

This kind of work is supposed to have originated in the East, to have been brought from Phenicia to Greece, and thence to Rome, where it was used more especially for pavements. These pavements consisted for the most part of patterns forming borders round a central figure or device, and sometimes a group or subject; others consisted solely of patterns worked out in two or three colours, usually black, white, and red. Of all places, however, the artists of Byzantium carried this art into most extensive practice, covering both walls, pavements, and ceilings with such decoration; mosaics became indeed a very common method of enrichment in Christian churches, both in Asia and Italy. They form the most characteristic decoration of the Basilica. As a style of art, as well as a manufacture, *musive* work may be said to have arisen wholly in the era of Christianity. The material of which the mediæval mosaics are formed being chiefly glass, distinguishes them completely from the tessellated pavements of the Romans. Perhaps the nearest approach to the manufacture, is the rude inlaid work of the columns and fountains in some of the Pompeii gardens: at all events, their application is entirely peculiar to Christianity. The apex of the apse was usually reserved for this species of decoration, which still constitutes the peculiar charm of the ancient Italian churches. The solemn gigantic figures and the mysterious imagery of the mosaics, dimly seen in the darkness of the sanctuary, produce an effect denied to more elaborate specimens of art. In one most important respect they are infinitely preferable to paintings, because, both from their position and their character, they never became the objects of adoration. Usually speaking, the main figure is the Saviour in the act of judging the world; on either side, St. Peter and St. Paul: other saints are added, usually with reference to the peculiar locality. Portraits of popes or emperors connect the sacred imagery with the annals of the age. Although not governed by any definite system, yet there is a uniform course in the adaptation of the ornaments.

Mosaic work is also common in Arabian edifices, so much so indeed as to become a feature of the style. Their mosaics were principally of porcelain, and were used in the decoration of the lower part of the walls, and also for pavements. *See* MOORISH ARCHITECTURE.

A kind of mosaic work was common on the exteriors of some of the mediæval churches of Italy, as the Duomo at Pisa, where the walls of the façade are decorated with a sor of pattern in black and white colours, brilliant reds and blue being interspersed occasionally. Another instance of externa decoration in mosaic is to be seen in the façade of St. Mark's Venice.

Pictures in mosaic, properly so termed, and which are o comparatively recent introduction, differ from the above i being merely copies or fac-similes of paintings, approaching i appearance as nearly to pictures as possible. This style o mosaic work dates only from the commencement of th seventeenth century. The tints are graduated off from ligh to darker shades by using an indefinite number of very sma pieces of glass of various intensities of colour, so placed tha those pieces which are contiguous exhibit scarcely any pe ceptible difference to the eye. In the more ancient mosai the tints are not blended one into the other, but kept qui distinct, the outlines being hard, and the joints between th tesseræ plainly visible. In these examples there is n attempt at making pictures; they are treated in a co ventional manner, so that such features are to be consider as characteristic proprieties rather than defects.

Florentine work may also be added to the list of mosaic it is employed principally in the inlaying of marble slabs for furniture, and decorative work upon a moderate scale.

One description of mosaic work is that of introducing, along with the finest marbles, the richest of precious stones, as lapis lazuli, agates, cornelians, emeralds, turquoises, &c. The practice of making mosaics with coloured glass and metals is now little in use, though of surprising lustre and durability; but that of marbles alone is in common use; the mosaic in precious stones being so very dear, that the few workmen who apply themselves to it, make little else but petty works, as ornaments for altar-pieces, tables for rich cabinets, &c.

MOSQUE, (from the Arabic, *Maschiad*, or *Medsched*, and intermediately the Spanish and Portuguese *Mezquita* and *Masqueta*,) a Mohammedan place of worship, the distinctive marks of which are generally cupolas and minarets. Internally they exhibit nothing remarkable as to plan or accommodation, forming merely a large hall or apartment, without any seats or other fittings-up, and with no other decoration than that of pavements and carpets, or arabesques and mosaics on the walls. In regard to these latter, some of the mosques at Cairo are highly embellished. Although more famed than any other, the mosque at Santa Sophia at Constantinople exhibits nothing of Mohammedan or Arabian architecture, but was originally built as a church, and is in the Byzantine style.

All mosques are square buildings, generally constructed of stone. Before the chief gate there is a square court paved with white marble; and low galleries round it, whose roof is supported by marble pillars. In these galleries the Turks wash themselves before they go into the mosque. In each mosque there is a great number of lamps; and between these hang many crystal rings, ostriches eggs, and other curiosities, which, when the lamps are lighted, make a fine show. As it is not lawful to enter the mosque with stockings on, the pavements are covered with pieces of stuff sewed together, each being wide enough to hold a row of men kneeling, sitting, or prostrate. The women are not allowed to enter the mosque, but stay in the porches without. About every mosque there are six high towers, called *minarets*, each of which has three little open galleries, one above another: these towers, as well as the mosques, are covered with lead, and adorned with gilding and other ornaments, and from thence, instead of a bell, the people are called to prayers by certain officers appointed for that purpose. Most of the mosques have a kind of hospital belonging to them, in which travellers of what religion soever, are entertained three days. Each mosque has also a place called *tarbe*, which is the burying-place of its founders; within which is a tomb six or seven feet long, covered with green velvet or satin; at the ends of which are two tapers, and round it several seats for those who read the koran and pray for the souls of the deceased. *See* Moorish Architecture.

MOTION, *Local*, a continued or successive change of place.

Motion, *Absolute*, the change of place in a moving body, independent of any other motion.

MOVEMENT, (from the French,) in architecture, a term used by some writers to express the rise and fall, the advance and recess, with other diversities of form, in the different parts of a building.

MOULD, *Glaziers'*. The glaziers have two kinds of moulds: in one they cast the lead into long rods, or canes, fit to be drawn through the vice, in which the grooves are formed; this they sometimes call *ingot-mould*. In the other, they mould those little pieces of lead, a line thick, and two lines broad, which are fastened to the iron bars of casements, &c.

Mould, among masons, a piece of hard wood, or iron, hollowed on the edge, answerable to the contours of the mouldings or cornices, &c., to be formed. It is otherwise called *a caliber;* and is made to a section of the stone intended to be cut. The ends, or heading-joints, being formed as in a cornice by means of the mould, the intermediate parts are wrought down by straight-edges, or circular templets, according as the work is straight or circular upon the plan.

When the intended surface is required to be very exact, a reverse mould is used, in order to prove the work, by applying the mould in a transverse direction to the arrises.

MOULDS, among plumbers, the tables on which they cast their sheets of lead; sometimes called simply *tables*. Besides these, they have others, in which they cast pipes, without soldering.

MOULDINGS, in architecture, prismatic or annular solids, formed by plane and curved surfaces, and employed as ornaments.

All parallel sections of straight mouldings, all the sections of annular mouldings, made by a plane at the same inclination to the axis, and, in general, all sections of mouldings made by a plane perpendicular to any one of the arrises, are similar figures. Mouldings are divided into two classes, or kinds; Grecian and Roman.

Grecian mouldings are formed of some conic section, as a portion of the ellipsis or hyperbola; and sometimes even of a straight line, in the form of a chamfer.

Roman mouldings have their sections composed of the arcs of circles, the same moulding having the same curvature throughout.

In both Grecian and Roman mouldings, their species is determined by the position of their extremities, or the circumstance of their being concave or convex: if the section be a semicircle projecting from a vertical diameter, the moulding is called an *astragal*, *bead*, or *torus*.

If the moulding be convex, and its section the quarter of a circle, or less, and if one extremity project beyond the other, that is, approach nearer to the eye than the other, it is termed a *Roman ovolo;* and if this Roman ovolo project equal to its height, and the portion employed be the quadrant of a circle, it is then called a *quarter-round*. If the section of a moulding be concave, but in all other respects the same as the last, it is denominated a *cavetto*.

If the section of a moulding be partly concave and partly straight, the straight part being vertical and a tangent to the concave part, and the concavity equal to, or less than the quadrant of a circle, the moulding is denominated an *apophygé*, *scape*, *spring*, or *congé:* this is used in the Ionic and Corinthian orders for joining the bottom of the shaft to the base, as well as to connect the top of the fillet to the shaft under the astragal.

If the section be one part concave and the other convex, and so joined as to have the same tangent, the moulding is named a *cymatium;* but Vitruvius calls all crowning or upper members cymatiums, whether they resemble the one now described or not.

If the upper projecting part of the cymatium be a concave, it is called a *sima-recta;* this is generally the crowning member of cornices, but is seldom found in other situations except on pedestals or altars.

If the upper projecting part of the cymatium be convex, it is called a *sima-reversa*, and is the smallest in any composition of mouldings, its office being to separate the larger members. Though seldom used as a crowning member of cornices, it is frequently employed with a small fillet over it, as the upper member of architraves, capitals, and imposts.

If the convex part of a moulding recede and meet a horizontal surface, the recess formed by the convexity and the horizontal surface is termed a *quirk.*

If the section of the moulding be a convex conic section, the intermediate part of the curve projecting only a small distance from the greatest projecting extremity, and the tangent to the curve at the receding extremity meeting a horizontal line, produced forward without the curve at the upper extremity, the moulding is called an *ovolo.* This is generally employed above the eye, as a crowning member in the Grecian Doric. Ovolos may be used in the same composition of different sizes; it is sometimes cut into egg-and-tongue, or egg-and-dart, when it is termed *echinus.* It is employed instead of a torus in the base of the monument of Lysicrates, at Athens. The contours of ovolos are generally elliptical or hyperbolical curves. These curves can be regulated to any degree of quickness or flatness; the parabola can also be drawn under these conditions, but its curvature, being of the intermediate species, does not afford the variety of change admitted by the other two.

If the section be a concave semi-ellipsis, having its conjugate diameter such that the one may unite the extremities of its projections, and the other diameter parallel to the horizon, the moulding is termed a *scotia.* This is always employed below the level of the eye, between two tori. One extremity has generally a greater projection than the other, the greater projection being nearest to the level of the eye.

If the section of the moulding be the two sides of a right angle, the one vertical, and the other, of course, horizontal, it is termed a *fillet, band,* or *corona.* A fillet is the smallest rectangular member in any composition of mouldings. Its altitude is generally equal to its projection; its purpose is to separate two principal members, and it is used in all situations under such circumstances. The corona is the principal member of a cornice. The facia is a principal member in an architrave as to height, but its projection is not more than that of a fillet, unless it be the lower facia, where the soffit is the whole breadth of the top, or sometimes even of the bottom of the shaft. Mouldings are either plain, or enriched with eggs, and with foliage displayed in a variety of forms; some enrichments are peculiar to certain forms, as egg-and-anchors, or egg-and-tongue, to the ovolo.

Mouldings in assemblage are used in the formation of cornices, architraves, bases, capitals, &c. *See* Apophyge, Cavetto, Cymatium, Echinus, Ovolo, Quarter-Round, Scape, Scotia, Sima-Recta, Sima-Reversa.

Plate I.—*Figure* 1, a quarter-round.

Figure 2, a cavetto, being exactly the reverse of the last figure; both being the quarter of a circle.

Figure 3, the sima-reversa, composed of two quadrants of a circle.

Figure 4, the sima-recta, being the reverse of the sima-reversa.

Figure 5, a torus, which is a semicircle described upon a vertical diameter.

Figure 6, a scotia, which, projecting equally at each extremity, occasions the contour to be exactly the reverse of the torus.

The following are the methods of describing Roman mouldings, where the projections and heights are unequal; the extremities of the moulding being given.

Figure 7.—*To describe the Roman ovolo.* Let A be the upper extremity, and B the lower; take the vertical line or height; from B, with that radius, describe an arc; from A, with the same radius, describe another arc, cutting the former at *c;* then from *c*, with the same radius, describe the arc A B, which will be the contour required.

Figure 8.—*To describe the cavetto.* With a radius equal to the height of the moulding, from the points A and B describe arcs, cutting each other in *c;* then from *c*, with the same radius, describe the arc A B, which will give the contour of the cavetto required.

Figure 9.—*To describe a sima-reversa, that shall touch a straight line at the points of contrary flexure.* Join the projections A and B by the straight line A B; bisect A B in D; draw the tangent E D, parallel to a line given in position; through D draw *c c*, perpendicular to E D; bisect A D by a perpendicular, *g c;* from the intersection *c*, describe the arc A *g* D; make D *c* equal to *c′;* from the lower point *c′*, describe the arc D B: then the curve of contrary flexure, A D B, will be the sima-reversa required.

Figure 10.—*To describe a sima-recta to touch a straight line at the points of contrary flexure, parallel to a line given in position.* Join the points of projection A and B; bisect A B in D, and draw the line D E parallel to the line given in position; bisect A D by the perpendicular *c g*; from *c*, with the radius *c* D, describe the arc A D; make D *c′* equal to D *c*, and from the other point *c′* within, describe D B: then A D B is the sima-recta required.

Figure 11.—*To describe the Grecian ovolo, two tangents being given, as also their points of contact.* Let A E and E B be the tangents; A and B the points of contact; complete the parallelogram B E A *d;* produce B *d* to *c*, and make *d c* equal to *d* B; divide E A and *d* A each into the same number of equal parts; through the points of division in E A, draw lines to B; draw lines to *c* through the corresponding points in *d* A, to meet the corresponding lines drawn to B; and the intersections will be in the curve of an ellipsis. The upper part, A Q, is a continuation of the same curve.

The same directions extend to *Figures* 12, 13, 14: but the following difference may be observed:

In *Figure* 11, the tangent B E is regulated by taking the point E in the middle of A D. In *Figure* 12, the point E is one-third of A D from the bottom. In *Figure* 13, in the middle of A D, as in *Figure* 11. In *Figure* 14, the point E is one-third of A D, from A. Then, according as the tangent is lower or higher, the curve will be quicker or flatter at the same projection: so that, among these curves, *Figure* 12 is the boldest, and *Figure* 14 the flattest.

When E B and A E are nearly equal, the moulding is the boldest of any, taking D E at the same height; but when the projection is very great, or very small, the moulding is extremely flat.

Figure 15.—*The same data being given, to describe the Grecian ovolo; supposing the point of contact,* B, *to be the extremity of one of the axes.* Draw B K perpendicular to E B; also P *c* perpendicular to B K, for the other axis, so that the point P may be above A; then E B and P *c* will be parallel. To find the major axis: from A, with the distance B *c*, describe an arc, cutting P *c* at F; draw A F, and produce it to meet B K in I; make *c* P equal to A I; then with *c* P, half the major axis, and *c* B, half the minor axis, describe the curve B A P Q, which will be the moulding required.

This method forms the most beautiful moulding of any, the curvature being continually increased from the point B to [illegible]

The same description applies to *Figures* 16 and 17. With regard to the quirk at the point Q, it will be more or less, [illegible] the point A is more or less distant from Q.

The quantity of curvature depends upon the angle E B [illegible] so that when the angle E B D is less, the curvature w[illegible] be greater.

For a description of mouldings employed in Norman a[nd] Gothic Architecture, we must refer the reader to t[he] subjects treated of under these respective titles.

MOULDING-PLANE. *See* Plane, and Tools.

Mouldings, *Raking*. *See* Raking Mouldings.

MOUTH, in the courts of princes, an apartment consisting f several rooms, as offices, kitchens, &c., where the meat ntended for the first tables is dressed by itself.

MULLIONS, in pointed architecture, all those parts of vindows which divide the light into compartments, and are ither curved or straight.

Vertical mullions are called *munnions;* and those which un horizontally are called *transoms*. The whole of the nullions of a window above the springing of the arch are alled the *head-work*.

MULTILATERAL, (from the Latin, *multus*, many, and *atera*, sides) in geometry, a term applied to figures which ave more than four sides or angles, more usually called *olygons*.

MULTIPLICATION, (from the Latin, *multiplicatio*) the ct of multiplying, or increasing a number. Accurately peaking, in every multiplication, the multiplier must always e considered as a number; and it is easy to conceive a quanty of any kind multiplied by a number. But to talk of a ound multiplied by a pound, a debt by a debt, or a line by line, &c., is unintelligible. However, by analogy, in the pplication of algebra to geometry, we meet with such expresions, and nothing is more common than to find A B × B C, ɔ denote the rectangle A B C D, the length of which is A B, nd the breadth B C. But this is only to be understood by nalogy; because, if the number expressing the measure of he side A B were multiplied by the number expressing the neasure of B C, the product would express the measure of B C D.

The sign of multiplication mostly used among algebraists, s ×. But the Germans, after Leibnitz, only make use of point placed between the quantities multiplying each other, hus: $a \cdot b$ is the same as $a \times b$; and A B . B C, the same s A B × B C, or the rectangle of A B into B C.

MUNIMENT-HOUSE, a small strong apartment in athedral and collegiate churches, castles, colleges, or the ke, destined for keeping the seal, evidences, charters, &c., f such church, colleges, &c., called *muniments*, or *miniments*.

MUNNIONS, see Mullions.

MURAL, (from the Latin *murus*) something belonging to wall. Thus mural monument, arch, and columns, *i. e.* ttached to the wall.

Mural Arch, a wall, or walled arch, placed exactly in ıe plane of the meridian, *i. e.* upon the meridian line, for ıe fixing of a large quadrant, sextant, or other instrument, ɔ observe the meridian altitudes, &c., of the heavenly odies. Tycho Brahe was the first who used a mural arch . his observations; after him, Helvelius, Flamsteed, De la Iire, &c., used the same means.

MUSES, (from the Greek μουσαι) fabulous divinities of ıe ancient heathens, who were supposed to preside over the rts and sciences.

The ancients admitted of nine Muses, and made them the aughters of Jupiter and Mnemosyne, or Memory. At first, ideed, their number was but three; *viz.*, Melete, Mneme, ıd Aœde; Greek words, signifying *meditation*, *memory*, ıd *singing:* but a certain sculptor of Sicyon, according to 'arro, having orders to make three statues of the three Iuses for the temple of Apollo, and mistaking his instructions, made three several statues of each Muse: these however, were found so beautiful, that they were all set up in the temple; and from that time they began to reckon nine Muses; to whom Hesiod afterward gave names; *viz.* Calliope, Clio, Erato, Thalia, Melpomene, Terpsichore, Euterpe, Polyhymnia, and Urania.

Each of these was to preside over her respective art; Calliope over heroic poetry; Clio over history; Melpomene over tragedy; Thalia over comedy; Euterpe over wind-music; Urania over astronomy; Terpsichore over the harp; Erato, the lute; Polyhymnia, rhetoric.

They are painted as young, handsome, and modest; agreeably dressed, and crowned with flowers. Their usual abodes were about mount Helicon, in Bœotia, and mount Parnassus, in Phocis. Their business was to celebrate the victories of the gods, and to inspire and assist the poets; and hence the custom of invoking their aid at the beginning of a poem.

MUSEUM, (from the Greek μουσειον) originally signified a palace of Alexandria, which occupied at least a fourth part of the city; and was so called from its being set apart to the Muses and the sciences.

Here were lodged and entertained a great number of learned men, who were divided into companies or colleges, according to the sciences or sects of which they were professors. And to each house or college was allotted a handsome revenue. This establishment is attributed to Ptolemy Philadelphus, who fixed his library in it.

Hence the word has passed into a general denomination, and is now applied to any place set apart as a repository for things that have some immediate relation to the arts, or to the Muses.

MUTILATED CORNICE, one that is broken or discontinued.

Mutilated Roof, see Roof.

MUTILATION, (from the Latin *mutilatio*, maiming) the retrenching or cutting away any part of a regular body. The word is extended to statues and buildings where any part is wanting, or the projection of any member discontinued.

MUTULE, in architecture, a part of the Doric cornice, appearing to support the corona and the superior members, formed by three vertical parallelograms at right angles, and an inclined plane which descends towards the front of the cornice, until it meets the rectangular vertical plane, the inclined plane being the soffit, and the two vertical parallel planes being at right angles to the surface of the frieze, and the vertical plane on the front parallel thereto.

Mutules had their origin from the ends of rafters in the original wooden structures, and are, therefore, properly represented with a declination towards the front of the corona; though represented by an architect of the last century with a level soffit. See Doric Order.

MYLASSENSE MARMOR, in the works of the ancients, a species of marble dug near the city of Mylassense in Caria. It was of a black colour, but with an admixture of purple, not disposed in veins, but diffused through the whole mass. It was much used in building among the Romans.

MYNCHERY, the same as Nunnery, which see.

MYRON, a celebrated statuary of Greece. He made a cow of brass, of admirable workmanship, much lauded by writers of that period.

N.

NAILS (from the Saxon *nægl*) in building, &c. small metalline-spikes, serving to bind or fasten the parts together, &c.

The several kinds of nails are very numerous; as *back-nails*, made with flat shanks to hold fast, and not open the wood. *Clamp-nails*, proper to fasten the clamps in buildings, &c. *Clasp-nails*. or *brads*, whose heads being flatted, clasp and stick into the wood, rendering the work smooth, so as to admit a plane over it: the most common in building are distinguished by the names *ten-penny*, *twenty-penny*, *two-shilling*, &c. *Clench-nails*, used by boat, barge, &c. builders, with boves or nuts, and often without: for fine work, they are made with clasp heads, or with the head beat flat on two sides. *Clout-nails*, ordinarily used for nailing on of clouts to axle-trees, are flat-headed, and iron-work is usually fixed with them. *Deck-nails* are for fastening of decks in ships, doubling of shipping, and floors laid with planks. *Dog-nails*, or *jobent-nails*, proper for fastening of hinges to doors, &c. *Flat-points* are of two kinds, *viz. long*, much used in shipping, and proper where there is occasion to draw and hold fast, yet no necessity of clenching; and *short*, which are fortified with points, to drive into oak, or other hard wood. *Lead-nails* used to nail lead, leather, and canvass, to hard wood, are the same as *clout-nails*, dipped in lead or solder. *Port-nails*, commonly used for nailing hinges to the ports of ships. *Ribbing-nails*, used to fasten the ribbing, to keep the ribs of ships in their place in building. *Rose-nails* are drawn square in the shank, and commonly in a round tool. *Rother-nails*, chiefly used to fasten rother-irons to ships. *Scupper-nails*, much used to fasten leather and canvass to wood. *Sharp-nails*, much used, especially in the West Indies, with sharp points and flat shanks. *Sheathing-nails*, used to fasten sheathing-boards to ships: the rule for their length is, to have them full three times as long as the board is thick. *Square-nails*, of the same shape as *sharp-nails;* chiefly used for hard wood. *Brads*, long and slender, without heads, used for thin deal work, to prevent splitting. To these may be added *tacks;* the *smallest* serving to fasten paper to wood; *middling*, for wool-cards and oars; and *larger*, for upholsterers and pumps. They are distinguished by the names of *white-tacks*, *two-penny*, *three-penny*, and *four-penny*, *tacks*.

NAIL-HEAD MOULDING, a Norman moulding, so named from its appearance, which is that of a surface studded with nails or nail heads.

NAKED FLOORING, the whole assemblage, or contignation of timber-work, for supporting the boarding of a floor on which to walk. Naked flooring consists of a row of parallel joists, called *floor-joists*.

When naked flooring consists of two rows of joists, of which the upper is supported by the under row, all the joists of the upper row crossing every one of the under at right angles, the supporting or lower row are called *binding-joists;* while the joists supported, or those of the upper row, are denominated *bridging-joists*. When the ends of binding-joists are framed into each side of a strong beam, such beam is called a *girder*. There are many curious methods of joining timbers in short lengths; for which the reader whose curiosity inclines to investigations of this nature, may consult the subsequent part of this article, from Wallis's *Opera Mathematica*, vol. I. prop. x. chap. vi., where he will find the demonstrations relating to the strength of timbers, according to their dispositions and bearings, and where several very ingenious methods of combining timbers in the forms of squares, oblongs, equilateral triangles, and pentagons, are shown by that renowned author. Of this species of flooring, Serlio has exhibited a design. Godfrey Richards, in his *Palladio*, exhibits the diagrams of two floors of this description, executed in Somerset House, which, he says, "was a novelty in England." Notwithstanding the ingenuity of this method of construction, it has been long out of use, probably, from the general introduction of foreign timber, which furnishes any lengths requisite for the purpose of building.

All the joists in the same floor, to which the boarding is attached, should be disposed in one direction, as the heading-joints of one set of boards should never meet the edges of another: the strength of the work, however, is by no means to be sacrificed, by a wrong disposition of the joisting, in order to make the joints of the boarding parallel to each other; symmetry of appearance being but a trifle compared to the strength of the work. Indeed the ends of the boards may be made to meet the edges of others under the bottom edge of the door in each apartment, should such a disposition be necessary.

In double naked flooring, when the binding-joists run parallel to the chimney side of the room, the joist nearest to such side ought to be placed at a distance from the breast of the chimney, equal to the breadth of the hearth, with an allowance for the brick trimmer by which the hearth is supported.

Floors are constructed by different methods, according to the bearing of the timber. When the rooms have small dimensions, the floor generally consists of single joists; when large, the framing for the support of the floor consists of two rows of beams, the lower supporting the higher: when the extent is so great, that the lower rows of beams would be too much weakened to support the upper rows and the floor for walking upon, a strong beam, called a *girder*, is introduced, so as to divide the length of the apartment; or two, three, &c., are introduced, so as to divide the length into three or four equal parts, as may be required for bearing the timber. The girders thus introduced should always be placed in the breadth or least dimension of the rectangle, or floor. The lower row of parallel beams are called *binding-joists*, and the transverse beams, which are supported by them, *bridgings* or *bridging-joists*. The binding-joists are framed into the girder, or girders, and the bridgings are notched upon the binding-joists.

Plate I. *Figure* 1.—A section of naked flooring, without binding-joists, but with a girder, into which the joists that support the flooring are framed, and the ceiling-joists into deep joists, which also support the boarding. The end of the girder is shown in No. 1, as also the sections of the ceiling joists. No. 2 is the transverse section of the floor, showing the sections of the boarding-joists, as also the sections of the strong joists, and the sides or longitudinal directions of the ceiling-joists.

Figure 2.—A section of a double floor. No. 1, shows the longitudinal section of the binding joists, a section of the girder, and the sections of the bridging and ceiling-joists. No. 2 shows the sections of the binding-joists, and the longitudinal directions of the bridging and ceiling-joists.

When girders are extended beyond a certain length, the

acquire a degree of curvature from their weight, which in time reduces them to a concavity on the upper side, called *sagging*. To prevent this disagreeable consequence, without any intermediate support from the floor below, a strong truss, in the form of a low roof, is introduced between two equal beams, so as to make the whole discharge the weight at each extremity. To prevent the bad effects resulting from the shrinking of the timber, the truss-posts are generally constructed of iron, screwed and nutted at the ends; and to give a firmer abutment, the braces are let into a groove in each fitch or side. The abutment at each end is also made of iron, and is either screwed, nutted, and bolted through the thickness of both halves, that the braces may abut the whole dimensions of their section; or otherwise the two abutments are made in the form of an inverted wedge, where they are screwed and nutted. These modes may either be constructed with one truss-bolt in the middle, or with two, dividing the whole length into three equal parts: a straining-piece being placed in the middle, shortens the braces, and elevates them at a higher angle, so that the truss may give a more powerful resistance to the superincumbent weight. The braces may be constructed of oak, or of cast-iron; the bolts, from their nature, must be of wrought-iron.

As iron is subject to contraction and expansion, it is less eligible for the braces than wood, which is almost invariable in any degree of temperature, as to heat or cold; oak is therefore generally employed for this purpose.

Figure 3.—A longitudinal section of a truss-girder, consisting of two braces, meeting the truss-bolt in the middle.

Figure 4.—A longitudinal section of a truss-girder, divided into three parts; consisting of two braces, with a straining piece in the middle. No. 1. A longitudinal vertical section. No. 2. The upper side.

When the bearing is very great, the truss would require to be deep, to enable it to resist with greater efficacy: this construction may be as in *Figure* 5.

Figure 6.—Middle bolt.

Figure 7.—Abutment, as shown in *Figures* 3 and 4.

Figure 8.—Washers, to prevent a partial sinking of the nuts.

"*To construct the plain raftering for a floor, by joining together rafters that otherwise would not extend across the given space, so that the whole extent of the area may be perfectly level; and to estimate, by calculation, the pressure upon the whole, and upon the parts separately.*

"I. *The construction of the raftering.*—Plate II. Let *Figure* 1 exhibit the square area, any side of which is about quadruple the length of the longest rafter: the rafters are so fitted into each other as reciprocally to support themselves. The rafters that are dovetailed into the beams laid on the wall, are cut the whole depth of the timber, into the tenon of the dovetail; the mortise for this tenon is therefore in the wall-beam. The other ends of these rafters, each of which is fitted into the wall-beams, is formed into a tenon of about half the depth of the rafter; the mortise for this tenon is therefore, in another rafter, notched to a correspondent depth, so that the upper parts of both may be flush with each other, as will also happen to the lower sides. And because the tenon is but half the depth of the wood, the rafter to which it belongs is supported by half the depth of the rafter in which is the mortise, every rafter carrying the one that is fitted into it; as this is the case throughout the whole extent of the area, they must necessarily support each other over all parts of the area: and the parts towards the middle of the area, where, from the natural flexibility of the timber, the only fear is to be apprehended, lest, by the weight above, the interior of the floor should sink down, have this disadvantage provided against, by the excavations not extending precisely to the middle of the timber, but being a little deficient towards the middle. For, as by this method the raftering will rise progressively with each joint from the exterior to the centre of the area, any small depression that, from the weight above, might take place, will not be sufficient to reduce it below the fair level throughout; the curvature produced on the whole will compensate the weight, and prevent any hollow taking place.

"*Figure* 2, exhibits the side face of one of the longer timbers; where the end tenons and mortises, at one-third and two-thirds of the whole lengths, are sufficiently well exhibited: and *Figure* 3, shows one of the shorter timbers in that view which offers the end tenons and the single mortise. The upper face of all the rafters appears very plainly from *Figure* 2.

"But since they are disposed in so compact an order in this last-named Figure, the process may be much more easily understood from a close investigation of the diagrams than it can be from any explanation.

"It is very obvious, that the four great beams laid upon the wall are the first with which we ought to begin; for we would naturally proceed from these principal beams to the secondaries or rafters. Now, if we examine these principal beams, we shall find, that into each there are dovetailed five rafters or secondaries, and these have their other ends supported by other rafters parallel to the wall-beams; and those which carry the rafters dovetailed into the wall-beams, are themselves supported by others in a transverse direction; and so on, till they arrive at the opposite wall.

"For example, the rafter & s has one end dovetailed into the wall-beam, but the other end is supported by the rafter & z; this last rafter, & z, has one end dovetailed into another wall-beam, but the other end, z, is supported by the rafter P Q: and the rafter U Y has one end dovetailed into the wall-beam, but the other end, Y, is carried by P Q in the same manner as & Z: P Q is supported at P by I K, and at Q by R S: but I K and R S do also support the rafter O N, which in its turn supports the ends F, M, of the rafters F E, M L; H M L supports R X and V W; then we have determined the support of R, one end of the rafter S R; and V W supporting V, the end of the rafter V U, we come to V U supporting H G and I K: but the end, U, of the rafter V U, is supported by Y U; Y is supported by P Q, and P Q supports also & Z, and is itself supported by S R: but S R is supported by R X and S &: and thus we trace round the exterior framing, and discover the aid which these rafters reciprocally lend each other, to render the whole secure and compact. For if we follow the concatenation, we shall discover, from the slightest inspection of the diagram, the principle upon which, in regular succession, the parts conduce to give strength to the whole. In the same manner, when we begin to trace, from the centre of the framing, every rafter, A B and C D are supported by A B and E F; and also from these we trace L M, G H, and N O, reciprocally supported and giving their support; and following the others that are connected with those now named, we go on till we arrive at those which terminate, and are supported by the principal beams on the wall; as clearly appears from the plan.

"This method enables us to construct a floor scantling of this description with many, or even with few rafters; but in any other method, as in the case of an oblong differing but little from a square, we shall have to employ the following conditions:

"For example, in this same case the whole wall can be laid out, so that the rafters R S, U V, and & S brace, and are themselves braced; or, where the rafters & Z, M L, and P Q, are braced by others, or themselves are bracers; whence the area is extended less widely, as by the paucity of the rafters it extends from wall to wall by the rafters S &c, Q P, U V, L M, R S, and Z &c; but so long as there is occasion for only four rafters, the construction may be similar to *Figure* 4, or even of only three, as in *Figure* 5, which is the most simple form of any.

"But even if there were occasion (*Figure* 1) the rafters X R, W V, (and the remaining shorter ones that terminate in the wall) might be produced to an equal length with the others, and would support the corresponding rafters parallel to the principal beams, in which are fixed X R, V W, and Y U; and thus the ends of these, continued, would either be supported by the beams lying upon the wall, or even by others, as far as the area is extended, parallel to M L and P Q; and so on, to any distance that the work may require. For in the continued area, the number of the rafters being augmented, the weight may be increased to as much as the walls are able to sustain; for rafters may be found that will not give way, nor break under any weight the walls will carry.

"But although we are able to proceed safely in this regular proportion, it is from calculation that we must discover the weight which such a piece of framing will bear. For if it appears, from the quantity of weight laid on, that the rafters will everywhere bear it, then as much of the weight as any situation, or place of the area, has laid upon it, being in like proportion also laid on another, it becomes regularly and fairly distributed over the whole; and hence is the best judgment formed of what may safely be done. The calculation when the number of timbers is few, is pretty easy; but more laborious where there are many.

"But I shall show by what method this may be effected; each rafter of the continued framing, joined to its fellow, is subjected to this calculation; perplexed in a manner, it is true, from their number, but producing the result much more rapidly where there are few rafters.

"*Calculation accommodated to the raftering now explained.*

"That the calculation delivered in the following synopsis may be more clearly understood, it is to be observed, as is indeed sufficiently indicated to the eye, that some of the rafters are longer than others; and that the longer are about one and a half of the shorter ones. On this account we shall designate the weight of each of the longer rafters by T; and that of each of the shorter by $\frac{2}{3}$ T.

"But the weight upon every one of the joints of the rafters, will be indicated by the letter written on that joint in the diagram.

"Let it be moreover observed, since it may tend to elucidate our subject, that there are always four points which, on account of their similarity of situation in regard to the whole framing, equally determine the weight laid on them: these we shall always designate by the same marks, lest the number of the symbols should increase, and the calculation be thereby perplexed. Hence we shall have four A's, similarly situated and equally loaded, the same number of B's, and so on with the others. Whence it will be, for example (to No. 2, or the following equation) $B = \frac{1}{2}T + \frac{2}{3}C + \frac{1}{3}A$; in the same way, also, if the point, B, of the rafter, A B, thus subjected, be said to sustain as much weight as is laid upon it; besides that firmness which is necessary to prevent the wood giving way from the weight it carries, as this equation does not involve it; so much then is $\frac{1}{2}T$ (one half of the weight lying on A B, one of the longer rafters); then $\frac{2}{3}C$ (two-thirds of the weight of the same A B, situated on the point C; seeing that in C, A, it is understood to be cut in three different ways by the points); then $\frac{1}{3}A$ (one-third of the weight of the same rafter A B is placed in A.) Whence also there will be (to No. 21.) $W = \frac{1}{3}T + \frac{1}{2}V$: here we discover that in the point W of the rafter L M, the weight placed upon it is as much as is $\frac{1}{3}T$ (one-half of the weight of the short rafter, which is also a third of the longer one); then $\frac{1}{2}V$ (one-half of the weight, which is placed over the middle point, V, of the rafter so lying upon this one); which, by similarity, enables us to obtain 25 in the first equations.

"The equation 26, and those which follow, are derived from the preceding, which we have cited by numbers written for those equations; whence the manner of the whole process may be more clearly deduced. These partly serve for abbreviating fractions, as often as the numerators and denominators may be divided by the same common measure: but their most essential use is, to reduce and explain the preceding equations, by substituting the value of every individual symbol, and explaining it by other marks, on which account, as often as any symbols are expunged, the number of those which remain is sensibly lessened, till at last some one of the symbols unknown from the beginning, is expressed by the known quantity T, the weight of the longer rafters, considered simply by itself; and then, by examining every step of the preceding equations, the values of the remaining symbols are also found first of the unknown weights.

"For example, when there is (No. 1.) $A = \frac{1}{2}T + \frac{2}{3}A + \frac{1}{3}C$ (on account of A being found on both sides of the equation) it is manifest, that on taking away $\frac{2}{3}A$ on both sides, there will remain $\frac{1}{3}A = \frac{1}{2}T + \frac{1}{3}C$; that is (by multiplying both sides by 3) $A = \frac{3}{2}T + C$; and thus we have (No. 26.) this equation, as derived from the first equation (No. 1.) and which we have cited.

"By similarity, since it may be (No. 2.) $B = \frac{1}{2}T + \frac{2}{3}C + \frac{1}{3}A$; and (by No. 26) it may be $A = \frac{3}{2}T + C$; and so $\frac{1}{3}A = \frac{1}{2}T + \frac{1}{3}C$; B will be $(= \frac{1}{2}T + \frac{2}{3}C + \frac{1}{3}A = \frac{1}{2}T + \frac{2}{3}C + \frac{1}{2}T + \frac{1}{3}C) = T + C$. Whence we have this equation ($B = T + C$) No. 27, as derived from No. 2 and 26. And in like manner for the others.

"But, at no time, as we have said, is there more than the abbreviation of the fraction, as a reduction to less results by a common divisor. As when (No. 64) we have

$$H = \frac{6912\,T + 672\,G + 552\,I + 2790}{2907 = 3 \times 969};$$

and then all the members can be divided by 3; we have No. 65 (as derived from No. 64) the equation

$$H = \frac{2304\,T + 224\,G \times 184\,I + 930}{969};$$

and so for others.

"But as all these reductions and abbreviations of the equations are deduced singly, as we have deduced these few, we shall here briefly express them all in a continued synopsis; indicating those antecedent equations upon which the other depend.

"SYNOPSIS OF THIS CALCULATION.—*Figure* 1.

No.

1. $A = \frac{1}{2}T + \frac{2}{3}A + \frac{1}{3}C.$
2. $B = \frac{1}{2}T + \frac{2}{3}C + \frac{1}{3}A.$
3. $C = \frac{1}{2}T + \frac{2}{3}G + \frac{1}{3}I.$
4. $D = \frac{1}{2}T + \frac{2}{3}I + \frac{1}{3}G.$
5. $E = \frac{1}{2}T + \frac{2}{3}B + \frac{1}{3}D.$
6. $F = \frac{1}{2}T + \frac{2}{3}D + \frac{1}{3}B.$
7. $G = \frac{1}{2}T + \frac{2}{3}E + \frac{1}{3}L.$
8. $H = \frac{1}{2}T + \frac{2}{3}L + \frac{1}{3}E.$
9. $I = \frac{1}{2}T + \frac{2}{3}N + \frac{1}{3}P.$
10. $K = \frac{1}{2}T + \frac{2}{3}P + \frac{1}{3}N.$
11. $L = \frac{1}{2}T + \frac{2}{3}W + \frac{1}{3}X.$

"All this weight lying on the building, or wall, is n necessarily distinguished by a distinct calculation; becaus those evidently correspond with others which are situated the ends of their respective rafters. For example, when th rafter X R does not rest exactly upon its middle, the fulcrum, whether it sustains one-half the weight of the rafter at X, and the other on the wall, then also the half of the burden is placed at R.

"It is obvious, from this calculation, that the joinings about A, toward the middle of the framing, press most of all. Since the particular weight of these is about nine of the longer rafters (but of the others, less by a ninth part of the wood) to each of which there will be added, half the weight of the rafter for firmness deducted, lest by its own weight it should break, and moreover one-half of the weight of the joint C lying upon it, being about four of the rafters. And so, by computing the whole, the strength requisite, lest a rafter should give way, will equal more than thirteen times the weight of the rafters, and be about fourteen times $9\frac{27191}{340167} + 4\frac{394549}{1360668} = 13\frac{503313}{1360668} = 13\frac{167771}{453556}$: the computation in weight of each rafter.

"No doubt can now remain that the rafters, even the longest, can be made of such firmness as shall enable them to sustain any weight that may be placed upon them individually to fourteen times the weight of the whole; neither can it be doubted, that raftering of this description is the safest that can possibly be applied to purposes where great weights are to be carried.

"Another form of this construction. *Figure* 6 exhibits another form, differing from the preceding in this, that where the ends of two of the rafters lie upon a third, they are jointed by two distinct dovetails; into these a third rafter is notched, and all are so placed as to be supported by those parts: hence to the middle part of each rafter are fastened two others, but to opposite parts.

"*Figure* 7 exhibits the lateral face: the upper face is sufficiently obvious from *Figure* 6. All these rafters are of an equal length, and similar among themselves.

"But here, as in the preceding construction, the work may be more or less extended, and the condition of the timber will be equally determined both as to the aid it gives and the weight it will carry. For, as in the protracted area, the number of the beams is augmented, so is also the weight. But this construction is attended with a disadvantage from both the beams' weight lying upon one, which having to endure the burden on an individual part of the beam, it is more strenuously pressed; that is, it has to sustain the entire weight of two ends, one entire beam; for, in this construction, equal to that of the half, which in the preceding was not borne, is here to be supported at one and the same point; on this account, also, the wood at that mortise is very much weakened, by being cut away to enable it to support the two beams, which rest their tenons in one place. This in some measure seems to be compensated by the resting timbers being placed towards opposite parts, which in the preceding construction lay towards the same parts; although, in this also it is not of much consequence, especially if the ends of the beams, resting on the others, are not extended toward the centre, but kept pretty close to the outer part of the framing, which is easily done by the judicious management of the architect.

"But this inconvenience forms no substantial objection to the plan, since the rafters are sufficiently strong and well joined to support any proportionate weight, as will be obvious from the subjoined investigation of their strength.

"In looking at what is before us, the former of these figures seems the stronger, because the timbers are so disposed that the workmanship is more obvious to the eye; while in the latter it is scarcely distinguishable, and the intervals are so varied as to give the work a distorted appearance: yet in both they are squares; and in the latter the spaces beyond the half-rafter from the wall-beams are also resolved into the same figure.

"The calculation in this construction, will result from the same principles as in the preceding; but here it will be much more expeditious, because, as all the timbers are of the same length, and they support the weight of the corresponding timbers about the centre, they are almost all pressed by an equality of weight about the same part: all which conduce to render the results more readily to be obtained.

"*Calculation adapted to this construction.*

"With respect to the facility of this calculation, it may be observed, that the points (whether five or four) which are similarly posited in respect of the scheme, and on that account support an equality of weight, are designated by the same symbol that was adopted in the preceding problem. But, here, on account of the individual pieces of wood supporting the same weight, and that too about the same part, the two ends of each rafter have to support the same weight; these ends we shall therefore express by the same symbols, the equal weight being denoted by a similar sign. Other methods of proof might be mentioned, but the foregoing will be sufficient for our purpose.

"SYNOPSIS OF THIS CALCULATION.

1. $\mathrm{A} = \alpha = \frac{1}{2}\mathrm{T} + \mathrm{B}$.
2. $\mathrm{B} = \beta = \frac{1}{2}\mathrm{T} + \frac{1}{2}\mathrm{K} + \frac{1}{2}\mathrm{F}$.
3. $\mathrm{C} = \frac{1}{2}\mathrm{T} + \mathrm{A}$.
4. $\mathrm{D} = \delta = \frac{1}{2}\mathrm{T} + \mathrm{L}$.
5. $\mathrm{E} = \varepsilon = \frac{1}{2}\mathrm{T} + \frac{1}{2}\beta + \frac{1}{2}\mathrm{R}$.
6. $\mathrm{F} = \frac{1}{2}\mathrm{T} + \frac{1}{2}\mathrm{C} + \frac{1}{2}\mathrm{G}$.
7. $\mathrm{G} = \gamma = \frac{1}{2}\mathrm{T} + \mathrm{E}$.
8. $\mathrm{H} = \frac{1}{2}\mathrm{T} + \frac{1}{2}\alpha + \frac{1}{2}\mathrm{D}$.
9. $\mathrm{I} = \iota = \frac{1}{2}\mathrm{T} + \frac{1}{2}\varepsilon + \frac{1}{2}\mathrm{N}$.
10. $\mathrm{K} = \kappa = \frac{1}{2}\mathrm{T} + \frac{1}{2}\mathrm{H} + \frac{1}{2}\mathrm{I}$.
11. $\mathrm{L} = \lambda = \frac{1}{2}\mathrm{T} + \frac{1}{2}\kappa$.
12. $\mathrm{M} = \mu = \frac{1}{2}\mathrm{T} + \frac{1}{2}\mathrm{P}$.
13. $\mathrm{N} = \nu = \frac{1}{2}\mathrm{T} + \frac{1}{2}\lambda + \frac{1}{2}\mathrm{M}$.
14. $\mathrm{P} = \pi = \frac{1}{2}\mathrm{T} + \frac{1}{2}\iota$.
15. $\mathrm{Q} = \frac{1}{2}\mathrm{T} + \frac{1}{2}\gamma$.
16. $\mathrm{R} = \rho = \frac{1}{2}\mathrm{T} + \frac{1}{2}\pi + \frac{1}{2}\mathrm{Q}$.
17. $\mathrm{C} = \mathrm{T} + \mathrm{B}$, by 3, 1.
18. $\mathrm{D} = \mathrm{T} + \frac{1}{2}\kappa$, by 4, 11.
19. $\mathrm{F} = \frac{5}{4}\mathrm{T} + \frac{1}{2}\mathrm{B} + \frac{1}{2}\mathrm{E}$, by 6, 7, 17.
20. $\mathrm{H} = \frac{5}{4}\mathrm{T} + \frac{1}{2}\mathrm{B} + \frac{1}{4}\kappa$, by 8, 1, 18.
21. $\mathrm{M} = \frac{3}{4}\mathrm{T} + \frac{1}{4}\iota$, by 12, 14.
22. $\mathrm{N} = \mathrm{T} + \frac{1}{4}\kappa + \frac{1}{4}\mathrm{P}$, by 13, 11, 12.
23. $\mathrm{N} = \frac{9}{8}\mathrm{T} + \frac{1}{4}\kappa + \frac{1}{8}\iota$, by 22, 14.
24. $\mathrm{Q} = \frac{3}{4}\mathrm{T} + \frac{1}{2}\mathrm{E}$, by 15, 7.
25. $\mathrm{R} = \frac{9}{8}\mathrm{T} + \frac{1}{4}\mathrm{E} + \frac{1}{4}\iota$, by 16, 14, 24.
26. $\mathrm{B} = \frac{9}{8}\mathrm{T} + \frac{1}{4}\mathrm{B} + \frac{1}{4}\mathrm{E} + \frac{1}{2}\mathrm{K}$, by 2, 19.
27. $\mathrm{B} = \frac{9\,\mathrm{T} + 2\,\mathrm{E} + 4\,\mathrm{K}}{6}$, by 26.
28. $\mathrm{E} = \frac{29}{16}\mathrm{T} + \frac{7}{24}\mathrm{E} + \frac{1}{8}\mathrm{I} + \frac{1}{3}\mathrm{K}$, by 5, 25, 27.
29. $\mathrm{E} = \frac{87\,\mathrm{T} + 6\,\mathrm{I} + 16\,\mathrm{K}}{34}$, by 28.
30. $\mathrm{H} = 2\,\mathrm{T} + \frac{1}{6}\mathrm{E} + \frac{1}{12}\mathrm{K}$, by 20, 27.
31. $\mathrm{I} = \frac{17}{16}\mathrm{T} + \frac{1}{2}\varepsilon + \frac{1}{16}\mathrm{I} + \frac{1}{8}\kappa$, by 9, 23.
32. $\mathrm{I} = \frac{17\,\mathrm{T} + 8\,\varepsilon + 2\,\kappa}{15}$, by 31.
33. $\mathrm{K} = \frac{31}{15}\mathrm{T} + \frac{7}{20}\mathrm{E} + \frac{43}{120}\mathrm{K}$, by 10, 30, 32.
34. $\mathrm{K} = \frac{248\,\mathrm{T} + 42\,\mathrm{E}}{77}$, by 33.

35. $I = \frac{361\,T + 140\,E}{3 \times 77 = 231}$, by 32, 34.

36. $E = \frac{11389\,T + 952\,E}{34 \times 77 = 2618}$, by 29, 34, 35.

37. $E = \frac{1627\,T + 136\,E}{34 \times 11 = 374}$, by 36.

38. $E = \frac{1627}{238}\,T$, by 37.

39. $G = \frac{1746}{238}\,T$, by 7, 38.

40. $Q = \frac{992}{238}\,T$, by 15, 39.

41. $K = \frac{1654}{238}\,T$, by 34, 38.

42. $L = \frac{946}{238}\,T$, by 11, 41.

43. $D = \frac{1065}{238}\,T$, by 4, 42.

44. $B = \frac{2002}{238}\,T$, by 27, 38, 41.

45. $A = \frac{2121}{238}\,T$, by 1, 44.

46. $C = \frac{2240}{238}\,T$, by 3, 45.

47. $F = \frac{2112}{238}\,T$, by 6, 39, 46.

48. $H = \frac{1712}{238}\,T$, by 8, 43, 45.

49. $I = \frac{1358}{238}\,T$, by 32, 38, 41.

50. $P = \frac{798}{238}\,T$, by 14, 49.

51. $M = \frac{518}{238}\,T$, by 12, 50.

52. $N = \frac{851}{238}\,T$, by 13, 42, 51.

53. $R = \frac{1014}{238}\,T$, by 16, 40, 50.

That is, in Alphabetical Order.

$A = 8\frac{217}{238}\,T.$	$I = 5\frac{168}{238}\,T.$
$B = 8\frac{98}{238}\,T.$	$K = 6\frac{226}{238}\,T.$
$C = 9\frac{98}{238}\,T.$	$L = 3\frac{232}{238}\,T.$
$D = 4\frac{113}{238}\,T.$	$M = 2\frac{42}{238}\,T.$
$E = 6\frac{199}{238}\,T.$	$N = 3\frac{137}{238}\,T.$
$F = 8\frac{208}{238}\,T.$	$P = 3\frac{84}{238}\,T.$
$G = 7\frac{80}{238}\,T.$	$Q = 4\frac{40}{238}\,T.$
$H = 7\frac{46}{238}\,T.$	$R = 4\frac{62}{238}\,T.$

It appears from this calculation that the greatest of the separate weights will be $A = 8\frac{217}{238}\,T$. When therefore upon this point (C C in the middle of the wood) there lie two A's (on both sides) it is $7\frac{196}{230}\,T$; and so on, in like manner, lest any rafter give way by its own weight. Whence one-half the weight of the timber is determined. The strength requisite there, is the same, lest that beam give way, which is equal to the weight of the respective beams $8\frac{217}{238} + 8\frac{217}{231} + \frac{1}{2} = 18\frac{77}{238} = 18\frac{11}{34}$. But indeed this weight is not so great as to occasion any apprehension for the strength of the timber; for even if the timbers be pretty long, they are sufficient to bear any weight that may be laid upon them, to eighteen or even to nineteen times their own weight.

"Here the weight is indeed heavier than in the preceding case; for there, the pressure amounted only to fourteen times the weight of the timber.

"In the mean time, the conditions of this construction dispense with a multiplicity of rafters, as the length of the area within the walls extends to twelve times the length of the whole, the length and breadth of the rafters remaining. For in this case the rafters being joined are equal to 49, but in the other the longer are 40 and the shorter 20."

Naked of a Column, or Pilaster, the surface of the shaft or trunk, when the mouldings are supposed to project. Thus we say, a pilaster ought to exceed the naked of the wall by so many inches, and that the foliages of capital ought to answer to the naked of the columns.

Naked of a Wall, the remote face whence the projectures take their rise. It is generally a plane surface, and when the plan is circular, the naked is the surface of a cylinder, with its axis perpendicular to the horizon.

NAOS or Nave (from the Greek *ναος*, *a temple*) the chamber or enclosed apartment of a temple. The part of the temple which stood before the naos, comprehended between the wall and the columns of the portico, was called the *pronaos*; while the corresponding part behind was called the *posticum*.

NAPIER'S BONES, or RODS, a contrivance of Napier to facilitate the performance of multiplication and division, explained by him, in his Rabdologia, published in 1617. The invention would perhaps have been more employed, but for his discovery of logarithms: but even yet it might be used with advantage by young arithmeticians in verification of their work.

These rods may be made of bone, ivory, horn, wood, pasteboard, or any other convenient material. There are five of them, and the face of each is divided into nine equal parts, each being subdivided by a diagonal line into two triangles. In these compartments or squares the numbers of the multiplication table are inserted, the units or right-hand figures being placed in the right hand triangle, and the tens in the left.

NARTHEX, the name of an enclosed space in the ancient Christian churches, and also of an ante-temple or vestibule without the church. To the Narthex the catechumens and penitents were admitted; and there appears to have been several such apartments in each church, but nothing certain is known of their position. Narthex is frequently used as synonymous with *porch* and *portico*.

NATTES, a name given to an ornament used in the decoration of surfaces in the architecture of the 12th century, from its resemblance to the interlaced widths of matting.

NATURAL BEDS, of a stone, the surfaces from which the laminæ were separated. It is of the utmost consequence to the duration of stone walls, that the laminæ should be placed perpendicular to the face of the work, and parallel to the horizon, as the connecting substance of these thin plates, or laminæ, is more friable than the laminæ themselves, and consequently liable to scale off in large flakes, and thus reduce the work to a state of rapid decay.

NAVE (from the Saxon *naf*) in architecture, the body of a church; or the place where the people are seated; reaching from the rail or baluster of the choir to the chief door. The ancient Greeks called the nave *pronaos*; the Latins frequently call it *cella*. *See* Naos.

The nave of the church belongs to the parishioners, who are bound to keep it in repair, &c.

NAUMACHIA, the representation of a sea-fight among the Romans, which was sometimes performed in the Circus Maximus or amphitheatre, water being introduced sufficient to float ships; but more frequently in places made especially for the purpose, which were called Naumachiæ. Julius Cæsar appears to have been the first who gave a representation of a sea-fight on an extensive scale. He dug a lake in the Campus Martius for the purpose, which, however, was filled up in his life-time. Augustus also dug a lake near the Tiber for the same purpose, which was afterwards turned into a park or plantation. Another lake was dug in the Campus Martius by Caligula; but Claudius exhibited a naumachia on the lake Fucinus, now Celano. The naumachia, in which Titus is said by Suetonius to have exhibited a sea-fight, has occasioned some dispute among the learned; some understanding it to be the Circus Maximus, and others the lake dug by order of Augustus. Domitian appears to have been the first who erected a building of stone around these artificial lakes. Previous to his time the spectators appear to have sat upon wooden benches, which might be easily made to rise gradually above one another with the earth which had been dug out of the artificial lake. In later times the naumachia were usually surrounded with buildings like the amphitheatre or circus.

The ships which were engaged in these sea-fights were divided into two parties, which were called respectively by the names of different maritime nations, as the Tyrian and Egyptian fleets, the Sicilian and Rhodian. The combatants, who were called Naumachiarii, were usually composed of captives or criminals, who fought to death, unless saved by the clemency of the emperor. These sea-fights were said to have been exhibited on such a scale of magnificence and splendour as almost to surpass our belief. In the naumachia exhibited by Nero, there were sea-monsters swimming about in the artificial lake, and Claudius caused a Triton, made of silver, to be placed in the middle of the lake Fucinus, who was made, by machinery, to give the signal of attack with a trumpet. In Domitian's naumachia the number of ships engaged was almost equal to two real fleets, and in the sea-fight on the lake Fucinus, there are said to have been no fewer than 19,000 combatants.

NEBULE (from the Latin *nebula*, a cloud) an ornament of the zig-zag form, but without angles. It is chiefly found in the remains of Saxon architecture, in the archivolts of doors and windows.

NECK, of a capital, the space between the channelures and the annulets of the Grecian Doric capital. In the Roman Doric, it is the space between the astragal and the annulet.

The rich Ionic capitals of Minerva Polias, and Erechtheus, at Athens, have neckings, but most other antique examples of the Ionic order are without them.

NEEFS, PETER, in biography, a painter of architecture, and a disciple of Henry Steenwick, born at Antwerp, in the year 1570. He was particularly skilful in perspective, and generally chose such subjects as required a considerable display of that science; such as the interior of churches, splendid halls, &c. These he drew with great neatness and effect, and painted very clear, gay, and agreeable, but he never equalled the truth of his master. His execution of the mouldings and masses of columns, in the various Gothic works which he chose as models, is too neat, and too much made up of lines, for real imitation; but that very defect gives them lightness; and the truth with which he drew the forms of the building, and proportioned his figures, which are very freely wrought, though not unfrequently by other artists, renders them very agreeable. Van Fulden, Teniers, and Breughel, were often called upon to assist Neefs, and by their skilful execution made amends for his want of knowledge of the human figure. He died at the age of 81, leaving a son, whose name also was Peter, and who is denominated *the Young*, in contradistinction to his father, whose excellence in the art of painting he never rivalled, although he had the advantage of his example and instruction, and practised in the same branch of the art.

NEGATIVE QUANTITIES, are those quantities which are preceded or effected with the negative sign.

Negative sign, in algebra, is that character or symbol, which denotes subtraction, being a short line preceding the quantity to be subtracted, and is read *minus*; thus, $a - b$ denotes that the quantity b is to be taken from the quantity a, and is read *a minus b*; like signs produce *plus*, and unlike signs *minus*, hence $-a \times b = +ab$. The introduction of this character has given rise to various controversies, with regard to the legality or illegality of certain conclusions depending upon it; some maintaining, that as a negative quantity is in itself totally imaginary, it ought not to be introduced into a science, the excellency of which depends upon the rigour and certainty of its conclusions; while others, running into the opposite extreme, have endeavoured to illustrate what will not admit of illustration, and thus, like other zealots, have been the greatest enemies of the cause they were endeavouring to defend.

It is in vain to attempt to define what can have no possible existence; a quantity less than nothing is totally incomprehensible; and to illustrate it, by reference to a debtor and creditor account, to say the least of it, says Barrow, is highly derogatory to this most extensive and comprehensive science.

NERVES, in architecture, the mouldings of the groined ribs of Gothic vaults.

NET, or RETE, (from the Saxon, *net*, derived from the Gothic, *nati*) the covering of a body or geometrical solid. *See* ENVELOPE and SOFFIT.

NET MEASURE, in building, is when no allowance is made for finishing; and in artificers' works, when no allowance is made for waste of materials.

NET MASONRY. *See* MASONRY and STONE WALLS.

NEWEL, in architecture, the upright post or central column, round which the steps of a circular staircase are made to wind; being that part of the staircase by which they are sustained.

The newel is, properly, a cylinder of stone, which bears on the ground, and is formed by the ends of the steps of the winding-stairs.

There are also newels of wood, which are pieces of timber placed perpendicularly, receiving the tenons of the steps of wooden stairs into their mortises, and wherein are fitted the shafts and rests of the staircase, and the flights of each story. In some of the Tudor and Elizabethan residences, some very fine examples may be seen of the newel richly ornamented, and adding much to the beauty of the staircase.

NICHE, (from the Italian, *niechia*, shell) in architecture, a cavity, or hollow place, in the thickness of a wall, to place a figure or statue in.

Niches are made to partake of all the segments under a semicircle. They are sometimes at an equal distance from the front, and parallel or square on the back with the front line; in which case they are called *square recesses*, or *square niches*. The larger niches serve for groups of figures, the smaller for single statues, and sometimes only for busts.

Great care must be taken to proportion the niches to the figures, and the pedestal of the figures to the niches.

Niches are sometimes made with rustic work.

Few niches are to be found in Grecian antiquity, but what may be supposed to have been erected under the dominion of the Romans.

In the Pantheon at Rome, the niches are all rectangular recesses, dressed in the same manner as the apertures of doors; the columns are insulated, and the entablatures crowned with triangular and circular pediments alternately. The large niches, or exedræ, on the sides, have cylindrical backs, but finish at top with the soffit of the architrave of the general entablature; these niches have each two columns placed in the aperture which supports the architrave. The entablature is continued without any break or interruption of recesses, except by the large cylindro-spherical niche opposite the entrance, and the side through which the entrance is made; but neither of these is supposed to have been in the original edifice, but to have been introduced at some later period. The large niches on the exterior side within the portico are cylindro-spherical, without any dressings. In the remains of the piazza of Nerva (see Desgodetz's *Antiquities of Rome*) a niche is exhibited upon a circular plan, with a rectangular front and cylindrical head in the middle of the attic, over the intercolumns; the axis of the cylinder, forming the head of the niche, is horizontal, and parallel to the naked of the wall. This niche is surrounded with an architrave, standing upon the base of the attic, which projects to receive it, and the head of the architrave supports the crowning of the attic.

The *Ruins of Palmyra*, by Wood, exhibit niches of various kinds, some of which are very fantastically dressed. The inside of the portico of the temple of the sun has two niches, one on each side of the doorway, with cylindrical backs, terminated at the head with spheroidal tops, which show an ellipsis on the face with its greater axis horizontal. These niches are decorated with four attached columns, whose axes are placed in the surface of a cylinder: the entablature over the columns terminates under the spheroidal head; the head is decorated with a shell, and surrounded on the front with an elliptic archivolt upon the face of the wall. *See Plates* VI. and IX. *of the Ruins of Palmyra.*

The inside of the portico of the court of the same edifice, shown in *Plate* XI. exhibits two niches on each side of the doorway, which terminate on the front in parallel lines, and with a semicircle at the head; they finish with a pilaster on each side: the capital, which is Corinthian, serving as an impost to the archivolt surrounding the head. Besides this dressing, a column is placed on each side, attached to the wall, so that the distance between the insides of the columns is greater than that between the outsides of the pilasters; the architrave of the entablature rests upon the archivolt of the head of the niche.

The inside of the court of the great temple of Balbec exhibits niches dressed in the most whimsical manner: the sides of the niches terminate with the wall in vertical lines, and the head with the said wall in a semicircle.

The sides finish with Corinthian pilasters; the entablature is horizontal over the pilasters; but the architrave and cornice are carried round the semicircular head of the niche, which appears to be spherical within, being decorated with a shell resting upon an impost, and corresponding in its situation to the height of the capital on each side. The inside of the temple of Jupiter, at Spalatra, is decorated with niches, one between every two columns; the one opposite the entrance, and those on each of the two sides, are rectangular below, but finish with cylindric heads: the axis of the cylinder, which forms the head, is parallel to the horizon, and in the direction of radii which belong to the cylindric wall, in which these niches are placed.

The other four niches are cylindro-spherical; that is, they have cylindrical backs, and are terminated with spherical heads. All these niches are decorated with an impost, continued from side to side, and the heads are furnished with archivolts.

In the pointed style of architecture, niches are sometimes highly decorated. The back very frequently consists of three sides of a hexagon, and the head is terminated with a rich canopy, forming a complete hexagon with the interior; the under part of each of the three projecting sides of the canopy has a Gothic arch, and the soffit represents a groined vault, decorated with tracery and ribs in the most beautiful manner.

The bottoms of these niches are formed by a table of the same shape as the head, and terminate below in the form of a pendant.

The ceiling of the canopy represents the groined roof of an hexagonal building in miniature, as some of the highly decorated chapter-houses exhibit; the top of the canopy finishes with battlements; and the vertical angles are sometimes finished with pendant buttresses, which are surmounted with pinnacles elaborately finished with crockets.

Niche, in carpentry, the wood-work to be lathed over for plastering.

The most usual construction of niches in carpentry, are those with cylindrical backs and spherical heads, called *cylindro-spheric niches;* the execution of which depends upon the principles of spheric sections.

As all the sections of a sphere are circles, and those passing through its centre are equal, and the greatest which can be formed by cutting the sphere; it is evident, that if the head of a niche is intended to form a spherical surface, the ribs may be all formed by one mould, whose curvature must be equal to that of a great circle of the sphere, viz., one passing through its centre: but the same spherical surface may be formed by ribs of wood moulded from the sections of lesser circles, in a variety of ways; though not so eligible for the purpose as those formed of great circles; because their disposition for sustaining the lath is not so good, and the trouble of moulding them to different circles, and of forming the edges according to different bevels, in order to range them in the spherical surface, is very great, compared with those made from great circles.

The regular dispositions for the head of a niche are the following:

The ribs of niches are generally disposed in a vertical plane, parallel to each other, or intersecting each other in a vertical line. When the line of intersection passes through the centre of the sphere, all the ribs are great circles; but if the line of intersection do not pass through the centre of the sphere, the circles which form the spherical surface are all of different radii.

When the ribs are fixed in parallel vertical planes, their disposition is either parallel to the face of the wall, or parallel to a vertical plane passing through the centre of the sphere perpendicular to the surface of the wall; and this will be understood whether the surface be a plane, or that of a cylinder, or that of a cylindroid.

Though these dispositions are the most common and most fit for the purpose, there is still another regular position of the ribs of a niche, which is easily constructed in practice, viz. by making all the ribs intersect in a line passing through the centre of the sphere perpendicular to the surface of the wall; but this method is not so eligible for lathing upon.

Another method is by making the planes of the ribs parallel to the horizon: this is not only attended with great labour in workmanship, but is incommodious for lathing upon.

The number of positions in which the ribs of a niche may be placed are almost infinite; as the ribs may have a common intersection in a line or axis obliquely situated to the horizon, or their position may be in parallel planes obliquely situated to the horizon: but the regular positions already enumerated, ought to be those to which the carpenter should direct his attention.

Plate I. *Figure* 1, No. 2, the elevation of a niche, where all the ribs intersect each other in a vertical line, coinciding with the inside of the front rib, as shown by the plan, No. 1.

To describe any one of the ribs, as $m\ n$, continue the inside circle of the plan round beyond the wall, as far as may b

found necessary: produce *f i*, the base of the rib, to meet the opposite circumference in *g*; bisect *g e* at *h*; from *h*, with the radius *h e*, describe the arc *e l*; draw *d f* perpendicular to the other side of the plan of the rib, cutting *g e* at *f*; from *h*, with the radius *h f*, describe the arc *f k*; from the centre draw *i n* perpendicular to *g e*, the base, cutting the other circles at *k* and *l*; from the same centre, *h*, draw *m n* at any convenient distance, so as to make the rib sufficiently strong: the two inner arcs *f k*, and *e l*, show the part to be taken from the side of the rib in order to range its inner edge. In the same manner every other rib may be described.

Figure 2, No. 2, the elevation of a niche, where the ribs are posited in parallel vertical places perpendicular to the face of the wall.

The method of describing the ribs is as follows: Draw a line through the centre of the circle which forms the plane, parallel to the face of the wall. Suppose it were required to describe the rib whose base is *f h*: produce *f h* to meet the line parallel to the face of the wall in *g*; from *g*, as a centre, with the distance *g f*, describe the arc *f k*; draw the short line *d e* perpendicular to *g f*, cutting *d f* in *e*: from *g*, with the radius *g e*, describe the arc *e i*, so that *e i* and *f k* may terminate upon the inside of the front rib, A C, in the points *i* and *k*: then *e i* and *f k* will show the bevelling of the edge in order to range in the spherical surface.

In the same manner may all the other ribs be described.

Figure 3, shows the method of forming the spherical head of a niche, when the planes of the ribs are parallel to the front rib, or to the face of the wall. No. 1, the plan; No. 2, the elevation. The figure is so obvious as hardly to require any description, the ribs being all semicircles of different diameters, as shown by the plan: the parts darkly shadowed, are the places where the ribs come in contact with the plate or sill on which they stand; and show the degree of bevelling requisite for the edges, in order that they may range with the spherical surface. This disposition of the ribs is very convenient for fixing the laths, which may be all directed towards the centre, the workmanship in bevelling is very considerable.

In order to strengthen the work, a vertical rib is made to pass through the centre of the sphere, perpendicular to the surface of the wall.

Figure 4, is a very convenient method of forming the head of a niche, by making the planes of all the ribs to intersect in a common axis, passing through the centre of the sphere, perpendicular to the surface of the wall; but it is not so convenient for fixing the laths.

Plate II. *Figure* 1, is the most convenient method of any for fixing the laths, and the ribs are all described from one mould: they need only be cut to different lengths in order to agree with their seats or plans.

No. 1, is the elevation; No. 2, the plan. The lengths of the ribs are shown below, at No. 3, 4, and 5. The bases of the different ribs are taken from their seats on the plan. The double lines show the bevel at the top, where they come in contact with the back of the front rib.

Figure 2, is a different construction from the foregoing methods, which all spring from a horizontal plane passing through the centre of the sphere, and consequently the cylindrical surface will be a tangent to the spherical surface, at their junction. Whereas, in the present instance, the head of the niche is still spherical, but the horizontal plane from which it springs is higher than the centre of the sphere: this occasions a little more difficulty in the formation of the ribs, of which the construction is as follows:

The plan, or springing rib, which forms the top of the cylindric back, and the front rib, which is the segment of a circle, being given; to form the moulds of the back ribs.

Through the centre, *d*, of the plan, draw L M parallel to G I, the seat of the front rib; from *d*, with the radius *d* G, or *d* I, describe the arcs G L and I M; draw *d e* perpendicular to L M; then find the centre, E of the front rib; and draw D E perpendicular to A C, cutting A C in D; make *d e* on the plan equal to D E; from *e*, as a centre, with the radius *e* L, or *e* M, describe the arc L *m n o* M, which will be the curve of all the ribs.

To find the length required for any rib.

Let *f*, *h*, and *k*, be the points where the back ribs join the back of the front rib: from *d*, as a centre, with the distance *d f*, describe the arc *f g*, cutting L M at *g*; draw *g m* perpendicular to L M: then the part *m* M is the length which will stand over the seat of the rib, which meets at *f*. In the same manner, the lengths of the other ribs, which meet at *h* and *k*, will be ascertained; and thus having obtained the ribs for one half, the other half is also found; they being duplicates of each other.

The method of bevelling the heads of these ribs is the same as in the preceding examples.

The plan of a niche in a circular wall being given, to find the front rib.

Plate III. *Figure* 1, *No.* 1, is the plan given, which is a semicircle, whose diameter is *a b*; and *a*, *i*, *k*, *l*, *m*, *h*, the front of the circular wall; suppose the semicircle to be turned round its diameter, *a b*, so the point *v* may stand perpendicular over *h* in the front of the wall, the seat of the semicircle standing in this position upon the plan will be an ellipsis; therefore divide half the interior arc of the plan into any number of equal parts, as five; draw the perpendiculars 1 *d*, 2 *e*, 3 *f*, 4 *g*, 5 *h*; upon the centre, *c*, with the radius *c h*, describe the quadrant of a smaller circle, which divide into the same number of equal parts as the interior of the plan; through the points 1, 2, 3, 4, 5, draw parallel lines to *a b*, to intersect the others at the points *d*, *e*, *f*, *g*, *h*; through these points draw a curve, and it will be an ellipsis; then take the stretch-out of the interior of the plan, round 1, 2, 3, 4, 5, and lay the divisions from the centre both ways at F, stretched out; take the same distances *d i*, *e k*, *f l*, *g m*, from the plan, and at F make *d i*, *e k*, *f l*, equal to them, which will give a mould to bend under the front rib, so that the edge of the front rib will be perpendicular to *a*, *i*, *k*, *l*, *m*.

Note, The curve of the front rib is a semicircle, the same as the ground-plan; and the back ribs at C, D, and E, are likewise of the same curve.

The reason of this is easily conceived, the niche being part of a sphere, the curvature must be everywhere the same, and consequently the ribs must fit upon that curvature.

Note, The curve of the mould F will not be exactly true, as the distances *d i*, *e k*, *f l*, &c. are rather too short for the same corresponding distance upon the soffit F; but in practice it will be sufficiently near for plaster-work.

In applying the mould F, when bent round the under edge of the front rib, the straight side of the mould, F, must be kept close to the back edge of the front rib; and the rib, being drawn by the other edge of the mould, will give its place over the plan.

C, D, E, are the back ribs shown separately.

The plan and elevation of an elliptic niche being given, to find the curve of the ribs.

PLATE IV. *Figure* 1.—Describe every rib with a trammel, by taking the extent of each base, from the plan whereon the ribs stand, to its centre, and the height of each rib to the height of the top of the niche; it will give the true sweep of each rib.

To range the ribs of the niche.—There will be no occasion for making any moulds for these ribs, but make the ribs themselves; then there will be two ribs of each kind: take the small distances 1 *c*, 2 *d*, from the plan at B, and put it to the bottom of the ribs D and E, from *d* to 2, and *e* to 1; then the ranging may be drawn off by the other corresponding rib, or with the trammel; as for example, at the rib E, by moving the centre of the trammel towards *e*, upon the line *e c*, from the centre, *e*, equal to the distance 1 *e*, the trammel-rod remaining the same as when the inside of the curve was struck.

Given one of the common ribs of the bracketing of a cove, to find the angle-bracket for a rectangular room.

Figure 2.—Let II be the common bracket, *b c* its base; draw *b a* perpendicular to *b c*, and equal to it draw the hypothenuse *a c*, which will be the place of the mitre; take any number of ordinates in II, perpendicular to *b c*, its base, and continue them to meet the mitre line, *a c*, that is, the base of the bracket, at I; draw the ordinates of I at right angles to its base; then the bracket at I, being pricked from II, as may be seen by the figures, will be the form of the angle-rib required.

Note.—The angle-rib must be ranged either externally or internally, according to the angle of the room.

NICHE, *Angular*, one formed in the corner of a building.

NICHE, *Cul de Four of a.* *See* CUL DE FOUR.

NICHE, *Ground*, that which instead of bearing on a massive base, or dado, has its rise from the ground; as the niches of the portico of the Pantheon at Rome. Their ordinary proportion is two diameters in height, and one in width.

NICHE, *Round*, one whose plan and circumference are circular.

NICHE, *Square*, a niche whose plan and circumference are square.

NICHED COLUMN. *See* COLUMN.

NICOMEDES, an ancient geometrician, celebrated for having been the inventor of the curve named the *conchoid*, which has been made to serve equally for the resolution of the two problems relating to the duplication of the cube, and the trisection of an angle. It was much used by the ancients, in the construction of solid problems. Sir Isaac Newton approved of it for trisecting angles, or finding two mean proportionals, and for constructing some other solid problems, as may be seen in his *Arithmetica Universalis*. It is not certain at what period Nicomedes flourished, but it was probably at no great distance from the time of Eratosthenes, who holds him up to ridicule on account of the mechanism of his *Mesolabe*, and also from the circumstance that Geminus, who lived in the second century before the Christian æra, wrote on conchoids, of which Nicomedes was then allowed to be the inventor.

NIDGED ASHLAR, a kind of ashlar used in Aberdeen, which is brought to the square by means of a cavil, or hammer, with a sharp point; whereby the asperities of the stone may be reduced in any degree proportioned to the time employed. As the species of stone found in that country is so very hard as to resist the mallet and chisel, this sort of operation becomes necessary.

NOGS, the same as WOOD-BRICKS, which see. The term is used in Liverpool, and perhaps in other parts of Lancashire.

NOGGING, a species of brickwork carried up in panels between quarters.

NOGGING-PIECES, horizontal boards placed in brick-nogging, nailed to the quarters, in order to strengthen the brickwork. They are disposed at equal altitudes in the brickwork.

NONAGON, (Greek,) a figure of nine sides, and consequently of as many angles.

NORMAL LINE, in geometry, a term used for a perpendicular line. *See* PERPENDICULAR and SUBNORMAL.

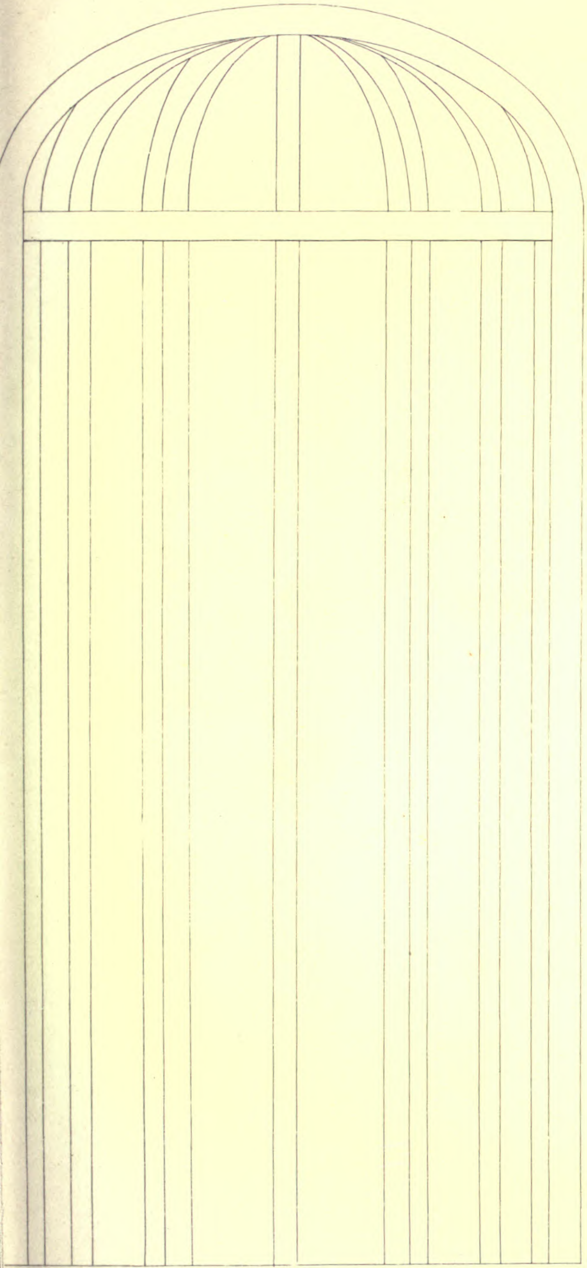
NORMAN ARCHITECTURE, a style of architecture closely allied to the debased Roman examples of the Eastern and Western empires, and with them may be conveniently included under the general title of Romanesque. It can scarcely, however, be ranked as a division of equal importance with either the Byzantine or Lombardic, of both of which it is a modification, approximating more closely to the latter, but maintaining a general resemblance with both. It may perhaps be correctly considered as a sub-division of the same style, viz., the Romanesque.

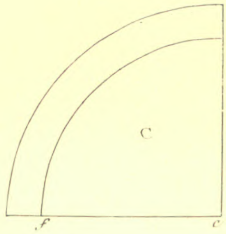
The Norman style flourished primarily and principally in Normandy, as its name implies, but became prevalent in many other places, wherever the Normans obtained influence or dominion; amongst others, in this country. When the style was first introduced into England, it is a matter of considerable difficulty to determine, some persons affirming that it was introduced by the Conqueror, others by Edward the Confessor, while a third party maintain that it was but a development of the Saxon, or style of building immediately preceding that under consideration, by whatever title it may be designated. Some writers entirely ignore the Saxon as a distinct style, including all the examples usually classified under that name, under the same designation as the latter, or Norman style, supposing the earlier examples to be but uncouth and unskilful imitations of the continental architecture. In favour of this assertion, it is argued, that it is very improbable that a method of building, practised on the continent, should have remained unknown in England for any length of time, notwithstanding the frequent intercourse of neighbouring nations, whereas we have good evidence that the Norman style was fully developed abroad at least a century before its general adoption in this island. The second statement, as to the introduction of the style by Edward, is founded, we believe on the authority of Matthew Paris, who says, that Edward rebuilt Westminster Abbey in a new style, from which others took the idea. This passage has led antiquaries to conclude, that the style referred to was the Norman, and that it was entirely unknown in England before that time; this, however, amounts to little better than conjecture.

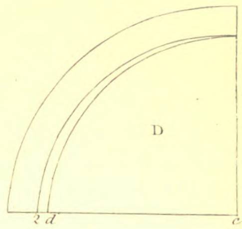
For our own part, we are inclined to consider the Saxon and Norman as, to a certain extent, distinct styles, although emanating from the same grand type, and, for that reason, in some sense modifications of each other. They are both derived from the Roman, and are both developments of the Romanesque or debased Roman, but here we imagine they part company, and take each its own course; they bear such a similarity to each other, as might be expected from descendants of a common stock, but of different branches of the same family. The Saxon style was reared on an uncultivated soil, and tended by rude hands, while the Norman was developed under more favourable circumstances. When the Romans invaded Britain, they naturally introduced the style of building then prevalent in their own country, as far, at least, as circumstances would permit. The want, however, of proper materials or tools, as well as the insufficiency of skilful workmen, must have put a limit to their success in this imitation, as we find to have been the case with their erections in this island, which were very rude in comparison with those of Rome. When the Romans were recalled, and the Britons left defenseless and unprotected against their formidable foes in the north, we may suppose that the art of building was

NICHES.

Fig. A.







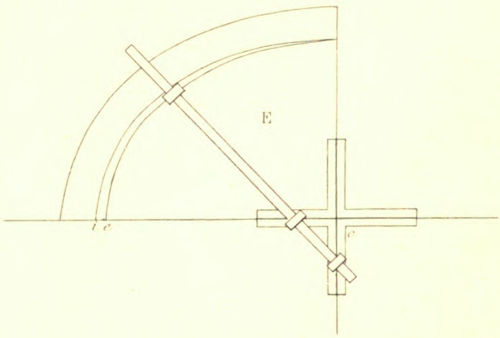


Fig. F.

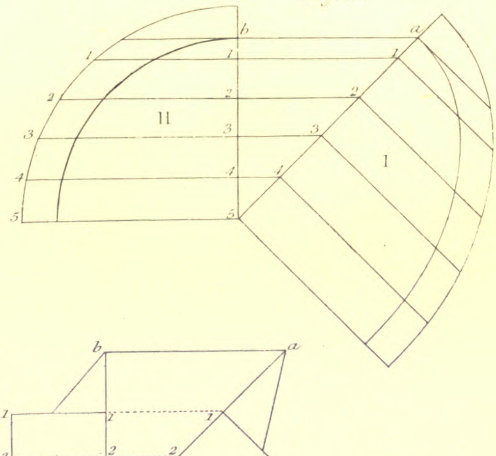

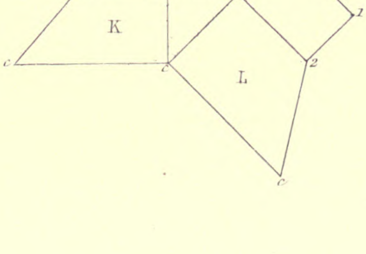

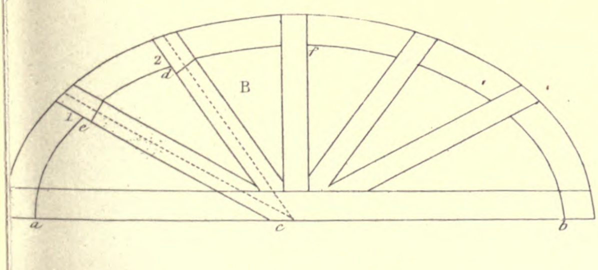

but little practised; and whatever edifices were erected during that period, must have been of a still ruder character than those of a preceding age. The Saxons do not seem to have had any mode of building of their own, but followed the method which they found practised in the country; their buildings were for the most part composed of timber, but sometimes of stone, and Bede speaks of the monastery at Wearmouth being erected after the Roman manner, and states that workmen were procured from France for the purpose. The Roman manner is contrasted with the Scotch, which latter term was applied apparently to the wooden structures. From the fact of foreign workmen being employed, it would appear reasonable to suppose that some foreign peculiarities might have been introduced by them. The mere fact, however, of French workmen being sent for into England, would prove that they were considerably further advanced in the art than those who sent for them; and it is probable that such importations of foreign artisans led to the introduction of some peculiarities of continental architecture, which however was not introduced in an entire and complete form until after the Conquest.

Many writers apply the term Lombardic to this style; but although, as we before observed, there is a near resemblance in many points, yet, on the other hand, there are not a few distinctions between the Norman and Italian Lombardic, *e. g.*, the former is wanting in a feature which is very conspicuous in Lombardic churches, the dome or cupola, nor has it the low pedimental roof extending over the whole façade. The sloping arcade in the gable is absent, as are likewise the tiers of external galleries or arcades in the façades and sides of buildings. Circular windows are not so common or prominent as in Italian buildings, nor do we meet with the peculiar projecting porch, with its columns resting on the backs of animals. Some of the details of the style, such as mouldings, windows, &c., are similar to those of the Byzantine. It agrees also with the Saxon in its massive proportions, the shape of its arches and piers, and in general construction; in some matters of detail also, such as the zig-zag ornament; it differs from it, however, amongst other matters, in finish and general decoration, the Norman bearing a much greater share of enrichment than its predecessor, and being, in fact, a much more highly-cultivated style of building.

Having given this general and rapid sketch of the origin and nature of Norman architecture, as well as of the relation it bears to other cognate modes of building, we shall proceed to consider the subject somewhat more in detail, referring more especially to the character and peculiarities of the style. We must premise, that it is our intention to confine ourselves almost exclusively to the consideration of the style as it is developed in this country; the difference, however, between the English and Continental mode of treatment, is not very considerable.

The style may be said to have been fully developed in this country soon after the successful invasion, by Duke William of Normandy; whether it had arrived at any degree of perfection before that time, it is difficult to say; but it may be said to have flourished from the middle of the eleventh century, and prevailed to the latter part of the twelfth, or the close of the reign of Henry II. It is styled generally, the architecture of the twelfth century, and dates from 1066 to 1170, or, if the Transition or Semi-Norman be included, to 1200. The conqueror and his countrymen were great builders, and the monkish chronicles tell us, that after their arrival, churches were erected in almost every village, and monasteries were seen to arise in the towns and cities, designed in a new style of architecture. From Doomsday book, we learn that the number of churches had increased to such an extent, that at the time of its compilation, there were no less than seventeen hundred in existence.

The *plans* of the larger churches belonging to this style, such as those of cathedrals, and other ecclesiastical establishments, are usually cruciform; having a low massive tower at the intersection between the nave, choir, and transepts; the choir being frequently terminated with a semicircular apse. The aisles of the nave are frequently continued at the sides of the choir and round the apse, and in this case the high altar is situated between the easternmost piers, with a screen or reredos at its back, stretching between the piers. Thus a space was left clear behind the altar, which was named the retro-altar, and this allowed of processions passing entirely round the church. In some instances, the choir is surrounded with chapels, having likewise apsidal terminations. The aisles were extremely narrow, sometimes not more than from four to six feet in width. The western façades are occasionally flanked by towers, but more frequently by only turrets or buttresses.

The parish churches are generally of small dimensions, and consist of a nave usually without either porch or aisles, chancel and tower, the latter being sometimes at the west end, and at others between the nave and choir, as in cruciform churches. This last disposition is somewhat curious, but in some instances of the kind, arches of construction have been discovered in the north and south walls of the tower, a fact which gives every reason to suppose, that transepts formed a part of the original design, and were intended to be added at some subsequent period. The chancel in these smaller churches also, sometimes terminated in a semicircular apse. Not unfrequently, small churches consisted of nave and chancel only, without any tower or other appendage.

The *walls* of buildings of this period, were of immense thickness, but the masonry was not solid, being composed of two external walls, or facings of ashlar-work, having the intermediate space filled in with grouted rubble, gravel, flints, &c. Sometimes, however, the walls are made up of solid rubble-work, with quoins of ashlar. The joints of ashlaring in early work are extremely wide, being frequently as much as an inch in thickness. Many walls of the first description have failed, from the outward pressure of the core of loose material, and it is not an unfrequent occurrence to see a Norman wall considerably out of the perpendicular. The introduction of buttresses at a later period, led to a great improvement in the construction of walls, adding materially to their efficiency and strength; while at the same time it lessened the consumption of material.

Arches are almost invariably of the semicircular form, but occasionally stilted, and the only variety in the proportions of arcades, depends upon the height of the piers, the height of the opening averaging in general about twice its width. The earliest arches are simply semicircular apertures in the wall, with a plain or single soffit; but owing to the extreme thickness of the walls, the intrados was very soon broken into two surfaces, so as to form a concentric rib or sub-arch attached to the soffit of the outer or main arch; in the majority of instances, the sub-arch is placed in the centre of the main arch, so as to form a recess or angle on either side, but occasionally, the sub-arch is set back, so as to present a recess on one side only, the other side being flush with the face of the wall. Sometimes we find two sub-arches, one under the other, thus presenting three soffits, and two recessions on either side of the arch. The edges of these soffits are for the most part rectangular, but are sometimes chamfered or rounded, which is an indication of later work; still later in the style, we find round and other mouldings introduced, and the intradosses and faces of the arches enriched with the zig-zag and other mouldings and ornaments, characteristic of the style. Some chancel-arches are deeply recessed, and enriched with a number of decorative mouldings, as are also the arches of doorways, of which we shall speak more particularly presently.

The *piers* supporting the principal arches of construction, such as those separating the nave and aisles, are exceedingly massive, and frequently of stunted proportions. The simplest form presents a plain *shaft* on a square plan, which was afterwards recessed at the four angles with a rectangular nook, and this again was frequently filled up with a slender shaft. The same form is not unfrequently varied in appearance by the addition of a semicircular projection on two sides of the pier, so that we have a square pier recessed at the angles, into which recesses slender circular shafts are introduced, and having half a cylindrical column of massive proportions engaged to two opposite sides of the pier, the remaining sides being left plain: the former answer the purpose of supports to the sub-arches, while the latter range with the length of the building. This plain face was sometimes broken by a lofty shaft reaching from the ground to the springing of the vault, commonly termed a vaulting-shaft. Massive cylindrical shafts are very common, and are sometimes enriched with spiral or longitudinal flutings or bands, and sometimes with the zig-zag ornament disposed in a variety of ways. Octagonal shafts are also to be met with, though not nearly so frequently as the preceding, with which they sometimes alternate in a series of arches: sometimes, too, the shafts are made to appear as made up of a cluster of slender pillars. Cylindrical shafts, such as form principal supports in an edifice, are most frequently, as we have just observed, of massive proportions, but in one or two instances we find them approximating to classical proportions, as in Becket's Crown, Canterbury, in which example they bear in every respect a closer resemblance to the classical than probably in any other in England. Slender circular shafts, however, are very much employed as subordinate members and ornamental accessories, an example of which has been alluded to in the case of the square pier with nook-shafts at the angles; they are also much employed in the jambs of doorways and windows in a similar position, and as bearing shafts where an arch is subdivided into two or three apertures, as in two-light windows, and in the triforia and clere-stories of large churches. They are used very largely in the blank arcades which decorate the walls, and also as vaulting-shafts. In all such cases their proportions and treatment differ very considerably: some are much more slender than others, and some are plain, whilst others are enriched with carving of various patterns, amongst which the spiral groove or band of the zig-zag ornament are of constant occurrence: sometimes, too, spiral bands intersect each other so as to form diamond-shaped compartments throughout the surface; and at other times the shaft is ornamented with scroll-work, or diamond-shaped leaves, and such like enrichment. In principal piers we occasionally but rarely find clustered shafts.

The *capitals* partake of great variety of character, some assimilating more or less closely to the Corinthian and other classical examples. They are for the most part, however, rude and unskilful imitations, and have a heavy appearance when contrasted with the originals; the foliage is more crowded and irregular, and the capital itself much more squat, and therefore less elegant, than the classical examples. Many specimens of sculptured foliage exist which can scarcely be said to have been borrowed from such sources, some of which are not unworthy of praise. Some have interlaced bands or foliage in slight relief from the surface, and others are sculptured with grotesque representations of men and animals. Many capitals are quite plain, the most common of which is the cushion capital: this is of cubical form, being rounded at the lower end to meet the shaft, the profile of the curve presenting somewhat the appearance of the ovolo moulding; or it may be described as an inverted cone of convex contour spreading upwards, but intersected at about half its height by four vertical planes parallel to the four sides of the abacus, which produce as many flat surfaces rectilinear at the top and sides, but convex at the lower side where it intersects with the curve. Sometimes the side of the capital consists of many such figures of smaller dimensions placed side by side, the lower edge of the flat surface presenting a scalloped appearance, and beneath each of the scallops is a kind of inverted semi-cone, which meets the neck-mould of the shaft. The variety of capitals is, however, so great, that it would be useless to attempt to describe them all; they almost invariably terminate with a heavy square abacus, with a plain face chamfered only on the lower edge.

The *base* mouldings are set upon a shallow rectangular plinth, and consist either simply of a quirked ovolo reversed, or otherwise of some imitation or modification of the classic bases; the angles of the plinth are often ornamented with leaves or other ornaments, falling over from the base mouldings.

Piers and pillars are very greatly varied even in the same building, and in the same part of it; and this, too, not only in the minutiæ of decoration, but also in the entire form of the shaft and capitals, so that two very dissimilar designs are frequently seen in close proximity, forming supports to the same arcade.

Mural or blank arcades are a very common feature in this, as also in the Lombardic style; they sometimes cover the greater portion of both external and internal walls, but are more common on the exterior, especially on the façades, the clere-stories, and the upper stories of towers. The arches are mostly semicircular, resting upon slender pillars with capitals and bases, which, together with the shafts, bear various degrees of enrichment; sometimes, however, the arches intersect each other, producing at their intersection arches of the pointed form; pointed arches are employed alone, but only in late examples. The arcades are for the most part of small dimensions, but they vary in size, as also in proportions, some of them being exceedingly high in comparison to their width. In the interiors of larger churches, the space or width occupied by each arch in the lower story is frequently divided into two arches, enclosed within a larger one in the triforia, and into three arches in the clere-story, the central one being loftier than the others, and the whole contained within a larger one.

Doorways in this style are to be found in great variety, from the most simple to the most elaborate. The simplest form consists of merely a plain semicircular-headed aperture, with a hood-mould springing from plain square-edged jambs; the arches spring directly from an impost resting on the jambs, which is frequently a simple plat-band, with the under angle chamfered off. More frequently, however, the doorways are recessed, having a nook-shaft in the angle formed by the recession, from the capital of which an archivolt springs, so that the arch in this case presents two soffits and two faces besides the hood-mould. Sometimes we have a succession of such receding arches, with a nook-shaft in each recess, from which the arches spring alternately with the projecting square-edged jambs. The depth of the doorways is owing mainly to the great thickness of the walls, but in many cases, in addition to this, that portion of the wall in which the entrance is inserted, is made to project forward beyond the general face, the projection being finished above either with a plain horizontal capping, or with a highly-pitched gable; at St. Sepulchre's, Cambridge, the outermost arch finishes the projection, or rather the arch itself projects from the face of the wall, but this is not a common practice. With this additional thickness of walling we sometimes find as many as six or eight recessions, so that the aperture of the door occupies but a very small proportion of space, when compared with the entire surface taken up by the doorway, including the dressings. In some cases, too, the archivolt mouldings extend on each side considerably beyond the jambs. The soffits and faces of the arch, as well as those of the jambs, are sometimes left plain, but more frequently sculptured with the zig-zag, or some other ornament peculiar to the style, such as those described under *mouldings;* and to such an extent is this decoration carried, that sometimes there is not a single surface left uncovered with some ornamentation; even the shafts of the pillars are sometimes decorated in a similar manner, but this is not often the case, they are more frequently plain, and of not inelegant proportions, with capitals of various degrees of enrichment. Above the capitals is an abacus, which is often continued along the jambs from one capital to the other, but sometimes the mouldings of the archivolt are carried without interruption to the ground; occasionally, also, an enriched band is carried across the shafts and jambs, for the apparent purpose of tying them together. The hood-mould is mostly enriched, and springs from a continuation of the abacus, but if not, is either returned horizontally as a string-course, or terminates on either side in a grotesque head. The aperture often follows the form of the arch, having a semicircular head, but is very frequently square-headed, having a semicircular tympanum of masonry above, which is generally enriched with sculpture, sometimes in a sort of diaper pattern of reticulated or scalloped work, but more usually representing, in low relief, some portion of scriptural or traditionary history. Not unfrequently the head of the aperture is in the form of a square-headed trefoil, and sometimes of a segment of a circle larger than that of the external arch. Over some doorways is to be found a small niche containing a rudely sculptured figure, and sometimes a Vesica Piscis is substituted for the sculptured subject in the tympanum under the arch.

A great many examples of Norman doorways still remain, even in churches which present no other features of this style, for it seems to have been a practice with the architects of later periods to preserve this portion of an old church, even when they rebuilt the entire structure in a later style; many of them are certainly very rich and beautiful, and their preservation does credit to the taste and judgment of succeeding ages.

In this style, *windows* form but subordinate members of an edifice, and in the earlier examples are small and insignificant, being little better than slits or narrow oblong apertures, often not exceeding a few inches in breadth, and finished with a plain semicircular head; the glass was inserted close to the external wall, and the sides of the aperture were splayed towards the interior, the circular heads being generally concentric on both sides of the wall; the height of such windows was usually little more than twice their breadth, but occasionally they were much longer in proportion. In cathedral and the larger churches we sometimes find windows of much greater dimensions. After a time, a slight degree of enrichment came to be added in the shape of zig-zag and other mouldings round the arch; and at a still later period, an important improvement was made by inserting nook-shafts in the jambs, similar to those in doorways; but in this case they seldom exceeded two in number, that is to say, one on either side; in Normandy, we have examples of a greater number, which add considerable importance to the window, but we do not know of any such in this country. Such shafts were mostly slender, with plain caps and abacus, and in such examples the archivolt was either moulded or recessed, so as to form two soffits; the zig-zag moulding was very common in this position. Windows of this kind were usually larger than the earlier ones, though not always so; they are also frequently protected by a hood-mould, and the same decoration is sometimes observed in the interior.

A window of still more advanced character is very often found in the upper stories of towers; it consists of two lights with semicircular heads, separated by a central shaft, and having a jamb-shaft on either side; the two lights are enclosed under another larger semicircular arch, the spandrel of which, however, is very rarely, if ever, perforated; the larger arch is surrounded by a hood-mould. These windows bear a remarkable resemblance to those of the Byzantine and Lombardic styles, many of which exist in Italy. Sometimes, apertures for windows are pierced in a continuous arcade, running along the church; and in that case, the apertures usually occur in regular order, the intermediate arcades being left blank.

Plain circular windows, of small dimensions, are sometimes seen in clere-stories and other positions; and in churches of a late date, are to be found occasionally in gable walls, larger windows of the same form, with small shafts radiating from the centre, connected at the circumference by small semicircular or trefoiled arches; a fine example exists at Barfreston, Kent.

Of *mouldings*, such as are distinguished by their profile, the most usual combinations are composed of plain surfaces, or bands, chamfers, and quarter, half and three-quarter cylindrical mouldings, but of ornamental bands of sculpture, which are employed as mouldings in this style, there are a great variety; amongst the most common of which we may mention the following:—

The *zig-zag* is formed of a series of salient and re-entrant angles, recessed or otherwise carved on the surface of the stone, sometimes in a single line, but perhaps more frequently in two, three, or more lines, running parallel to each other, but sometimes we find them reversed. The name will probably give a better idea of the moulding than any definition; it is also termed the chevron-mould. It is used more than any other enrichment, and is found in all situations.

Similar to this is the *indented* or *trowel-point*, which presents such an appearance as a stuccoed wall which has been indented with a trowel-point before setting, the point having been pressed further into the mass, than the wider portion of the blade.

The *beak-head*, *bird's-head*, and *cat's-head* mouldings, are of a similar character, and consist of a series of grotesque heads, somewhat similar to those of the animals whose names they bear, each being furnished with a pointed beak; they are set in close proximity to each other, frequently over one or more plain mouldings, with the beaks all pointing downwards.

The *nail-head* is composed of a row of shallow pyramids, similar to nail-heads, set in contact with each other; they probably originated the idea of the dog-tooth moulding, so common in the succeeding style.

The *billet*-moulding, of which there are two kinds, the square and cylindrical, consists of cubes or semi-cylinders, placed at short intervals from each other, on a plain surface.

The alternate billet is formed of two or more rows of billets, the billets and spaces alternating in each row. The square billet is often used for supporting a blocking-course, and is termed also the *corbel-bole.*

The *double cone* is formed of a series of two cones set base to base, and point to point, in a hollow moulding.

The *embattled* is formed of a band or channel following the form of a battlement, with alternate merlons and embrasures. Similar to this is the *dove-tail*, but in this the angles are acute, instead of right. There are several varieties of frets, trellis, and interlacing bands employed as mouldings, some plain, and others more or less enriched.

The *nebule*-moulding presents a wavy outline, and the *scalloped* such as its name implies. The *pellet* or *stud*-moulding is enriched with flat and slightly projecting circular pellets in close proximity, or at short intervals; while the *chain*, *star*, *medallion*, and *lozenge* mouldings are of a similar description, varying only in the forms of their respective ornaments.

The *cable*-moulding bears the appearance of a cable placed in a concave moulding.

The above are some of the most usual forms, but there are altogether such a variety of shapes and combinations, that it is impossible to describe them all.

The *string-courses* are very simple, consisting most frequently of a sloping water-table at top, with a plain vertical face splayed off at the lower edge; sometimes the vertical face is enriched with the zig-zag, indented, or other ornament, and occasionally a round moulding is introduced.

The *parapets* are usually plain and slightly projecting, supported upon *corbel-tables*, which consist either of cubical blocks placed at regular intervals under the parapet, and carved into grotesque heads and other devices, or of a series of small arches resting on such blocks; the arches are either semicircular, interlacing, or trefoiled. Sometimes the arches are seen without the blocks, and at others the table consists of a projecting course, the soffit of which presents a nebulous or undulating outline.

Buttresses can scarcely be said to exist in buildings of this style, the thickness and solidity of the walls not requiring such supports; somewhat similar, however, in appearance, are those projections which are termed by Mr. Whewell, *pilaster-strips.* They are precisely of the same character as the projections in Lombardic buildings, and resemble a broad flat pilaster, standing out but slightly from the general face of the wall, and terminating under the cornice or parapet, sometimes with a slope, but frequently carried up square to the soffit of the parapet, the face of the buttress being flush with that of the corbel-table. The basement consists merely of a ground-table, and the pilaster is often divided into two or more stages by string-courses, which are frequently continued along the walls, and over the arches of apertures, sometimes, however, they stop at the buttresses, and in such cases, the latter are merely plain projecting strips, without any divisions; it is seldom that the lower stages project beyond the upper ones, as in the later styles. The string-courses are mostly plain, with the under edge chamfered, or of a semi-hexagonal projection, but they are occasionally hatched or chevroned. At a later period, the angles of the buttresses are ornamented with slender nook-shafts.

The *towers* of this period are low and massive, with but little ornamentation, especially in the smaller churches. In many examples, the lower stages are plain, but the upper ones enriched with blank arcades, or with an arcade, some of the arches of which are blind, and others pierced for windows. The windows in the lower stages were quite plain, but in the higher stories, besides the arrangement just alluded to, we often see windows of two lights with semicircular heads, both included under a larger arch; the lights were divided by a central shaft, and flanked by a nook-shaft on either side. The towers are often divided into stories by string-courses, and terminated at the top with a corbel-table supporting a plain horizontal parapet or blocking-course. Towers were probably roofed with low pyramidal caps of masonry, tiles or shingles, in the latter cases with projecting eaves; wooden spires covered with lead, would seem also to have been occasionally employed. Sometimes a pinnacle adorned each angle of the tower.

The plans were mostly square, having in some cases a square or circular stair-turret at one of the angles; round towers, however, of this date, are frequent in the counties of Norfolk and Suffolk. They are mostly constructed of flint, and batter externally from the base upwards; they are sometimes divided into stages by string-courses, and the upper story is more enriched than those below. The windows in the lower stories are small and narrow, and exceedingly plain.

The *pinnacles* were usually cylindrical in plan, and covered with a conical capping, but occasionally the capping was polygonal or square on the plan.

Porches, as we before stated, rarely occur in this style, some few however do remain, but mostly belonging to the larger churches. They are most frequently vaulted, and sometimes consist of two stories having a small apartment above the porch properly so called. There are sometimes benches on either side, and the walls on the interior are ornamented with blank arcades. The doorways are often deeply recessed and of an ornamental character.

The *Roofs* of this period in large buildings are highly pitched, but in the smaller churches they are somewhat more depressed, forming a rectangle at the apex. In the interior they are most frequently vaulted, although we have some examples still remaining of timber roofs: there is one at Peterborough cathedral, which is flat, and covered with paintings of figures, which have recently been restored. A greater number of roofs of this material in all probability existed, but, from their liability to decay and destruction by other means, very few examples still remain. All wide spans, such as the naves of churches, and especially of the larger ones, were probably covered with timber roofs, as the builders of the period do not seem to have been bold enough to attempt vaulting over wide intervals: this circumstance is supposed to account for the narrowness of the aisles, which, together with crypts, porches, and other places where the bearings were inconsiderable, were always vaulted. Many examples of stone vaulting still remain, the quadripartite, or that consisting of four cells, with diagonal groins, being the most common; the barrel vault, however, was also employed, a specimen of which is to be seen in the Tower of London. At first the groins were simple arrises without any projecting moulding, but afterwards a square moulding was added, and still later this simple form was enriched by cylindrical mouldings of various projections, and sometimes with the zig-zag and other ornamental mouldings.

The later portion of this style, which has been named by some the *transition*, and by others the *Semi-Norman* style may be said to have commenced a little before the middl[e] of the twelfth century, and forms the connecting link be[-]tween the Romanesque and Pointed styles. It is distinguishe[d] generally by its amalgamation of Norman details with th[e] pointed arch, or perhaps we should rather say by the intro[-]duction of the pointed arch into what would otherwise b[e] Norman work.

Pointed *arches* are found treated in all respects in the sam[e] manner as the older semicircular form, having only one [or] two recessions on the soffit, and these generally square at th[e] dges without chamfering; sometimes we see only one soffit vith plain chamfered edges, and not unfrequently the faces f the arch are adorned with zig-zag and other mouldings f purely Norman character. These are supported upon nassive Norman piers, either cylindrical or of other orm, sometimes square with attached circular shafts on the ides, but occasionally consisting of several shafts clustered ogether, and banded about midway between the base and apital: this last forms a near approach to the clustered illars of a later style. The abacus was in almost all cases, quare, and of Norman character, as also were the bases, but he capital frequently exhibits a more chaste and delicate rnamentation, consisting of foliage which bears some pproach in design to the Early English.

The *doorways* are recessed similar to Norman examples, ut have pointed arches, and the shafts with their capitals are nore delicate than in pure Norman work. The arches, howver, are decorated with mouldings which are purely Norman.

The *windows* generally retain the same character as before, ut occasionally the pointed arch is introduced here also. In hurches of this period, we frequently find a triforium with semicircular arcade, and a clere-story with purely Norman vindows ranging above an arcade composed of pointed arches; s also a lower tier of mural arcades with pointed arches surnounted by semicircular or intersecting arcades. In short, he architecture of this period is nothing more than a combination of the pointed arch with work which is otherwise Jorman: it is true, the character of the arch did, in some ases, affect some other members of the building, but not to ny great extent, for the main features of the style, with this xception of the arch, still remain strictly and unmistakably Jorman.

During the whole of the period we have been considering, rchitecture was making rapid progress in England, and a umber of churches and other edifices were erected.

The prelates in the early Norman reigns were men of conummate skill in architecture; they applied themselves to the ebuilding of cathedral churches, and also the rebuilding of he greater abbeys. No less than fifteen of the twenty-two nglish cathedrals retain considerable portions which are ndoubtedly Norman workmanship, and of which the several ates are ascertained. The Normans, who either were archiects themselves, or under whose auspices architecture floushed, are Gundulph, Bishop of Rochester, who flourished om A.D. 1077 to 1107; Mauritius, Bishop of London, who ourished from 1086 to 1108; Roger, Bishop of Salisbury, om 1107 to 1140; Ernulf, Bishop of Rochester, from 1115 1125; Alexander, Bishop of Lincoln, from 1123 to 1147; enry of Blois, Bishop of Winchester, from 1129 to 1169; d Roger, Archbishop of York.

The works of Gundulph may be seen at Rochester, Canrbury, and Peterborough. Mauritius, of London, built Old . Paul's cathedral; Roger, of Salisbury, the cathedral of d Sarum; Ernulf completed the work begun by Gundulph Rochester; Alexander, of Lincoln, rebuilt his own catheal: and Henry of Blois, Bishop of Winchester, a most ninent architect, built the conventual churches of St. Cross d Rumsey, in Hampshire; but with respect to Roger, rchbishop of York, none of his works remain.

By these architects, the Norman style of architecture was ogressively brought to perfection in England; and it will casily supposed, that the improvements made by any of em were only adopted in succession.

Many of the churches belonging to the greater abbeys re constructed in this æra; but of these, few, indeed, ve escaped the general demolition that took place at the formation.

With respect to the military structures of the Normans they knew they could not live in security without building strong places of defence; they therefore erected a castle upon every lordship, or assimilated with their own, what they found already erected to their hands.

The leading distinction in a Norman fortress, is a lofty mound of earth thrown up in the centre of the other works, from the excavations necessary in forming the ditch, fosse, or moat. A square or circular tower, consisting of several stories, rose from the upper ballium, or a low circular story of considerable diameter, which was usually approached by a very steep stone staircase on the outside.

The gateway, or tower of entrance, and the barbican, or watch-tower, had both of them a communication with the keep. Remarkable instances in the square form are those of the towers of London, Norwich, Rochester, Dover castle, Hedingham (Essex,) Bamborough (Northumberland,) Porchester, Colchester, Kenilworth, Knaresborough, Carisbrooke, and Oxford. Of the circular are Arundel, Pontefract, and Conisburgh (Yorkshire,) Lincoln, and Tunbridge in Kent. Besides the above-stated towers, an irregular form, of which the plan consists of several segments of circles, may be seen in Clifford tower, in York, and Berkeley castle, Gloucestershire. These keeps, or citadels, in subsequent æras underwent no alteration, whatever additions or improvements took place in architecture.

Bishop Gundolph seems to have considered the lofty artificial mound, originally of Danish usage, as unnecessary. His central towers are so lofty as to contain four stories, as was also the case with most other keep-towers. The basement was the dungeon, without light: the portal or grand entrance was raised many feet above the ground; but his great merit consisted in various architectural contrivances, by which as much security during a siege was given to his keeps by stratagem, as by real strength. The walls were not unfrequently from 12 to 20 feet thick at the base. In the souterrain of the vaulted stone, the military engines and stores were deposited. In the thickness of the walls were placed winding staircases, the well for water, the vast oven, enclosed galleries and chimneys, with an aperture open to the sky, and communicating with the dungeon, in which prisoners were confined, and to whom it gave all the light and air they could receive. There was also a kind of flue for conveying sound to every part, not more than eight inches in diameter. The state apartment occupied the whole third story, and the staircases leading to it were much more commodious than the others, and even so large as to admit of military engines. Adjoining to the great chamber was the oriel, lighted by a window embowed withinside. In Rochester castle the chief room was 32 feet high, including the whole space within the walls. The walls of the ground story had no light, the second had only loop-holes; but the third had large arched windows placed so high as not to be looked through, and so defended by an internal arcade that no missile weapon could enter or fall with effect. Each floor had its communication with the well. The chimneys were very capacious, projected considerably into the rooms, and rested upon small pillars; and the sinks were so contrived, in an oblique direction, that no weapons could be sent up them.

Gundulph is said to have introduced the architectural ornaments of the ecclesiastic style into fortresses, both withinside and without. Most of the Norman castles had a richly carved door-case or portal, as the remains of Arundel and Berkeley amply testify. The windows were decorated with mouldings, frequently sculptured. Castle-Rising, Norfolk, and Norwich abound in admirable specimens of Norman arcades and mouldings.

The great tower of entrance was built at the foot of the artificial mount, from which was a sally-port, with stone stairs leading to the keep. It contained the portcullis and drawbridge affixed to the archway, and several spacious chambers. In point both of the formation of the mount and keep, and their connection with the entrance-tower, the remains of Tunbridge, and the more perfect state of Arundel castle, exhibit a singular resemblance. The walls were protected by strong buttresses, and the round towers had a central space left open, to admit light and air. At Arundel, the corbel-stones, which supported the beams of timber, are still to be seen. See Castle.

The well-authenticated buildings of Norman construction, erected from before A. D. 1100 to 1150, are the abbeys of Abingdon, Reading, and Cirencester, destroyed; Malling, Kent; Tewkesbury, nave, aisles, transept, and west front; Malmsbury, nave and west front; Buildwas, Salop; St. Botolph, Colchester; Bolton, Yorkshire; Winborn minster, Dorsetshire; Castle-Acre, Norfolk; Dunstable, Bedfordshire; St. Cross, Hants; Romsey, Hants; Furness, Lancashire, the most ancient parts; Llindisfarne, Northumberland; Byland, Yorkshire; Lanercost, Cumberland; Sherbourn, Dorset; Southwell, Nottinghamshire; Kirkstall, Yorkshire, nave. Of those now named Tewkesbury, Malmsbury, Winborn minster, St. Cross, Romsey, and Sherbourn, are now used as parochial churches.

From A. D. 1155, the style of architecture practised by the Normans began to be mixed with new forms and decorations, and was at length superseded by that much more elegant and lofty style of building, improperly denominated *Gothic*.

The principal works that may be consulted in Norman architecture, are the *Archæologia*, Carter's *Ancient Architecture of England*, Britton's *Architectural Antiquities of Great Britain*, and Dalaway's *English Architecture*.

NOSINGS OF STEPS, the projecting parts of the tread-board or cover, which stand before the riser. The nosings of steps are generally rounded, so as to have a semicircular section, and, in good staircases, a hollow is placed under them.

NOTCH-BOARD, a board notched or grooved out, to receive and support the ends of the steps of a staircase.

NOTCHING, the cutting of an excavation throughout the whole breadth of a substance.

By this method timbers are fastened together; or their surfaces, when joined at angles, are made to coincide.

NUCLEUS (Latin) the internal part of the flooring of the ancients, consisting of a strong cement, over which they laid the pavement, bound with mortar.

NUEL, see Newel and Staircase.

NUISANCE, or Nusance, (from the French, *nuire*, to hurt) in law, is used not only for a thing done to the hurt or annoyance of another, in his free lands or tenements, but also for the assize, or writ lying for the same.

Nuisances are either *public* or *private*: a *public* or *common* nuisance is an offence against the public in general, either by doing what tends to the annoyance of all the king's subjects, or by neglecting to do what the common good requires. A *private* nuisance is when only one person or family is annoyed, by the doing of anything; as where a person stops up the light of another's house, or builds in such a manner, that the rain falls from his house upon his neighbour's; as likewise the turning or diverting water from running to a man's house, mill, meadow, &c., corrupting or poisoning a water-course, by erecting a dye-house, or a lime-pit, for the use of trade, in the upper part of the stream; stopping up a way that leads from houses to lands; suffering a house to decay, to the damage of the next house; erecting a brew-house in any place not convenient; or a privy, &c., so near another person's house as to offend him; or exercising any offensive trade; or setting up a fair or market, to the prejudice of another.

The continuation of a nuisance is by the law considered as a new nuisance, and therefore, where a person suffers a nuisance to be set up, and then alienates and lets the land, &c., without removing it, an action of the case lies against him who erected it; and also against the alienee or lessee, for continuing it.

Writs of nuisance are now properly termed *trespasses* and *actions upon the case*.

Nuisance, *Abatement of* denotes the removal of it, which the party aggrieved is allowed to do, so as he commits no riot in the doing of it.

"If a house or wall is erected so near to mine, that it stops my ancient lights, which is a *private* nuisance, I may enter my neighbour's land, and peaceably pull it down." *Salk.* 459. "Or if a new gate is erected across the public highway, which is a *common* nuisance, any of the king's subjects passing that way may cut it down, and destroy it." *Cro. Car.* 184. The reason why the law allows this private and summary method of doing one's self justice, is, because injuries of this kind, which obstruct or annoy such things as are of daily convenience and use, require an immediate remedy; and cannot wait for the slow progress of the ordinary forms of justice.

O.

OAK, the well-known tree, styled by way of eminence the "lord of the forest." The oak grows to an enormous size, attaining frequently a height of from 80 to 100 feet, with a trunk from 6 to 12 feet or more in circumference. Some of the parks attached to the mansions of our great nobles are adorned with magnificent specimens of these monarchs of the woods. In Amphill Park stands an oak of very large size. The circumference of its base is upwards of 40 feet; its middle girt is about 30; it is quite hollow, forming a concavity sufficient to contain four or five middle-sized persons standing together withinside. The chief of its branches, which is much greater in dimensions than many parent oaks, is supported by a couple of large wooden props, on accoun[t] of its weight being too great to be kept up by the main bod[y] of the tree. There are many fine oaks in numerous othe[r] parts of the empire; as in Salcey forest, Northamptonshir[e] and in the Duke of Hamilton's park in Lanarkshire. Th[e] wood of this tree is the most durable that grows, an[d] its use in naval and domestic purposes is exceeding[ly] great.

There are several kinds of oak timber used in this countr[y] but none are equal to the common British oak, which is mo[re] durable than any other wood attaining the same siz[e]. The oak imported from America is very inferior to that [of]

England; the oak from the central parts of Europe is also inferior, especially in compactness and resistance of cleavage. The knotty oak of England, when cut down at a proper age, (from fifty to seventy years,) is the best timber known, for at once supporting a weight, resisting a strain, and not splintering by a cannon-shot; hence its value in ship-building.

OASIS, is the appellation given to those fertile spots, watered by springs and covered with verdure, which are scattered about the great sandy deserts of Africa. In Arabic they are called wadys. The Arabic and the Greek name seem to contain the same root, and possibly the word may be originally a native African term. The most noted are in the Libyan desert, namely, Angila, Siwah, the great oasis west of Thebes, or El Khargeh; the little oasis, or Wah el Bahryeh, and several smaller ones, which are noticed under Egypt. Fezzan also may be considered as a great oasis of the Sahara. Hornemann has described Fezzan; Brown has given an account of the oasis of El Khargeh, and Cailliaud of the smaller oases west of Egypt.

The oases appear to be depressions in the table-land of Libya. On going from the Nile westward, the traveller gradually ascends till he arrives at the summit of an elevated plain, which continues nearly level, or with slight undulations, for a considerable distance, and rises higher on advancing towards the south. The oases are valleys sunk in this plain, and when you descend to one of them you find the level space or plain of the oasis similar to a portion of the valley of Egypt, surrounded by steep hills of limestone at some distance from the cultivated land. The low plain of the oasis is sand-stone or clay, and from this last the water rises to the surface and fertilizes the country; and as the table-land is higher in the latitude of Thebes than in that of Lower Egypt, we may readily imagine that the water of the oases is conveyed from some elevated point to the south, and being retained by the bed of clay, rises to the surface wherever the limestone superstratum is removed.

OBELISK, (from the Latin, *obeliscus*,) a quadrangular pyramid, very slender and high; raised as an ornament in some public place, or to show some stone of enormous size; and frequently charged with inscriptions and hieroglyphics.

Borel derives the word from the Greek, οβελος, *a spit, broach, spindle*, or even a kind of *long javelin*. Pliny says, the Egyptians cut their obelisks in form of sunbeams; and that, in the Phœnician language, the word *obelisk* signifies *ray*.

The Egyptian priests called their obelisks the *sun's fingers;* because they served as styles, or gnomons, to mark the hours on the ground. The Arabs called them *Pharaoh's needles;* whence the Italians call them *aguglia;* and the English *Cleopatra's needles*. *See* Cleopatra's Needles.

The difference between obelisks and pyramids, according to some, consists in this, that the latter have large bases, and the former very small ones, compared with their height; though Cardan makes the difference to consist in this, that obelisks are to be all of a piece, or consist of a single stone; and pyramids of several.

The proportions of the height and thickness are nearly the same in all obelisks; that is, their height is nine, or nine and a half, sometimes ten times their thickness; and their thickness, or diameter, at top, is never less than half, nor greater than three-fourths, of that at bottom.

This kind of monument appears to have been very ancient; and, we are told, was first made use of to transmit to posterity the principal precepts of philosophy which were engraven on them in hieroglyphic characters. In after-times they were used to immortalize the actions of heroes, and the memory of persons beloved.

The first obelisk we know of was that raised by Rameses, king of Egypt, in the time of the Trojan war. It was 40 cubits high, and, according to Herodotus, employed 20,000 men in building. Phius, another king of Egypt, raised one of 45 cubits; and Ptolemy Philadelphus another, of 88 cubits, in memory of Arsenoë. *See* Porphyry.

Augustus erected an obelisk at Rome, in the Campus Martius, which served to mark the hours on an horizontal dial, drawn on the pavement.

F. Kircher reckons up fourteen obelisks, celebrated above the rest, viz., that of Alexandria, that of the Barberins, those of Constantinople, of the Mons Esquilinus, of the Campus Flaminius, of Florence, of Heliopolis, of Ludovisio, of St. Mahut, of the Medici, of the Vatican, of Mount Cœlius, and that of Pamphylia.

One of the uses of obelisks among the ancients was, to find the meridian altitudes of the sun at different times of the year. Hence they served instead of very large gnomons. One of the obelisks now standing at Rome, that of St. John's Lateran, is in height 108 English feet, without the pedestal; and the other obelisk, brought to Rome by Augustus, buried under the Campus Martius, wants but little of the same height. Pliny gives a description of this gnomon, lib. xxxvi. sect. 15. From him it appears, that there was laid down, from the foot of the obelisk northward, a level pavement of stone, equal in breadth to the breadth of the obelisk itself, and equal in length to its shadow at noon, upon the shortest day; that is to say, that its length was to the height of the obelisk, almost as 22 to 10, and that under this pavement, there were properly let in parallel rulers of brass, whose distance from the point, directly under the apex of the obelisk, were perfectly equal to the length of the shadow thereof at noon, on the several days of the year, as the same lengths decreased from the shortest day to the longest, and again increased from the longest day to the shortest. Vide *Phil. Trans.* No. 482, art. 5, vol. xliv. p. 365; where we also find some remarks by Mr. Folkes on Hardouin's *Amendment of a Passage in Pliny's Natural History*, lib. ii. sect. 74, about the length of the shadows of gnomons in different latitudes.

OBLIQUE LINE. When one straight line stands upon another, and makes unequal angles therewith, the angles are said to be *oblique*, the one being greater than a right-angle, and the other less. Hence a line is only oblique, as it relates to another line: without this distinction, the word would be destitute of meaning.

Oblique Angle, one that is greater or less than a right angle.

Oblique-angled Triangle, one that has no right angle.

Oblique Arches, are those which conduct high roads across a river, canal, open drain, &c., in an oblique direction. —Oblique arches are otherwise called *skew bridges*. *See* Bridge Arch.

OBLONG (from the Latin *oblongus*) a rectangle of unequal dimensions.

OBSERVATORY, or Observatorium, a place destined for observing the heavenly bodies; or a building usually in form of a tower, raised on some eminence, and covered with a terrace for making astronomical observations. The more celebrated observatories are, 1. The Greenwich Observatory, or Royal Observatory of England, was built in 1676, by order of Charles II. at the solicitation of Sir Jonas Moore and Sir Christopher Wren, and furnished with the most accurate instruments by the same, particularly a noble sextant of seven feet radius, with telescopic sights. The province of observing was first committed to Flamsteed, a man who seemed born for the employment. For fourteen years, with unwearied pains, he watched the motions of the planets, and particularly those of the moon, as he had been instructed; that a new theory of that planet being found, exhibiting all her irregularities, the longitude might thence be determined. In the year 1690, having provided himself with a mural arch of seven feet diameter, well fixed in the plane of the meridian, he verified his catalogue of the fixed stars, (which hitherto had depended altogether on the distances measured with the sextant,) after a new and very different manner, viz., by taking the meridian altitudes, and the movements of culmination, or the right ascension and declination. With this instrument he was so pleased, that he laid the use of the sextant almost wholly aside; and in this way was the astronomer-royal employed for thirty years; in the course of which time nothing had appeared in public worthy so much expense and preparation; so that the observer seemed rather to have been employed for his own sake, and that of a few friends, than for the public; though it was notorious, the observations that had been made were very numerous, and the papers swelled to a great bulk. This occasioned Prince George of Denmark, in 1704, to appoint certain members of the Royal Society, viz., the Hon. Fr. Robarts, Sir Christopher Wren, Sir Isaac Newton, Dr. Gregory, and Dr. Arbuthnot, to inspect Flamsteed's papers, and select such as they should think fit for the press, purposing to print them at his own expense, but the prince dying before the impression was half finished, it lay still for some time; till at length it was resumed by order of Queen Anne, and the care of the press committed to Dr. Arbuthnot, and that of correcting and supplying the copy to Dr. Halley. Such was the rise and progress of the "Historia Cœlestis," the principal part whereof is the catalogue of fixed stars, called also the Greenwich Catalogue. Flamsteed was succeeded by Dr. Halley; and Dr. Halley, in 1742, by Dr. Bradley, so deservedly celebrated for his discovery of the aberration of the stars, and the mutation of the earth's axis; after Dr. Bradley, the appointment was, in 1762, conferred upon Mr. Bliss, who was succeeded in 1785 by Dr. Maskelyne, the late worthy astronomer-royal; upon whose demise, in 1811, this important office was conferred upon Mr. Pond.

The Greenwich observatory is found, by very accurate observation, to lie in 51° 28′ 30″ north latitude.

2. The French Observatory, built by Louis XIV. in the Fauxbourg St. Jacques, Paris, is a very singular, but withal, a very magnificent building. It is eighty feet high, and at the top there is a terrace. It is here M. de Lahire, M. Cassini, &c., were employed. This observatory was begun in 1664, and finished in 1672. The difference in longitude between this and Greenwich Observatory is 20° 20′ 15″ each. In the Paris Observatory, is a cave, or cellar, of 170 feet descent, for making various experiments, particularly such as relate to congelations, refrigerations, indurations, conservations, &c. And in this cave there is a thermometer of M. de Lahire, which is always at the same height, indicating the temperature of the place to be always the same.

3. Tycho Brahe's observatory in the little island of Ween, or the Scarlet Island, between the coasts of Schonen and Zealand in the Baltic, was erected and furnished with instruments at his own expense; and was called by him Uranienburgh. In this place, he spent twenty years in observing the stars.

We may enumerate here some other observatories, as that of Pekin, erected by a late emperor of China in his capital, upon the recommendation of the Jesuit missionaries; and that of the Brahmins at Benares, in the East Indies, of which we give the following description:—

The observatory at Benares, built by order of the emperor Akbar, was once a magnificent structure; the lower part of it is now, however, converted into stables; the court-yards and apartments are still spacious. It stands on the banks of the Ganges, and the summit is approached by a staircase leading to a large terrace, where numerous instruments still remain in great preservation; stupendously large, immoveable from the spot, and built of stone, some of them being upwards of twenty feet in height. Their graduation is very exact.

OBTUNDING, (from the Latin *obtundo*,) the blunting or taking away a sharp corner.

OBTUSE, (from the Latin) anything that is blunt.

Obtuse-angled Triangle, a triangle which has an obtuse angle.

Obtuse Section of a Cone, a name given to the hyperbola, by ancient geometricians, because they considered it only in such a cone, whose section through the axis was an obtuse-angled triangle.

OCHRE, in painting, a colour prepared from a species of earth, also termed ochre, composed of fine, soft, smooth, and argillaceous particles, slightly coherent, rough to the touch, and easily diffusable in water; ochre is of various colours. Yellow is the most prevalent, but there are red, green, blue, and black ochres. The colouring matter of ochre is almost always oxide of iron. Red chalk is much used for drawing; for this purpose, it should be free from grit, and not too hard. In order to free it from grit, and render it better for use, it is sometimes pounded, washed, mixed with gum, and cast into moulds of convenient shape and size. Under the name of reddle, this substance is much used for the marking of sheep, and, when mixed with oil, for the painting of pales, gates, and the wood-work of out-buildings.

OCTAGON, (from ὀκτω, *eight*, and γωνία, *sides*) a figure of eight sides, and consequently as many angles. When all the sides and all the angles are equal, the figure is called *a regular octagon.*

OCTAHEDRON, or Octaedron, (Greek, ὀκτάεδρος) in geometry, one of the five regular bodies, consisting of eight equal and equilateral triangles.

The octahedron may be conceived as consisting of two quadrilateral pyramids put together at their bases.

Its solidity, therefore, is had by multiplying the quadrangular base of either by one-third of the perpendicular height of one of them, and then doubling the product. The square of the side of an octahedron is in a subduple ratio of the square of the diameter of the circumscribing sphere. See Regular Body.

OCTOGON, *See* Octagon.

OCTOSTYLE, (from ὀκτὼ, *eight*, and ςῦλος, *a column*) an ordonnance with eight columns. It is generally understood of columns when their axes are all in the same plane as in the portico of the Pantheon at Rome, and the Parthenon at Athens.

ODEUM, (Greek, ὠδειον) among the ancients, was a place for the rehearsal of music to be sung in the theatre.

Odeum was sometimes also extended to buildings that had no relation to the theatre. Pericles built an odeum at Athens where musical prizes were contended for. Pausanias says that Herod, the Athenian, built a magnificent odeum for the sepulchre of his wife.

Ecclesiastical writers also use odeum for the choir of church.

ODOMETER, an instrument for measuring the distance travelled over by a chaise or other carriage; it is attached to the wheel, and by means of an index and dial-plate, shows the distance gone over.

ŒCUS, (Greek) a word used by Vitruvius, to denote some apartment connected with the dining-room. The œci were very magnificent, as will appear by reading chapters v. and vi. book vi. of Newton's Vitruvius.

OFFICES, (French) in architecture, denote all the apartments that serve for the necessary occasions of a great house, or palace, or those where the servants are employed; as kitchens, pantries, brewhouses, confectioneries, fruiteries, granaries, &c., as also wash-houses, wood-houses, stables, &c. The offices are commonly in the *bassecour;* sometimes they are sunk under ground, and well vaulted.

OFFSETS, those planes of a wall which connect two faces in different parallel planes, where the upper part recedes from the lower.

OGEE, or O-G, in architecture, a moulding, consisting of two members, the one concave, the other convex, the same with what is otherwise called *cymatium.*

Vitruvius makes each member of the ogee a quadrant of a circle; Scammozzi, and some others, make them somewhat flatter, and strike them from two equilateral triangles.

The figure of an ogee bears some resemblance to that of an S.

OGIVES, in architecture, arches or branches of a Gothic vault, which, in lieu of being circular, pass diagonally from one angle to another, and form a cross with the other arches which make the side of the squares, whereof the ogives are diagonals.

The middle, where the ogives cut or cross each other, is called the *key*, which is sometimes carved in form of a rose, or a *cul de lampe.* The members or mouldings of the ogives are called *nerves*, *branches*, or *reins;* and the arches which separate the ogives, *double arches.*

OILLETS, OILLETTES, or OYLETS, (from the French *œil*, an eye). Eyelet-holes, small openings, or holes of various forms in the walls of fortified places, through which missiles were discharged on the besiegers.

OLD RED SANDSTONE, in *geology*, the lowest member of the carboniferous group of strata, extensively developed in the counties of Shropshire and Herefordshire, in England; Brecknockshire, in Wales; and Dumfrieshire and Forfarshire in Scotland. It lies between the carboniferous series and the silurian rocks. It consists of many varieties and alternations of silicious sandstones, and conglomerates of various colours, red predominating. According to Bakewell, the old red sandstone is a graywacke, coloured red by the accidental admixture of oxide of iron.

OLYMPIAN GAMES, the chief of the four great national festivals of the Greeks, were celebrated at Olympia, a sacred spot on the banks of the Alpheus, near Elis, every fifth year. The exact interval at which it recurred, was one of forty-nine and fifty lunar months alternately; so that it fell sometimes in the month of Appollonius (July) sometimes in the month of Parthenius (August.) The period between two celebrations, was called an Olympiad. It lasted during five days.

The Olympian festival consisted of religious ceremonies, athletic contests, and races. The chief deity who presided over it was Jupiter Olympius, whose temple at Olympia, containing the ivory and gold statue of the god by Phidias, was one of the most magnificent works of art in Greece. The games consisted of horse and foot races, leaping, throwing, wrestling, and boxing, and combinations of these exercises. The earliest of these games was the foot-race, which was the only one revived by Iphitus. The space run, was the length of the stadium in which the games were held, namely, about 600 English feet.

Wrestling was introduced in the 18th Olympiad (B.C.708). The wrestlers were matched in pairs by lot; when there was an odd number, the person who was left by the lot without an antagonist, wrestled last of all with him who had conquered the others. The athlete who gave his antagonist three throws, gained the victory. There was another kind of wrestling, in which, if the combatant who fell could drag down his antagonist with him, the struggle was continued on the ground, and the one who succeeded in getting uppermost and holding the other down gained the victory.

Boxing was introduced in the 23rd Olympiad (B.C. 688). The boxers had their hands and arms covered with thongs of leather, called cestus, which served both to defend them, and to annoy their antagonists. Virgil describes the cestus as armed with lead and iron; but this is not known to have been the case among the Greeks. In these games, the combatants fought naked.

The horse-races were of two kinds, with chariots, or without. The chariot-race was generally with four-horsed chariots, and was introduced in the 25th Olympiad (B.C. 680.) The course had two goals in the middle, at the distance probably of two stadii from each other. The chariots started from one of these goals, turned round the other, and returned along the other side of the hippodrome. This circuit was made twelve times. The great art of the charioteer consisted in turning as close as possible to the goals, but without running against them, or against the other chariots. The places at the starting-post were assigned to the chariots by lot.

There were two sorts of races on horseback, namely, that in which each competitor rode one horse throughout the course, and the other in which, as the horse approached the goal, the rider leaped from his back, and keeping hold of the bridle, finished the course on foot. *See* CIRCUS and HIPPODROME.

It seems to be generally admitted that the chief object of this festival was to form a bond of union for the Grecian states. Besides this, the great importance which such an institution gave to the exercises of the body, must have had an immense influence in forming the national character. Regarded as a bond of union, the Olympian festival seems to have had but little success in promoting kindly feelings between the Grecian states, and perhaps the rivalry of the contest may have tended to exasperate existing quarrels; but it undoubtedly furnished a striking exhibition of the nationality of the Greeks, of the distinction between them and other races. Perhaps the contingent effects of the ceremony were, after all, most important. During its celebration, Olympia was a centre for the commerce of all Greece, for the free interchange of opinions, and for the publication of knowledge. The concourse of people from all parts of Greece afforded a fit audience for literary productions, and gave a motive for the composition of works worthy to be laid before them. Poetry and statuary received an impulse from the demand made upon them to aid in perpetuating the victors fame.

ONE-PAIR-OF-STAIRS, signifies the first story, or floor, by passing up the stairs, or pair of stairs, as they are frequently called, from the entrance-floor to the next floor, which is denominated the one-pair-of-stairs floor, and frequently (though very improperly) the first floor, the entrance floor being naturally the first floor.

OOLITE. *See* ROE-STONE.

OPAE, the space, signifies the space between joists. *See* Newton's Vitruvius, book iv. chap. ii.

OPENING. *See* APERTURE.

OPERA HOUSE, a theatre for the express purpose of performing operas or musical dramas.

OPISTHODOMOS, the enclosed space behind a temple. The treasury at Athens was so called, because it stood behind the temple of Minerva.

OPPOSITE ANGLES, those which are formed by two straight lines crossing each other, but not two adjacent angles.

Opposite Cones, those to which a straight line can be everywhere applied on the surfaces of both cones.

Opposite Sections, the sections made by a plane cutting two opposite cones.

OPTIC PYRAMID. *See* Perspective.

Optic Rays. *See* Perspective.

OPTICS, (from the Latin, *optica*) is properly the science of direct vision. In a larger sense, the word is used for the science of vision, or visibles in general; in which sense, optics includes catoptrics and dioptrics, and even perspective.

In its more extensive acceptation, optics is a mixed mathematical science, which explains the manner by which vision is performed in the eye; treats of sight in the general; gives the reasons of the several modifications or alterations which the rays of light undergo in the eye; and shows why objects appear sometimes greater, sometimes smaller, sometimes more distinct, sometimes more confused, sometimes nearer, and sometimes more remote. In this extensive signification, it is considered by Sir Isaac Newton, in his admirable work called *Optics*.

Optics make a considerable branch of natural philosophy; both as it explains the laws of nature, according to which vision is performed; and as it accounts for abundance of physical phenomena, otherwise inexplicable.

From optics likewise arises perspective, all the rules of which have their foundation in optics. Indeed, Tacquet makes perspective a part of optics; though John, Archbishop of Canterbury, in his *Perspectiva Communis*, calls optics, catoptrics, and dioptrics, by the common name *perspective*.

This art, for so it should be considered rather than as a science, was revived, or re-invented, in the sixteenth century. It owes its birth to painting, and particularly to that branch of it which was employed in the decoration of the theatre. Vitruvius informs us, that Agatharchus, instructed by Æschylus, was the first who wrote upon this subject; and that afterwards the principles of this art were more distinctly taught by Democritus and Anaxagoras, the disciples of Agatharchus. How they described the theory of this art we are not informed, as their writings have been lost; however, the revival of painting in Italy was accompanied with a revival of this art; and the first person who attempted to lay down the rules of perspective, was Pietro del Borgo, an Italian. He supposed objects to be placed beyond a transparent tablet, and endeavoured to trace the images which rays of light, emitted from them, would make upon it. The book which he wrote upon this subject, is not now extant; and this is the more to be regretted, as it is very much commended by the famous Egnazio Dante. Upon the principles of Borgo, Albert Durer constructed a machine, by which he could trace the perspective appearance of objects. Balthazar Parussi, having studied the writings of Borgo, endeavoured to make them more intelligible. To him we owe the discovery of points of distance, to which all lines that make an angle of 45 degrees with the ground-line are drawn. Soon after, Guido Ubaldi, another Italian, found that all the lines, which are parallel to each other and to the horizon, if they be inclined to the ground-line, converge to some point in the horizontal line; and that through this point, also, a line drawn from the eye, parallel to them will pass. These principles combined, enabled him to make out a pretty complete theory of perspective. Great improvements were made in the rules of perspective by subsequent geometricians, particularly by Professor Gravesande, and still more by Dr. Brook Taylor, whose principles are, in a great measure, new, and much more general than those of any person before him. Although Dr. Taylor really invented this excellent method of perspective, yet it is suggested by Mr. Robins, that the same method was published by Guido Ubaldi in his *Perspective*, printed at Pesaro, in 1600. In this treatise the method is delivered very clearly, and confirmed by most excellent demonstrations. In the last book, Ubaldi applies his method to the delineation of the scenes of a theatre; and in this, as far as the practice is concerned, he is followed by Signor Sabatellini, in his *Practica di Fabrica Scene*, of which there was a new edition at Ravenna in 1638; and to this was added a second book, containing a description of the machines used for producing the sudden changes in the decorations of the stage. In the catalogue of the great Sir Isaac Newton's works, at the end of his *Life*, is a work on perspective, written in Latin; *Newtoni Elementa Perspectivæ Universalis*, 1746. 8vo. We are indebted to opticians of a much later period for ingenious devices to apply the knowledge they had of optics, and especially of perspective, to the purpose of amusement.

For the principles and practice of Perspective, see that article, where they will be fully treated of.

ORANGERY, a gallery in a garden, or parterre, exposed to the south, but well closed with a glass window, to preserve oranges in during the winter season.

The orangery of Versailles is the most magnificent that ever was built; it has wings, and is decorated with a Tuscan order.

ORATORY, (from the Latin, *oratorium*, a temple,) a closet or apartment in a large house, near a bedchamber, furnished with a small altar, or an image, for private devotion, among the Romanists. The ancient oratories were little chapels adjoining to monasteries, wherein the monks offered up their prayers, before they had churches.

In the sixth and seventh centuries, oratories were little churches built frequently in burial-grounds, without either baptistry, cardinal, priest, or any public office, the bishop sending a priest to officiate occasionally.

ORB, (from the Latin *orbis*, a sphere,) a knot of flowers, or herbs, in a Gothic ceiling, placed upon the intersection of several ribs, in order to cover the mitres of every two adjoining ribs. This is otherwise called *boss*.

ORCHESTRA, in ancient theatres, a place set apart for the chorus, and in modern theatres that division in which the musicians are located. *See* Theatre.

ORDER, the perfect arrangement and composition of any architectural work; but the term is more especially used to designate the various methods of arrangement employed in Grecian or Classical architecture, and is definitely applied to such a portion of a building as may comprehend the whole design by a continuity and repetition of its parts. By those who put faith in Vitruvius, the Grecian orders are supposed to be but an imitation of the parts of a primitive hut, and which, according to his theory, originally consisted of a roof or covering, supported by posts made of the trunks of trees in four rows, forming a quadrangular enclosure. Beams were laid upon the tops of the posts, in order to connect them, in their longitudinal direction, in one body. To support the covering, timbers were laid from beam to beam across the breadth; and to throw off the wet, other beams were laid parallel to those resting upon the posts, but jutting farther over on each side of the edifice; and these again supported inclined timbers, which overhung their supports, and formed

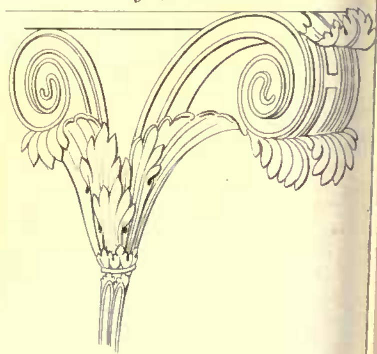

Fig. 12.

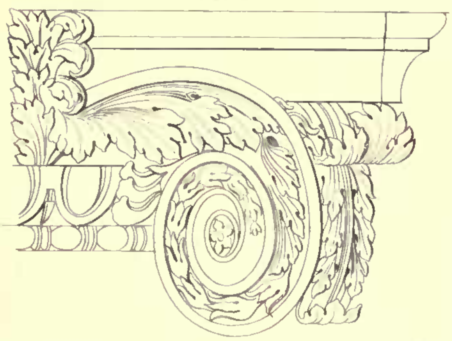

Fig. 11.

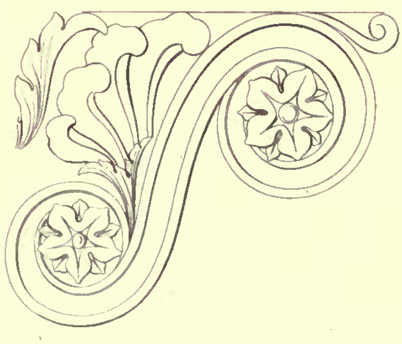

Fig. 10.

a ridge in the middle of the roof, for throwing off the wet; and thus the part supported formed three principal distinct portions, which, in process of time, were decorated with certain mouldings, or other ornaments, each part still preserving its distinct mass, though perhaps not exactly similar to the original form. The three parts, taken as a whole, were called *the entablature:* the lower part, consisting of the linteling beams, was called *the epistyle*, or *architrave:* the middle part, which receded from the epistyle, was called *the zoophorus*, or *frieze;* and the upper part, which projected considerably over the frieze, being in imitation of the ends of the roof, was called *the cornice*.

Therefore the entablature consists of a cornice, frieze, and architrave.

The posts received the name of *columns*, which always consist of two principal divisions at least, and frequently of three. The columns were ornamented at the top in imitation of the stones laid upon the posts in the original wooden hut, for throwing off the rain. These decorations at the top received the name of *capital*, and each of the wooden posts that of *shaft*.

When ornaments were added to the foot of the shaft, they were termed *the base*.

The order, therefore, consists principally of a column and entablature. The column is subdivided into a shaft and capital, or, at most, into three principal parts, a base, shaft, and capital; and the entablature, as has been observed, into architrave, frieze, and cornice. These parts are again divided into smaller portions, termed *mouldings*, or other ornaments. *See* Architecture, Orders of.

Order, *Attic*, the pilaster of an attic. *See* Attic.

Order, *Caryatic*, that in which the entablature is supported by women instead of columns. *See* Caryatic.

Order, *Gothic*, the pointed style of architecture, usually called *Gothic*. *See* Architecture, Castle, and Gothic.

Orders, *Greek*, are the Doric, Ionic, and Corinthian. *See* each of these articles.

Order, *Persian*, that where the entablature is supported by men instead of columns. The history is related in Newton's *Vitruvius*, book i. chap. i. page 3. *See* Persians.

Order of Temples, otherwise called Species, are the amphiprostyle, the antæ, the dipteral, the peripteral, and the prostyle. *See* those respective articles.

ORDINANCE, or Ordonnance, the same as Order: which see.

ORDINATES, in geometry and conics, are lines drawn from any point of the circumference of an ellipsis, or other conic section, perpendicularly across the axis, to the other side.

The Latins call them *ordinatim applicatæ*.

The halves of each of these are properly only *semi-ordinates*, though popularly called *ordinates*.

The ordinates of a curve may more generally be defined to be right lines parallel to each other, terminated by the curve, and bisected by a right line called the *diameter*. In curves of the second order, if any two parallel right lines be drawn so as to meet the curve in three points, a right line, which cuts these parallels, so as that the sum of two parts terminating at the curve on one side the secant, is equal to the third part terminated at the curve on the other side, will cut all other right lines parallel to these, which meet the curve in three points, after the same manner, *i. e.* so as that the sum of the two parts on one side will always be equal to the third part on the other side. And these three parts, equal on either side, Sir Isaac Newton calls *ordinatim applicatæ*, ordinates of curves of the second order.

Ordinate, in an ellipsis, hyperbola, and parabola. *See* the respective articles.

ORGANICAL DESCRIPTION OF CURVES, a method of describing curves upon a plane by continued motion.

ORIEL WINDOW, in architecture, a projecting angular window, mostly of a triagonal or pentagonal form, and divided by mullions and transomes into different bays and other compartments. These windows are not peculiar to the pointed style, as they are of frequent occurrence in the barbarous style which succeeded it. During the reigns of Elizabeth and James I. they became still more common than they had been before in the pointed style.

ORLE (French, formed from the Latin *orletum* or *orlum*, of *ora*, a border or list) a fillet under the ovolo or quarter-round of a capital.

When at the top or bottom of the shaft, it is called *cincture*.

Palladio also uses orle for the plinth of the bases of the columns and pedestals.

ORNAMENTS (from the Latin *ornamentum*, to embellish) in architecture, all the sculpture, or carved work, with which a piece of architecture is enriched.

Plate I. Some of the most beautiful specimens of ornaments, in scrolls and branches, used in the capitals of columns, in Grecian and Roman antiquity.

Figures 1, 2, 3, 4, 5, Specimens from the most beautiful remains of Grecian architecture. *Figure* 5 is taken from the capitals of that elegant piece of antiquity the Lantern of Demosthenes.

Figures 6, 7, 8, 9, 10, 11, 12, are from the ancient remains of Roman architecture. In particular, *Figure* 9, is taken from the temple of Vesta, at Tivoli; *Figure* 10, from the three remaining columns of the temple of Jupiter Stator, at Rome; *Figure* 12, from the arch of Titus.

Ornaments in Relievo, those carved on the contours of mouldings.

ORTHOGONAL FIGURE (from ὀρθὸς, *true*, and γωνία, *an angle*) the same as rectangular.

ORTHOGRAPHICAL PROJECTIONS. *See* Projection.

ORTHOGRAPHY (ὀρθὸς, *true*, and γραφω, *to describe*) in architecture, the elevation of a building, showing all the parts thereof in their true proportion. The orthography is either *external* or *internal*.

Orthography, *External*, a delineation of the outer face or front of a building, exhibiting the principal wall, with its apertures, roof, ornaments, and everything visible to an eye placed at a distance, before the building.

Orthography, *Internal*, called also Section, a delineation or draught of a building, such as it would appear were the external wall removed. *See* Perspective.

Orthography, in geometry, the art of drawing or delineating the fore-right plan or side of any object, and of expressing the heights or elevations of each part.

This art has received its name from its determining things by perpendicular right lines falling on the geometrical plan; or rather, because all the horizontal lines are here straight and parallel, and not oblique, as in perspective representations.

Orthography, in fortification, the profile or representation of a work; or a draught so conducted, as that the length, breadth, height, and thickness of the several parts are expressed; such as they would appear, if it were perpendicularly cut from top to bottom.

OSCULATING CIRCLE, or Kissing Circle, the circle of curvature. That circle whose radius is equal to the radius of curvature of any other curve at a particular or specified point. *See* CURVE.

OVA (from the Latin *ovum*, an egg) an ornament in form of an egg, usually employed in the echinus.

OVAL, a figure in geometry, bounded by a curve line returning to itself.

Under this general definition of an oval is included the ellipsis, which is a mathematical oval; also all other figures which resemble the ellipsis, though with very different properties; and, in short, all curves which return to themselves, go under the name of ovals.

For a description of the mathematical oval, the reader will turn to the article ELLIPSIS, where, it is presumed, he will meet with full satisfaction.

One of the most remarkable properties of the oval kind is the following:

Plate I. *Figure* 1.—Let C E F G be a circle, O its centre; draw any line, E I, through the centre O; then take any point, F, in the circumference. Let F I be an inflexible line, and let M be a given point in the line F I; then, if the point F be conceived to move round the circumference of the circle, while the point, I, the end of this line, F I, moves or slides along the line E I, the point M will describe an oval, almost similar to the conic ellipsis. As we have not seen any equation of this figure, it is presumed that the following investigation, by the author, will be acceptable:

Draw F H perpendicular to the diameter, E G, of the circle, cutting E G at H; also draw M P perpendicular to E I, cutting E I always in P, wherever the point M is situated. Let A be the point in the straight line E I, in which M will coincide when F is brought to E, and B the point where M will coincide when F comes to G.

Then let A P $= x$
P M $= y$
E H $=$
H F $= s$
I M $= a$
I F $= b$
and E G $= d$

From the property of the circle we have H F$^2 = d\,v - v^2$; then, by similar triangles, I F H and I M P, we have

$$\text{IF}^2 : \text{IM}^2 :: \text{HF}^2 : \text{PM}^2;$$

$$\text{That is, } b^2 : a^2 :: d\,v - v^2 : y^2 = \frac{a^2}{b^2}(d\,v - v^2)$$

$$\text{Therefore, } y = \frac{a}{b}(d\,v - v^2)^{\frac{1}{2}}$$

Then, to find the value of $x =$ A P, we have

$$\text{IP}^2 = \text{IM}^2 - \text{PM}^2 = a^2 - \frac{a^2}{b^2}(d\,v - v^2) = \frac{a^2}{b^2}(b^2 - d\,v + v^2);$$

$$\text{Therefore, IP} = \frac{a}{b}(b^2 - d\,v + v^2)^{\frac{1}{2}};$$

$$\text{But IM : IP :: MF : PH;}$$

$$\text{That is, } a : \frac{a}{b}(b^2 - d\,v + v^2)^{\frac{1}{2}} :: c : \text{PH} = \frac{c}{b}(b^2 - d\,v + v^2)^{\frac{1}{2}}$$

$$\text{IE} = \text{IP} + \text{PH} + \text{HE} = (b^2 - d\,v + v^2)^{\frac{1}{2}} \times \frac{a+c}{b} + v;$$

$$\text{IA} = \text{IE} - \text{AE} = \frac{a+c}{b} \times (b^2 - d\,v + v^2)^{\frac{1}{2}} + v - c;$$

$\text{AP} = \text{IA} - \text{IP} = \frac{c}{b}(b^2 - d\,v + v^2)^{\frac{1}{2}} + v - c$; by which the value of A P, corresponding to P M or $y = \frac{a}{b}(d\,v - v^2)^{\frac{1}{2}}$, may be found in the most simple manner.

Therefore, if A P in the figure were always equal to the versed sine E H of the circle, the curve described by the motion of the point M, would really be an ellipsis; and because P M or $y = \frac{a}{b}(d\,v - v^2)^{\frac{1}{2}}$ it follows, that the axis perpendicular to the ordinates, is to the axis parallel to the ordinates, in the ratio of b to a; that is, in the ratio of I F to I M nearly.

Let $a = 20$, $b = 40$, $c = 20$, and $d = 10$; then will $y = \frac{a}{b}d\,(v - v^2)^{\frac{1}{2}} = \frac{1}{2}(6\,v - v^2)^{\frac{1}{2}}$; from which the following values are obtained, according to the different assumptions of the versed sine, v, of the circle:

$$\text{Assume } v = 1, \text{ then } \frac{1}{2}(6 \times 1 - 1^2)^{\frac{1}{2}} = \frac{1}{2}(6 - 1)^{\frac{1}{2}} = \frac{5^{\frac{1}{2}}}{2} = 1.118;$$

$$v = 2, \quad \frac{1}{2}(6 \times 2 - 2^2)^{\frac{1}{2}} = \frac{1}{2}(12 - 4)^{\frac{1}{2}} = \frac{8^{\frac{1}{2}}}{2} = 1.4142;$$

$$v = 3, \quad \frac{1}{2}(6 \times 3 - 3^2)^{\frac{1}{2}} = \frac{1}{2}(18 - 9)^{\frac{1}{2}} = \frac{9^{\frac{1}{2}}}{2} = 1.5;$$

$$v = 4, \quad \frac{1}{2}(6 \times 4 - 4^2)^{\frac{1}{2}} = \frac{1}{2}(24 - 16)^{\frac{1}{2}} = \frac{8^{\frac{1}{2}}}{2} = 1.4142;$$

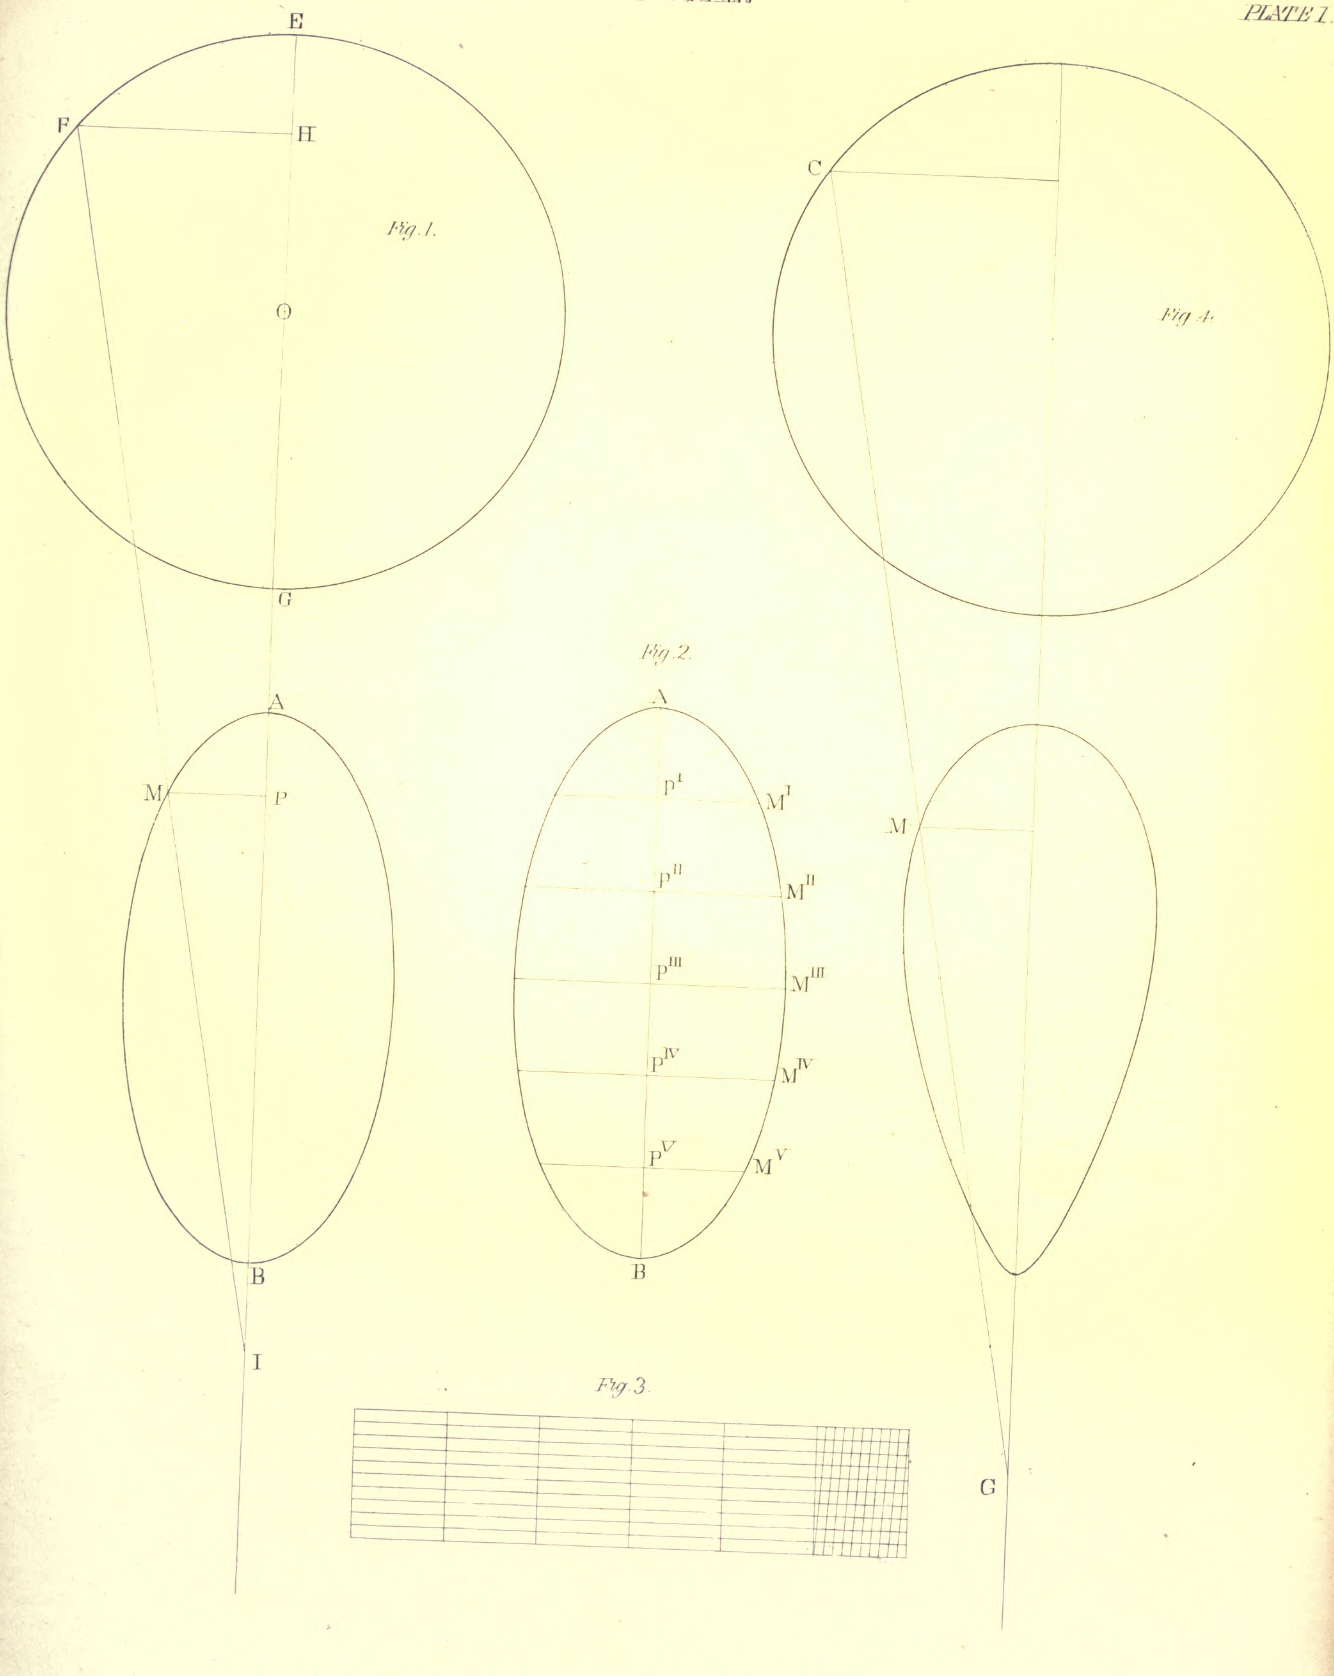
$$v = 5, \quad \frac{1}{2}(6 \times 5 - 5^2)^{\frac{1}{2}} = \frac{1}{2}(30 - 25)^{\frac{1}{2}} = \frac{5^{\frac{1}{2}}}{2} = 1.118.$$

Then, because $x = \frac{c}{b}(b^2 - d\,v + v^2)^{\frac{1}{2}} + v - c = \frac{1}{2}(1600 - 6\,v + v^2) + v - 20$, we shall have the following value of x, by the different assumptions of v, which must be those answering to y, as before:

$$v = 1, \text{ then } x = \frac{1}{2}(1600 - 6 \times 1 + 1^2)^{\frac{1}{2}} + 1 - 20 = 0.96872;$$

$$v = 2, \quad x = \frac{1}{2}(1600 - 6 \times 2 + 2^2)^{\frac{1}{2}} + 2 - 20 = 1.94993;$$

OVAL.



Invented by P. Nicholson.
Drawn by M. A. Nicholson.

Engraved by J. C. Buttre.

$$v = 3, \text{ then } x = \frac{1}{2}(1600 - 6 \times 3 + 3^2)^{\frac{1}{2}} + 3 - 20 = 2.94367;$$

$$v = 4, \quad x = \frac{1}{2}(1600 - 6 \times 4 + 4^2)^{\frac{1}{2}} + 4 - 20 = 3.94993;$$

$$v = 5, \quad x = \frac{1}{2}(1600 - 6 \times 5 + 5^2)^{\frac{1}{2}} + 5 - 20 = 4.96872;$$

Therefore the abscissas, and the corresponding ordinates of the figure, are as follow:

When $x = .96872$, then $y = 1.1180$;
$x = 1.94993$, $y = 1.4142$;
$x = 2.94367$, $y = 1.5$;
$x = 3.94993$, $y = 1.4142$;
$x = 4.96872$, $y = 1.1180$.

Figure 2.—Draw the line A B equal to the diameter d, which is 6, from any scale of equal parts, as *Figure* 3, (but the scale to be used ought to be a diagonal one); make A P′ = 0.96872, A P″ = 1.94993, A P‴ = 2.94367, A P^{iv} = 3.94993, A P^{v} = 4.96872; then, having drawn all the lines, P M, cutting A B at right angles, on both sides of A B make P′ M′ = 1.1180, P″ M″ = 1.4142, P‴ M‴ = 1.5, P^{iv} M^{iv} = 1.4142, and P^{v} M^{v} = 1.1180; and through all the points A, P′, P″, P‴, P^{iv}, P^{v}, draw a curve, which will be the oval required.

Abscissas.	Distances.	Differences.
A P′ = 0.96872	.96871 .98121	.01250
A P″ = 1.94993		.01253
A P‴ = 2.94367	.99374 1.00626	.01252
A P^{iv} = 3.94993		.01253
A P^{v} = 4.96872	1.01879 .98128	.03751
A P^{vi} = 6.		

So that the last distances, being a little wider than the first, show the figure to be an eggoid.

Another oval, which may be generated in a similar manner, is the following:

Figure 4.—Let C D H F be a circle; let any point, G, be taken in the plane of description; let C be the extremity of an inflexible line; let the point C be carried round the circumference of the circle, while the line always moves through the point G; then will any point, M, taken in this line, describe the oval required.

It is hoped that the reader will be satisfied with this mechanical description, as the investigation of the principle would extend this article to too great a length.

It is now upwards of twenty-five years since the author discovered the two above methods; and a machine for describing the former has been since exhibited for sale in Cornhill, which Mr. J. B. Taylor has applied to the art of engraving with considerable success; and though not mathematically true, it describes a beautiful curve, so very near to an ellipsis, that the defect cannot be detected by the eye. For describing concentric ellipses, or those which have their axes in the same ratio, no method can be so easily applied, as nothing more is required than to adopt the radius to the length of the curve.

A most beautiful figure of an oval may be derived from the equation of a circle of the higher orders; as $y^{m+1} = x^m (a - x)$. The proportion of the figure may be varied at pleasure.

To find the point in the axis through which the ordinate of the greatest breadth passes. As we have the value of $y = (a x^m - x^{m+1})^{\frac{1}{m+1}}$, it is evident that such value has a maximum; therefore, as $a x^m - x^{m+1}$ will have a maximum,

$$m a x^{m-1} \dot{x} - (m+1) x^m \dot{x} = o;$$

$$\frac{m a x^m}{x} = (m+1) x^m;$$

$$\frac{m a}{x} = (m+1);$$

$$m a = (m+1) x;$$

$$\text{and } x = \frac{m a}{m+1}.$$

Now let $m = 2$; then will $y = (a x^m - x^{m+1})^{\frac{1}{m+1}}$ become $y = (a x^2 - x^3)^{\frac{1}{3}}$; therefore, to make an oval of this description to any length and breadth, we have in this case $x = \frac{m a}{m+1} = \frac{2a}{3}$; consequently, the value of the ordinate, when it is a maximum, is $y = \left(\frac{4 a^3}{27}\right)^{\frac{1}{3}} = \frac{a}{3} 4^{\frac{1}{3}}$; hence, to make the length and breadth equal to each other, we have $y = \frac{3}{32^{\frac{1}{3}}} (a x^2 - x^3)^{\frac{1}{3}} = .945 (a x^2 - x^3)^{\frac{1}{3}}$ nearly, three decimal places only being used. Now let p be any proportion, as $\frac{1}{2}, \frac{2}{3}, \frac{3}{4}$, or any multiple of the semi-axis of the curve; then will $y = .945\, p\, (a x^2 - x^3)^{\frac{1}{3}}$. Let $p = \frac{1}{2}$, and $a = 9$; then $y = .4725 (9 x^2 - x^3)^{\frac{1}{3}}$.

Now when $x = o$, then will $y = o$; and when $x = a$, then will $y = o$ again; therefore, by assuming x equal to the following values:

$x = 1$, then will $y = .4725 \; (9 - 1)^{\frac{1}{3}} = .945$;
$x = 2$, $y = .4725 \; (36 - 8)^{\frac{1}{3}} = 1.435$;
$x = 3$, $y = .4725 \; (81 - 27)^{\frac{1}{3}} = 1.785$;
$x = 4$, $y = .4725 \; (144 - 64)^{\frac{1}{3}} = 2.036$;
$x = 5$, $y = .4725 \; (225 - 125)^{\frac{1}{3}} = 2.193$;
$x = 6$, $y = .4725 \; (324 - 216)^{\frac{1}{3}} = 2.250$;
$x = 7$, $y = .4725 \; (441 - 343)^{\frac{1}{3}} = 2.178$;
$x = 8$, $y = .4725 \; (576 - 512)^{\frac{1}{3}} = 1.890$;

Plate II. *Figure* 5. is a curve drawn, according to these abscissas, and ordinates drawn by the diagonal scale, *Figure* 6.

But if, in the following ordinates of the figure,

when $x = 1$, $y = 1.890$
$x = 2$, $y = 2.870$
$x = 3$, $y = 3.570$
$x = 4$, $y = 4.072$
$x = 5$, $y = 4.386$
$x = 6$, $y = 4.5$
$x = 7$, $y = 4.356$
$x = 8$, $y = 3.78$

be respectively multiplied by p, we shall have the axis to the maximum breadth of the figure in any given ratio, according to the value of p. Thus if $p = \frac{1}{2}$, then the axis of the curve will be to its greatest breadth, parallel to the ordinates, as 2 to 1; for instance,

when $x = 1,\ y = .945$;
$x = 2,\ y = 1.435$;
$x = 3,\ y = 1.785$;
$x = 4,\ y = 2.036$;
$x = 5,\ y = 2.193$;
$x = 6,\ y = 2.25$;
$x = 7,\ y = 2.178$;
$x = 8,\ y = 1.890$;

Again, suppose it were required to make the length of the axis to the greatest breadth, as 3 to 2;

then, when $x = 1,\ y = 1.890 \times \frac{2}{3} = 1.260$;

$x = 2,\ y = 2.870 \times \frac{2}{3} = 1.913$;

$x = 3,\ y = 3.570 \times \frac{2}{3} = 2.380$;

$x = 4,\ y = 4.072 \times \frac{2}{3} = 2.714$;

$x = 5,\ y = 4.386 \times \frac{2}{3} = 2.924$;

$x = 6,\ y = 4.500 \times \frac{2}{3} = 3.$

$x = 7,\ y = 4.356 \times \frac{2}{3} = 2.904$;

$x = 8,\ y = 3.780 \times \frac{2}{3} = 2.580$;

So that, fixing upon the length, divide that length into nine equal parts, and draw lines through the points of division; the length being thus the scale of the work, set off the ordinates on both sides of the axis, according to the value x; that is, each of the first pair of ordinates, 1.26; each of the next pair, 1.913; and so on.

The body of the vase, *Figure* 7, is drawn by this equation.

Another very useful proportion is that in which the greatest double ordinate is three-quarters of the length. From this we shall have the several values of y, as follow:

When $x = 1,\ y = 1.890 \times \frac{3}{4} = 1.417$;

$x = 2,\ y = 2.870 \times \frac{3}{4} = 2.152$;

$x = 3,\ y = 3.570 \times \frac{3}{4} = 2.677$;

$x = 4,\ y = 4.072 \times \frac{3}{4} = 3.054$;

$x = 5,\ y = 4.386 \times \frac{3}{4} = 3.289$;

$x = 6\ \ y = 4.500 \times \frac{3}{4} = 3.375$;

$x = 7,\ y = 4.356 \times \frac{3}{4} = 3.267$;

$x = 8,\ y = 3.780 \times \frac{3}{4} = 2.835$;

If the oval be required to have a longer taper, we may use the equation $v = (a x^3 - x^4)^{\frac{1}{4}}$, instead of $y = (a x^2 - x^3)^{\frac{1}{3}}$, which will produce a most beautiful figure; now the property being $y = (a x^3 - x^4)^{\frac{1}{4}}$; let $a = 8$, then $y = (8 x^3 - x^4)^{\frac{1}{4}}$

Let

$x = 1$ then $y = (8 - 1)^{\frac{1}{4}} = (7)^{\frac{1}{4}} = 1.626$;
$x = 2 \quad y = (8 \times 8 - 16)^{\frac{1}{4}} = (48)^{\frac{1}{4}} = 2.632$;
$x = 3 \quad y = (8 \times 27 - 81)^{\frac{1}{4}} = (135)^{\frac{1}{4}} = 3.408$;
$x = 4 \quad y = (8 \times 64 - 256)^{\frac{1}{4}} = (256)^{\frac{1}{4}} = 4.000$;
$x = 5 \quad y = (8 \times 125 - 625)^{\frac{1}{4}} = (375)^{\frac{1}{4}} = 4.400$;
$x = 6 \quad y = (8 \times 216 - 1296)^{\frac{1}{4}} = (432)^{\frac{1}{4}} = 4.559$;
$x = 7 \quad y = (8 \times 343 - 2401)^{\frac{1}{4}} = (343)^{\frac{1}{4}} = 4.303.$

These several roots are obtained from two extractions of the square root, as below; the last extraction is only carried to three places of decimals, as being amply sufficient, to construct the figure.

$(7)^{\frac{1}{4}} = (2.6457513)^{\frac{1}{2}} = 1.626$;
$(48)^{\frac{1}{4}} = (6.9282032)^{\frac{1}{2}} = 2.632$;
$(135)^{\frac{1}{4}} = (11.6189500)^{\frac{1}{2}} = 3.408$;
$(256)^{\frac{1}{4}} = (16.0000000)^{\frac{1}{2}} = 4.000$;
$(375)^{\frac{1}{4}} = (19.3649167)^{\frac{1}{2}} = 4.400$;
$(432)^{\frac{1}{4}} = (20.7846097)^{\frac{1}{2}} = 4.559$;
$(343)^{\frac{1}{4}} = (18.5202592)^{\frac{1}{2}} = 4.303.$

Since $x = \frac{m\,a}{m + 1}$ in every description of an oval; therefore, in this particular curve, where m is equal to 3, we shall have $x = \frac{3\,a}{4}$; that is, the greater double ordinate will pass through a point in the axis, distant from the extremity where the abscissa begins three-quarters of the length of the axis.

But in order to accommodate this equation to every length and breadth, it will be eligible in the first place to calculate the ordinates, so as to make the greatest double ordinate equal to the length of the axis, as in the preceding equation. The value of the greatest ordinate will therefore be $y =$

$$(a x^3 - x^4)^{\frac{1}{4}} = \left(\frac{27\,a^4}{64} - \frac{81\,a^4}{256}\right)^{\frac{1}{4}} = \left(\frac{27\,a^4}{256}\right)^{\frac{1}{4}} = \frac{a}{4} \times 27$$

$$= \frac{27^{\frac{1}{4}}\,a}{4}; \text{ hence } \frac{27^{\frac{1}{4}}\,a}{4} : \frac{a}{2} :: (a x^3 - x^4)^{\frac{1}{4}} : \frac{2}{27^{\frac{1}{4}}}(a x^3 - x^4)$$

So that $y = \frac{2}{27}(a x^3 - x^4)^{\frac{1}{4}}$ when the greatest double ordinate is equal in length to the axis; and if r be the ratio which the axis has to the greatest double ordinate, $y = \frac{2\,r}{27^{\frac{1}{4}}}(a x^3 - x^4)^{\frac{1}{4}} = .877\,r\,(a x^3 - x^4)^{\frac{1}{4}}$.

If the several values of y, as before calculated, be multiplied by .877, we shall obtain the following:

When $x = 1,\ y = 1.626 \times .878 = 1.427$;
$x = 2,\ y = 2.632 \times .878 = 2.311$;
$x = 3,\ y = 3.408 \times .878 = 2.999$;
$x = 4,\ y = 4.000 \times .878 = 3.511$;
$x = 5,\ y = 4.400 \times .878 = 3.866$;
$x = 6,\ y = 4.559 \times .878 = 4.$;
$x = 7,\ y = 4.303 \times .878 = 3.778$;

Each of these values being multiplied by r, will give the proportion of the figure required.

Now let $r = \frac{1}{8}$;

Figure 8 is drawn by these numbers; the vase, *Figure* … and the jug, *Figure* 10, are drawn by the same equation, varying the numbers.

then when $x = 1, y = 1.427\,r = .475$
$x = 2, y = 2.31\,r = .77$
$x = 3, y = 2.99\,r = .996$
$x = 4, y = 3.51\,r = 1.17$
$x = 5, y = 3.86\,r = 1.286$
$x = 6, y = 4.\,r = 1.333$
$x = 7, y = 3.778\,r = 1.259$

Again, let $r = \frac{1}{2}$;
then when $x = 1, y = 1.427\,r = .713$;
$x = 2, y = 2.31\,r = 1.155$;
$x = 3, y = 2.99\,r = 1.495$;
$x = 4, y = 3.51\,r = 1.755$;
$x = 5, y = 3.86\,r = 1.93$;
$x = 6, y = 4.\,r = 2.$
$x = 7, y = 3.778\,r = 1.889.$

Let $r = \frac{2}{3}$;
then when $x = 1, y = 1.427\,r = .951$;
$x = 2, y = 2.31\,r = 1.54$;
$x = 3, y = 2.99\,r = 1.99$;
$x = 4, y = 3.51\,r = 2.34$;
$x = 5, y = 3.86\,r = 2.57$;
$x = 6, y = 4.\,r = 2.66$;
$x = 7, y = 3.778\,r = 2.518.$

And, lastly, let $r = \frac{3}{4}$;
then when $x = 1, y = 1.427\,r = 1.07$;
$x = 2, y = 2.31\,r = 1.73$;
$x = 3, y = 2.99\,r = 2.24$;
$x = 4, y = 3.51\,r = 2.63$;
$x = 5, y = 3.86\,r = 2.89$;
$x = 6, y = 4.\,r = 3$;
$x = 7, y = 3.778\,r = 2.833.$

Another equation, which gives the oviform figure more well at the quicker end, is the following: $y = (a^2 x^2 - x^4)^{\frac{1}{2}}$. Let

$x = 1$ then $y = (100 - 1)^{\frac{1}{2}} = 99^{\frac{1}{2}} = 3.15$;
$x = 2$ $y = (400 - 16)^{\frac{1}{2}} = 384^{\frac{1}{2}} = 4.42$;
$x = 3$ $y = (900 - 81)^{\frac{1}{2}} = 819^{\frac{1}{2}} = 5.31$;
$x = 4$ $y = (1600 - 256)^{\frac{1}{2}} = 1344^{\frac{1}{2}} = 6.05$;
$x = 5$ $y = (2500 - 625)^{\frac{1}{2}} = 1875^{\frac{1}{2}} = 6.58$;
$x = 6$ $y = (3600 - 1296)^{\frac{1}{2}} = 2304^{\frac{1}{2}} = 6.92$;
$x = 7$ $y = (4900 - 2401)^{\frac{1}{2}} = 2499^{\frac{1}{2}} = 7.07$;
$x = 8$ $y = (6400 - 4096)^{\frac{1}{2}} = 2304^{\frac{1}{2}} = 6.92$;
$x = 9$ $y = (8100 - 6561) = 1539^{\frac{1}{2}} = 6.26.$

Calling the abscissal axis the height, the construction may e accommodated to any given dimensions, as follows; for is purpose we have the fluxion of $a^2 x^2 - x^4 = 0$; there-re $4 x^3 \dot{x} = 2 a^2 \dot{x}$; consequently $x^2 = \frac{a^2}{2}$; and hence $x = \frac{a}{2^{\frac{1}{2}}}$ ill give the point through which the greatest double ordi-ate passes. If therefore this quantity be substituted for x n the equation $y = (a^2 x^2 - x^4)^{\frac{1}{2}}$, then will $y = \left(\frac{a^4}{2} - \frac{a^4}{4}\right)^{\frac{1}{2}}$ $= \left(\frac{2a^4}{4} - \frac{a^4}{4}\right)^{\frac{1}{2}} = \left(\frac{a^4}{4}\right)\frac{a}{2^{\frac{1}{2}}} =$; therefore $\frac{a}{2^{\frac{1}{2}}} : \frac{a}{4} :: (a^2 x^2 - x^4)^{\frac{1}{2}}$ $\frac{1}{2^{\frac{1}{2}}}(a^2 x^2 - x^4)^{\frac{1}{2}} = 7071\,(a^2 x^2 - x^4)^{\frac{1}{2}}$; so that, taking $x =$, we shall have $y = \frac{a}{2}$, as it ought to be. Therefore, if the tio be r, we shall have $.7071\,r\,(a^2 x^2 - x^4)^{\frac{1}{2}}$, for any propor-on according to the nominal value of r. Now let $r = \frac{2}{3}$, then a being 10, as before, we shall have the several values of y as follow:

when $x = 1$, then $y = 2.23$;
$x = 2$ $y = 3.13$;
$x = 3$ $y = 3.75$:
$x = 4$ $y = 4.28$;
$x = 5$ $y = 4.65$;
$x = 6$ $y = 4.89$;
$x = 7$ $y = 5.00$;
$x = 8$ $y = 4.89$;
$x = 9$ $y = 4.43.$

If the equation of the curve be $y = (c^3 - x^3)^{\frac{1}{3}}$, the following values of y will be found, supposing $c = 5$;

when $x = 0, y = (125 - 0)^{\frac{1}{3}} = 5.$;
$x = 1, y = (125 - 1)^{\frac{1}{3}} = 4.986$;
$x = 2, y = (125 - 8)^{\frac{1}{3}} = 4.89$;
$x = 3, y = (125 - 27)^{\frac{1}{3}} = 4.610$;
$x = 4, y = (125 - 64)^{\frac{1}{3}} = 3.936$;
$x = 5, y = (125 - 125)^{\frac{1}{3}} = 0.$

Figure 11, is drawn by these numbers, according to the diagonal scale, *Figure* 13.

Figure 12, is drawn by the same equation, to a different set of numbers, to the same scale, *Figure* 13.

Another equation, by which figures of this description may be obtained, is the following:

$y = (a\,x - x^2)^{\frac{1}{2}}$. Let $a = 10$,
$x = 1, y = (10 - 1)^{\frac{1}{2}} = 1.73$;
$x = 2, y = (20 - 4)^{\frac{1}{2}} = 2.$;
$x = 3, y = (30 - 9)^{\frac{1}{2}} = 2.14$;
$x = 4, y = (40 - 16)^{\frac{1}{2}} = 2.21$;
$x = 5, y = (50 - 25)^{\frac{1}{2}} = 2.23.$

But perhaps the most beautiful figure of the oval species is the ellipsis. The equation of the circle is $y = (d\,x - x^2)^{\frac{1}{2}}$; let $d = 20$, then will $y = (20\,x - x^2)^{\frac{1}{2}}$; then when

$x = 1, y = (20 - 1)^{\frac{1}{2}} = 19^{\frac{1}{2}} = 4.3588989$;
$x = 2, y = (40 - 4)^{\frac{1}{2}} = 36^{\frac{1}{2}} = 6.$
$x = 3, y = (60 - 9)^{\frac{1}{2}} = 51^{\frac{1}{2}} = 7.1414284$;
$x = 4, y = (80 - 16)^{\frac{1}{2}} = 64^{\frac{1}{2}} = 8.$
$x = 5, y = (100 - 25)^{\frac{1}{2}} = 75^{\frac{1}{2}} = 8.660254$;
$x = 6, y = (120 - 36)^{\frac{1}{2}} = 84^{\frac{1}{2}} = 9.1651514$;
$x = 7, y = (140 - 49)^{\frac{1}{2}} = 91^{\frac{1}{2}} = 9.539392$;
$x = 8, y = (160 - 64)^{\frac{1}{2}} = 96^{\frac{1}{2}} = 9.797959$;
$x = 9, y = (180 - 81)^{\frac{1}{2}} = 99^{\frac{1}{2}} = 9.9493744$;
$x = 10, y = (200 - 100)^{\frac{1}{2}} = 100^{\frac{1}{2}} = 10.$

From these numbers, ellipses may be constructed, of any length and breadth, by multiplying them by the ratio of the axis $\frac{1}{4}, \frac{1}{2}, \frac{3}{4}, \frac{1}{3}, \frac{2}{3}$, supposing the breadth to be $\frac{1}{4}, \frac{1}{2}, \frac{3}{4}, \frac{1}{3}, \frac{2}{3}$ of the length.

A kind of oval, as it is called, which may easily be described through points, is the following:

Figure 14, No. 1, describe a semicircle, A P C, on the diameter A C, for the length: draw A D perpendicular and equal to A C; take any point, B, in A C; join B D; draw B p parallel to A D, cutting the circle in p; draw $p\ m$ perpendicular to B p, cutting B D at m; make A C, No. 2, equal to A C, No. 1; and every A P in No. 2, equal to every A B in No. 1; also every P M in No. 2, equal to the corresponding $p\ m$ in No. 1: through all the points, M, draw a curve.

This figure is of the form of a *pear*, and not what may be denominated *an oval*.

OVICULUM, in ancient architecture, a little ovum, or egg.

OVOLO, (from the Latin *ovum*, an egg) a convex moulding, of which the lower extremity recedes from a perpendicular or vertical line drawn from the upper. *See* MOULDINGS.

OUNCE, a small weight, the sixteenth part of a pound avoirdupois, and the twelfth part of a pound Troy.

OUTER DOORS, those which are common to both the exterior and interior sides of a building, made to prevent entrance at the pleasure of the occupier.

OUTFALL, or OUTLET, the exit or termination of a drain, &c., where it discharges its contents.

OUTLINE, the contour or boundary of an object.

OUT OF WINDING, a term used by artificers to signify that the surface of a body is that of a plane; or, when two straight edges are in the same plane, they are said to be out of winding.

OUT-TO-OUT, an expression used when a dimension is taken to the utmost bounds of a body or figure.

OUTWARD ANGLE, the same as salient angle.

OXYGON, (Greek, οξος, *sharp*, and γωνία, *an angle*), an acute-angled triangle.

P.

PACE, two and a half feet. The geometrical pace is five feet, and 60,000 such paces make one degree of the equator.

PACE, a raised platform, such as the dais at the upper end of the old halls, &c.

PADDLE, (from the Welsh, *pattal*) a small sluice, similar to those by which locks are filled or emptied.

PADDLE HOLES, the crooked arches through which the water passes from the upper pond of a canal into the lock, to fill it; or through which it is let out into the lower pond, on the entrance and exit of vessels. They are sometimes called CLOUGH ARCHES.

PADDLE WEIRS. *See* LOCK WEIRS.

PADDOCK, or PADDOCK COURSE (from the Saxon *pado*, or Dutch *padde*) a piece of ground generally taken out of a park, ordinarily a mile long, and a quarter of a mile broad, encompassed with pales or a wall, for the exhibiting of races with greyhounds, for wagers, plates, or the like.

At one end of the paddock was a little house, where the dogs were to be entered, and whence they were slipped; near which were pens to enclose two or three deer for the sport.

The deer, when turned loose, ran along by the pale; and the spectators were placed on the other side.

Along the course were several posts; viz., the lawpost, 160 yards from the dog-house and pens; the-quarter-of-a-mile post; half-mile post; and pinching post; beside the ditch, a place made to receive the deer, and preserve them from farther pursuit. Near the ditch were the judges, or triers.

PÆSTUM, a town of Italy, about sixty miles distant from Naples, remarkable for the remains of a large and very beautiful temple, dedicated to Neptune, and of the Doric order. Remains of other temples, an amphitheatre and the city wall, are also to be seen here.

PAGOD, or PAGODA, a name probably Indian, which the Portuguese have given to all the temples of the Indians, and all the idolaters of the East.

These pagods, or pagodas, are mostly square; they are stone buildings, which are not very lofty, and are crowned with a cupola. Within they are very dark; for they have no windows, and only receive their light through the entrance. The image of the idol stands in the deepest and darkest recess of the temple; it is of a monstrous shape, and of uncouth dimensions, having many arms and hands. Some of these idols have eight, and others sixteen arms; with a human body, and the head of a dog, with drawn bows and instruments of war in their hands. Some of them are black, others of a yellowish hue. In some pagodas there are no images, but only a single black polished stone, lying upon a round altar, covered with flowers and sandal-wood, which were strewed upon it. Greater veneration is manifested for these stones than for the idols themselves. Their worship of these divinities consists in throwing themselves upon the ground, and making their salam, or salutation, with their hands, and ejaculating their prayers in silence, in that posture. The offerings which they are accustomed to present to their gods, consist of flowers, rice, pieces of silk and cotton, and sometimes gold and silver. Everything is laid before the idols, and is taken care of by the Bramins, who profit the most by it. They guard the pagodas both by day and night. The pagodas of China are lofty towers, which sometimes rise to the height of nine stories, of more than 20 feet each. *See* CHINESE ARCHITECTURE.

In order to give such an idea of these buildings as may enable the reader to judge with respect to the early state of the arts in India, we shall briefly describe two, of which we have the most accurate accounts. The entry to the pagoda of Chillambrum, near Porto Novo, on the Coromandel coast, held in high veneration on account of its antiquity, is by a stately gate under a pyramid, 122 feet in height, built with large stones above forty feet long, and more than five feet square, and all covered with plates of copper, adorned with an immense variety of figures, neatly executed. The whole structure extends 1332 feet in one direction, and 936 in another. Some of the ornamental parts are finished with an elegance entitled to the admiration of the most ingenious artists. The pagoda of Seringham, superior in sanctity to that of Chillambrum, surpasses it as much in grandeur; and, fortunately, we can convey a more perfect idea of it by adopting the words of an elegant and accurate historian. This pagoda is situated about a mile from the western extremity of the island of Seringham, formed by the division of the great river Caveri, into two channels. "It is composed of seven square enclosures, one within the other, the walls of which are 25 feet high, and four thick. The enclosures are 350 feet distant from one another, and each has four large gates with a high tower; which are placed one in the middle of each side of the enclosure, and opposite to the four cardinal points. The outward wall is near four miles in circumference, and its gateway to the south is ornamented with pillars, several of which are single stones 33 feet long, and nearly five in diameter: and those wh form the roof are still larger; in the inmost inclosures are the chapels. About half a mile to the east of Seringham, and nearer to the Caveri than the Coleroon, is another large pagoda, called Jembikisma; but this has only one inclosure. The extreme veneration in which Seringham is held, arises from a belief that it contains that identical image of the god Wistchnu, which used to be worshipped by the god Brahma. Pilgrims from all parts of the Peninsula come here to obtain absolution, and none come without an offering of money; and a large part of the revenue of the island is allotted for the maintenance of the Brahmins who inhabit the pagoda; and these, with their families, formerly composed a multitude not less than forty thousand souls maintained without labour, by the liberality of superstition. Here, as in all the other great pagodas of India, the Brahmins live in a subordination which knows no resistance, and slumber in a voluptuousness which knows no wants."

The pagodas of the Chinese and Siamese are exceedingly magnificent. *See* Indian Architecture.

PAINTERS, *House*. Painter's work is measured by the square yard in the same manner as wainscoting, the mouldings being measured by a thread. The sashes of windows are paid for by the piece; and it is usual to allow double measure for carved mouldings, &c.

PAINTING, the art of imitating the appearances of natural objects, by means of artificial colours spread over a surface; the colouring substances being used either dry, as in crayon painting; or compounded with some fluid vehicle, as oil, water, or solutions of different gums and resins in oil or spirits, &c.

The theory and practice of this ingenious art are divided by its professors into five principal parts; viz., *invention*, or the power of conceiving the materials proper to be introduced into a picture; *composition*, that of arranging those materials; *design*, that of delineating them; *chiaro-scuro*, or the arrangement and management of the lights and shades, and of light and dark colours; and *colouring*, whose name sufficiently designates its end.

Painting, *Economical*, that application of artificial colours, compounded either with oils or water, which is employed in preserving or embellishing houses, ships, furniture, &c. &c. The term economical, applies more immediately to the power which oil and varnishes possess, of preventing the action of the atmosphere upon wood, iron, and stucco, by interposing an artificial surface; but it is here intended to use the term more generally; in allusion to the decorative part, as applied to buildings; as well as to its more essential ones; and as it is employed by the architect, throughout every part of his work, both externally and internally.

In every branch of painting in oil, as applicable either to churches, theatres, houses, or any other public or private buildings, or edifices, the general process will be found very similar; or with such variations, as will easily be suggested by the judicious artist or workman.

The first coatings, or layers, if on wood or iron, ought always to be of ceruse or white lead, the very best that can be obtained; which should have been previously ground very fine in nut or linseed oil, either over a stove with a muller, or, as that mode is too tedious for large quantities, it may be passed through a mill. If used on wood, as shutters, doors, or wainscoting made of fir or deal, it is highly requisite to destroy the effects of the knots; which are generally so completely saturated with turpentine, as to render it, perhaps, one of the most difficult processes in the business to conquer. The best mode in common cases, is to pass over the knots with ceruse ground in water; bound by a size made of parchment, or some other animal substance. When that is dry, paint the knots with white lead ground in oil, to which add some powerful siccative, or dryer; as red lead, or litharge of lead, about one-fourth part of the latter. These preparations should be done carefully, and laid very smoothly with the grain of the wood. When the last coat is dry, which will be in twelve or twenty-four hours, then smooth it with pumice-stone, or give the work the first coat of paint, prepared, or diluted with nut or linseed oil. When that is dry, all the nail-holes or other irregularities on the surface should be carefully stopped with a composition of oil and Spanish white, a whiting commonly known by the name of putty: but which is frequently made and sold in the shops of very inferior articles. When that is done, let the work be painted over again, with the same mixture of white lead and oil, somewhat diluted with the essence of oil of turpentine, which process should be repeated not less than three or four times, if the work is intended to be left, when finished, of a plain white or stone colour; if of the latter, the last coat should have a small quantity of ivory or lamp-black added to reduce its whiteness a little; and this is also of service in preserving the colour from changing: a circumstance which the oil is apt to produce. But if the work is to be finished of any other colour, either gray, green, &c., it will be requisite to provide for such colour, after the third operation, particularly if it is to be finished flat, or as the painters style it, dead white, gray, fawn, &c. In order to finish the work flatted or dead, (which is a mode much to be preferred for all superior works; not only for its appearance, but also for preserving the colour and purity of the tint) after the work, supposing it to be wood, has been painted four times in oil-colour, as directed in general cases, one coat of the flatted colour, or colour mixed up with a considerable quantity of turpentine, will be found sufficient; although in large surfaces it will frequently be requisite to give two coats of the flatting colour to make it quite complete. Indeed, on stucco it will be almost a general rule; but as that will be hereafter treated on, we shall at present say no more concerning it.

It must be observed, that in all the foregoing operations, it will be requisite to add some sort of siccative. A very general and useful one is made by grinding in linseed, or, perhaps, prepared oils, boiled, are better, about two parts of the best white copperas, which must be well dried, with one part of litharge of lead; the quantity to be added will much depend on the dryness or humidity of the atmosphere at the time of painting, as well as the local situation of the building.

It is highly proper here to observe, that there is a kind of copperas made in England, and said to be used for some purposes in medicine, that not only does not assist the operation of drying-in the colours, but absolutely prevents those colours drying, which would otherwise have done so by themselves. The best dryer for all fine whites, and other delicate tints, is saccharum saturni, or sugar of lead, ground in nut-oil; but which being very active, a small quantity, about the size of a walnut, will be sufficient for twenty pounds of colour, where the basis is ceruse. It will be always worthy to be observed, that the greatest care should be taken to keep all the utensils, brushes, &c., particularly clean, or the colours will soon become very foul, so as to destroy the surface of the work. If this should so happen, the colour should be passed through a fine sieve, or canvass; and the surface of the work be carefully rubbed down with sand-paper, or pumice-stone; and the latter should be prepared by being ground in water, if the paint be tender, or recently laid on.

The above may suffice as to painting on wood, either on outside or inside works; the former being seldom finished otherwise than in oil, four or five coats are generally quite sufficient.

We shall now proceed to note what is requisite for the painting of new walls, or stucco, not painted before and prepared for oil-colours.

It does not appear that any painting in oil can be done to any good or serviceable effect in stucco, unless not merely the surface appear dry, but that the walls have been erected a sufficient time to permit the mass of brick-work to have acquired a sufficient degree of dryness: when stucco is on battened work, it may be painted over much sooner than when prepared as brick. Indeed, the greatest part of the mystery of painting stucco, so as to stand or wear well, certainly consists in attending to these observations; for whoever has observed the expansive power of water, not only in congelation, but also in evaporation, must be well aware that when it meets with any foreign body obstructing its escape, as oil-paintings for instance, it immediately resists it; forming a number of vesicles, or particles, containing an acrid lime-water, which forces off the layers of plaster, and frequently causes large defective patches extremely difficult to get the better of.

Perhaps, in general cases, where persons are building on their own estates, or for themselves, two or three years are not too long to suffer the stucco to remain unpainted; though frequently, in speculative works, as many weeks are scarcely allowed. Indeed, there are some nostrums set forth in favour of which it is stated, in spite of all the natural properties of bodies, that stucco may, after having been washed over with these liquids, be painted immediately with oil-colours. It is true there may be instances, and in many experiments some will be found, that appear to counteract the general laws of nature; but, on following them up to their causes it will be found otherwise.

Supposing the foregoing precautions to have been attended to, there can be no better mode adopted for priming or laying on the first coat on stucco, than by linseed or nut-oil, boiled with dyers, as before mentioned, with a proper brush; taking care, in all cases, not to lay on too much, so as to render the surface rough and irregular, and not more than the stucco will absorb. It should then be covered with three or four coats of ceruse, or white lead, prepared as described for painting on wainscoting; letting each coat have sufficient time to dry hard. If time will permit, two or three days between each layer will not be too long.

If the stucco be intended to be finished of any given tint, as gray, light green, apricot, &c., it will then be proper, about the third coat of painting, to prepare the ground for such tint by a slight advance towards it.

Gray is made with ceruse, Prussian blue, ivory black, and lake; sage green, pea, and sea greens, with white, Prussian blue, and fine yellows; apricot and peach, with lake, white, and Chinese vermilion; fine yellow fawn colour, with burnt terra Sienna, or umber, and white; olive greens, with fine Prussian blue and Oxfordshire ochre.

Painting in distemper, or water-colours mixed with size, stucco, or plaster, which is intended to be painted in oil when finished, but not being sufficiently dry to receive the oil, may have a coating in water-colours, of any given tint required, in order to give a more finished appearance to that part of the building. *See* DISTEMPER FRESCO.

Straw colours may be made with French white, ceruse, and masticot, or Dutch pink. Grays, fine, with some whites, and refiners' verditer. An inferior gray may be made with blue-black, or bone-black, and indigo. Pea-greens, with French green, Olympian green, &c. Fawn colour with burnt terra de Sienna, or burnt umber and white: and so of any intermediate tint. The colours should all be ground very fine, and incorporated with white, and a size made of parchment, or some similar substance; isinglass being too expensive for common works.

It will not require less than two coats of any of the foregoing colours in order to cover the plaster, and bear out with a uniform appearance. It must be recollected, that when the stucco is sufficiently dry, and it is desirable to have it painted in oil, the whole of the water-colour ought to be removed; which may be easily done by washing; and when quite dry, proceed with it after the directions given in oil-painting of stucco.

When old plastering has become discoloured by stains, and it is desired to have it painted in distemper; it is then advisable to give the old plaster, when properly cleaned off and prepared, one coat at least of white lead ground in oil, and used with spirits of turpentine, which will generally fix all old stains; and when quite dry, will take the water-colours very kindly.

The above processes will also apply to old wainscoting, in cases where temporary painting is only required; but cannot be recommended for durability.

PADDLE WEIRS, see LOCK WEIRS.

PALACE, (from the Latin *palatium*), a word implying, in its stricter sense, a royal abode, but occasionally applied t the residences of other persons; the accompanying epithe indicating the quality of the inhabitants, as imperial palace ducal palace, &c. In Italy the term Palazzo, taken by itself is used for any large mansion or nobleman's house; an palaces of this class constitute, after churches, the principa architectural features of Genoa, Florence, Rome, Milan Vicenza, Venice, and other cities, to which they impart a air of grandeur which is wanting in the street architectur of this country; for in spite of all other defects, and the ba taste they frequently display, they generally possess th redeeming quality of dignity. Our own metropolis, on th contrary, possesses scarcely half a dozen private mansion that have any pretensions to external nobleness of style. I fact, the most palazzo-like buildings we have are our moder club-houses. Neither are any of our royal palaces, with th single exception of Windsor, stamped with architectur magnificence; both in extent and style they are surpassed b several of the country seats of our nobility. Througho the whole of Europe very few royal palaces, whatever may b their magnitude, are at all distinguished by superior arch tectural taste. In the French capital it is only the easte façade of the Louvre, the river-front, and the inner-cou which can lay claim to beauty or richness, the Tuileri being only a mass of quaint grotesqueness. The Vatican Rome is merely a huge irregular pile; and Versailles and t Escurial, notwithstanding the millions they cost, are both mon ments of exceedingly bad taste. Though far from beautif the royal palace at Madrid, begun in 1737, from the desig of Giambattista Sachetti, an Italian architect, is a stately a regular pile, it being 470 feet square, and 100 in height, b the effect such a mass would otherwise produce is grea impaired by the number of mezzanines. The same rema applies to the celebrated palace erected by the king of Napl about the middle of the last century, at Caserta, and of wh Vanvitelli was the architect. This building is certai characterized by magnitude, for it extends 731 feet from e to west, and 569 from north to south; yet of either grand of conception, or majesty of style, there is very little, c tainly not enough, to reconcile us to the prodigal execution so very indifferent a design. The royal palace at Stockh is a stately edifice in the Italian style, although the origi design, by Count Tessin, was considerably curtailed.

original imperial winter palace at St. Petersburgh was a vast pile erected by the Italian architect Rastrelli, in the reign of the empress Elizabeth, of most imposing aspect towards the quay of the Neva, but exceedingly heavy and grotesque as to style.

Enormous as have been the sums expended upon many of these edifices, every one of them falls very short of the ideal of a royal palace, in which, if anywhere, not only all the luxury and pomp of architecture, but a certain colossal dignity of aspect, should present itself. This can never be accomplished where stories above stories are allowed to display themselves externally. That is but a vulgar species of architectural grandeur which is produced by a numerical multiplication of little parts and features. All the rooms required for the accomodation of an extensive household should be turned towards inner courts, and the whole exterior, having only a single range of lofty windows above the ground-floor, should be left for the unrestrained display of architecture, and sculpture upon a noble scale, without any intermixture of littlenesses. By such a disposition, too, convenience would perhaps be found far better consulted than at present, because, while all the apartments for official and state receptions and court entertainments could be connected together, the whole of the vast number of subordinate rooms required in such a habitation would be concentrated within the general plan, and at the same time might be kept entirely apart, by means of galleries between the outer and inner range, communicating at intervals with lesser vestibules and staircases attached to the suites of lesser rooms and private apartments of every description.

PALÆSTRA, or Palestra, (from the Greek παλαιςρα) among the ancient Greeks, a public building, where the youth exercised themselves in wrestling, running, playing at quoits, &c.

Some say the palestræ consisted of a college and an academy; the one for exercises of the mind, the other for those of the body. But most authors rather take the palestra to be a xystus, or mere academy for bodily exercises, according to the etymology of the word, which comes from παλη, *wrestling*, one of the chief exercises among the ancients.

The length of the palæstra was marked out by stadia, each equal to 125 geometrical paces; and hence the name *studium* was given to the arena whereon they ran.

PALATINE BRIDGE, a bridge of ancient Rome, now called St. Mary's bridge, which crosses over from the present church of St. Mary the Egyptian, at the lower end of the Forum Boarium to the Via Transtiberina. This bridge is supposed to be that which Livy speaks of (*Decad.* 4. lib. 10.) built by M. Fulvius, washed down by the Tiber, and afterwards rebuilt by the censors Scipio Africanus and L. Mummius. Another indundation having damaged it, Pope Gregory XIII. repaired it, partly upon the old piles, in the year 1575. But another inundation sweeping away some of it in 1598, it has never since been repaired, so as to be serviceable.

PALE, (from the Latin *palus*) a little pointed stake, or piece of wood, used in making enclosures, separations, &c.

PALES, or Piles, in carpentry, rows of stakes driven deep in the ground to make wooden bridges over rivers, and to erect other edifices on.

Du-Cange derives the word from the Latin name *palla, a hanging* or *piece of tapestry*: the ancients gave the name *pales* to the hangings or linings of walls: thus a chamber was said to be *paled* with cloth of gold, with silk, &c., when covered with bands or stuffs of two colours. Hence also the original of the word pale, *a stake*, &c.

Tertullian observes, that the Romans planted pales to serve as boundaries of inheritances; and that they consecrated them to the god Terminus, under the name of *Pali Terminales.*

Ovid tells us, they were crowned and adorned with flowers, festoons, &c., and that the god was worshipped before these pales. *See* Terminalia.

Pales for building, serve to support the beams which are laid across them, from one row to another; and are strongly bound together with cross pieces. *See* Piles.

PALETTE (French) among painters, a little oval table, or piece of wood, or ivory, very thin and smooth; on and round which the painters place the several colours they have occasion for, to be ready for the pencil.

The middle serves to mix the colours on, and to make the teints required in the work. It has no handle, but a hole at one end, to put the thumb through to hold it.

PALING, in agriculture, a kind of fence-work for fruit-trees, &c., planted in exposed places.

It consists of three small posts driven into the ground, at a foot and half distance, with cross bars nailed to each other, near the top.

In fixing the pales in form of a triangle, room is to be left for the tree to play and bow by the high winds, without galling. The trees are to be bound to a stake for a year or two; after which fern or straw may be stuffed in between the tree and uppermost rails, to keep it upright.

If the place be open to deer, rabbits, or the like, a post is to be nailed to the bar between every two pales.

Paling Fence, that sort of fence which is constructed with pales.

PALISADE (French) or Palisado (Italian) in fortification, an enclosure of stakes or piles driven into the ground, each six or seven inches square, and nine or ten feet long: three of which are hid under ground. They are fixed about six inches asunder, and braced together by pieces nailed across them near the tops, and secured by thick posts at the distance of every four or five yards.

Palisades are placed in the covert-way, at three feet from, and parallel to, the parapet or ridge of the glacis, to secure it from being surprised. They are also used to fortify the avenues of open forts, gorges, half-moons, the bottoms of ditches, the parapets or covered ways; and, in general, all posts liable to surprise, and to which the access is easy.

Palisades are usually planted perpendicularly; though some make an angle inclining towards the ground next the enemy, that the ropes cast over them, to tear them up, may slip.

Palisades, *Turning*, are an invention of M. Coehorn, in order to preserve the palisades of the parapet of the covert-way from the besiegers' shot.

These palisades are so arranged that as many of them as stand in the length of a rod, or in about ten feet, turn up and down like traps; so as not to be in sight of the enemy till they just bring on their attack; and yet are always ready to do the proper service of palisades.

PALLADIAN ARCHITECTURE. A style of Italian Architecture introduced by Palladio, for an account of which see Italian Architecture, and the following article.

PALLADIO, ANDREA, in biography, a celebrated Italian architect, born at Vicenza in 1518. He obtained instructions from the poet Trissino, who discovering in him a genius for sculpture and the arts connected with it, taught him the elements of the mathematics, and explained to him the works of Vitruvius. He soon obtained distinction as an architect, and having an opportunity of accompanying his patron to Rome, he employed all his faculties in examining the remains of ancient edifices in that capital, and formed his taste upon them. On his return, many works of importance were committed to him, which he managed with great skill, and obtained for himself a high reputation. He was now sent for to Venice, where he built the palace Foscari in the style of pure antiquity. Several other Italian cities were afterwards decorated with magnificent edifices, public and private, of his construction, and he was invited to the court of Emanuel Philibert, Duke of Savoy, who received him with distinguished honours. To Palladio is chiefly attributed the classic taste which reigns in so many of the buildings of Italy. His master-piece is reckoned the Olympic theatre at Vicenza, in imitation of that of Marcellus at Rome. He died in that city in 1580, having greatly improved the art, not only by his edifices, but by his writings, which are standard performances. Of these the following account is given: his *Treatise on Architecture*, in four books, was first published at Venice in 1570, folio, and has several times been reprinted. A magnificent edition, in three volumes, folio, was published at London in 1715, in Italian, French, and English. Another, equally splendid, has since been published at Venice, in four volumes, folio, with the addition of his inedited buildings. Lord Burlington published in London, in 1730, a volume entitled, *Idisegni delle Terme Antiche di Andrea Palladio*. He composed a small work, intitled *Le Antichità di Roma*, not printed till after his death. He illustrated Cæsar's *Commentaries*, by annexing to Badelli's translation of that work, a preface on the military system of the Romans, with copper-plates, designed, for the most part, by his two sons, Leonida and Orazio, who both died soon after. Palladio was modest in regard to his own merit, but he was a friend to all men of talents; his memory is highly honoured by the votaries of the fine arts; and the simplicity and purity of his taste have given him the appellation of the Raphaël of architects.

PALLADIUM (from the Greek Παλλας, *the goddess of war*) in antiquity, a statue of the goddess Pallas, or Minerva, three cubits high, holding a pike in the right hand, and a distaff and spindle in the left, preserved in Troy, in the temple of Minerva, on which the fate of that city is said to have depended.

The tradition is, that in building a citadel, in honour of Pallas, and a temple in the most elevated part of it, the palladium dropped from heaven, and marked out the place which the goddess was pleased to possess. After this, Apollo gave an oracle, importing that Troy should never be taken while the palladium was found within its walls: which occasioned Diomedes and Ulysses, during the Trojan war, to undertake the stealing of it. For this purpose having entered the citadel by night, or by means of secret intelligence, they stole away this valuable pledge of the security of the Trojans, and conveyed it into their camp; where they had scarcely arrived, when the goddess gave testimonies of her wrath

It is said, there was, anciently, a statue of Pallas preserved at Rome, in the temple of Vesta; which some pretended to be the true palladium of Troy, brought into Italy by Æneas: it was kept among the sacred things of the temple, and only known to the priests and vestals. This statue was esteemed the destiny of Rome; and there were several others made perfectly like it, to secure it from being stolen. There was also a palladium in the citadel of Athens, placed there by Nicias.

PALLIER, or Paillier (French) in building, a landing-place in a stair-case, which being broader than the rest of the stairs, serves to rest upon. The term, which is pure French, is not much used by English builders. On large staircases, where there are sometimes several pillars in a range or line, the palliers ought each to have, at least, the width of two steps. Vitruvius calls the palliers on landing-places of the theatres *diazomata*.

PALLIFICATION, or Piling, in architecture, the act of piling the ground-work, or strengthening it with piles, or timber driven into the ground; this plan is adopted upon moist or marshy soils, where an edifice is intended to be erected.

PALM, a measure of length among the Italians, but varying in value in different localities. The palm of Genoa measures nine inches, nine lines, that of Naples eight inches seven lines, that of Palermo eight inches five lines, and the modern Roman palm eight inches three and a half lines.

PALMYRA, *Ruins of*, or Palmyrene Ruins, the ruins of a celebrated city of this name, situate in a desert of Syria, in the pachalic of Damascus, about 48 leagues from Aleppo, and as far from Damascus. This city, under the name of Tadmor, appears to have been originally built by Solomon (1 Kings, ix. 18. 2 Chron. viii. 4.) Josephus assures us, that this was the same city which the Greeks and Romans afterwards called Palmyra; and it is still called Tadmor by the Arabs of the country. But many circumstances besides the style of the buildings, render it probable that the present ruins are not those of the city built by Solomon, though neither history nor tradition mention the building of any other.

With respect to the ruins, they appear to be of two distinct periods; the oldest are so far decayed as not to admit of mensuration, and seem to have been reduced to that state by the hand of time; the others appear to have been broken into fragments by violence. Of the inscriptions, none are earlier than the birth of Christ, nor are any later than the destruction of the city by Aurelian, except one, which mentions Dioclesian. It is scarcely less difficult to account for the situation of this city than for its magnificence; the most probable conjecture is, that as soon as the springs of Palmyra were discovered by those who first traversed the desert in which it is situated, a settlement was made there for the purpose of carrying on the trade to India, and preserving an intercourse between the Mediterranean and the Red Sea. This trade, which flourished long before the Christian æra, accounts not only for its situation, but also for its wealth. As it lay between Egypt, Persia, and Greece, it was natural to expect, that traces of the manners and sciences of those nations should be discovered among the Palmyrenes; who accordingly appear to have imitated the Egyptians in their funeral rites, the Persians in their luxury, and the Greeks in their buildings; and therefore the buildings, which now lie in ruins, were probably neither the works of Solomon, nor of the Seleucidæ, nor, few excepted, by the Roman emperors, but of the Palmyrenes themselves.

Palmyra was formerly encompassed by palms and fig trees, and covered an area, according to the Arabs, of near ten miles in circumference; and might probably hav[e] been reduced to its present confined and ruined state b[y] quantities of sand, driven over it by whirlwinds. Th[e] walls of the city are flanked with square towers; and it i[s] probable, from their general direction, that they include the great temple, and are three miles in circumference. Bu[t] of all the monuments of art and magnificence in this cit[y] the most considerable is the temple of the sun. The who[le] space containing its ruins, is a square of 220 yards, encon[-] passed with a stately wall, and adorned with pilasters with[in] and without, to the number of sixty-two on a side. With[in] the court are the remains of two rows of very noble marb[le] pillars, 37 feet high; the temple was encompassed w[ith] another row of pillars 50 feet high ; but the temple itself was only 33 yards in length, and 13 or 14 in breadth. This is now converted into a mosque, and ornamented after the Turkish manner. North of this place is an obelisk, consisting of seven large stones, besides its capital and the wreathed work about it, about 50 feet high, and, just above the pedestal, 12 in circumference. Upon this there was, probably, a statue, which the Turks have destroyed. At a small distance there are two others, and a fragment of a third, which gives reason for concluding that they were once a continued row. There is also a piazza 40 feet broad, and more than half a mile in length, enclosed with two rows of marble pillars, 26 feet high, and 8 or 9 feet in compass ; and the number of these, it is computed, could not have been less than 560. Near this piazza appear the ruins of a stately building, supposed to have been a banqueting house, elegantly finished with the best sort of marble. In the west side of the piazza there are several apertures for gates into the court of the palace, each adorned with four porphyry pillars, 30 feet long and 9 in circumference. There are several other marble pillars differently arranged, on the pedestals of which there appear to have been inscriptions both in the Greek and Palmyrene languages, which are now altogether illegible. Among these ruins there are also many sepulchres, which are square towers, four or five stories high, and varying in size and splendour. We are indebted for an account of these very magnificent remains of antiquity, partly to some English merchants who visited them in 1678 and 1691, (*Phil. Trans.* No. 217, 218, or Lowthorp's *Abr.* vol. iii.) but chiefly to Mr. Bouverie and Mr. Dawkins, accompanied by Mr. R. Wood, who travelled thither in 1751. The result of their observation was published in 1753, in the form of an Atlas, containing 57 copper-plates, admirably executed. Since this publication, it is universally acknowledged that antiquity has left nothing, either in Greece or Italy, to be compared with the magnificence of the ruins of Palmyra.

PAMPRE, a wreath composed of the leaves and fruit of the vine, employed to decorate the spiral grooves of twisted columns.

PANCARPI, garlands or festoons of flowers, fruit, &c.

PANEL, or Pannel (from the Latin *panellum*, a small pane), in joinery, a tympan, or square piece of wainscot, sometimes carved, framed, or grooved in a large piece, between two mounters or upright pieces, and two traverses or cross pieces. Hence also panels or panes of glass, are compartments, or pieces of glass of various forms ; square, hexagonal, &c.

Panel, in masonry, one of the faces of a hewn stone.

PANNIER, the same as Corbel ; which see.

PANORAMA, a picture exhibiting a succession of objects upon a spherical or cylindrical surface, the rays of light being supposed to pass from all points of external objects, through the surface, to the eye in the centre of the sphere, or axis of the cylinder.

This ingenious pictorial contrivance was first devised by an English artist, Robert Barker, about the year 1794 ; and is not so much a new mode of painting—the process itself being similar to scene-painting, or in distemper—as a novel application of it. Contrary to the diorama [*See* Diorama], the panorama forms the surface of a hollow cylinder, or rotunda (whence it is frequently called, in German, *Rundgemalde*, or *Rundbild*, cyclorama), in the centre of which is a detached circular platform for the spectators, covered over head to conceal the skylight, and thereby increase the illusion, and give greater effect to the painting itself. This latter is not painted on the walls, but upon canvass, like the scenes of a theatre, and afterwards fixed up, in order that the views may be changed, and a fresh one may be in progress while another is open for exhibition. Yet, although there is nothing whatever particular in regard to the execution or process of such pictures, they are attended with difficulties which can be mastered only by practice and experience.

The first of these arises from the circumstance, that the artist cannot either concentrate his light, or adapt the direction of it arbitrarily, as best suits his purpose ; but while portions of his view will be entirely in sunshine, the opposite one will be almost a mass of shadow ; the second is the difficulty of representing, on a curved surface, the straight horizontal lines of buildings ; the third and greatest of all is, that there can be no single fixed point of sight, since the eye traverses around the whole circle of the horizon. Hence it may be supposed, that many parts of such a picture would appear, if not quite distorted, more or less out of perspective. Yet such is not the case, no doubt partly because the eye accommodates itself to certain principal points fixed upon by the artist as centres of vision, and on account of the optical fascination attending the whole. The subjects generally chosen are views of cities, or interesting sites, whose entire locality and buildings may thus be vividly placed before the eye in a manner no less instructive than it is interesting.

Panoramic Projection is the method of forming a panorama from the geometrical consideration of the properties of vision.

In the following principles of the panorama, the surface on which objects are supposed to be represented is that of a cylinder ; though a sphere may be considered still more perfect, as its surface is everywhere equally distant from the eye ; but a cylindric surface is more convenient for the purpose of delineation ; and if the objects are not very distant from the intersection of a plane passing through the eye perpendicular to the axis, the distortion will not be perceptible. We premise the following definitions :

1. The cylindric surface on which objects are to be represented, is called, also, *the panoramic surface ;* and the picture formed is called *a panoramic view*, or *panoramic picture*.

2. *The point of sight* is the place where the organ of vision is placed, in order to receive the impression of the images of the objects on the panoramic picture.

3. *An original object* is any object in nature, or an object which may be supposed to exist, in a given position and distance, as a point, line, or solid.

4. *An original plane* is the plane on which original objects are supposed to be placed.

5. The point, where an indefinite original line cuts the picture, is called *the intersection of that original line.*

6. The line on the picture where an original plane meets or intersects it, is called *the intersection of that original plane.*

7. A line drawn through the point of sight parallel to an original line, is called *the parallel of that original line.*

8. A plane passing through the point of sight parallel to any original plane, is called *the parallel plane.*

9. A *surface of rays* is that which proceeds from an original line, or from any line of the original object, by rays from all points of that line terminating in the eye. If the line in the original object be straight, the surface of rays is called *a plane of rays*, *optic plane*, or *visual plane.*

10. When the rays proceed from one or more surfaces of an original object, the whole is called *a pyramid of rays*, or *optic pyramid ;* and if the base be circular, it is called *a cone of rays*, *visual cone*, or *optic cone.*

In every kind of projection from a given point, the projection of a straight line upon any surface is the intersection of a plane of rays with the surface from all points of the straight line to the given point. Therefore, the panoramic projection of a straight line is the intersection of the cylindric surface and a plane. If a right cylinder be cut by a plane perpendicular to its axis, the section is a circle; if cut parallel to the axis, the section is a rectangle; and if cut obliquely to the axis, the section is an ellipsis. If the surface of the cylinder be extended upon a plane with the sections of the cylindric surface, and a plane cut in each of the positions here stated, the section made by the plane perpendicular to the axis will be a straight line; and the section made by cutting it parallel to the axis will also be a straight line; but the section made by cutting it obliquely will be a curve of similar properties with that known to mathematicians by the name of *the figure of the lines;* therefore, the projection of every straight line in a plane passing through the eye perpendicular to the axis of the cylinder, will also be a straight line on the extended surface; and every straight line in a plane passing through the axis will also be a straight line on the extended surface, perpendicular to that formed by the plane passing through the eye perpendicular to the axis.

The panoramic projection of any straight line not in a plane passing through the eye perpendicular to the axis, nor in a plane passing through the axis, is in the curve of an ellipsis; for in this case the optic rays which cut the cylinder will neither be in a plane parallel to the axis, nor in a plane perpendicular to it.

The panoramic representation of any straight line in a plane perpendicular to the axis, but not passing through the eye, is in the curve of an ellipsis, and the optic plane will be at right angles to another plane passing through the axis at right angles to the original line.

In the panoramic representation of any series of parallel lines, the optic planes have a common intersection in a straight line passing through the eye, and the common intersection will be parallel to each of the original straight lines; therefore, the indefinite representations will pass through the extremities of the common intersection.

In the panoramic representation of any series of parallel lines in a plane perpendicular to the axis, but not passing through the eye, the common intersection of the optic planes is parallel to the plane on which the original lines are situated.

In the indefinite representations of any number of straight lines parallel to the axis, the visual planes will have a common intersection in the axis, and will divide the circumference of the cylinder into portions which have the same ratio to each other as the inclination of the visual planes.

If an original straight line parallel to the axis be divided into portions, the representations of the portions will have the same ratio to each other as the originals.

If in any original plane there be a series of straight lines parallel to each other, and also another series of straight lines parallel to each other, and at any given angle with the former series, the common intersections of the visual planes will make the same angle with each other, which any line of the one series makes with any one of the other series, and the common intersections will be in a plane parallel to the original plane; and, therefore, if the original plane be perpendicular to the axis, the common intersections of the visual planes will also be in a plane perpendicular to the axis. Hence the common intersections of visual planes from any two systems of straight lines, parallel to any two straight lines at a given angle with each other in a plane perpendicular to the axis, are also in a plane perpendicular to the axis, and make the same angle with each other which the two lines in the original plane make with each other.

11. The two points where the parallel of an original line inclined to the axis of the cylinder meets the panoramic surface, are called *the vanishing points of that original line.*

12. The intersection of the parallel of an original plane is called *the vanishing line of that plane.*

13. A straight line drawn from any point in the axis of the cylinder, at right angles to the same, to meet the panoramic surface, is called *the distance of the picture.*

14. *The centre of a plane parallel to the axis*, is the point where a straight line from the eye perpendicular to the plane meets it.

15. *The panoramic centre of a plane parallel to the axis*, is the point where a straight line drawn from the eye perpendicular to the plane, cuts the picture.

16. *The station point*, is the point where the axis intersects the original plane.

17. *The centre of an original line*, is the point where a straight line, drawn from the station point perpendicular to the original line, cuts the original line.

18. *The panoramic centre of an original line*, is the point where a straight line, drawn from the station point perpendicular to the original line, cuts the picture.

19. *The distance of an original plane parallel to the axis from the picture*, is the straight line drawn from the panoramic centre to the centre of the original plane.

20. *The distance of an original line from the picture*, is the straight line drawn from the panoramic centre to the centre of the original line.

21. *The distance of an original plane*, is the straight line drawn from the eye to the centre of the original plane.

22. *The distance of an original line*, is the straight line drawn from the station point to the centre of the line.

An original line parallel to the axis of the panorama ha[s] no vanishing points.

An original plane parallel to the axis of the panorama ha[s] two vanishing lines.

The vanishing line of a plane perpendicular to the axis o[f] the panorama, is a circle on the panoramic picture; but i[f] the panoramic surface be extended upon a plane, it becom[es] a straight line.

The vanishing lines of all planes inclined to the axis a[re] ellipses, and when extended upon a plane become sinic curves, which are also termed *panoramic curves*, as being t[he] only kind of curve which the cylindric picture produces wh[en] developed.

Problem I.—*Plate* I.—*Figure* 1.—*To describe the pan[o]ramic curve to given dimensions.*—Let A B be the length [of] the curve; bisect A D in C, draw C D perpendicular to A [B]; make C D equal to the deflection of the arc from the cho[rd] A B; from the point C, with the distance C D, describe t[he] quadrant D E; divide the arc D E into any number of eq[ual] parts, (say four) also divide either half, C B, into the sa[me] number (four) of equal parts; let *l*, *i*, *g*, be the points [of] division in the quadrantal arc; draw *l k*, *i h*, *g f*, perpen[di]cular to A B, cutting it at *k*, *h*, *f;* and let K, H, F, be the poi[nts] of division in C B; draw K L, H I, F G, perpendicular to A [B]; make K L, H I, F G, respectively equal to *k l*, *h i*, *f g;* c[on]struct perpendiculars upon C A, in the same manner; thro[ugh] all the points G, I, L, D, describe a curve, which will be t[he] ... of the panorama.

The curve A D B is that which would be found by cutt[ing] a semi-cylinder, whose circumference is A B, at an altit[ude] C D, distant on the surface from a plane perpendicular to [the] axis, at a quadrant distance from the point A or B in [the] extremity of the diameter of the plane perpendicular to [the] axis. Therefore the whole panoramic curve will be do[uble] the length of A B; the other part being a similar and e[qual]

Invented by P. Nicholson. Engraved by J. C

curve above the line A B, produced, and consequently a curve of contrary flexure.

The panoramic curve takes place when the cylinder is cut by a plane at oblique angles to the axis.

PROBLEM II.—*To find the indefinite representation of lines parallel to the original plane, in a plane parallel to the axis of the picture; given the height of the eye, the intersection of the original plane, and the distance of the original plane from the picture.*

Figure 2, No. 1.—Let P be the station point; G K H I the intersection of the picture; and A B a line in the original plane, on which the plane parallel to the axis stands.

In *Figure* 2, No. 5, draw P K, which make equal to P K, No. 1. In No. 5, draw P O and K w perpendicular to P K; make P O equal to the height of the eye; draw O w parallel to P K; produce P K to r; in No. 1, draw P r perpendicular to A B, cutting A B at r, and the intersection of the original plane with the panoramic surface at K; make P r, No. 5, equal to P r, No. 1: draw r s perpendicular to K P: in No. 5, make r t, t u, u v, equal to the height of the several lines, whose indefinite representations are required, above the original plane; produce O w, meeting r s at s; produce K z to meet O s at w; draw O r, O t, O u, and O v, cutting K w respectively at v, x, y, and z. In No. 2, make G H equal to the semi-circumference G K H, No. 1; bisect G H at w; draw w v perpendicular to G H; make w v, w x, w y, and w z, respectively equal to w v, w x, w y, and w z, No. 5; then with the common length G H, and the deflections w v, w x, w y, and w z, describe the curves G v H, G x H, G y H, G z H, which will be the development of the representation of the lines required, and G and H will be their vanishing points. For O P r s, No. 5, may be considered as a plane passing along the axis of the cylinder; O P the axis, O the eye, P the station point, K w a section of the cylindric surface, and O r, O t, O u, and O v, visual rays; and, consequently, the points v, x, y, z, will be the representations of r, t, u, v; and since r, t, u, v, may be considered as the centres of the original lines, whose representations are required, and since the optic planes of these lines cut the cylinder obliquely, the sections will be elliptical, and, consequently, their envelope will be the figure of the sines, as here described.

PROBLEM III.—*To describe the representation of a line in a plane perpendicular to the axis of the cylinder, giving the seat of the line on the original plane.*

In No. 2, draw G d perpendicular to G H; make G d equal to the descent or deflection of the curve, and describe the quadrantal sinical curve d w, and d w will be the representation of a line perpendicular to the plane, in which the originals of G v H, G x H, G y H, and G z H, are situated.

PROBLEM IV.—*Given the indefinite representation*, G z H, No. 2, *of a straight line, to determine the finite portion, whose seat is* A B, No. 1.

Draw P A and P B, No. 1, cutting the intersection at a and b; make w a, No. 2, equal to the extension of K a, No. 1; and w b, No. 2, equal to the extension of K b, No. 1; draw a a^{I} and b b^{I}, No, 2, perpendicular to G H, cutting the curve G z H at a^{I} and b^{I}, and a^{I} z b^{I} will be the finite portion required; a^{II} y b^{II}, a^{III} x b^{III}, and a^{IV} v b^{IV}, will be the same portions of the indefinite representations G y H, G x H, and G v H.

The following examples show the application of the principles in the representation of solid objects.

Example 1. *Figure* 2, No. 1.—Let C D E F, be the plan of a house, in contact with the picture at C. Through the station point P, draw G H, parallel to D C, cutting the intersection of the panoramic picture in the points G and H; also through P draw K I, parallel to E D, or F C, cutting the picture in I and K; then G and H are the vanishing points of all lines parallel to E F or D C, and I and K the vanishing points of all lines parallel to C F or D E; draw F P and D P, cutting the picture at f and d. Let W V be the ridge of the building, bisecting E D at W, and E C at V; produce W V to Y, cutting I K at U; make U Y equal to the height of the house, Nos. 3 and 4; and make the angle U Y Z equal to half the vertical angle of the roof, and let Y Z cut I K at Z; draw X Q parallel to Y Z, cutting K I, or K I produced at Q; draw Z x parallel to V W; produce E D to x, and F C to meet x Z at T; join Q x and Q T, which are the intersections of the optic planes formed by the inclined side of the roof, and the vertical planes standing upon D E and C F; draw I N parallel to P O, and O N parallel to I P. To find the inclination of the optic planes; draw P M perpendicular to x Q, cutting x Q at u, and the panoramic intersection at M; from P, with the distance P u, describe the arc u J, cutting P I at J; join O J; produce N I and O J to meet each other in S. In like manner, draw P t perpendicular to T Q, cutting T Q at v, and the panoramic intersection at t; from P, as a centre, with the radius P v, describe the arc v w, cutting I P at w; join O w; produce N I and O w to meet each other in R; then N O S is the inclination of the optic plane, whose intersection is Q x; and N O R is the inclination of the optic plane, whose intersection is Q T.

Figure 2, No. 6.—Upon any convenient line, I H, extend the panoramic intersection; according to the corresponding places of No. 1, as shown by similar letters; that is, I t, t G, G d', d C', C' f,' f' K, and K H, No. 6, would cover I t, t G, G d', d' C', C' f', f' K, and K H, No. 1. In No. 6, draw t R, O o, d' d, C' o, f' f, K k perpendicular to I H.

In No. 5, produce K P to a; make P a equal to the radius of the cylinder; through a draw i o parallel to O P; on P a make P j equal to P j, No. 1, and P q, No. 5, equal to P q, No. 1; draw j g and q h, No. 5, perpendicular to P a; make q h and j g each equal to the height of the walls, Nos. 3 and 4; join O g and O h; produce O g to l, and O h to i, meeting o i; produce O j and O q to meet G o at o and k.

In No. 6, make t R equal to N R, No. 1; G o equal to G o, No. 5; G l equal to G l; K k equal to G k; K i equal to G i; describe the panoramic curves I l K, I O K, G k H, G i H; then the curves I O K and G k H will cut each other at c, and the curves I l k, G i H, will cut each other at C, so that the points C', C, c, will be in the same perpendicular; C c will thus represent the angular line of the building. Let the perpendicular d' d cut the curve G i H at D, and the curve G k H at d; and the intercepted portion D d is the angular line at one end; in like manner, let the perpendicular f' f cut the curve I l k at F, and the curve I O K at f; and the intercepted portion F f of the perpendicular f' f, is the representation of the angular line at the other end; therefore c C D d represent the front, and c C F f the end, exclusive of the triangular part adjoining the roof, which will be formed in the following manner: make t x and x u equal to G K each; describe the same panoramic curve, R C x; and if the other semi-panoramic curve, x v w, is described, and if k K be produced to v, v will be the vanishing point for the gable top; and if K n be made equal to K, v, n will be the vanishing point of the other inclined plane of the roof; and thus the representation of lines and planes will have vanishing points and vanishing lines, as in the methods of describing the perspective representation of objects upon a plane surface; and if the points d, D, c, C, f, F, are found, and the lines c d, C D, and c f, C F, are made straight instead of being curved and produced, they will find their own vanishing points in the line I H; but more remote from each other than the points G and K.

What is here observed, is exemplified in No. 7, as will appear sufficiently clear by a little reflection.

The example here shown is very distorted, on account of the smallness of the panoramic cylinder, and the size of the object, which was obliged to be very large, in order to give a clear elucidation of the principles.

Example 2.—*Figure* 3, shows the panoramic representation of a row of houses, upon the surface of a cylinder of greater radius than that of *Figure* 2, No. 1, where the pictural objects appear much more agreeable to the eye than that of *Figure* 2; the lines which form the roofs are in this example represented as straight, though in reality they are curves, as a great deal of trouble is saved, and the error occasioned by their introduction is too trifling to be observed.

It remains to show the truth of the operations used in the construction of *Figure* 2. Let it now be proved that x Q and T Q are the intersections of the optic planes, formed by the inclined lines of the gables. From the definition given, an optic plane is one passing along an original line, and through the eye; therefore, if a straight line be drawn through the eye parallel to the original line, the line, thus passing through the eye, and the original line, will both be in the same plane, that is, both in the optic plane; and if two planes be drawn along two parallel lines, their intersections with a third plane will be parallel; now the parallels F T and K I are the intersections of two parallel planes; F T that of the vertical plane, in which the inclined original line is situated, and K I that in which the eye is situated, or in which the line parallel to the inclined line is situated; the point T is the intersection of the inclined line of the roof, and the point Q the intersection of the line drawn through the eye parallel to the inclined line of the roof; therefore the optic plane will pass through the points T and Q, and consequently T Q is the intersection of the optic plane and the original plane. In the same manner, it may be shown that x Q is the intersection of the optic plane, formed by the other inclined line of the farther gable in the same plane with the former line.

Next let it be shown that the angles N O S and N O R, No. 1, are the inclinations of the optic planes, whose intersections are x Q and T Q. The inclination of any two planes is measured by a third plane, perpendicular to their common intersection; now T Q is the intersection of the optic plane, and P v is perpendicular to T Q; and because P w is equal to P v, and P o perpendicular to P w, and equal to the height of the eye; conceive the plane of the triangle w P O to be raised perpendicular to the original plane, so that the base P w may coincide with P v; then O will represent the eye in its true place, and the point w will be upon v; and since the intersection T Q would be perpendicular to the plane of the triangle, every line drawn in the plane of the triangle from v, would be perpendicular to the intersection T Q, and consequently, the line drawn in this plane from v to O, would also be perpendicular to the intersection; therefore the angle P w O is the inclination of the plane, and, consequently, the alternate angle N O R. In the same manner, it may be shown, that N O S is the inclination of the plane whose intersection is x Q.

Now to show that N R is the deflection of the curve made by the optic plane, it only requires to be considered, that the transverse axis of the ellipsis made by the optic plane, is in the plane which measures the inclination of the optic plane to the original plane: for this purpose, P O N R may be considered as a semi-section of the cylinder along the axis, and N R a section upon the surface; therefore O R will represent half the greater axis, and N R the deflexion of the curve, or its descent below the vanishing line of the horizon. *Figure* 2, No. 5, is also to be considered as a section of the cylinder, of which O P represents the axis, G O and w K the sides: and because the appearance of all points in the same plane perpendicular to the axis, at equal distances from the station point, will be at the same height on the surface from the original plane, or from the plane passing through the eye parallel to the original plane, their heights will be found by setting their distances upon P a, then erecting lines perpendicular to P a, from each point of the section; then setting the heights of the points upon these lines, and drawing lines from O, through the top of each perpendicular till they cut G o; then the distance from G, to each point of section, gives the distance of each point from the plane passing through the eye upon the panoramic surface.

Now let the cylinder be conceived to be enveloped by No. 6, so that I H may fall upon the circumference of a circle in a plane perpendicular to the axis; then every line will fall in its true position, and the representative object will produce the same pyramid of rays as the original, the eye being supposed to be fixed at its true distance above the line I H; and, consequently, nothing more will be required to excite an idea of the existence of the object, than to give the representative surfaces their proper colours, light, and shade, according to the distance of the original. Hitherto straight lines have been represented by portions of the sinical curve when extended, or by portions of an ellipsis, when the sheet on which the objects are represented, is brought in contact with the surface of the cylinder, as they ought properly to be; but if the radius of the cylinder is of sufficient extension, and the objects to be represented of proper magnitude, any attempt to represent straight lines by curves from the hands of an artist would be absurd, except when the object to be represented is very near to the panoramic surface, in which case a curvature in the line may be sensible, also at a moderate distance: the curve can only be observed in a series of objects in a straight line; it will therefore be sufficient to represent the straight lines of each individual object by straight lines also, but to preserve the curve, or rather the polygonal figure inscribed in the sinical curve in the series, as the inflexions or angles will hardly be visible.

A straight line will therefore be represented by finding the representation of its extremities, and joining the representative points; but if it is of great extent, it may be obtained by finding a number of points, and joining every two adjoining points in succession by a straight line, and the whole will assume the form of a curve, which will be the representative of the straight line.

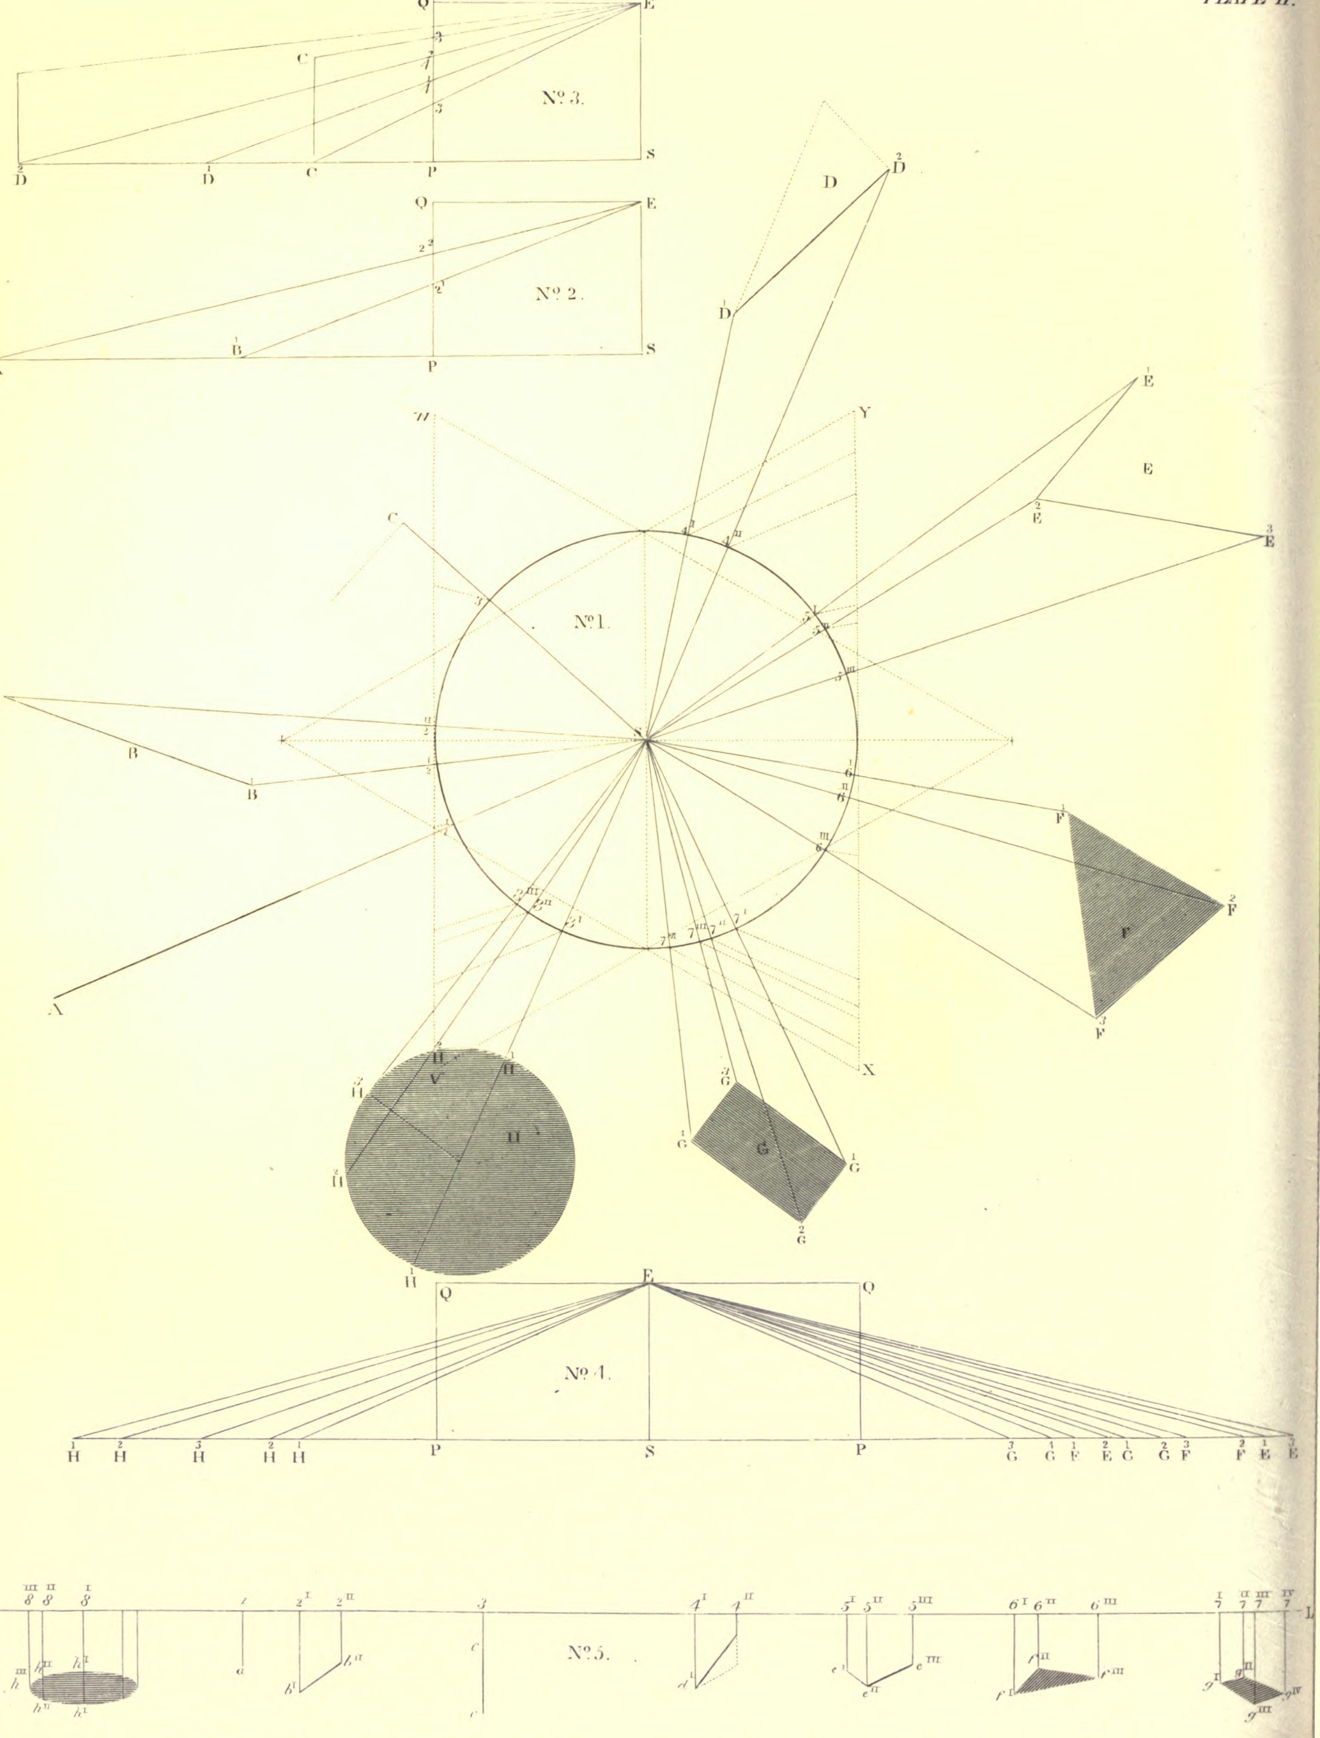
Plate II. shows a series of figures, such as may be supposed to constitute the whole of the practice of representing panoramic objects. S is the station point; the objects are referred to in alphabetical order from A, B, C, &c. to H; each extreme point of the linear parts of the same object has the same letter affixed, with a numerical index, which increases, by unity, in tracing round the circumference in progressive order. The points where the optic lines cut the panoramic surface, are numbered with the same figure from the same object, each number having an index corresponding to that of the point of the object to be represented. The numbers are placed in successive order, agreeing with that of the alphabet. No. 1 the intersection of the panorama and the original plane, with the figures of the objects to be represented.

No. 2, 3, 4, vertical sections of the panorama, passing along its axis, in order to ascertain the heights of the several places of each object; E the point of sight, or place of the eye; S the station point; P Q a section of the cylinder, showing the heights of the objects.

The objects to be represented are, A, a point, the optic ray from which cutting the intersection at 1; B a straight line, the optic ray from which cutting the intersection

PANORAMA

PLATE II.



; c a line standing upon c, the optic ray from which tting the intersection at 3; D an inclined plane, whose at is represented by D^1, D^2, the optic rays from which cutng the intersection at 4^1, 4^2; E an angle, the optic rays om which cutting the intersection at 5^1, 5^2, 5^3; F a triangle, e optic rays from which cutting the intersection at 6^1, 6^2, 6^3; a rectangle, the optic rays from which cutting the intersecon at 7^1, 7^2, 7^3, 7^4; and, lastly, H a circle, the optic rays om which cutting the intersection at 8^1, 8^2, 8^3.

The distances of the objects are placed upon the panoramic ctions No. 2, 3, 4, from S, upon the lines S P, or upon S P oduced; then drawing lines from the points to E, give the ights upon P Q.

The perpendicular standing upon c, No. 1, is thus found: No. 3, draw c c from c, perpendicular to S P, equal to the ight of the perpendicular upon c No. 1, and draw the raight lines c E, c E, No. 3, cutting P Q at 3 3, then 3 3 is e panoramic length of c c. The upper extremity of the clined line, D, will be found by ascertaining the panoramic ight of the perpendicular, from the elevated end to the iginal plane. No. 5 shows the panoramic representation of e several objects; V L the vanishing line of the horizon; e intersections of the optic rays are extended upon V L from o. 1, the references upon the intersection No. 1, and upon L, No. 5, being the same. The heights of the several points e taken from the sections No. 2, 3, and 4, from Q downwards wards P, and placed from the corresponding points in V L, o. 5, also downwards upon the perpendiculars, gives the veral points of the objects; thus *a* is the representation of e point A, No. 1; b^1, b^2, of B^1, B^2, &c. In the circle, the ints for half the curve are found, the other half being peated in the same order from the middle line, each line rving for two points, so that the three lines give eight ints; the extreme lines are tangents which are equivalent two points.

The points around the circumference of the intersection o. 1, are extended upon V W and X Y, according to the prinple of Renaldinus, by setting three-fourths of the radius, thout the circle, upon the opposite side of the tangents V W, d X Y, and transferring the divisions of V W and X Y upon L, No. 5, gives the points corresponding to the intersection. The panoramic surface being enveloped by No. 5, and the presentations of the objects placed in their true position, ll form the same picture at the point of sight, if correctly nted, as the objects themselves would in nature.

A practical method of forming all straight lines on the noramic surface in its place, without development, is to ertain the position of the objects, also the heights of the ntres of the lines to be represented; then fixing the eye in position, and holding a straight-edge parallel to the line be drawn in a plane with the point of sight and the point resenting the centre of the line, mark several points in same plane, on the panoramic surface; these points being ned, will give the representation of the line required. In paring for panoramic projections, whatever objects are inded to be represented, a proper point of view should be sen from this situation; a sketch of all the surrounding ects should be made according to the development of the orama; for though the painting itself may be performed on the cylindric surface, it is more eligible to sketch upon lane. The next thing to be done is to take a survey of objects, observing their positions to each other; then, a a plane table fixed on the point of view, quite level, e the successive angles of the surrounding objects by ans of a moveable limb, which may carry two pieces, one ach extremity, perpendicular to the surface of the plane e; one piece being fixed in the supposed axis of the panorama, containing a sight-hole for the point of view, so that the moveable part will consist of three bars, the bottom one serving as a straight edge for drawing the angles of position: the heights of the object may be marked upon the other limb parallel to that fixed in the axis; and let it be observed, that the point of view in the axis, the edge of the limb which gives the heights of the objects, and the edge of the bottom bar by which the angles are drawn, must be in a plane passing along the axis: mark the vertical lines on the sketch, and the lines on the plane table, which show their position, with corresponding characters, otherwise it would be difficult to distinguish what the numerous lines apply to. The moveable edge of the index, which describes the circumference of the cylinder, should be of ivory, as the various heights may be marked with pencil, and rubbed out at pleasure, as these heights may be transferred to a piece of paper, marking them with the same character as that of the sketch, and with the addition of the words *top of chymney*, *shaft*, *ridge of roof top of wall*, &c., as the heights may be the terminations of such parts of the said objects, or, instead of writing any word, a slight representation may be drawn of the parts of the object.

Instead of the ivory edge of the bar, which describes the panoramic surface, a slit, or very narrow aperture, formed by a double bar, may be used. The tendency of every line, horizontal or inclined, may be found by a fifth bar, moveable round a centre, which centre must also be moveable upon the edge of the limb which gives the panoramic heights of the objects; the plane in which this fourth bar moves must be a tangent to the panoramic surface, at the line which is intersected by the plane passing along the axis, along the straight-edge of the bottom bar, and along the edge where the heights of the objects are marked; then if the edge of this fourth moveable bar be brought in a plane with the eye and the original line, the angle which it forms with the edge of the vertical limb is the inclination of the line on the picture.

PANT, a conduit for water.

PANTHEON, (from the Greek παν, *all*, and θειον, *gods*,) in architecture, a temple or church, of a circular form, dedicated to all the gods, or to all the saints.

The Pantheon of ancient Rome is of all these edifices the most celebrated, and that from which all the rest take their name. It was built by Agrippa, son-in-law to Augustus, in his third consulate, twenty-five years before the Christian era; though several antiquaries and artists have supposed that the Pantheon existed long before, during the commonwealth, and that Agrippa only embellished it and added the portico. To this purpose they allege the authority of Dion Cassius, who, speaking of Agrippa, says, he also finished or perfected the Pantheon.

It was dedicated by him to Jupiter Ultor, Jupiter the Avenger, according to Pliny's account; according to Dion Cassius, to Mars, Venus, and Julius Cæsar; but, according to the most probable opinion, to all the gods; and had the name *Pantheon*, on account of the great number of statues of the gods, raised in seven niches all round it; and because it was built of a circular form, to represent heaven, the residence of the gods, or, because it was dedicated to all the gods, (*quasi* παντον θειον.) It had but one door. It was 144, or, as Fabricius says, 140 feet diameter within, and just as much in height, and of the Corinthian order. The roof was curiously vaulted, void spaces being left here and there for greater strength. The rafters, 40 feet long, were plated with brass. There were no windows in the whole edifice; but sufficient light was let in through a round hole in the top of the roof. Before each niche were two columns of antique yellow marble, fluted, each of one entire block.

The whole wall of the temple, as high as the grand cornice inclusive, was cased with divers sorts of precious marble in compartments; and the frieze was entirely of porphyry. The outside of the front was anciently covered with plates of gilt brass, and the top with plates of silver; in lieu of which, lead was afterwards substituted. The gates were of brass, and of extraordinary size and workmanship. The eruption of Vesuvius, in the reign of Tiberius, and a great fire in the reign of Titus, damaged the Pantheon very considerably; but it was successively repaired by Domitian, Adrian, and Septimius Severus: and having subsisted in all its grandeur till the incursion of Alaric, in the reign of Honorius, it was then stripped of several of its statues and ornaments of gold and silver. About thirty-nine years after this, Genseric, king of the Vandals, took away part of its marbles and statues; and, at length, Pope Boniface IV. obtaining this Pantheon of the Emperor Phocas, converted it into a church, without any alteration in the building, and dedicated it to the Virgin and all the martyrs; but, in 1665, Constantius II. stripped it of its inside and outside brazen coverings, which he transported to Syracuse. It still subsists at Rome, under the title of Notre Dame de la Rotonda.

The square of the Pantheon, or *Piazza della Rotonda*, is adorned with a fountain and an obelisk, and terminated by the portico of Agrippa. This noble colonnade consists of a double range of Corinthian pillars of red granite. Between the middle columns a passage opens to the brazen portals, which, as they unfold, expose to view a circular hall of immense extent, crowned with a lofty dome, and lighted solely from above. It is paved and lined with marble. Its cornice of white marble is supported by sixteen columns, and as many pilasters of Giotto antico; in the circumference there are eight niches, and between these niches are eight altars, adorned each with two pillars of less size, but the same materials. The niches were anciently occupied by statues of the great deities; the intermediate altars served as pedestals for the inferior powers. The proportions of this temple are admirable for the effect intended to be produced; its height being equal to its diameter, and its dome not an oval, but an exact hemisphere. The Pantheon is the most noble and perfect specimen of Roman art and magnificence which time has spared, or the ancients could have wished to transmit to posterity. It has served, in fact, as a model to succeeding generations, and to it Constantinople is indebted for Santa Sophia, and to it Rome, or rather the universe, owes the unrivalled dome of the Vatican. Upon the whole, this is the most ancient edifice that now remains in a state of full and almost perfect preservation.

There was also another Pantheon at Rome, dedicated to Minerva, as the goddess of medicine. It was in form of a decagon, and the distance from one angle to another measured $22\frac{1}{2}$ feet. Between the angles there were nine chapels of a round figure, designed for so many deities: and over the gate there was a statue of Minerva.

The Pantheon of Nismes, was a temple in that city, in which were twelve niches, for statues supposed to have been destined for the twelve great gods.

The Pantheon of Athens was, in many respects, little inferior to that at Rome, built by Agrippa. The Greek Christians converted it into a church, dedicated to the Virgin, under the name of *Panegia*, but the Turks changed it into a mosque.

In the Escurial is a magnificent chapel, called Pantheon, 35 feet in diameter, and 38 high from the pavement, which is of marble and jasper inlaid. The whole inside of the chapel is of black marble, except the lantern, and some ornaments of jasper and red marble. In this chapel are deposited the bodies of the kings and queens: there are only places made for twenty-six, eight of which are already filled.

PAN-TILES, *see* Tiles.

PANTOMETER, an instrument for measuring all sorts of elevations, angles, and distances.

PAPER, *Drawing*, a stout coarse kind of paper used for drawing upon, of which sheets are manufactured of the following sizes:

	Inches.		Inches.
Demy	20 by 15	Atlas	34 by 26
Medium . . .	22 " 17	Double Elephant	40 " 26

Super royal . .	27 " 19	Extra-Antiquarian	56 " 40
Imperial . . .	30 " 21	Emperor . . .	68 " 48
Colombier . .	34 " 23		

PARABOLA, (from the Greek παρα, *through*, and βαλλω, *to throw*) in geometry a curve line made by the common intersection of a conic surface and a plane which cuts it, and is parallel to another plane that touches the conic surface.

A conic section made by a plane ever so little inclined to the parabola on the one side, is an ellipsis; and a section made by a plane inclined ever so little on the other side, is an hyperbola; thus the parabola is the limit between these two curves, to which they both continually approach, while their transverse axes increase more and more; being, as it were, the passage from one of them to the other.

Parabola, a plain figure, bounded by a curve and a straight line, possessing the property that $a\,x = y^2$; in which x is the abscissa, and y the ordinate.

Parabolic Asymptote, in geometry, a parabolic line approaching to a curve, but never meeting it; yet by producing both indefinitely, their distance from each other becomes less than any given line.

There may be as many different kinds of asymptotes as there are parabolas of different orders.

When a curve has a common parabola for its asymptote, the ratio of the subtangent to the abscissa approaches continually to the ratio of two to one, when the axis of the parabola coincides with the base; but this ratio of the subtangent to the abscissa approaches to that of one to two, when the axis is perpendicular to the base. And by observing the limit to which the ratio of the subtangent and abscissa approaches, parabolic asymptotes of various kinds may be discovered.

Parabolic Conoid, See Paraboloid.

Parabolic Curve, the curved boundary of a parabola which terminates its area, except at the double ordinate.

Parabolic Spiral, or Helicoid, a curve arising from a supposition of the axis of the common parabola being bent into the periphery of a circle while the ordinates are portions of the radii next to the circumference.

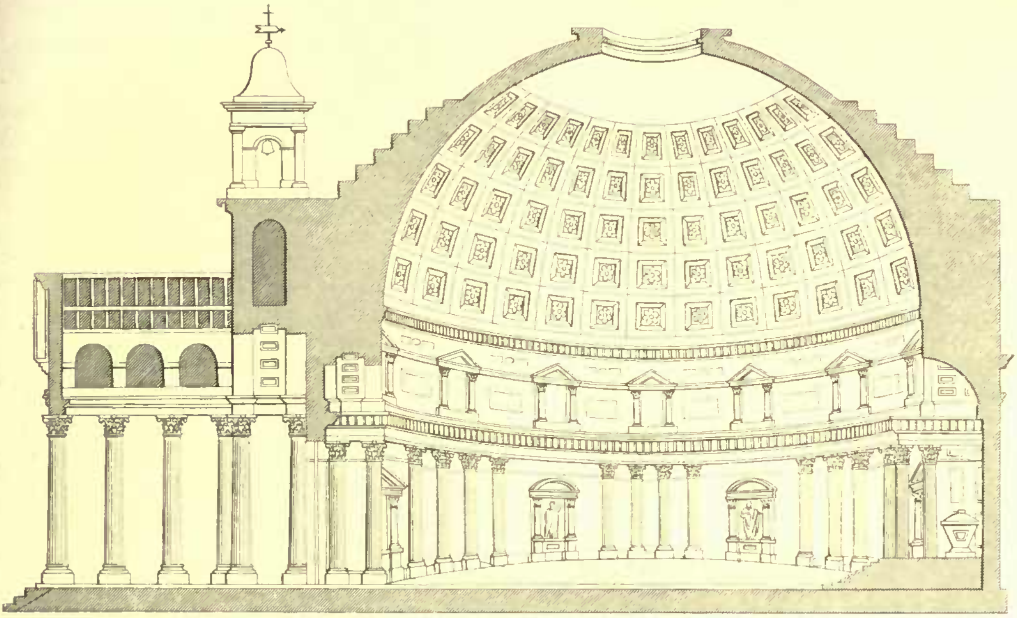
Paraboloid (from παραβολή and εἶδος) a solid formed by the revolution of a parabola about its axis. It is described by Harris as a parabolic firm curve, whose ordinates are supposed to be in subtriplicate, subquadruplicate, &c., ratio of their respective abscissas.

PARADIGRAMMATIZE, (from the Greek παραδειγμα, *an example*, and γραμμα, *a letter*) the act of forming all sorts of figures in plaster. The artists themselves are called *gypsochi*. Neither term is much used.

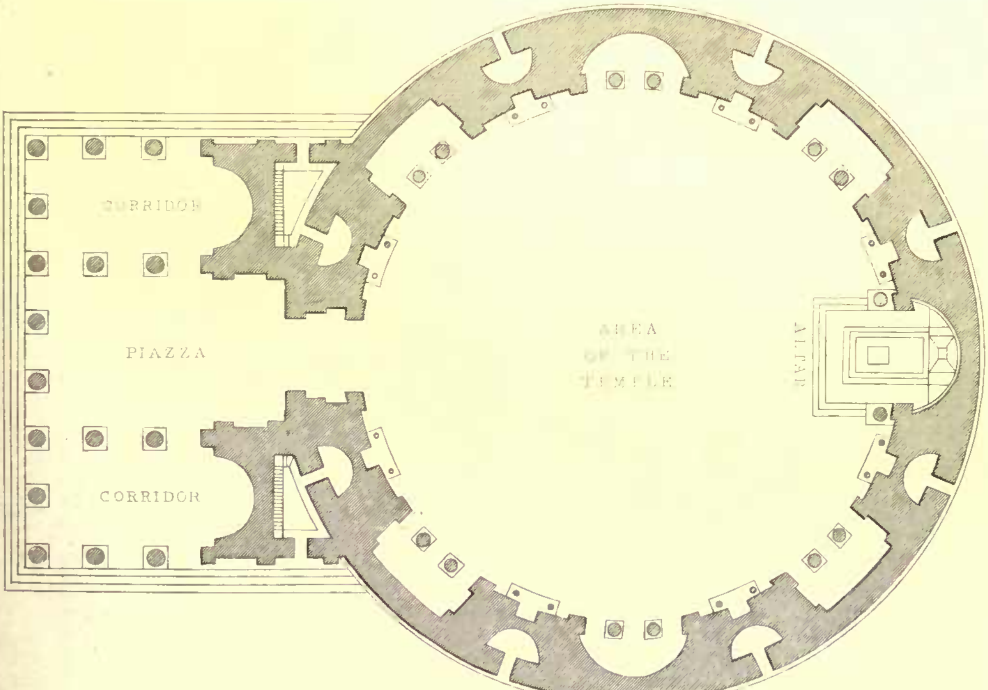
PARADOX (from the Greek παρα, *against*, and δοξα, *opinion*) in philosophy, a proposition seemingly absurd because contrary to the received opinions; but yet true in effect.

The Copernican system is a paradox to the common people; but the learned are all agreed as to its truth.

PLAN AND SECTION OF THE HEATHEN PANTHEON AT ROME.



PERSPECTIVE SECTION



GENERAL PLAN OF THE TEMPLE

own Arch^t. R. Thew. Sc

Geometricians have been accused of maintaining paradoxes; and, it must be owned, that some use very mysterious terms in expressing themselves about asymptotes, the sums of infinite progressions, the areas comprehended between curves and their asymptotes, and the solids generated from these areas, the length of some spirals, &c. But all these paradoxes and mysteries amount to no more than that the line or number may be continually acquiring increments, and those increments may decrease in such a manner, that the whole line or number shall never amount to a given line or number.

The necessity of admitting this is obvious from the nature of the most common geometrical figures; thus, while the tangent of a circle increases, the area of the corresponding sector increases, but never amounts to a quadrant. Neither is it difficult to conceive, that if a figure be concave towards a base, and have an asymptote parallel to the base (as it happens when we take a parallel to the asymptote of the logarithmic curve, or of the hyperbola, for a base) that the ordinate in this case always increases while the base is produced, but never amounts to the distance between the asymptote and the base. In like manner, a curvilinear area may increase while the base is produced, and approach continually to a certain finite space, but never amount to it; and a solid may increase in the same manner, and yet never amount to a given solid.

A spiral may in like manner approach to a point continually, and yet in any number of revolutions never arrive at it; and there are progressions of fractions, which may be continued at pleasure, and yet the sum of the terms shall be always less than a given number. In Maclaurin's *Fluxions* (book i. ch. 10. *et seq.*) various rules are demonstrated, and illustrated by examples, for determining the asymptotes and limits of figures and progressions, without having recourse to those mysterious expressions which have of late years crept into the writings of mathematicians. For, as that excellent author observes elsewhere, though philosophy has, and probably always will have, mysteries to us, geometry ought to have none.

PARALLEL, (from the Greek παραλληλος,) in geometry, a term applied to lines, figures, and bodies, which are every where equidistant from each other; or which, though infinitely produced, would never approach nearer to, nor recede farther from, each other.

Parallel Copings, such copings as have their upper surface parallel to the bed of the stone, as in those which cover the gable of a house.

Parallel Right Lines, such lines, as, though infinitely produced, could not meet at any finite distance.

Parallel Motion, among practical mechanics, denotes the rectilinear motion of a piston-rod, &c., in the direction of its length; and contrivances, by which such alternate rectilinear motions are converted into continuous rotatory ones, or *vice versa*, for pumps, steam-engines, saw-mills, &c., are usually called *parallel motions* or *parallel levers*. The object of the parallel motion is, to convert the motion of the end of a reciprocating beam or lever, into a vertical or rectilinear motion; or the continuous motion of a crank at once into a reciprocating motion.

The simplest and most obvious method of producing either of these effects, is to connect the end of the piston-rod to the beam, or the crank, by means of joints, with a connecting rod of a proper length between them, and confine the former, to preserve its rectilinear movement, by sliding through a collar, or in grooves. Friction-wheels may be used to make it work easily; but in machines which have great strains, the constant wear of the grooves or wheels, would soon produce looseness, and destroy the parallelism of the motion: recourse must, therefore, be had to parallel levers.

Parallel-Planes, those which if produced cannot meet at any finite distance.

Parallel Ruler, *See* Instruments.

Parallel Cut, in inland navigation, a counter drain, to carry off water, and prevent the adjoining lands from being flooded.

PARALLELOPIPED, (from the Greek παραλληλος, *parallel*) in geometry, one of the regular bodies, or solids, comprehended under six parallelograms, the opposite sides of which are similar, parallel, and equal.

A parallelopiped is by some defined an upright prism, whose base is a parallelogram, and the planes of whose sides are perpendicular to the plane of the base.

A rectangular parallelopiped is one whose bounding planes are all rectangles, and which stand at right angles to each other. Every rectangular parallelopiped is said to be contained under the planes that constitute its length, breadth, and altitude.

It is demonstrated, that if from one of the angular points of any parallelogram, a right line be elevated above the plane of the parallelogram, so as to make any angles with the contiguous sides of it, and there be also drawn, from the three remaining angular points, three other right lines parallel and equal to the former, and the extremes of these lines be joined, the figure thus described will be a parallelopiped. If the angle of the parallelogram be right, and the elevated line be erected perpendicular to the plane of the base, then will the parallelopiped be a rectangular one.

Parallelopiped, *Properties of the.* All parallelopipeds, prisms, and cylinders, &c., whose bases and heights are equal, are themselves equal.

Every upright prism is equal to a rectangular parallelopiped of equal base and altitude.

A diagonal plane divides the parallelopiped into two equal prisms: a rectangular prism, therefore, is half a parallelopiped upon the same base, and of the same altitude.

All parallelopipeds, prisms, cylinders, &c., are in a ratio compounded of their bases and altitudes; wherefore, if their bases be equal, they are in proportion to their altitudes; and conversely.

All parallelopipeds, cylinders, &c., are in a triplicate ratio of the homologous sides; and also of their altitudes.

Equal parallelopipeds, prisms, cones, cylinders, &c., are in the reciprocal ratio of their bases and altitudes.

Rectangular parallelopipeds, contained under the corresponding lines of three ranks of proportionals, are themselves proportionals.

To measure the surface and solidity of a parallelopiped.—Find the areas of the parallelograms I L M K, L M O N, and O M K P (*See* Parallelogram); add these into one sum, multiply that sum by 2, and the product will be the surface of the parallelopiped.

"If, then, the base, I L M K, be multiplied by the altitude, M O, the product will be the solidity.

Suppose L M $= 36$, M K $= 15$, M O $= 12$; then L I K M $= 36 \times 15 = 540$; L M O N $= 36 \times 12 = 432$; M O K P $= 15 \times 12 = 180$. The sum of which is $= 1152$, which multiplied by 2, gives the superficies equal to 2304. And 540×12 gives the solidity equal to 6480. Or the solid content of a parallelopiped may be obtained by multiplying the area of the base by the altitude of the parallelopiped. Thus, if the two dimensions of the base be 16 and 12 inches, and the height of the solid 10 inches; then the area of the base being 192, the content of the solid will be 1920 cubical inches.

The parallelopiped with oblique angles is a figure very common to many kinds of stones, especially of the softer sort.

PARALLELOGRAM, (from the Greek παραλληλος, *a parallel*, and γραμμα, *a figure*) in geometry, a quadrilateral right-lined figure, whose opposite sides are parallel and equal to each other.

A parallelogram is generated by the equable motion of a right line always parallel to itself.

When the parallelogram has all its four angles right, and only its opposite sides equal, it is called *a rectangle*, or *an oblong*.

When the angles are all right, and the sides are all equal, it is called *a square*, which some make a species of parallelogram, others not.

If all the sides are equal, and the angles unequal, it is called *a rhombus*, or *lozenge*.

If both the sides and angles be unequal, it is called *a rhomboides*.

Every other quadrilateral, whose opposite sides are neither parallel nor equal, is called *a trapezium*. See each of these articles.

In every species of parallelogram, a diagonal divides it into two equal parts; the angles diagonally opposite are equal; the opposite angles of the same side are, together, equal to two right angles; and every two sides are, together, greater than the diagonal. Every quadrilateral, whose opposite sides are equal, is a parallelogram.

Two parallelograms on the same, or on an equal base, and of the same height, or between the same parallels, are equal. Hence two triangles on the same base, and of the same height are also equal; as are all parallelograms or triangles whatever, whose bases and altitudes are equal among themselves.

Hence, also, every triangle is half a parallelogram upon the same or an equal base, and of the same altitude, or between the same parallels. Hence, also, a triangle is equal to a parallelogram having the same base and half the altitude, or half the base and the same altitude.

Parallelograms, therefore, are, in a given ratio, compounded of their bases and altitudes. If then the altitudes be equal, they are as the bases; and conversely.

In similar parallelograms and triangles, the altitudes are proportional to the homologous sides; and the bases are cut proportionally thereby. Hence similar parallelograms and triangles are in a duplicate ratio of their homologous sides, also of their altitudes, and the segments of their bases; they are, therefore, as the squares of the sides, altitudes, and homologous segments of the bases.

In every parallelogram, the sum of the squares of the two diagonals is equal to the sum of the squares of the four sides: and the two diagonals bisect each other.

This proposition M. de Lagny takes to be one of the most important in all geometry; he even ranks it with the celebrated forty-seventh of Euclid, and with that of the similitude of triangles; and adds, that the whole first book of Euclid is only a particular case of it. For if the parallelogram be rectangular, it follows, that the two diagonals are equal; and, of consequence, the square of a diagonal, or, which comes to the same thing, the square of the hypothenuse of a right angle is equal to the squares of the sides.

If the parallelogram be not rectangular, and, of consequence, the two diagonals be not equal, which is the most general case, the proposition becomes of vast extent; it may serve, for instance, in the whole theory of compound motions, &c.

There are three ways of demonstrating this proposition: the first by trigonometry, which requires twenty-one operations; the second geometrical and analytical, which requires fifteen. But M. De Lagny gives a more concise one, in the *Memoires de l' Acad.*, which only requires seven.

PARALLELOGRAM, *See* PENTAGRAPH.

PARAMETER (from the Greek παρα, *through*, and μετρεω, *to measure*) in conic sections, a constant right line in each of the three sections; called also *latus rectum*. In the parabola, the rectangle of the parameter and an abscissa are equal to the square of the correspondent semi-ordinate. *See* PARABOLA.

In an ellipsis and hyperbola, the parameter is a third proportional to a conjugate and transverse axis. *See* ELLIPSIS and HYPERBOLA.

PARAPET, (French) or BREASTWORK, in fortification, a defence or screen, on the extreme of a rampart, or other work, serving to cover the soldiers and the cannon from the enemy's fire.

The thickness of the parapet should be about eighteen or twenty feet, in order to be cannon-proof, and it should be about seven or eight feet high, when the enemy has no command above the battery; otherwise it should be raised high enough to cover the men while they load the guns. Its length depends on the number of guns to be employed in the battery: for one gun, it is common to allow eight yards in length, and six yards more for every other gun. The parapet consists of two parts; the wall contained in one piece from end to end, and about two and half or three feet high; and the merions, which are detached pieces of the parapet, leaving openings, called embrasures, through which the cannon deliver their shot.

The parapet of the wall is sometimes of stone. The parapet of the trenches is either made of the earth dug up; or of gabions, fascines, barrels, sacks of earth, or the like.

PARAPET, is also a little wall, breast-high, raised on the brinks of bridges, quays, or high buildings; to serve as a stay and prevent accidents from falling over.

In roof buildings, it assists in forming the gutter, and tends to resist the outward thrust of the roof by its weight or vertical pressure. It is worthy of remark, that in the late Gothic buildings, when the roofs were of a low pitch, and consequently had considerable lateral thrust, the walls were almost invariably terminated by a parapet.

PARASTATA, (Greek,) in ancient architecture, a kind of pier, or piedroit, serving as a defence or support to a column or arch.

Mr. Evelyn makes the parastata the same with pilaster; Barbaro and others, the same with antæ; and Daviler, the same with piedroit.

PARCLOSE, a screen frequently of open-work, employed in churches to separate chapels, tombs, and other portions of the church from the main body.

PARENT, ANTHONY, in biography, an eminent mathematician, born at Paris in the year 1666. At a very early period, he discovered a strong propensity to the study of mathematics; for, at the age of fourteen, accidentally meeting with a dodecahedron, upon every face of which was delineated a sundial, excepting the lowest, upon which it stood, he attempted to imitate them, and was led from the practice to investigate the theory, and in a short time wrote a treatise upon *Gnomonics*, which, though said to be extremely rude and unpolished, had the merit of being his own invention, as was a work on *Geometry*, which he wrote about the same time. At the earnest desire of his relations, he entered upon the study of the law, as a profession for his life; but he sooner completed his studies in that faculty, than he betook himself, with increased ardour, to those pursuits which accorded best with his genius and inclination. He attended, very diligently, the lectures of M. de la Hire and M. Sauveur, and, as soon as he felt himself capable of teaching others, he took pupils; and fortification being a branch of study which the war had brought into particular notice, he was called upon frequently to teach the principles of that science. In 1699, M. Fillau des Billets having been admitted a member of the Academy of Sciences at Paris, with the title of their academician, nominated M. Parent for his *élève*, who particularly excelled in that branch of knowledge. It was soon discovered that he directed his attention to all the subjects that came before the Academy, and that he was competent to the investigation of every topic which was recommended to their notice. In the year 1716, the king abolished the class of *élèves*, and on this occasion he made M. Parent an adjunct, or assistant member of the class of geometry. He lived but a short time to enjoy his honour, being in the same year cut off by the small-pox, when he was about fifty years of age. Although of a very irritable disposition, he is said to have possessed great goodness of heart; and though his means were extremely limited, he devoted much of his income to acts of benificence. He was author of *Elements of Mechanics and Natural Philosophy*, *Mathematical and Physical Researches*, a sort of journal, which first appeared in 1705, and which, in 1712, was greatly enlarged, and published in three vols., 4to.; and *A Treatise on Arithmetic*. Besides these, he wrote a great number of papers in the different French *Journals*, and in the volumes of the *Memoirs of the Academy of Sciences*, from the year 1700 to 1714, and he left behind him, in manuscript, many works of considerable research; among which were some complete treatises on divers branches of mathematics, and a work containing proofs of the divinity of Jesus Christ, in four parts.

PARGET, (from the Latin, *parces*, a wall,) in natural history, a name given to the several kinds of gypsum or plaster-stone, which, when slightly calcined, make what is called *plaster of Paris*, used in casting statues, in stuccoing floors and ceilings, &c.

The word *parget*, though generally applied to all the gypsums, is, however, given by the workmen principally to the two species which make up the first genus of that class, called by Dr. Hill the *pholides*. These are the Montmartre kind, and that of Derbyshire.

Pargeting, in building, a term used for the plastering of walls; sometimes for the plaster itself.

Pargeting is of various kinds; as, 1. White lime and hair mortar laid on bare walls. 2. On bare laths, as in partitioning and plain ceiling. 3. Rendering the insides of walls, or doubling partition walls. 4. Rough-casting on heart-laths. 5. Plastering on brickwork, with finishing mortar, in imitation of stone work; and the like upon heart-laths.

The term pargeting is also applied to the ornamental plaster-work common in timber houses of the Elizabethan period.

PARKER'S CEMENT. *See* Cement, Mortar, &c.

PARLOUR, (French, *parler*, to speak,) a room for conversation. Primarily, the apartment in a nunnery where the nuns are permitted to meet and converse with friends and visitors; hence with us the parlour is the room in a house which the family usually occupy when there are no visitors, as distinguished from a drawing-room, for the reception of company, or from a dining-room, when a distinct apartment is allotted for that purpose. The term is likewise used to signify a room on the ground-floor, and a better sort of apartment in houses of entertainment.

PARQUETRY, inlaid work, the same as Marquetry, which see.

PARSONAGE, a house adjoining, or in proximity to a church, the residence of the officiating priest.

PARTHENON, one of the finest temples of ancient Athens, dedicated to Minerva. It was of the Doric order, erected by Ictinas in the palmy days of Greek art, the sculptor being Phidias. It is situated about the middle of the citidal, and is built altogether of admirable white marble; the plan of it is above twice as long as it is broad, being 217 feet 9 inches long, and 98 feet 6 inches broad. It has an ascent on all sides of five steps. The peristyle consists of 46 pillars of the Doric order, chennelled, 8 whereof are distributed at each end of 17 on either side; they are 42 feet high, and 17½ feet in circumference, the intercolumns measuring 7 feet four inches.

The following particulars are extracted from Stuart:—"Within the peristyle, at either end, there was an interior range of 6 columns of 5½ feet in diameter, forming a vestibule to the door of the cella or *adytum*, these vestibules were ascended by two steps from the peristyle.

"The cella, 62½ feet broad within, was divided into two unequal chambers, of which one was nearly 44 feet long, and the other about 97½ feet long. The ceilings of the smaller chamber was supported by 4 columns, and of the larger by 16 columns; the order of these interior columns is unknown, as all traces of their ornaments appear to have perished; even their existence can be but conjectured by means of the construction of the pavement, and by a trace of *one* of the columns in either chamber.

"The existence of these internal columns is not, however, admitted by Wilkins, who made a very minute inspection of the building in 1801. The metopes were enriched with sculptures executed in high relief; the subject a series of combats between one of the Lapithæ and the Centaurs; in the tympan of the pediments, were sculptured groups of a colossal size, many of the figures being perfect *statues, wholly detached from the tympanum, and sculptured all round.* The circumstances attending the birth of Minerva, were represented over the one entrance, and also the contest between the goddess and Neptune for the *honour* of presiding over the affairs of the city; for the Athenians, in choosing a tutelary diety, did not omit the opportunity of paying a compliment to their national vanity. Behind the columns of both fronts, was another range of columns of lesser dimensions, advanced before the antæ of the pronaos and pasticum, contrary to the usual Greek practice, as the area of the pronaos and of the pasticum was elevated two steps above the peristyle. The entablature or frieze of the inner range was continued along the side-walls of the temple, and enriched with sculptures executed in bas relief; it was not broken by the insertion of triglyphs, but in the epistylium, the guttæ or drapo are introduced in the same manner as when the usual insertion of triglyphs was made. This afforded an opportunity for an uninterrupted representation of the grand procession which took place at the celebration of the Panathenæan festival.

"The transverse walls terminating the pronaos and pasticum, receded 12 feet behind the columns of the interior ranges, and doorways of ample width and height were left in them for the approaches to the cella. Stuart imagined the Parthenon to have been of that description of temples called Hypæthral, or those of which the cella was divided into three aisles, of which the two next the side-walls were covered with a roof, and the middle aisle left open to the sky. The researches of recent travellers having thrown additional light on this subject, his opinion is no longer tenable, and the passage in Vitruvius, which was considered to allude to this temple, has been shown to be a corruption of that author's text. There were no columns in the cella of the temple. The roof was unquestionably of timber, and covered with marble, sculptured so as to represent large tiles, after the mode observed in the temple of Jupiter at Olympia.

Some of the blocks of stone, of which the Parthenon is composed, are so closely fitted, that no separation is visible; and in some instances, where the adjoining fragments of two contiguous stones have broken off, they adhere almost as firmly as though they had never been disjoined; this cohesion is, however, only observable in the *vertical* joints, the separation between the horizontal beds of the blocks, is far more conspicuous. The want of cement was amply supplied by the liberal use of *iron cramps;* in a block of four feet in length, three cramps are sometimes found connecting it with the next adjoining. One set of cramps being used for connecting the stones of the same bed together, and the other for connecting the superincumbent courses; the first, which united both the end and at the sides, resembled the letter H, protracted so as to be from 11 to 15 inches in length. The others were plates of iron, 5 inches in depth, 3 in width, and $\frac{3}{4}$ of an inch thick. They are usually inserted half their depth into the stones beneath the vertical joints of the next superior course, the other remaining to be received into a groove made across the common joint of the two blocks meeting above it. Holes of the same form, but of greater dimensions, were sunk for the reception of the first sort of cramps, the space being filled around with melted lead; lead was also used in fixing the second sort of cramps in the horizontal courses, but no means appear to have been employed for its introduction at the angles of two blocks, whose vertical joint is immediately above them. The stones composing the shaft of each column, were held together by round pins of wood; *square* sockets of the same material were first sunk in the centre of two adjoining blocks, the socket of the lower course received half the pin, and the other half projected into the socket in the upper stone. The pins which have been found, appear to have shrunk very considerably; besides these, there were usually two metal plates of the kind already mentioned, inserted in those blocks composing the column, as in the other part of the building.

PARTITION, (from the Latin, *partitio*, to divide,) a wall which divides and separates one apartment from another. It may be either of brick, stone, or timber. When a partition wall has no support from below, it ought to be so constructed as to lay no stress upon the floor; and, therefore, a truss partition should be employed to discharge the weight. *See* TRUSS.

PARTY WALLS, in building, partitions of brick made between buildings in separate occupations, for preventing the spread of fire. For the regulations prescribed by act of Parliament, *see* HOUSE.

PARVIS, or PARVISE, a name formerly given to the porch of a church, but now applied to the area round a church. Of late, it has been used to signify the room often found above the porch of a church. It is supposed to be a corruption of *paradise.*

PASCAL, BLAISE, a celebrated mathematician and philosopher, born at Clermont, in Auvergne, in the year 1623. His father, who was a man of great consideration in his province, was also illustrious as a general scholar, as well as an able mathematician. To promote the studies of his only son, Blaise, he relinquished his official situation, settled at Paris, and undertook the employment of being his tutor. The pupil was, from a very early period, remarkably inquisitive, and desirous of knowing the principles of things; and when good reasons were not given to him, he would search for better; nor would he rest contented with any that did not appear to his mind well founded. His father soon discovered that the bent of his genius was decidedly to mathematics, from which he was determined, if possible, to keep him, lest he should, by this pursuit, be prevented from learning the languages. He accordingly locked up all the books that treated of geometry and the sciences, properly so called, and refrained even from speaking of them in his presence. On one occasion, however, the youth asked, with an importunity not to be put off, what was geometry? to which the father replied, "geometry is a science which teaches the way of making exact figures, and of finding out the proportions between them;" but, at the same time, he forbade him to speak or think of the subject any more; which was, perhaps, the very readiest way to excite in him an earnest desire to become acquainted with it. Accordingly, the science soon occupied all his thoughts; and though but twelve years of age, he was found, in the hours of recreation, making figures on the chamber-floor, with charcoal, the proportions of which he sought out by means of a regular, though perhaps uncouth, series of definitions, axioms, and demonstrations. It is said, apparently upon unquestionable authority, that he had proceeded with his inquiries so far as to have come to what was just the same with the thirty-second proposition of the first book of Euclid, and that without any assistance either from living instructors or the works of the illustrious dead. From this time, young Pascal had full liberty to indulge his genius in mathematical pursuits, and was furnished by his father with Euclid's Elements, of which he made himself master in a very short time. So great was his proficiency in the sciences, that, at the age of sixteen, he wrote a *Treatise on Conic Sec-tions*, which, in the judgment of the most learned men of the time, was considered as a great effort of genius. At the age of nineteen he contrived his admirable arithmetical machine furnishing an easy and expeditious method of making arith-metical calculations, in the fundamental rules, without an[y] other aid than that of the eye and the hand. About th[is] time, owing to ill health, he was obliged to suspend his studies which he was unable to renew for four years; when, havin[g] been witness to the famous Torricellian experiment respec[t]ing the weight of air, he instantly directed his attention t[o] discoveries in the science of pneumatics. He made a va[st] number of experiments, of which he circulated a printe[d] account through the whole of Europe. He soon ascertaine[d] the fact of the general pressure of the atmosphere, and com[-]posed a large treatise, in which he fully explained the subjec[t] and answered the objections which were advanced again[st] his theory: afterwards, thinking it too prolix, he divided [it] into two small treatises, one of which he entitled, *A Disse[r]tation on the Equilibrium of Fluids;* and the other, *An Ess[ay] on the Weight of the Atmosphere.* These treatises were n[ot] published till after the author's death.

The high reputation which M. Pascal had acquired, caus[ed] him to be looked up to by the most considerable mat[he]maticians and philosophers of the age, who applied for [his] assistance in the resolution of various difficult questions a[nd] problems. Among other subjects on which his ingenu[ity] was employed, was the solution of a problem suggested [by] Mersenne, which had baffled the penetration of all who h[ad] attempted it; this was to determine the curve described [in] the air by the nail of a coach-wheel, while the machine [is] in motion; which curve was at that time known by the na[me] of the *roullette*, but is now designated the *cycloid.*

Before this time he had drawn up a table of numbers, wh[ich,] from the form in which the figures were disposed, he ca[lled] his *Arithmetical Triangle.* He might perhaps have bee[n] ıventor of it, but it is certain that it had been treated of, century before Pascal's time, by Cardan, and other arithıetical writers.

When M. Pascal was in the twenty-fourth year of his age, nd the highest expectations were formed of the advantages o be attained in science from his labours, he on a sudden enounced the study of mathematics, and all human learning; evoted himself wholly to a life of mortification and prayer; nd became as great a devotee as almost any age has prouced. He was not, however, so completely abstracted from ne world, as to be wholly indifferent to what was passing in ; and in the disputes between the Jesuits and the Jansenists, he became a partisan of the latter, and wrote his elebrated *Provincial Letters*, published in 1656, under the ame of Lewis de Montalte, in which he only employed his alents of wit and humour in ridiculing the former. These etters have been translated into almost all the European anguages, and probably nothing did more injury to the cause f the Jesuits. The course of life which he prescribed to imself, proved unfavourable to his health of body and mind. His reason became in some measure affected, and in these ircumstances, an accident produced on his mind an impresion which could not be effaced. In 1654, while he was rossing the Seine in a coach-and-four, the two leading orses became unmanageable at a part of the bridge where he parapet was partly down, and plunged over the side into he river. Their weight fortunately broke the traces, by which means the other horses and the carriage were extriated on the bank of the precipice. In his then enfeebled tate, this fright was too much for the unfortunate Pascal; nd so serious were its effects on him, that he never afterwards had the possession of his mental faculties. He always magined that he was on the edge of a vast abyss on the left ide of him, and he would at no time sit down till a chair was placed there, to assure him there was no real danger. After languishing some years in this miserable state, he died t Paris in 1662, at the age of 39.

PASSAGES, the avenues or accesses which lead to the various apartments of a building.

Passages must always be convenient to give ready access, nd proportional in width and height to the magnitude of the ther apartments, and with suitable decorations.

PASTIL, or PASTEL, (from the Latin *pastillus*,) among ainters, &c. a sort of paste, made of several colours ground p with gum-water, either together or separately, in order to ıake crayons, to paint with on paper or parchment.

PASTOPHORIA, (Greek) in antiquity, apartments near ıe temples, for lodging the pastophori, or priests, whose usiness it was, at solemn festivals, to carry the shrine of the eity.

Clemens Alexandrinus, describing the temples of the gyptians, says, that "after having passed through magificent courts, you are conducted to a temple, which is at ıe farther end of these courts, and when a pastophorus ravely lifts up the veil, which is the door, to show you the eity within, which is nothing but a dog or a cat, or some ther animal." Apuleius speaks of the pastophori that cared the Syrian goddess.

In the temple of Jerusalem there were two courts surounded with galleries, and round about were several lodgingooms for the priests to lay up wood, wine, oil, salt, meal, pices, incense, vestments, valuable vessels, and provisions, ecessary for the sacrifices and lamps, as also for the support nd maintenance of the priests. *See* 1 Chron. ix. 26, 33; xvi. 16. Ezek. xl. 17, 18.

PASTORAL-STAFF, the official staff used by a bishop. ee CROZIER.

PATE, in fortification, a kind of platform, like what they call a horse-shoe; not always regular, but generally oval, encompassed only with a parapet, and having nothing to flank it. It is usually erected in marshy grounds, to cover a gate of a town, or the like.

PATEN, a plate or salver employed in the eucharist.

PATERA, (from *pateo*, I am open,) among antiquaries, a goblet, or vessel, used by the Romans in their sacrifices, in which they received the blood of their victims, offered their consecrated meats to the gods, and made libations.

On medals, the patera is seen in the hands of several deities; and frequently in the hands of princes, to mark the sacerdotal authority joined with the imperial, &c. Hence F. Joubert observes, that besides the patera, there is frequently an altar, upon which the patera seems to be pouring its contents.

The patera is an ornament in architecture, frequently introduced in friezes, fascias, and imposts, over which are hung festoons of husks or flowers; or they are sometimes used by themselves, to ornament a space; and in this case it is common to hang a string of husks or drapery over them; sometimes they are much enriched with foliage, and have a mask or head in the centre.

In vol. xiv. of the Archæologia, a description and plate are given of a Roman patera and vase dug up when sinking a ditch in Essex, in June, 1800. They were found near an ancient Roman road, between Camelodunum and Camboritum. "The metal vase and patera merit attention, as none similar to the first have been figured or described in the works of the society; nor do I know that any like either have been presented for their inspection. The vase is of that form which Montfaucon has figured in his 2d. vol., pl. 19, fig. 10, and calls a *præfericulum*, used by the Romans at their sacrifices, for pouring wine into the patera. *See* p. 88, where he controverts Festus's opinion that the præfericula were without handles. Another, more nearly resembling that here represented, is given in his 3d. vol., pl. 24, fig. 9, and called by Beger an *epichysis*, but not allowed to be such by Montfaucon. The metal patera which belongs to the above, differs from the earthen pateræ in general, by being bossed in the centre, a circumstance not easily to be accounted for, unless it was for the firmer fixing the præfericulum upon, when placed with the body at the time of interment." With the above Roman antiquities were found several little cups of Samian ware. "The uses of these elegant little cups have not," the antiquary continues, "that I know of, been ascertained by any author. The real purposes to which they were applied must remain at present in obscurity."

It may be stated, also, that the Hindoos, in their sacrifices and ceremonies, have immemorially used, and still use, articles exactly similar to those described in vol. xiv. of the Archæologia, plates 1 and 5; and it is curious to see how nearly they agree in form. A comparison of the article in the plates just adverted to, with those in plates 83, 86, and 105 of the Hindoo Pantheon, will strikingly evince this. The *sacrificial vase*, in the latter plate, has the same form, though more elaborately ornamented, as the above described præfericulum; and the others exhibit metallic circular pateræ, and the central embossment, which, though "not easily accounted for," is found among Hindoo mystics to have very profound allusions. The Roman patera has also the mysterious rim, or *yoni*, respecting which the reader may consult the work last referred to. Dr. Clarke, in his Travels, notices that "the patera used by priestesses in the rites of Ceres, had this pyramidal node or cone in the centre. A priestess is represented holding one of these, on a bas-relief, in the vestibule of Cambridge University library." Vol. ii., p. 334. Greek

Marbles, No. xv., p. 37. Similar articles are still used in the rites of the Hindoo Ceres; as are also the "little cups" described and exhibited in the Archæologia, as above referred to, and in many of the plates of the Hindoo Pantheon. In India, they are used for holding clarified butter, a common ingredient in the frequent oblations to fire; and unguents, and holy water, in the *sradha*, or funeral obsequies, and in other rites and ceremonies.

PATERNOSTERS, in architecture, a sort of ornaments in form of beads, either round or oval, used on baguettes, astragals, &c.

PAVEMENT, (from the Latin *pavimentum*, derived from *pavire*, to make the earth firm and strong by beating,) a layer or stratum of stone, or other matter, serving to cover and strengthen the ground of divers places, for the more commodious walking on, or for the passage of carriages.

The paving of streets is one of the most beneficial regulations of police that have been transmitted to us from our ancestors. Several cities had paved streets before the commencement of the Christian era; nevertheless, those which are at present the ornament of Europe (Rome excepted) were destitute of this great advantage till almost the twelfth or thirteenth century. It is probable that those people who first carried on the greatest trade, were the first who paid attention to have good streets and highways, in order to facilitate that intercourse which is so necessary to keep up the spirit of commerce. Accordingly, we are told by Isidorus (*Origin.* lib. xv. cap. 16), that the Carthaginians had the first paved streets, and that their example was soon copied by the Romans. Long before that period, however, Semiramis paved highways, as appears by the vain-glorious inscription which she herself caused to be put up (Strabo, lib. 16. Diod. Sicul. lib. ii. v. 13. Polyæni, *Stratagem*, lib. viii. cap. 26.) The streets of Thebes, and probably those of Jerusalem, were paved; but neither the streets of Rome nor the roads around it were paved during the time of its kings. In the year U. C. 188, after the abolition of the monarchical form of government, Appius Claudius, being then censor, constructed the first real highway, called after him the *Appian Way*, and, on account of its excellence, the *queen of roads*. The time when the streets were first paved cannot be precisely ascertained; some have referred this improvement to the year 578, after the building of the city; others to 584; and others to 459; at which several periods some parts of the city and suburbs might have been paved. That streets paved with lava, having deep ruts made by the wheels of carriages, and raised banks on each side, for the accommodation of foot-passengers, were found both at Herculaneum and Pompeii, is well known.

Of modern cities, the oldest pavement is commonly ascribed to that of Paris; but it is certain that Cordova, in Spain, was paved so early as in the middle of the ninth century, or about A. D. 850. The capital of France was not paved in the twelfth century, but the orders for this purpose were issued by the government in the year 1184, on which occasion it is said that the name of Lutetia, deduced from its dirtiness, was changed into that of Paris. Nevertheless, in the year 1641, the streets in many quarters of Paris were not paved. That the streets of London were not paved at the end of the eleventh century is asserted by all historians. It does not appear when paving was first introduced; but it was gradually extended as trade and opulence increased. Several of the principal streets, such as Holborn, which are at present in the middle of the city, were paved for the first time by royal command, in the year 1417; others were paved under Henry VIII.; some in the suburbs in 1544: others in 1571 and 1605: and the great market of Smithfield in 1614.

In England, the pavements of the principal streets &c., are made of various descriptions of materials, according to the kind of stone most readily procured. In London, Aberdeen granite, broken-stone, &c. are used. Wood and asphalte have also been used to a great extent. Courts, stables, kitchens, halls, churches, &c. are paved with tiles, bricks, flags, or fire-stone; sometimes with a kind of free-stone, and rag-stone.

In some cities, as at Venice, the streets, &c. are paved with brick; churches sometimes are paved with marble, and sometimes with mosaic work, as the Church of St. Mark, at Venice. In France, many of the public roads, streets, courts, &c., are paved with *gres*, or *grit*, a kind of free-stone.

In Amsterdam, and the chief cities of Holland, they call their brick pavement the *burgher-master's pavement*, to distinguish it from the stone or flint pavement, which usually takes up the middle of the street, and which serves for carriages; that which borders it being for the passage of people on foot.

The several kinds of pavement are as various as the materials of which they are composed, and whence they derive the name by which they are distinguished; as,

1. *Pebble-paving*, which is done with stones collected from the sea-beach, mostly brought from the islands of Guernsey and Jersey; they are very durable, indeed, the most so of any stone used for this purpose. They are used of various sizes, but those which are from six to nine inches deep are esteemed the most serviceable. When they are about three inches deep, they are denominated *bolders* or *bowlers;* these are used for paving court-yards, and other places not accustomed to receive carriages with heavy weights: when laid in geometrical figures, they have a very pleasing appearance.

2. *Rag paving* was formerly much used in London, but is very inferior to the pebbles; it is dug in the vicinity of Maidstone, in Kent, from whence it has the name of Kentish rag-stone; there are squared stones of this material fo paving coach-tracks and foot-ways.

3. *Purbeck pitchens;* squared stones used in foot-ways they are brought from the island of Purbeck, and als frequently used in court-yards; they are in general from si to ten inches square, and about five inches deep.

4. *Squared paving*, for distinction by some called *Scotc paving*, because the first of the kind paved in the manne that has been, and continues to be paved, came from Scotland the first was a clear close stone, called *blue wynn*, which now disused, because it has been found inferior to other since introduced, in the order they are hereafter placed.

5. *Granite of various kinds*, as:—

First—Guernsey Granite, a very close, hard, and durab stone, exceedingly well adapted for pavement, but subje to become polished, and consequently slippery. It is th kind of slipperiness which, for distinction sake, may called *dry*, as if black-lead had been rubbed upon it.

Second—Heron Granite; not so fine in its grain Guernsey, but very close, hard, and durable. Its defect a tendency to become *greasily* slippery—a very dangerc quality as respects the foot-passengers.

Third—Mount Sorrel Stone. This stone is pronounc by mineralogists to be not a Granite, but a Sienite. I extremely close, hard, and durable, and it has the r quality of neither becoming dryly nor greasily slippery. has all the very best qualifications of good paving-stone, (and it is a drawback of some importance) its intense ha ness makes it brittle under the hammer when be re-dressed.

Fourth—Aberdeen Granite. That which is commo ırmed the Old Blue Aberdeen, is a very fine stone, not so ırk in colour, more brilliant in appearance, almost as close texture, and equally durable, under wear, as the best uernsey stone; but there is sometimes a difficulty in)taining an ample supply for the London market. The ranites from Aberdeen vary much in colour and in texture ren in the same paving-stone, one end being often much inrior to the other.

Fifth—The Tyar Baggar Stone, also from Aberdeen, is dder in colour, and, although beautifully brilliant and close, ıd apparently hard, is decidedly inferior in durability to the ld Blue Aberdeen.

Sixth—The Foggintor Devonshire Granite is not, in its pearance, equal to Aberdeen, but there is an equality and ughness in its composition, which, as far as experience it has gone, leads us to consider it durable and servicele.

Seventh—The Haytor Devonshire Granite, perhaps from eater inequality of texture, has not proved so durable.

Eighth—The White Rock, a Cornish Granite, has worn ceedingly well in some streets of London.

The Cornish Granites are, however, generally too soft for e as paving-stones.

All these stones are less slippery than Guernsey or Hermme.

Ninth—The Budle Stone, from Northumberland, and the st of the Red and the Blue Scotch whinstones, scarcely now ke their appearance. They are very good stones.

An extremely dark-green Whinstone, from near Queensry, has been manufactured into curbstone and paving-stone, t it is decidedly too soft for use, for either purpose. Vari- kinds of limestone, or coarse marble, and ragstones and)bles, are used in provincial places, as they formerly were the streets of London; they are not now sent to the tropolis in any quantity.

. *Purbeck paving*, for footways, is, in general, got in large faces, about two inches and a half thick; the blue sort is hardest and the best of this kind of paving.

. *Yorkshire paving* is an exceedingly good material for same purpose, and is got of almost any dimensions, of the ıe thickness as the Purbeck; this stone will not admit the to pass through it, nor is it affected by the frost.

. *Ryegate*, or *fire-stone paving*, is used for hearths, stoves, ns, and such places as are liable to great heat, which does affect this stone, if kept dry.

. *Newcastle flags*, are stones about two feet square, and and a half or two inches thick; they answer very well paving out-offices; they are somewhat like the Yorke.

0. *Portland paving*, with stone from the island of Portl; this is sometimes ornamented with black marble s.

1. *Sweedland paving*, is a black slate, dug in Leicestere, and looks well for paving halls, or in party-coloured ing.

2. *Marble paving*, is mostly variegated with different rbles, sometimes inlaid in mosaic.

3. *Flat brick paving*, done with brick laid in sand, tar, or grout, as when liquid lime is poured into the ts.

4. *Brick-on-edge paving*, done with bricks laid edgewise he same manner.

5. Bricks are also laid flat or edgewise in herringe.

6. Bricks are also sometimes set endwise in sand, tar, or grout.

7. Paving is also performed with paving-bricks.

18. With ten-inch tiles.

19. With foot tiles.

20. With clinkers, for stables and out-offices.

21. With the bones of animals, for gardens, &c. And,

22. We have nob-paving, with large gravel-stones, for porticoes, garden-seats, &c.

By most writers, common stone pavements are divided into two classes: *rubble* causeway, in which the stones are of irregular shape, and very imperfectly dressed with the hammer; and *aisler* causeway, which is formed of stones of larger size accurately squared and dressed. In both kinds the excellence of the pavement depends greatly on the firmness and evenness of the bed, and the careful fitting of the stones to each other, which may be accomplished with very irregular stones by judicious selection. If one stone be left a little higher or lower than those adjoining it, or if it become so in consequence of defective building, the jolting of carriages in passing over the defective place, will quickly damage the pavement; the wheels acting like a rammer in driving the depressed stones deeper into the earth, while the derangement of the lateral support that each stone should receive from those adjoining it, occasions the dislocation of the pavement to a considerable distance, and the consequent working up of the earth through the disturbed joints. Defective joints form another fruitful source of injury and inconvenience both to the pavement itself and the vehicles jolted over it. If, as is often the case in inferior pavements, the edges of two adjoining stones do not meet with accuracy, narrow wheels will have a tendency to slip into the joint, and by doing so, to wear the edges of the stones, till, as may be frequently seen, the surface of each stone is worn into a convex that renders the footing of horses insecure, and causes the motion of vehicles drawn rapidly over them to consist of a series of bounds or leaps from one stone to another, accompanied by a degree of lateral slipping highly injurious to the carriage, while the irregular percussion produced tends greatly to the destruction of the pavement.

The formation of the bed on which the stones are to rest is of great importance, and various substances, as sand, gravel, broken-stone, &c., have been used by paviours for this purpose; the general introduction of concrete, however, has removed the difficulty formerly experienced, as, by means of this valuable composition, a firm, hard, and dry foundation is easily obtained.

The bed of the pavement should be laid with concrete.

For paving stones, hard rectangular blocks of granite are preferred, though whinstone, limestone, and even free-stone, may be used. Guernsey granite, as we have shown, appears to be the most durable, but it is more liable to become inconveniently smooth than some stones of inferior hardness. The stones may vary according to the traffic, from 6 to 10 inches deep, 6 to 18 inches long, and 4 to 18 inches wide; but it is very essential that the depth of all the blocks in one piece of pavement should be alike, and that where the width is unequal, the stones may be so sorted that all used in one course are uniform in this particular. The accurate dressing of the stones is a point often too little attended to; and an injudicious mode of forming contracts for paving, in which the payment has been by the square yard of paving laid, has, in connection with the effect of competition in bringing prices below the remunerating point, led to the use of stones in which the base is smaller than the upper surface, and which, when laid, scarcely come in contact with each other except at their upper edges. In some pavements the stones are made smaller at the top than at the bottom, the joints being filled up with stone-chips, concrete, or an asphaltic composition; and in those of the more common construction, the sides of the stones are occasionally hollowed, so as to receive a small quantity of gravel or mortar, which serves as a kind of dowelling. Ramming the stones with a heavy wooden rammer is a practice that has been much recommended, and it is considered that a more efficient application of the process, by means of a ramming machine, or *portable monkey*, would remove some of the defects arising from imperfect bedding; but when the stones are well laid, and bedded in strong mortar, as the best recent pavements are, a few blows with a wooden maul, of about fourteen pounds weight, are sufficient to fix them firmly in their place. Grouting with lime-water, poured all over the pavement, facilitates the binding of the whole together, and fills up the joints, so as effectually to prevent the working up of the substratum. The blocks are commonly laid in rows across the road, the joints in each row being different from those of the adjoining ones; but pavements of superior smoothness have been laid in courses stretching diagonally across the street, by which means all the joints are passed over by carriages with greater ease. This arrangement is particularly desirable at the intersection of streets, as it diminishes the risk of horses slipping. Longitudinal courses are objectionable, on account of the tendency of narrow wheels to enter the joints. In paving steep inclinations, it is well to use narrow stones, on account of the number of cross joints; or if large stones be used, to cut deep furrows across their surface, to afford secure footing.

The enormous expense of maintaining some of the great metropolitan thoroughfares, led to the introduction of various plans for paving with wood, asphalte, and other materials. Of these, with the exception of wood, little need be said, as a very short trial of any of them proved that they were not suited to bear the wear of London traffic. Wood-pavement, however, has been tried on so large a scale, and though not equal to broken granite, or a well-paved road, for durability, has yet so many advantages, that some account of it seems necessary. The most primitive descriptionof a wooden road, perhaps, is that known in America by the name of *corduroy road*, consisting of rough logs of timber laid close together across the track, but the wooden pavement, properly so called, seems to have been first used in Russia, and tried on a limited scale at Vienna, New York, and some other places. One of the earliest kind used consisted of blocks of fir or other wood cut in hexagonal cylinders of six or eight inches diameter, and from eight to twelve or fifteen inches deep, and placed close together, with the grain vertically. Such a pavement is smooth when first laid, but, unless the foundation be very carefully prepared, it is liable to sink into hollows like the common stone-pavement, owing to the want of cohesion between the individual blocks, a deficiency which it has been proposed to remedy by pegging or dowelling the pieces together, though their form is not very suitable for the purpose. Of the numerous other plans of wood-paving proposed, but one has been tried on an extensive scale, that of the Metropolitan Patent Wood-Paving Company. The mode of paving by this Company was invented by the Count de Lisle. In this the blocks are sawn into a rhomboidal shape, the upper surface forming an angle of about 65° with the direction of the grain, by which the durability of an end-section is in a great degree preserved, while the inclination of the sides causes each block to receive support from those adjoining it, and affords facilities for pinning the whole paving together by pegs. One course, or transverse row of blocks being laid so that they all incline in one direction, each block has on one side two projecting pegs, and on the other, two holes. The adjoining course is laid in like manner, but sloping in the opposite direction. By this disposition the two pegs on one side of a block enter two distinct blocks in the adjoining row, while the holes on the other side receive in like manner the pegs of two other blocks, so that each block is pinned to four others, besides receiving support from the adjoining blocks of its own course. Where this principle of construction is fully carried out, the whole pavement of a street becomes, as it were, one mass, being so pinned together that no block could be raised without breaking the dowels; but as it is necessary sometimes to disturb the pavement in order to get at the gas and water pipes, the practice of this Company has been to lay down the wood in masses of twenty-four or thirty-six blocks, so united by iron cramps that the blocks, thus connected together, may be laid down and taken up when necessary, at once. This sort of pavement is always laid on a well-formed foundation of concrete, about six inches deep.

Wood-pavement has been laid, to a great extent, in the principal thoroughfares of London, and in many provincial towns. Its undeniable advantages were its smoothness when first laid, producing great ease of draught, quietness, and cleanliness, but, on the other hand, its slipperiness rendered it, in some states of the weather, extremely dangerous to horses. Besides this objection, unless kept in a very high state of repair, it became rough and uneven, and if so kept, its expense was quite equal to a good broken-stone road, and much more so than a well-paved granite road.

The advocates of wood-pavement, however, have been obliged to abandon, in a great measure, its use for the public streets, and from these it is gradually disappearing, though it is still retained, and extensively used, for stables, warehouses, railway stations, &c.; in such places it answers exceedingly well, and is, perhaps, the best description of paving that can be adopted.

Foot-pavements of flag-stones require very little remark. The curb-stones should be very hard, and firmly set in cement, or in a bed of gravel or concrete. They should be set from four to six inches above the surface of the carriage-way, which may be made to abut immediately upon them without the intervention of a gutter. Where gutters are introduced, cast iron ones have sometimes been used; but in our opinion, dressed granite stone channels are to be preferred. The flag-stones, which should never be less than two inches and a half thick, are commonly bedded in mortar in a layer of gravel; but sometimes, when there are no cellars underneath, are laid dry. A slight degree of slope should be given to the pavement, to conduct water to the gutters, for which purpose a fall of one inch in ten feet is sufficient; while a steep inclination is objectionable from its danger in slippery weather. The best material for foot-pavements is Yorkshire stone.

Among the substitutes for common flagstones that hav been recommended, may be mentioned slate, which appear to be very durable. Some pavements or floors of thi material have been laid at the London Docks, where, amon other advantages, it is found preferable to wood in point o cleanliness. Tramways of slate two inches thick are foun strong enough to bear waggons or carts with four or five ton of goods; and some are laid, of only half that thickness, o an old wooden floor.

Several descriptions of asphalte have also been used f footways with various success. The best is that known Claridge's Asphalte of Syssel; this answered extremely we though not equal to Yorkshire stone. It has been us extensively for footways in railway stations and similar sit ations, for which it is well adapted.

PAVEMENT OF TERRACE, that which serves f covering in manner of a platform; whether it be over a va or a wooden floor. Those over vaults are usually of ston

squared and bedded in lead. Those on wood, called by the Latins, *pavimentum contignata*, are either stones with beds for bridges, tiles for ceiling of rooms, or lays of mortar made of cement and lime, with flints or bricks laid flat, as is still practised by eastern and southern nations on the tops of houses. All those pavements which lie open, were called by the Latins, *pavimenta subdialia.*

Pavement, Diamond, those pavements of which the stones, flags, or bricks, are laid with their diagonals parallel and perpendicular to the sides of the apartment.

PAVILION, (French, from the Italian, *padiglione, a tent;* derived from the Latin, *papilio*) in architecture, a kind of turret, or building usually insulated, and contained under a single roof; sometimes square, and sometimes in form of a dome; and thus called from the resemblance of its roof to a tent.

Pavilions are sometimes also projecting parts, in the front of a building, marking their middle. Sometimes the pavilion flanks a corner, in which case it is called *an angular pavilion.* The Louvre is flanked with four pavilions. They are usually higher than the rest of the building.

There are pavilions built in gardens, popularly called *summer-houses*, *pleasure-houses*, &c. Some castles or forts consist only of a single pavilion.

PAUTRE, ANTONY LE, in biography, an eminent French architect, born at Paris in 1614, who distinguished himself by his taste in the decoration of buildings. Several edifices from his designs were erected in the capital and its neighbourhood, of which the most noted were the wings of St. Cloud, the church of the nunnery of Port-Royal, and the hotels of Gevres and Beauvais. He was appointed architect to the king's brother, and afterwards to the king himself. He was a member of the Academy of Architecture from its first institution, and published a work on that art, intitled *Les Œuvres d'Architecture d'Antoine le Pautre*, of which the first edition appeared in 1652. He died in 1691. His son Peter was eminent as a sculptor.

PAX, a small tablet, generally of metal, with a handle used for the *osculum pacis*, or kiss of peace.

PEDESTAL, (from the Latin, *pes, pedis, foot*, and *ςυλος, column*) in architecture, the lowest part of an order of columns; being that which sustains the column, and serves it as a foot to stand on.

The pedestal, called by the Greeks *stylobates*, and *stereobates*, consists of three principal parts: viz., a square trunk, or dye, which makes the body; a cornice, the head; and a base, the foot of the pedestal.

The pedestal is properly an appendage to a column; not an essential part thereof; though M. Le Clerc thinks it is essential to a complete order.

The proportions or ornaments of the pedestal are different in the different orders: Vignola, indeed, and most of the moderns, make the pedestal, and its ornaments, in all the orders, one-third of the height of the column, including the base and capital: but some deviate from this rule.

M. Perrault makes the proportion of the three constituent parts of pedestals the same in all the orders, viz., the base one-fourth of the pedestal; the cornice an eighth part; and the socle, or plinth, of the base, two-thirds of the base itself. The height of the dye is what remains of the whole height of the pedestal.

Pedestal, Tuscan, is the simplest and the lowest of all. Palladio and Scamozzi make it three modules high; Vignola five. Its members, in Vignola, are only a plinth, for a base; the dye; and a talon crowned, for a cornice. This has rarely any base.

Pedestal, Doric, Palladio makes four modules five minutes high; and Vignola, five modules four minutes.

In the antique, we not only do not meet with any pedestals, but even not with any base, in the Doric order.

The members in Vignola's Doric pedestal are the same with those in the Tuscan, with the addition of a mouchette in its cornice.

Pedestal, Ionic, in Vignola and Serlio, is six modules high; in Scamozzi five; in the temple of Fortuna Virilis it is seven modules twelve minutes. Its members and ornaments are mostly the same with those of the Doric, only a little richer. The pedestal now usually followed, is that of Vitruvius, though we do not find it in any work of the antique. Some, in lieu hereof, use the attic base, in imitation of the ancient.

Pedestal, Corinthian, is the richest and most delicate of all. In Vignola it is seven modules high; in Palladio five modules one minute; in Serlio six modules fifteen minutes; in the Coliseum, four modules two minutes.

Its members, in Vignola, are as follow: in the base are a plinth for a socle, over that a tore carved, then a reglet, a gula inverted and enriched, and an astragal. In the dye are a reglet, with a conge over it; and near the cornice a reglet, with a conge underneath. In the cornice is an astragal, a frieze, fillet, astragal, gorge, and a talon. See each under its proper article.

Pedestal, Composite, in Vignola, is of the same height with the Corinthian, viz. seven modules; in Scamozzi six modules two minutes, in Palladio six modules seven minutes, in the Goldsmiths' arch seven modules eight minutes.

Its members, in Vignola, are the same with those of the Corinthian; with this difference, that, whereas these are most of them enriched with carvings in the Corinthian, they are all plain in the Composite. Nor must it be omitted, that there is a difference in the profiles of the base and cornice, in the two orders.

The generality of architects, Daviler observes, use tables, or panels, either in relievo or creux, in the dyes of pedestals, without any regard to the character of the order. Those in relievo, he observes, only fit the Tuscan and Doric; the three others must be indented; but this, he adds, is a thing the ancients never practised, as being contrary to the rules of solidity and strength.

Pedestal, *Square*, that whose height and width are equal; as that of the arch of the lions at Verona, of the Corinthian order; and such some followers of Vitruvius, as Serlio, Philander, &c., have given to their Tuscan orders.

Pedestal, *Double*, that which supports two columns, and is larger in width than height.

Pedestal, *Continued*, that which supports a row of columns without any break or interruption; such is that which sustains the fluted Ionic columns of the palace of the Tuileries, on the side of the garden.

Pedestals or Statues, are those serving to support figures or statues.

Vignola observes there is no part of architecture more arbitrary, and in which more liberty may be taken, than in the pedestals of statues; there being no laws prescribed for them by antiquity, nor any even settled by the moderns.

There is no settled proportion for these pedestals; but the height depends on the situation, and the figure they sustain. Yet, when on the ground, the pedestal is usually two-thirds, or two-fifths, of that of the statue; but always the more massive the statue, the stronger must be the pedestal. Their form, character, &c., are to be extraordinary and ingenious, far from the regularity and simplicity of the pedestals of columns. The same author gives a great variety of forms—oval, triangular, multangular, &c.

PEDIMENT, in architecture, a kind of low pinnacle, serving to crown porticos, or finish a frontispiece; and placed as an ornament over gates, doors, windows, niches, altars, &c.

The pinnacles of the ancient houses, Vitruvius observes, gave architects the first idea of this noble part; which still retains the appearance of its original.

The parts of the pediment are, the tympanum and its cornice. The first is the panel, naked, or area of the pediment, enclosed between the cornice, which crowns it, and the entablature, which serves as a base, or socle.

Architects have taken a great deal of liberty in the form of this member; nor do they vary less as to the proportion of the pediment. The most beautiful, according to Daviler, is that where its height is about one-fifth of the length of its base. The pediment is usually triangular, and sometimes an equilateral triangle; this is also called a *pointed pediment.* Sometimes it is circular; though Pelibien observes, that we have no instances of round pediments in the antique, beside those in the chapels of the Rotunda. Sometimes its upper cornice is divided into three or four sides, or right lines; sometimes the cornice is cut, or open at top, which is an abuse introduced by the moderns, particularly by Michael Angelo. For the design of this part, at least over doors, windows, &c., being chiefly for the purpose of sheltering those underneath from the rain, to leave it open in the middle is evidently to frustrate its end.

Sometimes the pediment is formed of a couple of scrolls or wreaths, like two consoles joined together. *See* CONSOLE.

Sometimes, again, the pediment is without base, or its lower cornice is cut out, all but what is bestowed on two columns, or pilasters, and on these an arch or sweep, raised in lieu of an entablature; of which Serlio gives an instance in the antique, in a Corinthian gate at Foligny, in Umbria; and Daviler, a more modern one, in the church of St. Peter at Rome.

Under this kind of pediments, also come those little arched cornices, which form pediments over doors and windows, supported by two consoles, in lieu either of entablature or columns.

Sometimes the pediment is made double, *i. e.* a less pediment is made in the tympanum of the larger, on account of some projecture in the middle; as in the frontispiece of the church of the great Jesus, at Rome: but this repetition is an abuse in architecture, though authorized by some very good buildings; as may be seen in the large pavilion of the Louvre, where the Caryatides support three pediments, one in another.

Sometimes the tympanum of the pediment is cut out, or left open, to let in light; as we see under the portico of the Capitol, at Rome.

In all the remains of Grecian architecture, the horizontal cornice is never interrupted or broken, nor is there any instance of a circular pediment, nor of any open at the top. The proportion of the tympanum is from one-fifth to one-ninth part of the span, in the pediments which remain of Grecian edifices. In the Doric tetrastyle portico at Athens, the height of the tympanum is about one-seventh part of its triangular base. The portico of the temple of Theseus is hexastyle; and the height of the tympanum of the pediment is about an eighth part of the span of its triangular base. The portico of the temple of Minerva is octostyle; and the height of the triangular tympanum, about one-ninth of its base. So that the higher the pediment, the less is the height in proportion. And thus the pediments of doors and windows ought to be still higher, as is verified in the frontispiece of the entrance-door of the Tower of the Winds, at Athens, where the height of the tympanum is only one-fifth part of the triangular base.

Vitruvius expressly disapproves of the use of dentils, modillions, or mutules, in pediments, for this reason; that as mutules and modillions were the representations of rafters, and dentils the representations of laths, and as these essential parts were always placed in the inclined sides of the roof from the ridge, to overhang the eves, it would certainly have been improper to use mutules, modillions, or dentils, in a situation where the originals themselves never existed.

Arches under pediments, is an abuse in architecture.

PELASGIAN, or CYCLOPEAN ARCHITECTURE. These titles are applied indiscriminately to a class of ancient buildings, to be found in various parts of Greece, which consist principally of walls and fortifications, such as the walls surrounding their acropoles. They are of colossal dimensions, and composed of immense stones, or rather masses of rock, from which circumstance they have obtained the title of Cyclopean, as also because structures of a similar description have been attributed to the labours of the Cyclopes by many of the Greek historians. The erections it is certain are of very early date, and are in all probability of Pelasgic origin, though whether the Pelasgi and Cyclopes are of the same race or not, it would be difficult if not impossible to decide. The Pelasgi, it is well known, were settled in Greece at a very early period, and were spread over the greater part of the country, until the arrival of the Hellenes: it is also very probable that they had emigrated originally from Asia across the Hellespont, and round the northern shores of the Ægean sea. It is true that this is somewhat opposed to the Greek traditions, which make the Peloponnesus the original seat of the Pelasgi; but this is probably but a national boast, and may be classed in the same category as the Athenian claim to the title of *αυτοκθενες*. This matter, however, as well as the whole of the early history of Greece, is involved in great obscurity, and has been the subject of much learned controversy, into which it is not our intention to enter in this place, nor is it at all requisite to the due consideration of the matter before us. There is also a striking similarity in the construction of these edifices, and of those described under CELTIC ARCHITECTURE; but here again it is next to impossible to tell what connection existed between the builders of Stonehenge and those of Argos or Mycenæ, although this circumstance, as well as others, would lead us to suppose that they had a common origin. The investigation of such subjects are interesting, but are attended with great uncertainty. We shall hereafter have occasion to call attention to a particular instance of the similarity existing between buildings of the two classes, which is very remarkable; one of the structures existing in Ireland, the other at Mycenæ.

The Pelasgian buildings are remarkable chiefly, as we have before stated, for the rudeness of their construction, and the enormous dimensions of the stones of which they are composed; indeed, they are little better than piles of rock heaped together, and sustained in their places by their own gravity without the assistance of any cementitious preparation. Mr. Hamilton divides the existing remains into four classes; the earliest and most rude being that in which vast masses of rock were piled one upon the other in the same state as they came to hand, without any squaring or other adaptation for the position they were to occupy. In such masonry, there must have been, of course, apertures of considerable size left between the separate masses, and these were filled up with smaller stones, so as to render the work solid and compact. Of the larger stones, some of the masses are of such vast dimensions, as to contain as much as 216 cubic feet. Of the description are the walls of Tiryns and Mycenæ, although the latter are probably of more recent date than the former, the sides of the stones being somewhat adapted to each other.

In the second method, the stones are somewhat smaller, and are of irregular size and figure, the different stones varying from each other in both respects; but the surfaces of each are adapted to the others with great nicety. It would seem as if the stones, when taken from the quarry, were worked according to the shape in which they happened to be detached from their beds, by reducing the sides to an even surface, but still preserving the general form of the mass. These polygonal stones were generally of seven or eight sides, but sometimes of as many as thirteen; they form a wall of considerable stability and strength.

In the third mode, the stones were laid in horizontal courses, but were of different dimensions, one stone occasionally rising above the level of the adjoining ones, so that the courses were somewhat irregular; the joints, too, were sometimes perpendicular, but at others inclined to the horizon at various angles.

The fourth method comprises walls composed of stones squared on all sides, and of the form of parallelopipedons, layed in regular horizontal courses. In all these methods, the stones were layed dry without any mortar, and yet they are so strong as to have resisted the vicissitudes of three thousand years. Sometimes we find more than one method adopted in the same structure, but this is probably owing to more recent additions or repairs.

Amongst the more noted examples of this mode of building, stand the walls of Tiryns and Mycenæ, and the treasury of Atreus, which we proceed to describe *seriatim;* but we must premise, that we are indebted for the descriptions to the accounts of Stuart and Hughes.

The ruins of Tiryns are probably the oldest and best examples now in existence, and are supposed to have been erected about fourteen centuries B. C. This acropolis is built on a small mount about 50 feet above the level of the plain, and the foundations of the enclosure are still perfect. It had entrances from the east and west, and one at the south-eastern angle. That at the east is still in tolerable preservation, and is approached by an incline, 15 feet wide, along the eastern and southern sides of a tower 20 feet square, and 40 feet high, passing at the end of the second side under a gateway composed of immense blocks of stone; the stone forming the architrave being 10½ feet long. It is thought that there was formerly a triangular stone above the architrave of this portal, forming a kind of pediment; the fragments are now lying on the spot, but without any appearance of having been sculptured. The walls are generally 25 feet thick, and are formed of three parallel ranks of stones, five feet thick, which separate two ranges of galleries in the walls, each five feet broad, and about twelve feet high; the sides of the galleries are formed of two courses of stone, and the covering of other two horizontal courses, which project until they meet.

The roof is pointed when seen from below, the lower surfaces of the stones being cut at an angle of 45 degrees. That part of the gallery which is now uncovered, is about 90 feet long, and has six openings or recesses towards the east, one of which is a kind of window or door, which probably communicated with some exterior building, of which there are still some traces of the foundation in existence; the space between these niches varies from 10 feet 6 inches to 9 feet 8 inches, and the niches themselves are from 5 feet 6 inches to 5 feet 10 inches wide. These galleries probably continued all round the citadel; but they are only accessible at present where the walls are least perfect, at the southern part of the enclosure. They were probably constructed for shelter of the garrison in case of siege, as no loopholes or other apertures open from them into the plain, which would have been the case had they been constructed for any defensive purpose. If the inner gallery received light from the arched area, the exterior must have remained almost dark.

No remains of the south-eastern portal remain: it appears to have been connected with the eastern gate by an avenue enclosed between the outer wall and the inner curtain, yet it is not easy to conjecture the use of this singular place. Others of a similar kind are met with at Argos, and in some other ancient cities of Greece.

The northern point of the hill is less elevated than any other, and its wall is composed of stones of a smaller size than those employed in the galleries. All the exterior walls are composed of rough stones, some of them 9 feet 4 inches in length, and 4 feet thick—their usual size is from 3 to 7 feet. The wall, when entire, must have been about 60 feet high. On the eastern side, the wall has been entirely destroyed, probably by the Argives, about 460 years before Christ, that the city might be left entirely unprotected.

There is a small entrance-gate, in the *pointed* form, 6 feet 1 inch wide, situated in the recess of the western wall; it is defended by a wall projecting in a curve.

The whole length of the citadel is about 660 feet, and the breadth about 180 feet; and the walls are constructed upon a straight line, without any reference to the sinuosities of the rock.

"The Propylæa, or massive portal of the Acropolis of Mycenæ, is one of the most interesting antiquities which time has spared. It is of Cyclopean architecture, constructed with blocks of surprising magnitude, the architrave consisting of a single stone, 15 feet in length, by 4½ in height: two parallel walls, composed of huge masses, piled up in an uncouth manner, which nothing but their size and weight would ever have kept firm, project from the gateway, and form an oblong court about 50 feet deep." "Over the architrave of this portal is one of the most ancient pieces of sculpture existing perhaps in the world; it is cut in high relief upon a triangular stone, the base of which is 11 feet, and the perpendicular height 10, being very similar in appearance to an armorial shield. The subject is an inverted column resting upon a portion of its entablature, between two lions rampant for supporters; each animal stands on a columnar plinth, at equal distances from the pillar, whose inverted pedestal is decorated with a kind of beaded string, consisting of four spherical balls; there is also seen on the frieze of the entablature immediately under the capital of the column, an elliptical excavation, and half the same device appears under each of the plinths on which the lions stand."

To the south of the gate of the lions, the wall of the capital is much ruined. In one part something like a tower is visible, which being perpendicular, while the curtain inclines a little inward from its base, there remained a projection at the top sufficient for an archer to defend the wall below. The blocks of the superstructure are in general of large dimensions, while those of the foundation are considerably smaller.

With the exception of the gates, the whole circuit of the citadel is constructed of rough masses of rock, very accurately adjusted and fitted to each other, though the smaller stones which filled up the interstices have generally disappeared: this style of building has commonly been called Cyclopean. It certainly appears that the walls of the most ancient cities of the Peloponnesus, whether attributed to the Cyclops or not, were of this construction. Tiryns and Mycenæ differ from other acropoles in their galleries and gates, so that perhaps the ponderous method which so nearly resembles the style used by the Egyptians, of which the gate of the lions is the best specimen in Europe, is the real Cyclopean; while the remainder of the circuit is the work of the natives. These fortifications were reputed to be impregnable, and were so in ancient times. At the siege of Mycenæ by the Argives, these warriors found themselves unable to destroy the city, but they forced the inhabitants to surrender through famine. Mycenæ was demolished by the Argives at the time of the destruction of Tiryns; the buildings were overthrown, and the city for nearly 3,000 years has been desolate.

The southern ramparts of the citadel and all the other walls follow the natural irregularity of the precipice on which they are founded. At its eastern point it is attached by a narrow isthmus to the mountain. It is a long, irregular triangle, standing nearly east and west; the walls are mostly constructed of the second style of well-jointed polygons, although the rough construction is occasionally seen.

So small a fortress seems unworthy of the Tirynthian hero; but though the space it occupies is so circumscribed, the walls are truly herculean; their general thickness is 21 feet, in some places they are 25; their present height, in the most perfect part, is 43 feet. In some places there are square projections from the walls, in form of towers; but the projection is very slight: the most perfect of these is at the south-east angle, its breadth is 33 feet, and its height 43 feet.

The construction of the lateral walls is nearly regular, differing from the walls which constitute the peribolus, or boundary, of the acropolis, which are irregular polygons; they are of the hard breccia stone found on the spot, but the block ornamented with the lions resembles in its appearance the green basalt of Egypt. The back or inner part of the gate of the lions is highly interesting, as it exhibits two styles of construction totally differing from each other; that side which is towards the plain of Argos is of the rough Cyclopean masonry, while the other side is regularly constructed like the front of the gate and two lateral walls which diverge from it. It would appear that the gate had been made some time after the original Cyclopean structure. Without presuming to decide whether the regular as well as the irregular or polygonal construction were not sometimes employed at the same period, there are indeed reasons for believing, that while the walls of acropoles, or citadels, and other strong places, were composed of Cyclopean masonry, the temples, sepulchres, and sacred edifices were formed of a more regular construction; as the former were principally adapted to resist the impulse of warlike engines, while the sanctuaries of the gods, and the chambers of the dead, were regarded with reverential awe even by enemies.

A magnificent wall, composed of irregular polygons, closely united and carefully smoothed, supports the terrace on which the gate of the lions is situated.

The area of the acropolis is a long irregular triangle, standing nearly east and west. On the northern side, the declivity also is very steep, and there is a gate which consists of two stones, covered by a third. The opening is 5 feet 11 inches wide at bottom, and 5 feet 4 inches at top. Above the architrave is a large stone approaching the form of a triangle, with which the ruin is about 14 feet high. The gates folded, and were secured by bars. The access to this entrance was by an artificial terrace, which was completely commanded by the wall. A curtain nearly in a right line extends from this gate to that of the lions; and it is very probable that certain holes in the earth above this wall, which are shown by the natives as cisterns, are actually connected with galleries similar to those of Tirynthus. After entering the gate, there was a road, commanded by a wall, which traversed the hill almost to the opposite side before it turned to the summit; so that the acropolis was defended by at least a triple enclosure: on the northern side is a small gate, with its lintel, entire. The structure is so disposed, that those who entered it would have their left arm, which was guarded by the shield, on the side of the acropolis, which is a deviation from the common rule followed in constructing ancient Greek fortresses of all ages. The grooves for the bolts in the jambs of the door are of large dimensions. A deep rocky glen separates the acropolis from the neighbouring hill: there was anciently a bridge over the ravine: one of the side-walls still remains, consisting in well-jointed polygons.

Of the treasury at Atreus, near Mycenæ, which is a very remarkable building, Mr. Hughes gives us the following description, which we would beg the reader to compare with the account of a structure at New Grange, near Drogheda, Ireland, given under CELTIC ARCHITECTURE. It is the opinion of many archæologists that the Titan Celtæ were of the same race as the Cyclops, who built the acropolis of Tiryns.

"Descending down a slope flanked by enormous walls, we arrived at a plain entrance, noble in its simplicity and magnitude; it is 10 feet in breadth by 18 in depth—one of the stones composing the architrave or lintel being a single block, 27 feet long, 16 broad, and 4 deep. Immediately over it is a triangular aperture, which probably contained sculpture appertaining to Egyptian rites; the pyramidal form of the triangle being considered an emblem of the fiery element. The chief apartment of this treasury is a dome, very similar in shape to an English bee-hive, constructed, like the galleries of Tiryns, with large blocks in horizontal courses, each course projecting over the one immediately below it, whilst the interior surface is cut into form by the chisel. The diameter of its area is 47 feet; and at the end of the first quadrant, to the right of the entrance, is a passage leading into an inner room, about 27 feet by 20 in dimensions, the walls of which are not lined with any kind of masonry. This vault, near 50 feet high, is finished at the top by a single stone, like the treasury of Minyas, at Orchomenos; however, it is not a key-stone, for the principle of the arch is unapplied to this peculiar mode of construction. The inner surfaces of the blocks are pierced with holes, from whence many bronze nails have been extracted, which are supposed, not without probability, to have fastened plates of that metal over the interior surface of the edifice, as at the Pantheon, Rome."

The approach to the treasury is 20 feet in width. The blocks of stone composing the larger chamber are laid in regular courses, of which there are thirty-four visible, each course being about two feet in thickness. The stones, however, are not all of equal dimensions, but are united with the greatest precision, and without the aid of cement; they are composed of the hard and beautiful breccia of which the neighbouring rocks almost entirely consist. The entrance to the inner chamber is $9\frac{1}{2}$ feet high, 4 feet 7 inches wide at the base, and 4 feet 3 inches at top: it has also a triangular cavity above, similar to that over the larger chamber. These triangular spaces have been thought by some to be a rude method of relieving the centre of the lintel stone, and throwing the weight upon its ends; but others suppose them to have some mystical allusion, which is not improbable.

Various other examples besides those just described s

PENDENTIVE CRADLING.

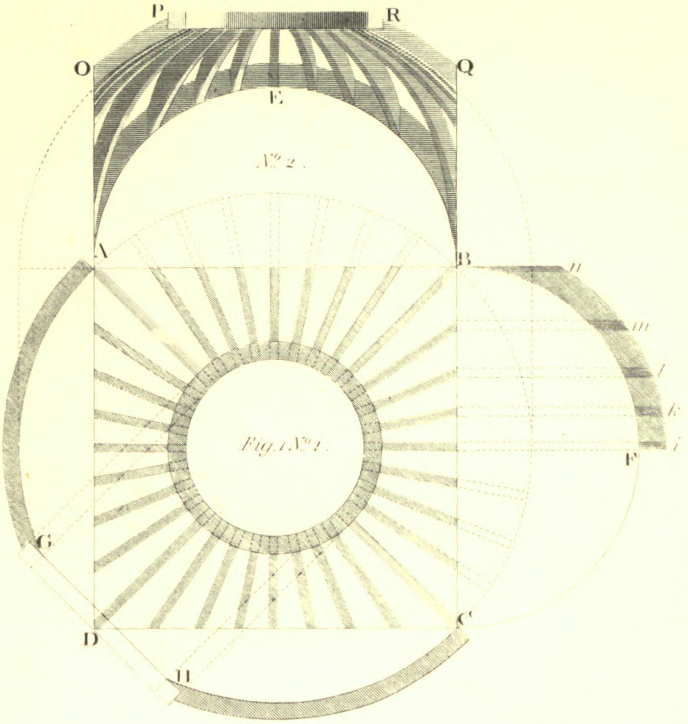

Fig. 2.

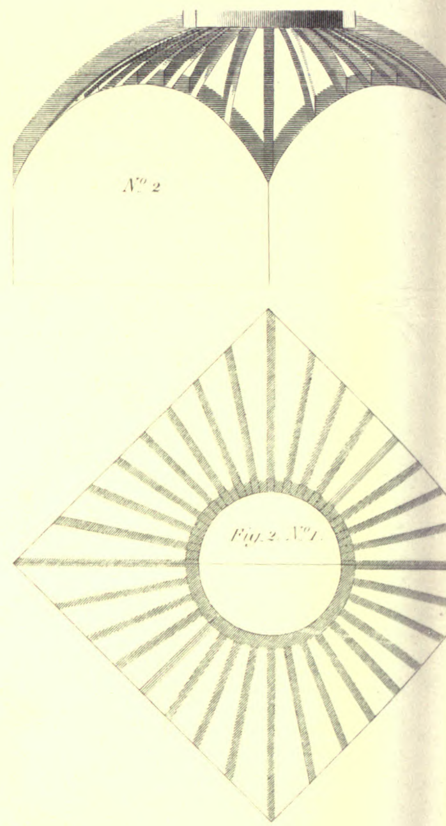
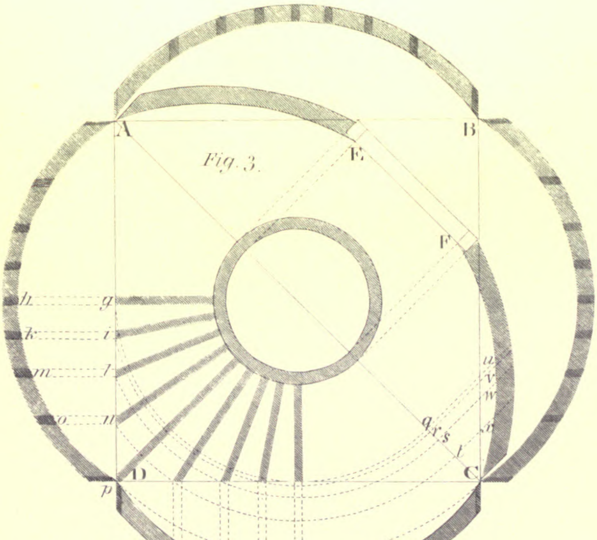
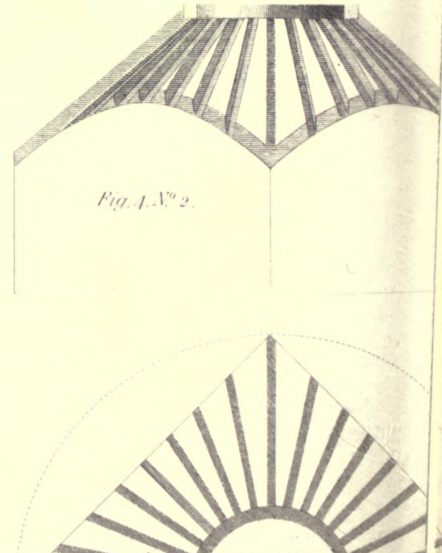
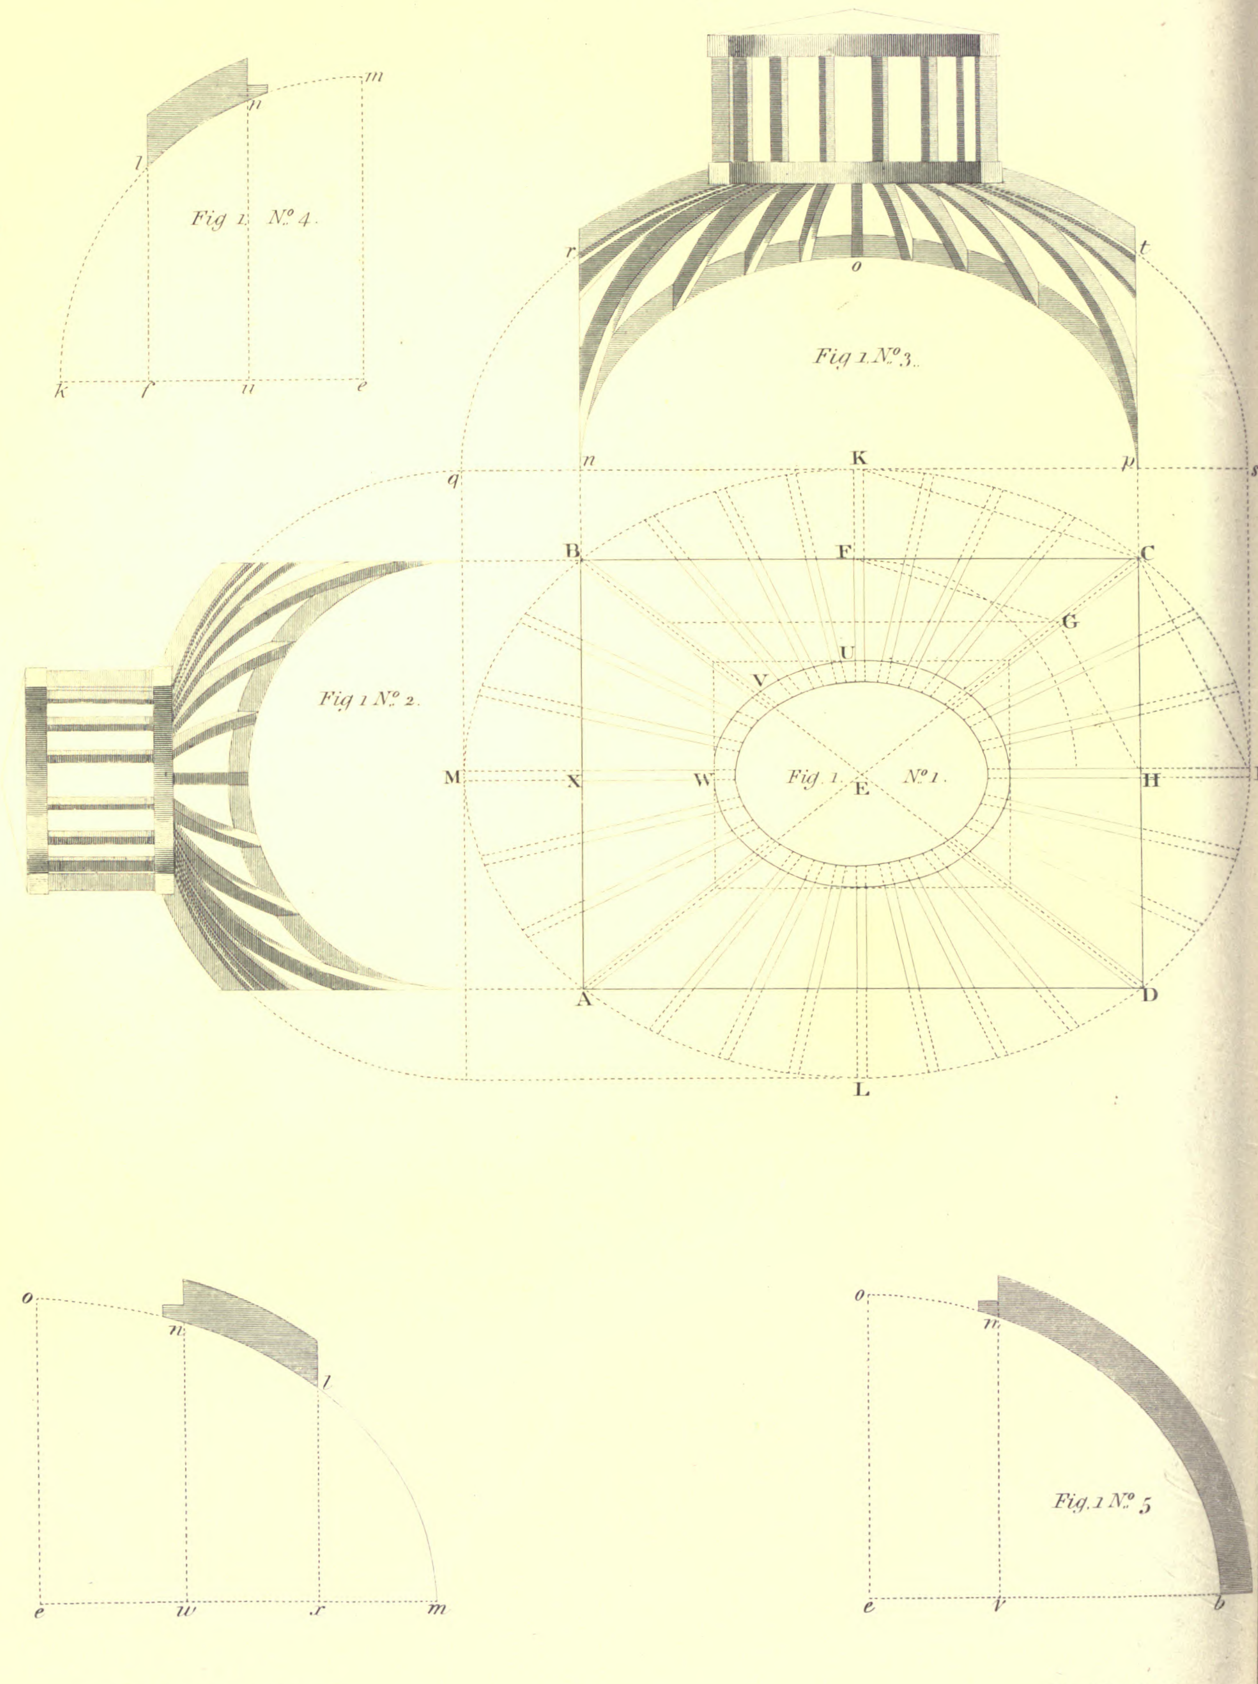






Invented & Drawn by P. Nicholson.

PENDENTIVE CRADLING.



Invented & drawn by P. Nicholson

Eng.d by R. Thew.

remain in various parts of Greece, in Bœotia, Attica, Argolis, and Phocis; also at Julis and Delphi; but the above will probably give a sufficiently explicit idea of their general character.

PELECOIDES, (from the Greek πελεκυς, *a hatchet*, and ειδος, *form*) a figure in the form of a hatchet. Such is the figure B C D A, contained under the inverted quadrantal arcs A B and A D, and the semicircle B C D.

The area of the pelecoides is demonstrated to be equal to the square A C; and that, again, to the rectangle E B. It is equal to the square A C, because it wants, of the square on the left hand, the two segments A B, and A D, which are equal to the two segments B C and C D, by which it exceeds on the right hand.

PEND, a vaulted roof without groining.

PENDENT, or Philosophical Bridge, a wooden bridge supported by posts and pillars, and sustained only by butments at the ends. *See* Bridge.

Pendent, an ornament not uncommon in the vaulted roofs of the late or perpendicular period of Gothic architecture. It consists of a boss of foliage, or other ornament, suspended from the summit of the vaulting at the end of ribs, which, converging from the soffit of the roof, meet at a point below, which is covered with the boss alluded to. Beautiful examples exist at Henry VII.'s chapel, Westminster.

Ornaments of a similar description occur also in the timber roofs of the same date, as likewise attached to the ends of the hammer-beams, or to the extremities of the ridge-pieces of a roof, to receive the ends of the barge-boards.

PENDENTIVE, in architecture, the whole body of a vault, suspended out of the perpendicular of the walls, and bearing against the arc-boutants.

Daviler defines it a portion of a vault between the arches of a dome, usually enriched with sculpture. Felibien, the main of the vault contained between the double arches, the forming arches, and the ogives.

The pendentives are usually of brick, or soft stone; and care must be taken that the joints of the masonry be always laid level, and in right lines proceeding from the sweep whence the rise is taken.

The joints, too, must be made as small as possible, to save the necessity of filling them up with slips of wood, or using much mortar.

Pendentive Bracketing, a cove bracketing, springing from the rectangular walls of an apartment upwards to the ceiling, so as to form the horizontal part of the ceiling into a complete circle, or ellipsis.

The proper criterion for such bracketing is, that if the walls are cut by horizontal planes through the coved parts, the sections through such parts will be portions of circles, or portions of ellipses, having their axes proportional to the sides of the apartment, so that each section will be a compound figure. Besides having four curvilinear parts, it will have four other parts, which are portions of the sides of the rectangular apartment; and the axis of the ellipsis will bisect each side of the rectangle.

Pendentive Cradling. The surface to be formed may be thus conceived. Let a square be inscribed within the circumference of the base of a hemisphere, and let the hemisphere be cut by four planes through the sides of the square, perpendicular to the plane of the base; then let this hemisphere be again cut by another plane parallel to the plane of the base, to touch the section of the four parts cut off; the surface of the remaining solid will then consist of a portion of the hemisphere, one entire circle, and four equal semicircles, each at right angles to the entire great circle. Therefore, if the ribs be fixed in planes passing through the axis of the sphere, and the two ribs, which stand upon the diagonals, will be entire semicircles; or, if a dome be perforated by a cylindric surface, of which the axis is that of the dome, the ribs will still have the same position at any springing, which is one of the semicircular arches.

Plate I. *Figure* 1.—The representation of the pendentive cradling of a dome. No. 1, A B C D, the plan; B F C the springing-line of a semicircular form, described on the diameter, B C. The shaded parts, at *i*, *k*, *l*, *m*, *n*, mark the places for the feet of the ribs to stand upon. G, H, sections of the curb, No. 2. The elevation, O P and Q R, the shortest ribs used; of these, there are four each, standing in the middle.

Figure 2. No. 1, 2.—Plan and elevation, representing the pendentive cradling of a dome.

Figure 3.—The geometrical construction of the pendentive cradling of a segment dome. This figure shows the portions of the ribs that must be used in the construction of the carpentry: thus, C *u*, C *v*, C *w*, C *x*, are the ribs which every eighth-part of the plan requires.

Figure 4. No. 1, 2.—The plan and elevation of the pendentive cradling of a cone.

Plate 2. *Figure* 1.—Plans, sections, and ribs of pendentive cradling.

To construct this cradling, let A B C D, No. 1, be the plan, which is an oblong figure. We must find the circumscribing plan of the spheroid, so that the length and breadth shall be in the same ratio as the two dimensions of the plan. For this purpose, draw the diagonals, A C and B D, cutting each other in E. Through the centre E, draw M I parallel to B C, or A D, cutting the plan at X and H; also, through E draw K L, parallel to B A, or C D, cutting the side B C, at F. From the centre, E, describe a quadrant, to touch the side of the plan at F, so that the portion of the circumference may be contained between K E and I E; bisect the arc, and through the point of bisection, draw a line parallel to B C, or any of its parallels, cutting the diagonal, A C, in G; join F G and G H, and draw C K and C I respectively parallel to G F and G H; make E L equal to E K, and E M equal to E I; then about the two axes, M I and K I, describe an ellipsis, which will be the base of the spheroid that will form the surface for the ribs.

When the plane of th figure to be covered is square, draw the seats of the ribs as in preceding examples. Also, draw the kirb for the skylight in the same proportion as the sides of the plan: then the rib which stands upon F U will be the portion of the quadrant of a circle, described with the radius E K, as at No. 4, where *e k*, No. 4, answers to E K, No. 1; *k f* to K F; and *f u* to F U; then, by drawing the perpendicular, *f l* and *u n*, No. 4, to cut the quadrant, *k m*, at *l* and *n*, *l n* will show the portion of the curve which will form the complete edge of the rib to cover the part F U.

Take half the transverse axis, M E, No. 1, and apply it in the straight line, *m e*, the left-hand figure at the bottom; draw *e o* perpendicular to *m e*, and make *e o* equal E K, No. 1; describe the quadrant of an ellipsis, *o n l m*; make *m x*, *x w*, respectively, equal to M X, X W, No. 1, draw the perpendiculars, *w n* and *x l*, then the portion of the ellipsis, intersected at *n* and *l*, will be the edge of the rib to cover X W on the plan.

In like manner *b n*, No. 5, is the edge of the ribs to cover the half of either diagonal, A C or B D.

No. 2, the transverse section and elevation.

No. 3, the longitudinal section and elevation, showing how the ribs are to be fixed.

PENETRALE, the most sacred chamber of a heathen temple.

PENETRALIA, chapels in Roman houses, in which the females or household gods were placed.

PENITENTIARY HOUSE. *See* Prison.

PENSTOCK, in engineering, a gate employed for ponding back-water; it works up vertically in a grooved frame.

PENTADORON, a Roman brick, whose length measures five palms. *See* Brick.

PENTAGON (from the Greek πενταγονος, *quinquangulus*, compounded of πεντε, *five*, and γωνια, *an angle*) in geometry, a figure of five sides and five angles.

If the five sides are equal, the angles are so too; and the figure is called a *regular pentagon*. Most citadels are regular pentagons.

The most considerable property of a pentagon is, that one of its sides, for example, D E, is equal in power to the sides of a hexagon and a decagon inscribed in the same circle, A B C D E; that is, the square of the side D E is equal to the sum of the squares of the sides D *a* and D *b*.

A pentagon, and also a decagon, may be inscribed in a circle, by drawing the two diameters, A P, *m n*, perpendicular to each other, and bisecting the radius *o n* at *q*. With the centre *q*, and distance *q* A, describe the arc A *r*; and with the centre A, and radius A *r*, describe the arc *r* B; then A B is one-fifth of the circumference; and A B, carried five times over, will form the pentagon; and the arc A B bisected in *s*, will give A *s*, the tenth-part of the circumference, or the side of the decagon.

If tangents be drawn through the angular points, they will form the circumscribing pentagon, or decagon. *See* Polygon, and Regular Figure.

Pappus has also demonstrated, that twelve regular pentagons contain more than twenty triangles inscribed in the same circle, lib. v. probl. 45.

The dodecahedron, which is the fourth regular body, consists of twelve pentagons.

PENTAGRAPH, or more correctly Pantagraph, or Parallelogram, an instrument for copying plans, maps, designs, &c., with expedition, even by a person unskilled in the art of drawing.

This instrument consists of four brass or wooden rulers, in the form of a parallelogram, with moveable joints at the angles; two of the rulers are extended beyond the parallelogram, one for the purpose of carrying a fixed socket, called C, with a metal tracer, in order to trace over the outlines of the original drawing or print; and the other, called B, for carrying a moveable socket; also called B, with a pencil, in order to trace out a drawing similar to the original. The parts, B and C, of the rulers thus extended, being upon the same side of one of the diagonals, the side of the parallelogram, called D, which adjoins the ruler with the moveable socket, has another moveable socket, also called D, in order to insert a vertical pin, which is fixed in a flat piece of lead; both of the moveable sockets, B and D, are clamped by means of a screw. As the metal tracer, C, the pin in the socket D, and the pencil in the socket B, are cylindrical, in fixing the instrument, the axes of the three cylinders must be set all in the same plane, and they will remain so throughout every movement of the instrument.

The pins which fasten the parallelogram at the angles being also vertical cylinders to the plane of the instrument, the axis of the metal tracing point, in the socket C, and those of the two pins in the sockets of B and D, must be in the same plane; also, the axis of the pin, in the socket D, and those of the ruler D at the joints, must also be in a plane. In order to make the movement of the instrument easy, it is provided with casters, or rollers, each of which turns on an axis in the same line with the axis at the joints or angles.

The extended part of the ruler B, on which the socket and pencil are carried, has several graduations, or divisions, which show the proportion of the drawing to be made to the original and thus calling the centre of the joint connecting the extended bars, the *apex of the instrument*, the first division on the extended part, B, is equally distant from the apex with the axis of the tracing point on the other extended part, C; and the ruler, D, which has the steel pin, has a corresponding division, exactly opposite the vertex, when the extended rulers, B and C, are brought into a straight line, and, consequently, the instrument is divided thereby into two equal parts; and thus it becomes necessary to have the two opposite sides of the parallelogram, which has the side marked D, longer than the other two sides, one of which has the extended part B.

The divisions upon the extended part, B, being fixed upon, and numbered from 1-1, 1-2, 1-3, 1-4, to 1-12; that is, 1, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, &c., towards the vertex, the other divisions upon the side of the parallelogram, D, are marked with corresponding figures, 1-1, 1-2, 1-3, &c., in such a manner, that when the extended sides are brought into a straight line, the division marked 1-2, on the side D, divides the instrument into three equal parts, from the division 1-2 on B, to the point C, on the axis of the tracing point on the other extended leg, C; and thus the distance from 1-2, on the side D, to 1-2 on the side B, will be half the distance between 1-2 on the side D and the point C, on the extended part C.

In like manner, the division marked 1-3, on the side D, divides the instrument into four equal parts, from 1-3 on B, to the tracer on C; and thus 1-3 on D will be distant from 1-3 on B, and one-third of the distance from 1-3 on D to the axis of the tracer on C.

The other proportions are found in a similar manner.

The fiducial edges of the clamps, which carry the socket for the steel pin, and the socket for holding the pencil, cross the rulers, to which they are attached, at right angles, and would, if produced, cut the axis of the cylindrical socket in each of the said rulers. The upper part of the cylindrical case, which holds the pencil, is provided with a cup, to contain shot, or a small weight, in order to make the pencil press sufficiently, so as to mark the paper. In order to prevent the pencil from tracing the same path it has already described a silk thread, or catgut string, connected with the pencil, passes through an eye at the vertex, returns to the hand of the operator, and being drawn tight, raises the pencil from the paper.

To use the instrument, suppose the drawing required to be one-half of the original; set the fiducial edge of the clamp B upon 1-2 in the extended part B, and the fiducial edge of the clamp D, upon 1-2 of the ruler D; slide the socket D upon the pin fixed into the lead weight, then having adjusted the original drawing, or print, under the tracer, and the paper under the pencil, trace over all the lines of the original, and the pencil at the remote extremity will trace out a similar figure.

Again, let us take another example: suppose the drawing required to be one-third of the original; set the fiducial edge of the clamp B upon 1-3 in the extended part B, and the fiducial edge of the clamp D upon 1-3 of the ruler D; slide the socket D upon the pin fixed into the leaden weight, then proceed as before. In the same manner the drawing may be reduced to $\frac{1}{4}$, $\frac{1}{5}$, &c. of the lineal dimensions, as shown by the graduations: but if any intermediate proportion is required, as between a third and a fourth; bring the fiducial edge of the clamp B to the intermediate point, and the fiducial edge of the clamp D in a straight line, then proceed as above. On the contrary, should it be required to enlarge the drawing, it is only necessary to change the pencil in the socket tube of the clamp B, for that of the metal tracer, and paper for the original, and proceed as before.

PENTASTYLE, (from πεντε, *five*, and στυλος, *a column*) . architecture, a work containing five rows of columns.

The portico begun by the emperor Gallienus, and which as to have been continued from the Flaminian-gate to the idge Milvius, *i. e.* from the Porto del Popolo to the Porte ole, was a pentastyle.

PENT-HOUSE, an open shed or projection placed over door, window, clock, statue, &c., to project them from e weather.

Pent-Roof, a roof consisting of two equally inclined sides eeting in a common apex, the former being that of a iangular prism.

PERAMBULATOR, (from the Latin, *perambulo*, to avel) an instrument for the measuring of distances, and in equent use for measuring distances on roads, for settling sputes concerning the charges of the drivers of hackney-rriages, and for other purposes. It consists principally of wheel, upon which it runs, and an index which shows the umber of turns of such wheel, reduced into miles, furlongs, les, and yards.

The carriage or stock is made of wood, and is about 3 et long. At one end is a handle for the person who uses and the other is furnished with sockets in which the axle the wheel turns; this end of the stock has the centre rt removed, by which are left two arms between which e wheel works. Upon the stock, and just in front of the ndle, is the dial-plate, with its two hands by which the stance is registered. The wheel is 8 feet 3 inches, or $\frac{1}{2}$ le in circumference. Upon one end of the axis of this eel is a small pinion, which works into a smaller pinion at e end of a rod, which passes up the stock or carriage to the rks beneath the dial-plate. Motion is communicated by eans of this rod to a worm or micrometer screw, which ras once round for each revolution of the carriage-wheel of e perambulator. This worm works into a wheel of 80 eth, which is moved forward one tooth for every $\frac{1}{2}$ pole, d carries a hand or index, which makes one revolution for poles or one furlong. On the axis of this wheel, is a ion of 8 teeth, which works into a wheel of 40 teeth, and the axis of this second wheel is a pinion of 10 teeth, ich moves a wheel of 160 teeth. This last wheel carries other hand, which makes one revolution for 80 of the mer. These hands are arranged in the same manner as hour and minute hand of a watch, so that the three cir-s on the dial-plate are all concentric. The first of these cles is divided into 220, and the second into 40, the number yards and poles contained in a furlong; the figures in these cles are read off by the first mentioned index, that which ttached to the wheel of 80 teeth. The third circle is ided into 80, the number of furlongs in 10 miles, and to s circle belongs the index attached to the wheel of 160 th. The distance is ascertained by reading off the figures the reverse order in which the circles are given above; ide the number on the first circle by 8, and you will e the distance required in miles, furlongs, poles, and yards. e instrument is furnished with a stop or strap, so that after distance is measured, the perambulator may be conveyed hout the index being altered.

Unlike the pedometer, it requires no regulating, and the y risk of its giving the distance incorrectly, if well con-ucted, is passing over rugged and uneven roads, which will course cause the index to show more than the true distance. general, however, for short distances, this error is very ling.

When about to commence a measurement, the wheel should turned round until the first mentioned index points to 220 the circle of yards. Some are provided with a click and racket, by which this may be done with much less trouble than by the wheel.

There are other instruments for the same or similar purposes, bearing different names, as *waywiser* and *odometer*, but the construction of all of them is very similar.

Waywiser is the name generally given to that form of the instrument which is applied to a carriage, in which, by a slight adaptation to one of the wheels of the carriage, the instrument is made to register the number of turns of such wheel, in the same manner as the perambulator.

PERCH, in land-measure, the 40th part of a square rood, containing $30\frac{1}{4}$ square yards; also used as a measure of length, being equal to $5\frac{1}{2}$ yards, or $16\frac{1}{2}$ feet, called otherwise a rod or pole.

Perch, a bracket or corbel, a small projecting beam near the altar of a church.

PERCLOSE. *See* Parclose.

PERIBOLUS, the enclosure surrounding a Grecian temple, which frequently contained a grove, and was adorned with altars, statues, &c.

PERIDROME, Peridromus, in ancient architecture, the space, or an aisle in a periptere, between the columns and the wall.

Salmasius observes, that the peridromes served for walks among the Greeks.

PERIMETER, (from the Greek περι, *about*, and περιφερω, *measure*) in geometry, the ambit or extent that bounds a figure or body.

The perimeters of surfaces, or figures, are lines; those of bodies are surfaces.

In circular figures, &c., instead of perimeter, we say *circumference*, or *periphery*.

PERIPHERY, (from the Greek περιφερω, *I surround*, or περι, *about*, and φερω, *I bear*, or *carry*) in geometry, the circumference or bounding line of a circle, ellipsis, parabola, or other regular curvilinear figure.

The periphery of every circle is supposed to be divided into three hundred and sixty degrees; which are again subdivided, each into sixty minutes, the minutes into seconds, &c.

The division of degrees, therefore, are fractions, whose denominators proceed in a sexigesimal ratio; as the minute $\frac{1}{60}$, second $\frac{1}{3600}$, third $\frac{1}{216000}$. *See* Sexigesimal.

But these denominators being troublesome, in their stead are used the indices of their logarithms; hence the degree, being the integer, or unit, is marked by °, the minute by ′, second by ″, &c. *See* Circle.

PERIPTERE, (from the Greek περιπτερος, formed of περι, *about*, and πτερων, *wing*, winged on every side) in ancient architecture, a building encompassed on the outside with a series of insulated columns, forming a kind of aisle, or portico, all round. Such were the basilica of Antonine, the septizon of Severus, the portico of Pompey, &c.

Peripteres were properly temples with columns on all the four sides, by which they were distinguished from prostyles and amphiprostyles, the one of which had no columns before, and the other none on the sides.

M. Perrault observes, that periptere, in its general sense, includes all the species of temples which have porticos of columns all round, whether the column be diptere, or pseudo-diptere, or simple periptere; which is a species that bears the name of the genus, and has its columns distant from the wall by the breadth of an intercolumniation. For the difference between periptere and peristyle. *See* Peristyle.

PERIPTERAL, surrounded by a periptere or continuous colonnade; the term is applied to a class of temples which answers to this description.

PERIRRANTERION, (from the Greek *περι, about,* and *ραινω, to sprinkle,*) lustral vases placed at the entrances of heathen temples, in which the priests washed their hands, and with which they sprinkled their worshippers.

PERISTYLE, (from the Greek *περιςυλος*, formed from *περι, about,* and *ςυλος, column,*) in ancient architecture, a place or building, encompassed with a row of columns on the inside; by which it is distinguished from the periptere, where the columns are disposed on the outside. Such was the hypæthral temple of Vitruvius, and such are now some basilicas in Rome, several places in Italy, and most cloisters of religious houses.

PERISTYLE is also used by modern writers for a range of columns, either within or without a building: thus we say, the Corinthian peristyle of the portal of the Louvre, &c.

PERISTYLION, (from the Greek *περιςυλιον,*) among the Athenians, a large square place, though sometimes oblong, in the middle of the gymnasium, designed for walking, and the performance of those exercises which were not peculiar to the palæstra.

PERISTYLIUM, a continued row or series of rows of columns all round a court or building, in contradistinction to porticos, in which the pillars do not surround a space, but are arranged in one or more parallel lines.

PERITHERIDES, the same as ANCONES.

PERITROCHIUM, (from *περι, about,* and *τροκιλος, a circle,*) in mechanics, a wheel, or circle, concentric with the base of a cylinder, and moveable together with it, about an axis. The axis, with the wheel and levers fixed in it, to move it, constitutes that mechanical power called *axis in peritrochio.*

PERPENDICULAR, (from the Latin *perpendicularis,*) in geometry, a line falling directly on another line, so as to make equal angles on each side; called also a *normal line.*

From the very notion of a perpendicular, it follows:—

1. That the perpendicularity is mutual; *i. e.*, if a line, as I O, be perpendicular to another, K H; that other is also perpendicular to the first.

2. That only one perpendicular can be drawn from one point in the same plane.

3. That if a perpendicular be continued through the line to which it was drawn perpendicular, the continuation will also be perpendicular to it.

4. That if there be two points of a right line, each of which is at an equal perpendicular distance from two points of another right line, the two lines are parallel to each other.

5. That two right lines perpendicular to one and the same line, are parallel to each other.

6. That a line, which is perpendicular to another, is also perpendicular to all the parallels of the other.

7. That perpendiculars to one of two parallel lines, terminated by those lines, are equal to each other.

8. That a perpendicular line is the shortest of all those which can be drawn from the same point to the same right line.

Hence the distance of a point from a line, is a right line drawn from the point perpendicular to the line or plane; and hence the altitude of a figure is a perpendicular let fall from the vertex to the base.

Perpendiculars are best described in practice by means of a square; one of whose legs is applied along that line, to or from which the perpendicular is to be let fall or raised.

A line is said to be perpendicular to a plane, when it is perpendicular to all right lines, that can be drawn in that plane, from the point on which it insists.

A plane is said to be perpendicular to another plane, when all right lines drawn in the one, perpendicular to the common section, are perpendicular to the other.

If a right line be perpendicular to two other right lines intersecting each other at the common section, it will be perpendicular to the plane passing by those two lines.

Two right lines perpendicular to the same plane are parallel to each other.

If, of two parallel right lines, the one is perpendicular to any plane, the other must also be perpendicular to such plane.

If a right line be perpendicular to a plane, any plane passing by that line will be perpendicular to the same plane.

Planes, to which one and the same right line is perpendicular, are parallel to each other: hence all right lines perpendicular to one of two parallel planes, are also perpendicular to the other.

If two planes, cutting each other, be both perpendicular to a third plane, their common section will also be perpendicular to the same plane.

PERPENDICULAR TO A CURVE, is a right line cutting the curve in the point in which any other right line touches it, and is also itself perpendicular to that tangent.

PERPENT-STONE, a long stone reaching right through a wall; a bond or thorough-stone.

PERPEYN-WALL, a projecting pier, buttress, or other support employed to sustain a beam or other weight.

PERRAULT, CLAUDE, an eminent architect, born at Paris in 1613. He was brought up to the medical profession, and took his degree as doctor of the faculty of Paris in 1641. He practised little, however, excepting among his friends and the poor; and having a decided taste for drawing and the fine arts, he turned his attention to the science of architecture, in which he became greatly distinguished. When the Academy of Sciences was founded, under the patronage of Colbert, in the year 1666, Perrault, who was one of the first members, was appointed to select a spot for an observatory; and he also gave a plan of the building which was to be executed. When it was resolved, under Louis XIV., to proceed in completing the palace of the Louvre, all the eminent architects were invited to give in designs of the façade; and that of Perrault was preferred. This is accounted the masterpiece of French architecture, and it would alone suffice to transmit his name with honour to posterity. It was in vain that persons, jealous of his reputation, endeavoured to make the public believe that the real designer was Le Veau; they entirely failed in their proof, and the glory of Perrault remained untarnished. When Colbert, after the king's first conquests, proposed to construct a grand triumphal arch to his honour, Perrault's design had the preference, and the edifice was commenced. It was, however, never finished. In its masonry, Perrault employed the practice of the ancients, of rubbing the surface of the stones together with grit and water, so as to make them cohere without mortar. Other works of this architect were, the chapel at Sceaux, that of Notre Dame, the church of the Petits Pères in Paris, the water-alley at Versailles, and most of the designs of the vases in the park of that palace. By the king's command, he undertook a translation of Vitruvius, with notes, published in 1673. All the designs for the plates of this work were drawn by himself, and have been esteemed as master-pieces of the kind. He afterwards published an abridgement of that author, for the use of students. He likewise facilitated the study of architecture by a work entitled *Ordonnance de Cinq Espèces de Colonnes selon la Méthode des Anciens.* In the preface to this work, he maintains that there is no natural foundation for the architectural proportions; but that they may be infinitely varied, according to taste and fancy—a opinion which gave much offence, though justified by the practice of the ancients themselves. A collection of the drawings of several machines, which he at different times invented, was published after his death in 4to. This excellent artist holds a respectable place among writers in his original profession, and, besides various memoirs on this subject, communicated to the Academy of Sciences, he published *Memoirs pour serviràl' Histoire Naturelle des Animaux*, in 2 vols. His other writings of this class are contained in his *Essais de Physique*, 4 vols. One of these volumes relates entirely to the organ of hearing, under the title of *Traité de Bruit.* Another relates to the mechanism of animals, in which he anticipated Stahl in some of his opinions respecting the functions of the animal soul. In other parts of these essays, he treats on the peristaltic motion of the intestines,—on the senses,—on nutrition, &c. He died in Paris in 1688, aged 75.

Perrault published a *Dissertation upon the Music of the Ancients*, in 1680. He had, indeed, given his opinion upon the subject very freely, in the notes to his translation of Vitruvius, in 1673; where, in his commentary of the chapter upon *Harmonic Music according to the doctrine of Aristoxenus*, he declares that "there is nothing in Aristoxenus, who was the first that wrote upon concords and discords, nor in any of the Greek authors who wrote after him, that manifests the ancients to have had the least idea of the use of concords in music of many parts."

PERRON, (French), in architecture, a staircase lying open, or withoutside the building; properly the steps before the front of the building, leading into the first story, when raised to a little above the level of the ground. Perrons are of different forms and sizes, according to the space and height they are to lead to. Sometimes the steps are round, or oval; more usually they are square.

PERRONET, JOHN RODOLPHUS, director of the bridges and roads of France, born in 1708. He was brought up to the profession of architecture in the city of Paris, and made great progress in the art. In 1745, he became inspector of the school of engineers, of which he was afterwards a director. France is indebted to him for several of its finest bridges and best roads, the canal of Burgundy, and other great works. He was, for his public services, honoured with the order of St. Michael, and admitted a member of the Academy of Sciences at Paris, of the Royal Society of London, and of the Academy of Stockholm. He died at Paris in 1794. He wrote a *Description of the Bridges* which he had constructed, 2 vols. 12mo.; and *Memoirs on the Method of constructing Grand Arches of Stone from* 200 *to* 500 *Feet in span.*

PERSEPOLIS, a town of Persia, formerly called Elymaïs, now known only by its ruins and monuments, which have been described by many travellers, from Chardin to Niebuhr and Franklin. They are situated at the bottom of a mountain, fronting the south-west, about 40 miles to the north of Shirauz. They command a view of the extensive plain of Merdasht; and the mountain of Rehumut encircles them, in the form of an amphitheatre. Here are many inscriptions, in a character not yet explained; but which Niebuhr seems to have represented with great accuracy. The letters somewhat resemble nails, disposed in various directions, in which singularity they approach to what are called the *Helsing Runes* of Scandinavia, but the form and disposition seem more complex. Behind the ruin, to the north, is a curious apartment cut in the solid rock, and a subterraneous passage, apparently carried to a very considerable extent. Situated about three miles and a half to the north-east of these ruins is the tomb of Rustan, the ancient Persian hero. The temple, or palace, at Persepolis, now called *the throne of Jemshid*, is supposed to have been erected in the time of Jemshid, and to have been posterior to the reign of the Hindoo monarchs. The figures at Persepolis differ from those of Elephanta, which are manifestly Hindoo; and Sir William Jones conjectures that they are Sabian, which conjecture is confirmed by a circumstance, which he believes to have been a fact, *viz.*, that the *Takhti Jemshid* was erected after the time of Cayúmers, when the Brahmans had migrated from Irán, and when their intricate mythology had been superseded by the simpler adoration of the planets and of fire. Chardin, who observed the inscriptions on these ancient monuments on the spot, observes, that they bear no resemblance whatever to the letters used by the Guebres, in their copies of the Vendidád; whence Sir William Jones inferred that the Zend letters were a modern invention; and in an amicable debate with a friend named Bahman, that friend insisted that the letters, to which he had alluded, and which he had often seen, were monumental characters, never used in books, and intended either to conceal some religious mysteries from the vulgar, or to display the art of the sculptor, like the embellished Cúfick and Nágari on several Arabian and Indian monuments. *See* NEXT ARTICLE.

PERSIAN or PERSEPOLITAN ARCHITECTURE, is that style of building employed by the ancient Persians; it is called Persepolitan from Persepolis, the capital of Persia, where also are found the principal remains of this style. The Persian architecture bears some resemblance to that of India and Egypt in general character, but differs from it considerably in matters of detail. In all three places we meet with excavated tombs and sepulchral chambers hewn out of the perpendicular face of the rock; yet beyond the circumstance of their position and method of formation, we find little in common between those of Persepolis and the other countries: in the latter, the excavations are usually of very great extent, and consist of one or more passages leading into a large number of different apartments; whereas those of Persia are very shallow, and consist mainly of an architectural façade or portico, richly adorned with sculpture and other embellishments. Such are those at Naksh-i-Rustam; also the tomb of Darius, at the foot of Mount Rachmed, near the ancient Araxes. Another similarity is to be found in their massive proportions; and although in the works of Persia there is less real massiveness than in those of Egypt, yet the similarity of appearance points to a common origin. The pyramidal inclination of their walls is another indication of the same fact; and great resemblance in this point and in others may be observed in their porticos or propylæa, which, besides the pyramidal form of the erection, present us with the same description of entablature which, in the ruins of Persepolis as well as in those of Egypt, consist of a lofty crowning hollow or concave member, ornamented with vertical ribs or leaves, and in both cases terminated with a large fillet. The sculpture of the two countries is also of similar character, stiff and formal, and, together with the arrow-headed characters which are found equally in both styles, presents a very fair argument in favour of their relationship.

The principal ruins of this style, as we have before mentioned, are to be found in Persepolis, in the great plain of Merdasht or Istakhr; but others are also existing at Shapur, where they cover an area of six miles in circumference, amidst rocks and precipices, many of which are decorated with sculpture. At Moorghab, forty-nine miles north-east of Istakhr, are other extensive ruins, amongst which a ruin, called by the natives Musjed-i-Madre-Solyman, is remarkable, being considered by some as the tomb of Cyrus the

Great. Somewhat nearer to the ruins of Persepolis are the Naksh-i-Rejib, and the Naksh-i-Roostan, both of which are supposed to be the tombs of regal personages. The ruins of the neighbourhood of Firoze-abad are very extensive, occupying a space of about 17 miles by about half the distance: other ruins exist at Darabgherd, and many in other places, of some of which we shall attempt to give a short description, and as the ruins of Persepolis are amongst the most remarkable and better-known examples, we proceed with their description forthwith.

These ruins are situated in the plains of Merdasht, at the foot of the mountain of Kuliraj-met, and stand upon an elevated terrace or platform, formed by levelling the surface of the rock. The platform is in the shape of a parallelogram, but somewhat irregular in its outline, which follows the profile of the rock; its dimensions are on the south face 802 feet, on the north 926, and on the west 1,425. On each of these sides the terrace is elevated above the general surface of the surrounding country, but on the east side the mountain rises above it; the vertical height of the three sides varies from 14 to 40 feet, the faces being formed of gigantic square blocks of a dark-grey marble, beautifully polished, and fitted to each other with the greatest exactness without the aid of cement. The surface of the platform is not on the same level throughout, those parts which were covered with buildings being somewhat elevated above the rest. On the west side, which may be considered the principal one, and at a spot about midway between the centre and the north-west angle, is the approach, which consists of two flights of steps in contrary directions, which return again to the upper landing-place. The height of the platform at this place is about 20 feet, and the flight on the north side consists of 55, and that on the south of 53 steps, the risers measuring 4 inches, and the threads 14; the width of the flights is 25 feet 7 inches, and the distance between them at the base 42 feet. The steps are cut out of immense masses of solid marble, sufficiently large to compose from 10 to 14 steps. The half space at the top of the first flight is 51 feet 4 inches between the flights, and that at the top of the upper flight 75 feet; the upper flights are separated from the lower by a wall.

Having arrived at the top of these steps, the first thing which presents itself to your notice is a portal or propylon, standing at about 42 feet east of the steps. This lofty mass, which is similar in all respects to the propyla of Egypt, forms an entrance to the ruins, and consists of a pyramidal mass of masonry, diminishing upwards on all sides, and crowned by a cavetto, or hollow cornice, having a large aperture, which forms a doorway or entrance. The interior faces of this propylon are sculptured into the forms of two colossal bulls, which are elevated on a pedestal five feet above the level of the platform. At a considerable height above their backs are three small compartments filled with inscriptions in the arrow-headed characters. Passing forward through this portal still in an easterly direction, we find the ruins of a fine group of columns, at a distance of 24 feet from the portal; there were originally 4 columns, which were all erect in Chardin's time, but when Sir Robert Ker Porter visited the place, two of them only remained. They are the most perfect examples among the ruins, and were placed equidistant from each other, at a distance of 22 feet apart. Their bases are buried in the ruins; their capitals are singular and beautiful, consisting, as it were, of three combined in one. The shaft gradually narrows towards the top, varied by 39 flutings near the cincture, each of which is four inches in breadth; the total height of the columns is 54 feet. A space of 24 feet separates these columns from a second propylon, resembling the former both in shape and dimensions, except that its length is 18 feet instead of 21. The remains of the first portal are 39 feet high, and of the second 28 feet; the base of the piers is 5 feet 2 inches high, and projects inwards, and the bases upon which the figures stand are 1 foot 2 inches high. The second propylon is sculptured on the inner faces similarly to the first, but the animals represented have the body and legs of a bull, an enormous pair of wings projecting from the shoulders, and the heads looking to the east, showing the faces of men. On the head is a cylindrical diadem, on both sides of which horns are clearly represented winding from the brows upwards, to the front of the crown; the whole being surmounted with a sort of coronet, formed of a range of leaves like the lotus, and bound with a fillet beautifully carved in roses. At the distance of 52 feet south-eastward from the second portal is a water-trough, cut out of a single stone 20 feet long, and 17 feet 5 inches broad, and standing three feet high from the ground. From hence to the northern wall of the platform is covered with fragments, and the remains of one column not channelled as the others are, which is 12 feet 4 inches high.

The propyla, in all probability, lead to some main court or building of which there are no remains, for it would seem unreasonable to suppose that these portals formed only an entrance to the Palace of Forty Pillars as it is termed, and which now forms the principal mass of remains; this palace is to the south of the portals, which are placed east and west of each other, and east of the staircase, or approach from below, so that to a person approaching from that quarter the Palace of Forty Pillars would be invisible, and it would be necessary to turn to the right immediately after passing under the first propylon. Owing to these difficulties, it has been suggested that the principal ruins are not those of a palace, but of a temple, and that the palace was eastward of them. This conjecture is somewhat confirmed by the nature of the court, which from its remains would seem to be too crowded with columns for a hall of entertainment; and further, it is precisely similar in arrangement to the Egyptian temples. If such be the case, it must be supposed that the ruins of the buildings of which the propyla formed the entrance, have been removed from the north-east portion of the platform. Be this as it may, at the distance of 172 feet from the propyla, in a southward direction, is the approach to the court, which consists of a staircase of two flights, one west and the other east, giving access to the platform on which the court is erected. "On drawing near the Chehel-minar, or Palace of Forty Pillars," says Sir Robert Ker Porter, "the eye is riveted by the grandeur and beautiful decorations of the flight of steps which lead up to them. This superb approach consists of a double staircase, projecting considerably before the northern face of the terrace, the whole length of which is 212 feet; at each extremity, east and west, rises another range of steps, and again, about the middle, projecting from it 18 feet, appear two smaller flights rising from the same point. Here, the extent of the range, including a landing-place of 20 feet, amounts to 86 feet. The ascent, like that of the great entrance from the plain, is extremely gradual, each flight containing only 32 steps, none exceeding 4 inches in height, in breadth 14 inches, and in length 16 feet. The whole front of the advanced range is covered with sculpture. The eye at first roves over it, lost and bewildered by the multitude of figures." Amongst these sculptures, the figures of the bull and the lion, and representations of the flower of the lotus, repeatedly occur; some of the figures exceed the natural size. The wall occupied by these sculptures extends for a length of 98 feet, and the sculptures are arranged in three rows, one above the other; the faces of the inner terrace walls were also decorated with bas-reliefs. The staircase itself is half-buried and the flights are of unequal height, the western consisting of 28 steps and the eastern, where the ground is higher, of only 18.

On arriving at the top of this staircase, another large platform presents itself, paved with large blocks of stone, and covered with fragments of pillars; it is of large extent, stretching north and south 350 feet, and from east to west 380 feet. The distribution of the columns comprised four divisions, consisting of a central phalanx of six deep every way, an advance body of twelve in two ranks, and the same number similarly disposed flanking the central body. At the distance of 22 feet from the parapet of the landing, are the most northern or advanced body of columns, originally 12 in number, but of which, in Sir R. K. Porter's time, only one remained. At 71 feet southward from these, stood the central phalanx of 36, at intervals of 22 feet 2 inches from each other, of which only 5 now remain: the bases, however, of all the others are in their places, though most of them much mutilated. To the east and west of this group are two other groups of 12 each, whereof 5 still remain in the eastern one, and 4 in the western. The form of the columns which compose the three smaller colonnades at the front and sides of the main body is the same in all. The total height of each column is 60 feet, of which the shaft from capital to base occupies 44; the circumference of the shaft is 16 feet. The base consists of a plinth 8 inches high, and 24 feet 6 inches in circumference, from which rises the pedestal in the form of the cup and leaves of a pendant or inverted lotus; above this is a torus one foot deep, and upon this again, a cincture connecting the base with the shaft only 2 inches deep. The total height of the base from the cincture to the plinth measures 5 feet 10 inches. The capitals consist of two demi-bulls, comprising the fore-part of two bulls with head and fore-legs overhanging the shaft on either side, the bodies connected in the middle, and sustaining a sort of abacus; the heads of the animals project very considerably beyond the shaft, and form a kind of bracket to sustain the entablature. The columns of the central group are only 55 feet high, and differ considerably from the others; the shafts are fluted, and about 35 feet in length, and the capitals which resemble those of the great portal, occupy a large proportion of the height, and are adorned with a series of small scrolls, one above another, beneath which, and immediately above the necking, the shaft presents a bulging appearance, widening rapidly at the lower part, and gathering in gradually towards the scrolls, then spreading out again in the shape of a calyx or cup to receive the scrolls.

Eastward of this hall, and towards the mountainous side of the platform is situate a large mass of ruins, consisting of portals, passages, &c., the plot of ground on which they stand is about 95 paces from east to west, and 125 paces from north to south. In the centre are scattered fragments of columns and other stones, and in the interior there seems to have been a group of 76 columns.

To the south-west of the hall of Forty Columns, is a building elevated on a platform about 8 feet above the plane of the colonnades, which measures 170 feet from north to south, and 95 from east to west. It is approached from the west by a double flight of steps, which appear to have been enriched with sculpture similar to those of the great platform; another flight on the south extends the whole width of the terrace, the landing place of which is 48 feet long by 10 wide: the east side is buried in fallen ruins. The platform outside the building is occupied with fragments of portals, colossal statuary, &c. "From the western landing-place two portals lead into a room 48 feet square; it has two doors on the north, two to the west, one to the south, and, originally, two to the east. On three sides of the room are several square-headed niches, each excavated in one solid stone to a depth of 3 feet, 5 feet high, and 6 feet wide; they appear to have been exquisitely polished within, while upright lines of cuneiform characters run along their edges. Four windows 10 feet high, open to the south. There is another apartment of the same building 30 feet by 48, open to the south."

South-east of this building is another large edifice covering a space of 160 feet from north to south, and 190 feet from east to west; the plan seems to have been very regular, and consists of a polystylar hall of 36 columns, arranged in 6 rows of 6 each, surrounded with no less than 10 portals. The ground is covered with fragments, and beneath the pavement has been discovered a subterraneous aqueduct. To the west of this, and 100 feet south of the previous building, have been found traces of columns belonging to a smaller structure, and amongst them Le Bruyn discovered a staircase leading to a subterranean apartment.

The above are the principal edifices of Persepolis; there are some others of smaller size, which we do not think necessary to describe; the entire area too, which is equal to nearly thirty acres, is covered with innumerable fragments of various descriptions. Excavated out of the rock at the east side of the platform are two tombs, which are probably of the same date as the structures we have been describing; they are about 400 yards apart, and each contains a chamber about 30 feet wide, 18 deep, and 10 or 12 high; the façades are richly sculptured in both cases.

About four miles from this place are the sculptured tombs, called by the natives Naksh-i-Rustam, the entrances to which are nearly 60 feet above the general surface of the ground. One of the tombs consists of a chamber 35 feet long, 7 broad at each end, and 8 in the middle; in the sides are three arched recesses cut out of the rock, and measuring 9 feet in length, by 5½ in breadth. The roof of the chamber is arched, and its height measures 10 feet at the highest point. Opposite these tombs is a square building about 24 feet wide, and 35 high, constructed of white marble. At about 11 feet above the ground is a small doorway, which gives access to a chamber about 12 feet square, and 20 feet high, the roof being composed of two immense slabs of marble. On the outside the walls are varied with many oblong recesses, and are surmounted by a cornice enriched with dentils, that on the north side being formed of a single slab 22 feet 6 inches in length.

A building somewhat resembling a pyramid exists amongst the ruins of Pasargadæ, and is thus described by Mr. Morier: "It rests upon a square base of large blocks of marble, which rise in seven layers pyramidically. It is in the form of a parallelogram, the lowest range of the foundation is 43 feet, by 37; and the edifice itself, which crowns the summit, diminishes to 21 feet by 16 feet 5 inches. It is covered with a shelving roof, built of the same massy stone as its base and sides, which are all fixed together by clamps of iron. Around it, besides a great profusion of broken marbles, are the shafts of 14 columns, once, perhaps, a colonnade, but now arranged in the square wall of mud which surrounds the whole remains." This monument contains a small and plain chamber; it is considered by some to be the tomb of Cyrus, but the Mohammedan writers call it the tomb of the mother of Solomon.

The fire-altars, which are of not unfrequent occurrence, consist often of a single upright stone about 12 feet high, and 3 or 4 feet square at the bottom, being slightly pyramidical, and therefore of somewhat smaller dimensions at the top, in which there is a deep hollow to receive the fire.

A rude, low wall of large stones forms an enclosure round the altar, having an entrance in one of its sides. Sir W. Ouseley observed several structures resembling those of the Druids in our own country; he mentions one at Darabgerd, which consisted of an irregular cluster of large, rude stones, some of which were from 20 to 25 feet in height. One, taller than the rest, stood in the centre, and another towards the west resembled a table or altar, being flat at the top; and under two or three others were recesses or small caverns.

It would be useless to attempt any description of the details of the style, with such slender information; some idea may be formed from the above descriptions, and for further information we must refer the reader to the writings of those travellers who have visited the spot, amongst whom we may mention Porter, Ouseley, Morier, Rich, Niebuhr, Le Brun, and Chardin.

PERSIANS, or PERSIC ORDER, in architecture a name common to all statues of men, serving instead of columns to support entablatures. They only differ from caryatides, in that the latter represent women.

The Persian is a kind of order of columns, first practised among the Athenians, on occasion of a victory their general, Pausanias, obtained over the Persians. As a trophy of this victory, the figures of men dressed in the Persian mode, with their hands bound before them, and other characters of slavery, were charged with the weight of Doric entablatures, and made to supply the place of Doric columns. Persian columns, M. le Clerc observes, are not always accompanied with the marks of slavery; but are frequently used as symbols of virtues, vices, joy, strength, valour, &c., as when made in the figures of Hercules, to represent strength; and of Mars, Mercury, Fauns, Satyrs, &c., on other occasions. *See* Caryatic Order.

PERSPECTIVE (from the Latin *perspicio*, to see,) the art of representing objects on a definite surface, so as to affect the eye when seen from a certain position, in the same manner as the object itself would, when the eye is fixed on the point in view.

The art of perspective owes its birth to painting, and particularly to that branch of it which was employed in the decorations of the theatre, where landscapes were principally introduced, and which would have looked unnatural and horrid, if the size of the objects had not been pretty nearly proportioned to their distance from the eye. The ancients must, therefore, have had considerable knowledge of this art, though the only ancient author from whom we can obtain any information relative to its antiquity is Vitruvius, who, in the proem of his seventeenth book, informs us, that Agatharcus, at Athens, was the first who wrote on this subject, on occasion of a play exhibited by Æschylus, for which he prepared a tragic scene; and that afterwards the principles of the art were more distinctly taught in the writings of Democritus and Anaxagoras, disciples of Agatharcus, which are no longer extant. The perspective of Euclid and of Heliodorus Larisseus contains only some general elements of optics, that are by no means adapted to any particular practice; though they furnish some materials that might be of service even in the linear perspective of painters. Geminus of Rhodes, who was a celebrated mathematician in the time of Cicero, hath likewise written on the subject. It seems probable that the Roman artists were acquainted with the rules of perspective, from the account given of their scenic representations; but of the theory of this art among the ancients we know nothing—perspective, no doubt, having been lost when painting and sculpture no longer existed. John Tzetzes, who lived in the twelfth century, speaks of perspective as if well acquainted with its importance; and the Greek painters, who were employed by the Venetians and Florentines in the thirteenth century, seem to have brought some knowledge of it into Italy. The disciples of Giotto are commended for observing perspective more than their predecessors had done; they lived in the beginning of the fourteenth century.

The Arabians were not ignorant of this art, as we may presume from the optical writings of Alhazen, who lived about the year 1100, cited by Roger Bacon, when treating on this subject. Vitellus, a Polander, about the year 1270, wrote largely and learnedly on optics; and our own Friar Bacon, as well as John Peckham, Archbishop of Canterbury, treated the subject with surprising accuracy, considering the times in which they lived.

The most ancient authors who professedly laid down rules of perspective, were Bartolomeo Bramantino, of Milan, whose book, entitled *Regole di Perspettiva, e Misure delle Antichita di Lombardia*, is dated 1440; and Pietro del Borgo, who is supposed to have died in 1443. He supposed objects to be placed beyond a transparent tablet, and endeavoured to trace the images, which rays of light, emitted from them, would make upon it. His work is not now extant; but Albert Durer constructed a machine upon the same principles, by which he could trace the perspective appearance of objects. In 1450, Leon Battista Alberetti wrote his treatise *De Pittura*, in which he treats principally of perspective.

Balthazar Peruzzi, of Sienna, wrote his *Method of Perspective*, published by Serlio in 1540. To him, it is said, we owe the discovery of points of distance, to which all lines that make an angle of 45° with the ground line are drawn. Guido Ubaldi, another Italian, soon after discovered that all lines parallel to each other, if inclined to the ground-line, converge to some point in the horizontal line; and that through this point, also, a line drawn from the eye, parallel to them, will pass. His *Perspective* was printed at Pessaro in 1600, and contained the first principles of the method afterwards discovered by Dr. B. Taylor. In 1583, a book was published by Giacomo Barozzi, of Vignola, commonly called Vignola, entitled, *The Two Rules of Perspective; with a learned Comment, by Ignotius Dante*. In 1615, the work of Marolois was printed, in Latin, at the Hague, and engraved and published by Hondius. And in 1625, Sirigatti published a treatise of perspective, which is little more than an abstract of Vignola's. The art of perspective has been gradually improved by subsequent geometricians, particularly by Professor Gravesande and Dr. Brook Taylor. The latter did not confine his rules, as his predecessors had done, to the horizontal plane only, but made them general, so as to affect every species of planes and lines, whether parallel to the horizon or not; and thus the principles were made universal. Farther, from the simplicity of his rules, the whole tedious process of drawing out plans and elevations for any object is rendered entirely useless, and therefore avoided; for by this method, not only the fewest lines imaginable are required to produce any perspective representation, but every figure thus drawn will bear the nicest mathematical examination.

Vanishing points, in every position, were known to Guido Ubaldi; and Gravesande not only understood the use of vanishing points, but the use of directors also, in the representation of a point, prior to the appearance of any thing published by Brook Taylor; but the latter has extended his theory not only to vanishing points, but to the vanishing lines of planes in every situation, which, when once ascertained, the representation of an object is found by the same means in each plane, consequently with the same facility. Hamilton seems to be the first writer who introduced the

›ractice of setting the radial, or parallel of the original line ›rom the vanishing point, upon the vanishing line, and the ›riginal line from the intersecting point upon the intersecting ine, in order to ascertain the representation of any point, or ıny part or parts of the original line, and to find the origi-ıals from the representations given. This author is the first who has applied the harmonical division of lines to perspec-ive. Noble's *Perspective* contains several inventions; par-icularly his methods of drawing indefinite representations o inaccessible vanishing points, both by scales and other neans. Thomas Malton's treatise on this subject is also an ıble performance.

In the following list will be found the names of some of he principal writers on perspective, with the dates of their performances, down to a comparatively modern period. Some of these authors have been already mentioned; but in ıddition, several mathematicians of eminence have written on perspective; the latter have treated the art as the subject of pure geometry, as it really is. The performances of Dr. Brook Taylor, Gravesande, Wolf, De la Caille, and Emerson, especially, are truly valuable, from the perspicuous simplicity and universality with which they have treated the subject.

Within the last few years, writers on perspective have ›een so numerous, that it is impossible, as indeed it is un-ıecessary, to enumerate them.

We shall now proceed to describe the art of perspective, ı such a manner as will, we trust, be found a very easy vay of acquiring a general knowledge of the subject. Let he student place himself in a darkened chamber, and then et him make a small hole, not larger than a pea, in the door r window, opposite to some remarkable objects, such as ouses or trees, the distance of which should be at least qual to their height, and may, with propriety, be two or ıree times that distance; and the experiment will be most greeably conducted, when the sun shines strongly on the ırfaces facing the hole. If a sheet of paper, or any white reen, be placed within the room before the hole, an image the external objects opposite the aperture will be depicted pon it. The image will be beautiful, although the outline the objects will not be very well defined, nor their colours ery distinct, for reasons which the study of optics will fully plain. The instruction, however, to be derived from the periment, will, for the present object, be the same. It ill be observed that the images of all objects are inverted; and, to understand this, the student must be reminded of the rectilinear motion of light. The image on the screen can, of course, be formed only by those rays of light which enter the chamber at the aperture, and it will be admitted that the rays from the top of the external objects cannot proceed in a right line to the screen, unless they proceed to the bottom of the screen, and the objects on the left hand will be on the right of the image. That the rays of light from the objects cross each other at the aperture, and spread afterwards as they advance, may be proved by varying the distance of the screen; the size of the image upon which is enlarged by drawing it back, and lessened by placing it nearer the aper-ture. The student must further be informed, that if he could trace the image on the screen exactly as it is there delineated, he would, on reversing the screen, have an out-line of the external objects in accurate perspective. As the proportions of the several parts, therefore, are not altered by the inverted position of the image, they may be contemplated and compared with the original objects, as if no inversion took place. Suppose the front of a single house to be paral-lel to the surface of the screen, and its centre very nearly opposite to the centre of the aperture, its image upon the screen will be of the same shape as the front itself is known to have, and its dimensions will be obtained by a rule easily discoverable; for the image will be very nearly as much less than the original as the distance between the original and the aperture. This estimate of the proportion between the image and the object, would not require the qualifying term *nearly*, but would be correct, if the aperture were exactly opposite the centre of the front of the house; but we have supposed the aperture to be nearer one side of the building than the other, in order that the rays from the nearest gable of the house may pass through the aperture. This being attended to, there will be an image of the gable end upon the screen; and the size and shape of this part of the image must be particularly noticed. It will be found, that, though the gable may be in reality as broad as the front, its image is extremely narrow; that its ground-line, instead of being level with that of the front, inclines more and more towards the top as it recedes from the eye, and that the further edge of the inclined roof inclines to this line with a greater degree of inclination than the original is known to have: thus, besides the narrowness in point of breadth, the height of the most distant corner of the gable is in the image shorter than the hithermost corner. This visual contraction of surfaces is called fore-shortening.

To understand how it happens, let the student suppose a thread stretched from any given point in the most distant angle or vertical edge of the gable to its image on the screen, or spot on which it would fall by taking a rectilinear course; let another line be supposed to be drawn from an opposite point of the nearest angle of the gable, and it will be per-ceived that as these lines, like the rays of light, cross the aperture, they will, at the screen, form but a very narrow opening; and as the breadth of the image cannot be greater than this opening, the breadth of the gable must be incon-siderable on the screen. It will be obvious at the same time, that the more nearly the gable is taken in front, the greater will be the breadth of its image, while that of the apparent extent of the front will be proportionally contracted. The incli-nation of the ground-line of the gable will be explained, by sup-posing lines to be drawn from the four corners or limits of the gable, to their respective places on the screen; for the line which bounds the further side of the gable must have a less image on the screen than the hithermost, because it is more distant, and at an intermediate distance, any vertical line in the gable must have an intermediate height; therefore, there must be in the picture a gradual rising of the ground-line towards a point horizontally opposite the place of the aperture:—Now the whole art of perspective consists in observing rules which teach us to discover the diminutions of all objects seen obliquely, like the gable-end of the house. To render this experiment, and the inferences drawn from it, perfectly clear, it ought to be tried and fully considered. It will then speak to the eye, and the object to be obtained by perspective can scarcely be misunderstood, whereas the impression of mere words is speedily effaced.

To prevent any incorrect inference, we shall, however, refer to fig. 1, where, let C D represent the window-shutter of the darkened chamber, and *g* the aperture in it, A B an external object, and E F the screen which receives its image. It must be observed, that the darkened chamber is used only as a means of separating the rays which form an image from any other; and that if the direction of the rays could be ascertained as much before the shutter, as they are here behind it, an image of the original object would be obtained of the same size as that upon the screen, and in its erect position, because the rays have not crossed. Accordingly in the practice of perspective, the rays of light from an object are always supposed to be intercepted as they converge to the eye at some point, as at *h*, between the original object and the eye. In the experiment, therefore, the aperture in the window-shutter must be considered as representing the pupil of the eye, the darkened chamber of the eye, and the screen the retina, or as a means of rendering visible the pictures which the eye receives of visible objects. We need not observe, that a larger aperture, with a convex glass set in it, would, in fact, form a camera obscura, and a very distinct image would be painted on the screen, at the focus of the glass, but the experiment would then be less simple, and the direction of the rays not so evident. Without a glass, the distinctness of the picture is sufficient to be agreeable, when the eye has been sometime in the chamber.

To consider the foundation of perspective in another point of view, let A B C D, fig. 2, represent a house, seen by the eye at N. The eye N, is supposed to be opposite the corner *q* of the house; its distance from which is equal to N *q*, and its height five feet from the ground. The situation of the eye corresponds to that of the hole in the window-shutter of the former experiment, and the picture of the house formed in the eye itself corresponds to that which the screen received. In this situation, as in every other, straight lines drawn from every part of the house to the eye, represent the direction of the rays which form the images of those parts respectively, and thereby render the house visible. The eye, it must be understood, is fixed upon the point *q*, directly before it, and in order that no sensible deviation may be possible, we may suppose it to be looking through a very small aperture in a piece of thin brass, *g*. If now a transparent plane, for example a pane of glass, K L, be interposed between the house and the eye, at a short distance from the eye, the whole of the house will be seen through the transparent plane, although the latter is, comparatively with the house, of very small dimensions, because the rays, in proceeding to their point of convergence at the eye, have approached each other in a proportion inversely as the distance; that is, at half the distance from the object, they only extend over half the space contained between the points of emission; at one-fourth of the distance from the eye, they only take up one-fourth of the space; and the same proportion for other distances. Suppose the pane of glass to be within arm's reach of the eye at N, and that it is coated with gum-water or isinglass, so as to receive the marks of a pencil, without having its transparency destroyed; trace the outlines of the house upon the glass, by observing and following exactly the direction in which they are seen through the small aperture in the piece of brass. When this is done, it will be found that the real or measured extents, forming the different external surfaces of the house, are represented by extents modified by the distance and obliquity of these surfaces to the eye; in short, as shown in the figure, a representation of the house in true perspective will be obtained, in the given situation of the eye. To young persons, the difficulty of understanding an explanation of this kind is occasioned by their indistinct perception of the relation between the rays and lines from a real object, and the projection of those lines upon a flat surface, as a sheet of paper. It appears confusing to them to say that the eye is opposite to the corner *q* of the house, and yet to represent it at N on one side. Unless this difficulty be overcome, and the mind can form a distinct image of the direction which the line shown on paper would have if drawn from a real object, perspective diagrams will be contemplated with pain, and the remembrance of them will soon be effaced. We shall therefore propose a little experiment, which we recommend to be tried by those who feel the difficulty alluded to.

Let a small model of a house be made of wood, and to every corner of it which can be seen in any one situation, affix a thread of silk, two or three times as long as the model of the house is high. These threads will represent the rays of light proceeding from the corners A B C D, *f k l m* of the house in *Figure* 2. Let the threads be drawn through a hole in a piece of thin brass, just large enough to admit them to be moved freely. The hole in the piece of brass will represent the eye. Let small weights be attached to the extremities of the threads which have been passed through the hole in the brass; the threads being thus stretched, will form a right line from the house to the brass, and the apparatus will be ready for elucidating the nature of perspective. Whil the model of the house remains stationary, let the position o the brass be varied, sometimes placing it higher, sometime lower, at different distances, and towards different sides and let the angles formed by the threads in each situation b attentively considered, by the observer placing himself behin the brass, and supposing himself to regard the house as if h saw it through the hole. Let him after each remove of th brass, suppose that the threads representing the rays of ligh without altering their direction, were to pass through a shee of paper, interposed at any distance between the brass an the house, and he would find that by drawing lines to joi the points thus obtained, an outline representation of th house would be produced, and this representation would b in true perspective. For any one situation, it would n be a troublesome matter to perforate a piece of paper, to b slipped upon the threads without distorting them; and f other situations, a good idea of what the representation wou be, or, in other words, of the perspective space between a given points, would be obtained by measuring the openin between the threads at equal distances from the brass. Aft the trial and proper consideration of this experiment, it w be easy to form a tolerably correct idea of the perspecti appearance of any object, or assemblage of objects, and n difficult to exhibit that appearance on paper. In perspect diagrams, lines must be drawn to represent the rays, t direction of which in this experiment is indicated by threa and as the view of an object varies from the point in wh it is seen, the situation of the eye, both in height and distan must be laid down upon paper, on which the perspect drawing of an object is to be made, unless we propose to l at the object itself as through a transparent plane. question then occurs, how shall the position of the eye esignated on paper? It can no way be represented so clearly s by placing it on one side, as shown in the figure, or by lacing it vertically beneath the object to be drawn, as re-resented in *Figure* 12.

By whatever means the representation *t u*, *Figure* 2, of an bject A B C D, is obtained, if the outline be accurate, and ewed at a proper distance, it is plain it will make an out-ne of the same form in the eye as the object itself; and if e colouring were equally perfect, the eye might mistake the gure for the original. But even when colours are not em-loyed, correct dimensions give the whole a pleasing ap-earance, and constitute the first great requisite to every good cture.

Having thus endeavoured to explain the nature of perspec-ve, we may next advert to the limits of vision. We may onsider the eye, in whatever direction we look, as situated the centre of a sphere, which we may suppose to be repre-nted by the circle E K F I, *Figure* 3. The hemisphere E L F behind the eye, and therefore obviously invisible; and it is so certain, that the eye, looking forward horizontally to K, annot take in at once the whole of the hemisphere E K F. o far from this, it cannot take in a larger angle than S R T, hich is but half a hemisphere, or equal to 90 degrees. And s the rays which the eye takes in, extend all round to an qual distance from the central ray K R, it follows that the hole of the rays which enter the eye at once, will be in the orm of a cone, of which the apex is at the eye; and of such cone of rays, S R T may be considered as the profile. It is owever found, that to have an agreeable view of large ob-ects, such as buildings, the angle of vision should not exceed 0 degrees, or one-third of an hemisphere; in other words, at we cannot distinctly see the whole of an object, unless s distance from the eye be at least equal to its height; and e appearance of a picture will be more agreeable, if not ade to comprehend above 45, or at most 50 degrees; in-eed, for small objects, or such as do not exceed the length f a foot in any of their dimensions, it is not advisable to xceed an angle of 30 degrees. As a picture therefore should ever comprise more than the eye can easily take in at one iew, a distance of 25 degrees on either side of the point of ight, may be considered a standard limit. Fifty degrees to e eye at B, are comprehended in the angle *x* R *y*; and we eed scarcely observe, that the measure of an angle, is the pace it takes up on the circumference of a circle, which has e point of the angle for its centre; a circle being always pposed to contain 360 degrees. Hence, if the lines form-g the angle *x* R *y* were extended, the angle *v* R *t* would still e only one of fifty degrees, because, whatever were the ze of a circle drawn from the point R, through its two gs, if that circle were divided into 360 parts, the number those parts enclosed by the angle, could not be more an fifty.

We shall now proceed to the definition of the terms used treating of perspective, and then show the method of put-g into perspective, those forms which may be considered the elements of all others.

DEFINITIONS.—1. An *original object* is any object what-er, which is rendered the subject of a picture.

2. *Original planes* or *lines* are the surfaces or lines of iginal objects.

3. *Perspective plane* is the surface on which a picture is lineated. It may be here observed, that painters regard e frame of a picture merely as an aperture through which iginal objects are seen; and they therefore consider the rspective plane to be transparent, to admit of this view. s on this account that the perspective plane is frequently led the *transparent* plane.

4. *Ground-plane* is the earth or surface on which stand the objects to be delineated, as well as the spectator.

5. *Ground-line* is the line on which the perspective plane is supposed to rest.

6. *Visual rays* are those which, passing through the transparent plane, render original objects visible.

7. *Principal visual ray* is that which passes through the axis or centre of the eye, and the course of which, therefore, from the perspective plane, is shorter than any other, because it is perfectly direct. Its height above the ground-line is, of course, always the same as that of the eye.

8. *Point of sight* is that fixed point from which the spectator looks upon the perspective plane, when any original object is delineated.

9. *Centre of the picture* is that point of the perspective plane which is exactly opposite the point of sight, that is, where the principal visual ray enters the transparent or perspective plane. It must, therefore, be carefully distinguished from the measured centre of any picture, as it can never exceed the height of the eye from the ground-line.

10. *The distance of the picture*, or *point of distance*, is the distance between the eye and point of sight, and the centre of the picture.

11. *Vanishing points* are those points to which all lines inclined to the picture appear to converge, and which those lines meet when produced. Vanishing points have no place in a finished picture; they are used to facilitate drawing in perspective.

12. *The horizontal line* is a line parallel with the horizon, at the height of the eye,—that is, it passes horizontally through the centre of the picture.

Distance of a vanishing point is the distance upon the vanishing point on the picture to the eye of the spectator. It may also be proper to remind some, of the difference between a perpendicular and a vertical line or plane: a vertical line points directly to the centre of the earth; it is therefore at right angles to the plane of the horizon, and is the same with the direction of a plumb-line: a perpendicular line is any line which is at right angles to another; it may therefore be sometimes a vertical line, sometimes a horizontal one, or in any other position, according to the direction of the line or surface with which it forms a right angle.

Methods of putting squares into perspective.—Suppose a square to be traced upon the ground at some distance before us; that we find, upon admeasurement, the length of each side to be 8 feet, and that we are opposite the centre of the nearest side, at the distance of 18 feet. We know, that if we wish to obtain what is called a ground-plan of this square, we must represent it by a square upon paper, as in *Figure* 4, and thus we shall have its real appearance, supposing the eye to be looking down upon it, just over its centre; but looking upon it obliquely, as we have stated, and with the eye at the height of 6 feet from the ground, we are convinced, from the nature of perspective, as before explained, that the side nearest to us will make a longer line upon the retina than any of the rest. The question is, therefore, to obtain the true appearance of the whole square,—that is, the true form of the image it makes on the retina. In the first place, determine the scale to be observed,—that is, what space shall correspond to a foot of the original. For example, suppose one-tenth of an inch; then draw a line, A B, *Figure* 5, eight-tenths of an inch long, and another line, H D, parallel with this base-line, at the height of six-tenths of an inch from it. Raise a perpendicular from the centre of the line A B, and the point C, in which cuts the horizontal line, will be the centre of the picture. From C on the horizontal line, set off the distance at which the square is seen, which will here be eighteen-tenths of an inch, and the point of distance D will be obtained. From A, draw the line A C; and from B, the line B C; then from A, draw the line A D, and to the point *h*, in which A D intersects B C, draw a line *g h*, parallel with the ground-line A B; then will A *g* D *h* form the perspective outline of the square required. Let it be supposed that the square above described is viewed by an eye situated opposite one of its corners, as in *Figure* 6. Draw a base-line, B L, as before, and on each side of any assumed point, *k*, set off half the measured length of the diagonal of the square, viz., half the distance between the corners *y* Z, *Figure* 4. Parallel to the base-line, at the height of six-tenths of an inch from it, draw the horizontal line P H D, and raise from *k* the perpendicular *k* C. From F, draw the line F C, and from G, the line G C. On each side of the centre C, set off on the horizontal line the points of distance P D, and from each side of them draw lines to the centre of the base *k;* then from *a*, draw the line *a* P, and from *b*, the line Z D, and the diagonal view, *a b f k*, of the square, will be completed.

We shall give one more example respecting squares:—Suppose we have a square pavement, composed of equal alternate pieces of black and white marble; the total number of small pieces to be 144, and each of them 1 foot square, as—

Here there will be six black and six white pieces on each side of the square. Suppose the spectator to stand opposite the middle of the third square on the left, and that, for greater clearness, the scale be two-tenths of an inch to a foot, with the eye 5 feet above the ground, but at the distance of 18 feet, as before. Draw a base line *r k*, and divide a part of it into as many equal divisions as there are squares on one side of the original, as 1, 2, 3, 4, &c. These divisions, by the scale now adopted, will each be two-tenths of an inch. Draw the horizontal line at the distance of 5 feet (according to the scale) from the base. From the middle of the space between 2 and 3, raise a perpendicular, and to the point C, in which it cuts the horizontal line, draw lines from the commencement and the termination of the divisions on the ground-line, viz., *r* C and 12 C. From C, set off the distance C D, 18 feet, for the distance of the eye. Draw the line *r* D; and from *e*, where it intersects the line 12 C, draw a line, *e f*, parallel with the base-line *r k;* then will *r f e* 12, give the boundaries of the pavement. To obtain the reticulations, draw lines from each of the divisions, 1, 2, 3, &c., on the base-line, to the centre of the picture C, and from each of the same divisions to the point of the distance D. The lines drawn from the divisions to C, from the right and left sides of the small squares, and the lines drawn from the divisions to D, give the points on the line C 12, from which the horizontal lines may be drawn to form the other sides of the squares. Or, after all the lines are drawn from the divisions on the ground-line to the centre C, and also the line *r* D, the remaining sides of the squares may be obtained by drawing parallel lines through the various points in which the part *r e*, of the line *r* D, intersects the lines drawn to the centre C.

It is often thought by those who are commencing this study, that representations such as the one now given, have no resemblance to the originals; but if they be examined, as every picture ought to be examined, opposite to the point of sight, and at the distance for which they are drawn, the idea of their incorrectness will disappear; to render the illusion the more complete, the figure should be viewed through a small tube or aperture, to prevent the intrusion of surrounding objects. It must also be observed, that diagrams upon paper have frequently, for the sake of convenience, a vanishing point so near, that the eye has not the power of distinct vision at the distance for which they are drawn. Such designs, therefore, although correct in principle, will not appear correct to the eye unless enlarged.

To put a circle into perspective.—The perspective or oblique view of a circle, is an ellipse, and it is usually obtained by drawing a square of a size just sufficient to contain the circle, and dividing it into small circles, then putting the divided square into the perspective, and drawing within it a line through the corresponding parts of the small squares, and this line will be an ellipse. Thus, to obtain the perspective of a circle E F G H, fig. 8, draw round it the square A B C D. Divide the square into small squares, the number of which should be increased in proportion to the exactness with which the perspective curve must be obtained; draw also the diagonals, C B and A D. Throw the square and reticulations into perspective, as represented in fig. 9, where C is the centre of the picture, and D the point of distance; then draw the curve by hand through the parts corresponding to those through which the circle passes in fig. 8. The perspective view of a circle will be an ellipse, whether the square opposite the middle of one of its sides, as in fig. 9; or even with one of its angles, as in fig. 10, where D C is the line of sight; or at a distance on one side, as in fig. 11, where L C is the line of sight. The point of distance, in figs. 10 and 11, is the same as in fig. 9, though in fig. 11 it could not be drawn without extending beyond the limits of the plate.

To put a triangular prism into perspective.—To represent in perspective a triangular prism or solid, standing vertically upon one of its ends, and viewed by an eye just opposite one of its angles; draw by admeasurement a plan of a prism, as *a b c*, fig. 12; then draw the line G K across the outermost boundary of the triangle, and make E F parallel with G K. From *e* let fall the line *e d*, perpendicular to G K. On *c d* set off the measured distance of the eye from the prism, and mark the place of the eye at *d*. From *a* and *b*, draw lines meeting each other in *d*. From *d*, draw the line *d m* parallel with *a c* of the triangle, and on the other side of the line *d l* parallel with *b c*. From *e* raise the perpendicular *e f* to the measured height of the nearest angle of the prism to which the eye is opposite. On *e f*, measure the height of the eye from the ground-line G K, and draw the horizontal line H H. Take the distance *c m*, set it off on each side from *n*, and it will give the vanishing points V P and V. Draw the lines *e* V P and *e* V. Then from *o* and *p*, where the lines from *a* and *b*, in proceeding to the eye, cut the line E F, draw the lines *p q* and *o s*, parallel with *e f*. Draw the lines V *x f* and *f w* V P, and the perspective outlines *w f x r e z*, of the prism, whose base is equal to the triangle *a b c*, will be obtained, and may be finished by shading it according to the direction in which the light falls upon it. This mode of drawing from a ground-plan is extremely useful, and well calculated to show the difference between the visual and real dimensions of objects. The outlines of the house A B C F in fig. 2, were obtained by it; it should be rendered familiar by frequent practice on figures in different positions.

To put a cube and cylinder into perspective.—As the base of a cube is a square, it may, when viewed as in the present example, opposite one of the angles, be put into perspective by the same process as the square in fig. 13, and figs. 9, 10 and 11, will explain the manner in which the perspective of a square, seen in other positions, may be obtained. Having then obtained the base, we shall find that when H is the horizontal line, P D the points of distance, and *a b* half the measured length of the diagonal of the cube, the perspective of the base will be represented by *a f d g*. Make the height of *a c* equal to the measured length according to the scale, of one of the sides of the cube, then draw the lines C D and *e*

From *f* and *g* draw lines parallel with *a e*, for the sides of the figure; draw the line *e* F to a perpendicular let fall from the horizontal line at P to M. From F draw a line to any part of the horizontal line, as to L, and draw from M a line to meet this in L. To *f* draw the line *f h*, and to *d* the line *i d;* then from *h* and *i* raise perpendiculars to intersect F L, and from the points of intersection draw the lines *p l* and *r k;* thus will be obtained the perspective outline of the cube *k l f a g o e.* If the cube had not been viewed directly opposite one of its angles, the points of distance would not on each side have coincided with the vanishing points, and the vanishing points would have been best obtained as for the triangular prism, fig. 12.

The procedure of a parallelopiped, is essentially the same as for a cube. To put a cylinder into perspective, first proceed as for a cube or parallelopiped, draw on the perspective of each, and such an ellipse as it will admit; let the longer or conjugate axes be equal, and join the opposite extremities of these axes by two parallel lines, as shown in *Figure* 14. Having thus obtained the perspective of the cylinder, it only remains to erase the lines which belong to the cube or parallelopiped.

Of shadows, and description for drawing perspective.—Having now shown the mode of putting into perspective those elementary forms which enter into the composition of drawings of every description, we shall be obliged to be concise with the remainder of the subject. The student must be aware how much difference of position affects the visual appearance of objects. And that by a proper attention to this circumstance, the few rules which have been given, may be applied to subjects of considerable complication. To acquire a knowledge of the principles of perspective, it is recommended not merely to compare the plates with the printed page, but to copy the diagrams, and, for the sake of greater perspicuity, to do this on as large a scale as may be convenient. Afterwards, some treatise especially devoted to the subject may be perused, and perhaps Brook Taylor's and Matton's may be the best; for although these authors will require considerable attention, they have the merit of being sure guides.

With respect to shadows, the proper distribution of which give such life to perspective drawings, it may be useful to remark, that the shadow cast by any object, covers the precise space which that object would prevent the eye from seeing, if the eye were in the place of the luminous body. The position, therefore, of the luminous body must always be ascertained, and the shadow to be assigned to any object in a picture, will be a perspective view of the space which the eye would be prevented from seeing, if in the place of the luminous body. A few experiments with a candle at night will be an easy mode of gaining a little acquaintance with this subject; it must, however, be observed, that the shadow from a candle is every way larger than that part of the object which intercepts the rays; but in point of breadth, this never happens with the shadows of the sun. The reason is, that the rays from the candle considerably diverge, while those from the sun, on account of the immense distance of that luminary, have no perceptible deviation from parallelism. It must be remembered also, that strong reflections from surrounding objects will diminish the intensity of shades, and that not only the quantity of light which falls on an object, but the quantity which can be reflected to the eye, must be considered.

As it frequently happens that persons have occasion to draw in perspective, who have acquired no theoretical knowledge of the art; for the use of such, a great variety of machines have been constructed. Most of these machines are on optical principles; the camera obscura, which we have already described, is one of them, and the camera lucida is another. In praise of the latter, much has lately been said; but although it must be admitted to be a very portable and beautiful instrument, the acquisition of the proper art of using it is extremely difficult to all, and to some impossible. Its chief use will be, that of affording the means of contemplating the real perspective appearance of objects, and perhaps to obtain the position of a few points; but for very minute delineation, it is of little value. For general use we may venture to recommend an instrument described by Ferguson, to whom the knowledge of it was communicated by Dr. Bevis. It has the advantage of other machines in two points; it may be constructed at a small expense by any tolerably skilful artisan in wood, and the use of it will constantly tend to render the practice of perspective drawing more easy, by the manner in which it produces the measure of surfaces or angles. It will therefore, better than most other instruments for the same purpose, supply the want of a more extended essay.

The machine in question is represented at *Figures* 15 and 16. *Figure* 15 is a plan, and *Figure* 16 a view of it on a larger scale. The same letters refer to the corresponding parts in both figures. A B E F is an oblong board, and X Y are two hinges on which the part C L D is moveable. This part consists of two arches or portions of arches, C M L, and D N L, joined together at the top L, and at the bottom to the cross bar D C, to which one part of each hinge is fixed, and the other part to a flat board, half the length of the board A B E F, and glued to its uppermost side. The centre of the arch C M L is at D, and the centre of the arch D N L is at C.

On the outer side of the arch D N L is a sliding piece, N, (much like the nut of the quadrant of altitude belonging to a common globe) which may be moved to any part of the arch between D and L; and there is such another slider O, on the arch C M L, which may be set to any part between C and L. A thread C P N is stretched tight from the centre C to the slider N, and such another thread is stretched from the centre D to the slider O; the ends of the threads being fastened to these centres and sliders. It is plain, therefore, that by moving the sliders on their respective arches, the intersection P of the threads may be brought to any point of the open space within those arches.

In the groove K is a straight sliding bar I, which may be drawn farther out, or pushed further in, at pleasure. To the outer end of this bar I, *Figure* 16, is fixed the upright piece H Z, in which is a groove for receiving the sliding piece Q. In this slider is a small hole R, for the eye to look through in using the machine; and there is a long slit in H Z, to let the hole R be seen through when the eye is placed behind it, at any height of the hole above the level of the bar I.

Suppose a house, *q s r p*, to be at a considerable distance beyond the limits of the plate, to obtain a perspective representation of it, place the machine on a table, with the end E F, of the horizontal board A B E F towards the house, so that, when the arch D L C is set upright, the middle part of the open space (about P) within it, may be even with the house when the eye is placed at Z, and looking at the house through the small hole R; and then fix the corners of a square piece of paper with four wafers, on the surface of that half of the horizontal board which is nearest the house.

To complete the arrangement of the apparatus for drawing, set the arch upright, as in the figure, which it will be when it comes to the perpendicular side T, of the upright piece S T, fixed to the horizontal board behind D. Then placing the eye at Z, look through the hole at R at any point of the house, as *q*; and move the sliders N and O, till the intersection of the threads at P, is directly between the eye and the point *q*; then put down the arch flat upon the paper on the board, as *s t*, and the intersection of the threads will be at W. Mark the point W on the paper with the dot of a blacklead pencil, and set the arch upright again as before; then look through the hole R, and move the sliders N and O, till the intersection of the threads comes between the eye and any other point of the house, as *w*; this being done put down the arch again to the paper, and make a pencil-mark thereon at the intersection of the thread as before; obtain the point *p* in the same manner, and draw a line from that mark to the one at *w*. The line *p w*, thus obtained, will be a representation in true perspective of the corner *p q* of the house.

By thus bringing the intersection of the threads successively between the eye and other points of the outlines of the house, as *r s*, &c., and putting down the arch to mark the corresponding points, on the paper, at the intersection of the threads, then connecting these points by straight lines, the entire perspective outline of the house will be obtained. In like manner, find points for the corners of the doors, windows, &c., and draw the finishing lines from point to point. The perspective drawing thus produced, may then be completed, by shading it according to the manner in which the light is observed to fall on the original.

Great care must be taken, during the whole of the time, that the position of the machine be not shifted on the table; and to prevent such an accident, the table or support employed should be perfectly steady, and the machine fixed down upon it by screws or clamps.

It is obvious that a landscape, or any number of objects within the field of view through the arch, may be delineated, by finding a sufficient number of points, and connecting them by straight or curved lines, as they appear in the original objects.

The arch ought to be not less than a foot wide at the bottom, that the eye at Z may have a large field of view through it; and the eye should be then at least ten inches and a half from the intersection of the threads at P, when the arch is set upright. If the eye be nearer, the boundaries of the view at the sides near the foot of the arch will subtend an angle at Z of more than sixty degrees, which will not only strain the eye, but will cause the outermost parts of the drawing to have a disagreeable appearance. To avoid this it will be proper to draw back the sliding bar I till Z be fourteen inches and a half distant from P; then the whole field of view through the foot-wide arch, will not subtend an angle to the eye at Z of more than forty-five degrees: which will give a more easy and pleasant view not only of the objects themselves, but of their representations upon the paper on which they are delineated. Hence, whatever may be the width of the arch, the distance of the eye from it should be in this proportion: as twelve is to the width of the arch, so is fourteen and a half to the distance of the eye (at Z) from it.

If a pane of glass, previously coated with thin gum-water, and dried, be fixed in the arch, a person who looks through the hole at R, may delineate upon the glass the objects which he sees at a distance, and the delineation may be afterwards transferred to paper. By this means will be saved the trouble of putting down the arch to take the position of every point, but it will not be so easy to obtain a correct representation.

Perspective of Shadows.—The shadow of an object is no more than the projection of its contour upon one or more planes, from a given luminous point, and is therefore the dark space upon these planes, occasioned by the intervention of the object, which hides the rays of light from proceeding in straight lines. To avoid difficulties, the luminary, whether the sun or artificial light, is considered as a point, and the sun's rays are considered as parallel.

Problem.—*Given the vanishing line of a plane, the image of a line insisting upon that plane, and its vanishing point; also the vanishing point of the sun's rays; to find the shadow of the line.*

Plate I. *Figure* 1.—Let A B be the vanishing line of the plane, *a b* the image of the line, V its vanishing point, and S the vanishing point of the sun's rays; join V S, and produce it to meet A B in *s*: join *b s* and *a* S, cutting each other in *c*, then *b c* is the shadow of the line required.

For the vanishing point of the line, and that of the sun's rays, are in the vanishing line of the plane of shade; therefore V S *s* is the vanishing line of the plane of shade; but the shadow is occasioned by the intersection of the plane of shade with the original plane, whose vanishing line is given; therefore the point *s*, the intersection of the vanishing line of the plane on which the line insists, with the vanishing line of the plane of shade occasioned by the line, is the vanishing point of the shadow.

Example to find the shadow of a cube.

Figures 2 and 3.—A B being the vanishing line of the plane of its base, and of the surface on which it rests; the edges *g d*, *b a*, *m n*, being supposed to be perpendicular to the base; then, if the picture be perpendicular to the original plane, the vanishing line of a plane of shade occasioned by the vertical arrises, will be perpendicular to the vanishing line A B; therefore let S *s* be the vanishing line of the plane of shade occasioned by the vertical edges, S being the vanishing point of the sun's rays, and *s* the intersection of the vanishing line of the plane of shade with that of the plane on which the shadow is to be thrown.

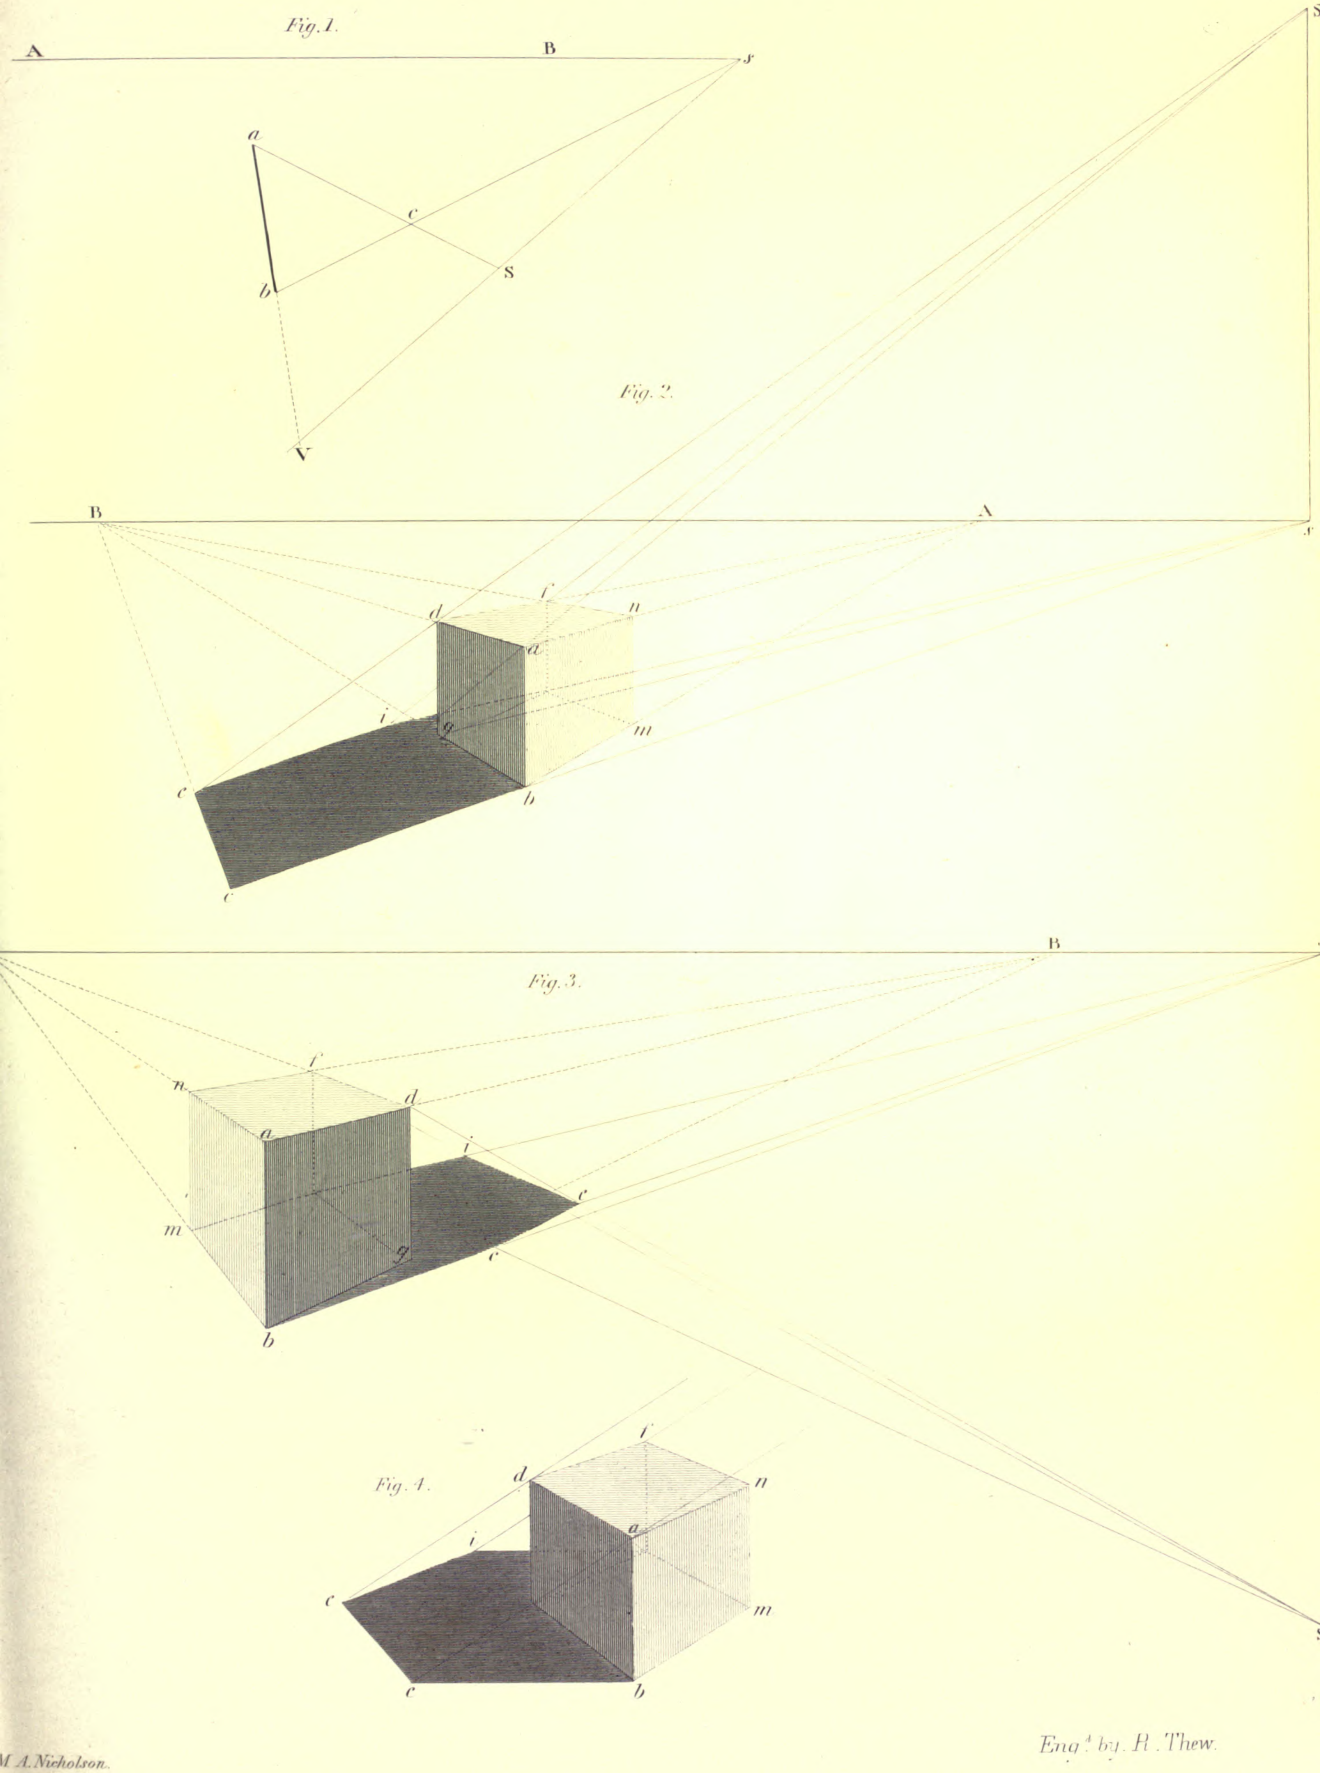
Join *b s* and *a* S, cutting each other in *c*; then *b c* is the shadow occasioned by the edge *b a*; join *c* B and *d* S, cutting each other in *e*, or, if necessary, produce them to cut in *e*, and *c e* is the shadow occasioned by the edge, *a d*, parallel to the plane of its base; also join *e* A and S *f*, cutting each other in *i*, or, if necessary, produce them to cut each other in *i*; then *e i* will be the shadow of the edge *d f*; lastly draw *i s*, which will complete the shadow of the cube, as required.

Figure 2 shows the shadow when the sun is before the picture: *Figure* 3 shows the shadow when the sun is behind the picture; and *Figure* 4, the shadow when the sun is in the plane of the picture.

Many more examples of the shadows of objects might be given, but if the principles here shown are understood, the student will not be at a loss to find the shadow of any right-lined object whatever. To find the shadow of any right-lined object, is no more than to find the shadow of the lines, or arrises, formed by the meeting of the sides, and those only of the lines forming the contour; if a circle be given, the circumference may be divided by parallel lines into parts, and the shadows of the points of division may be found by finding the shadows of the intercepted parts, then drawing a curve round the extremities. If it were required to find the shadows upon several planes; first, find the shadow in the plane on which the object rests; then, observe where the shadow meets the next plane; then, having the vanishing line of this second plane, observe where the vanishing line of the plane of shade cuts the vanishing line of the second plane; then the point of intersection is the vanishing point of the shadow in this second plane. See more of shadows under the article Projection, where the principles apply as well to perspective as to orthographical projection.

PERUZZI, BALDASSARE, in biography, was born at Accajano, in the territory of Sienna, in 1481, in poor and dis-

PERSPECTIVE OF SHADOWS, PLATE I.



M A. Nicholson.

Eng.d by. R. Thew.

tressed circumstances; his father having been reduced from a state of comparative affluence, by the civil wars which ravaged Florence and its territory. Baldassare exhibited his genius at a very early age; first by imitation of the works of others, and afterwards by original productions in the city of Volterra, where his family resided. Thence he went to Rome, where he placed himself with the father of Maturino; and becoming conspicuous for ability, he was at length employed by pope Alexander VI., and also in many churches and convents in that city, in which he produced pictures justly entitled to exalted praise.

Together with painting, he studied architecture; and practised it with considerable success. He was also renowned for his knowledge of perspective; and the works he produced in imitation of architectural projections, excited even the surprise and admiration of Titian. But his highest renown is founded upon works of a much more elevated class; viz., his paintings in fresco and in oil; in which he exhibited a taste and style not unworthy of Raphael. There is at Wilton a picture of his of the Four Evangelists in Glory, with their peculiar characteristic accompaniments, which bears ample testimony to the truth of this remark; and perhaps it is the only real specimen of his pencil in England. He wrote a treatise upon the antiquities of Rome, and a commentary on Vitruvius, but did not live to publish them; being poisoned by some who were probably envious of his reputation and talents, in 1536, at the age of 55.

PEST-HOUSE, a lazaretto, or infirmary, where goods, persons, &c., infected, or suspected to be infected, with some contagious disease, are disposed, and provided for.

PETER OF COLECHURCH, an architect and priest, who built the late London Bridge, in the reigns of Henry II. and his sons Richard and John.

PEW, or Pue, a wooden seat or bench used in churches, of sufficient length to contain several persons. The term has, of late years, been particularly applied to the closed boxes provided with doors, but is equally applicable to the open seats of a previous age, which are now again happily superseding the closed pews. We have many beautiful examples of such benches, some very richly carved; they consist, for the most part, of a low seat and back, fixed into a standard at each end, which is either plain or carved, and is sometimes finished at the top with a finial, boss, or poppy-head.

PHALANGÆ, a term applied by Vitruvius to wooden rollers employed to transport heavy weights from place to place.

PHAROS, or Phare, a lighthouse, or pile raised near a port, where a fire is kept burning in the night, to guide and direct vessels near at hand. The pharos of Alexandria, built in a small island at the mouth of the Nile, was anciently very famous, insomuch as to communicate its name to all the rest. It was so magnificent a structure, being built by the celebrated architect Sostrates, a native of Cnidos, or, as some say, by Deiphanes, the father of Sostrates, that it cost Ptolemy Philadelphus eight hundred talents. It had several stories, raised one over another, adorned with columns, balustrades, and galleries, of the finest marble and workmanship; to which some add, that the architect had contrived to fasten looking-glasses so artificially against the highest galleries, that in them could be seen all the ships that sailed in the sea for a great way; instead of which noble structure, there is now only a kind of irregular castle, without ditches, or outworks of any strength, the whole being accommodated to the inequality of the ground on which it stands, and which, it seems, is no higher than that which it should command. Out of the midst of this clumsy building rises a tower, which serves for a lighthouse, but possessing nothing of the beauty and grandeur of the old one. The colossus of Rhodes also served as a pharos. *See* Eddystone, and Lighthouse.

PHEASANTRY, a building or place constructed for the purpose of breeding, rearing, and keeping pheasants, which should always be near to, and well covered with, plenty of wood, in different states of growth; the whole being enclosed with a high fence, that the young may, as soon as possible, run freely through it, and pick up their food, &c.

PHENGITES, in the natural history of the ancients, the name of a very beautiful species of alabaster. It is a very rude and irregular mass, very friable, yet of a brightness superior to that of most of the other marbles, and excelling them all in transparency; it is in colour of an agreeable pale yellowish white, or honey colour; the yellowish is more intense in some places than in others, and sometimes has an obscure resemblance of veins. It is very weak and brittle in the mass; and when reduced to small pieces, easily crumbles between the fingers into loose, but considerably large angular pieces, some perfect, others complex, irregular, or mutilated, and all approaching to a flat shape.

The ancients were very fond of this species in their public buildings; and the Temple of Fortune, built wholly of it, has long been celebrated. Its great beauty is its transparency, from which alone this temple was perfectly light when the doors were shut, though it was built without a window, and had no other light but what was transmitted through the stone walls. It was anciently found in Cappadocia, and is still plentiful there: it is also met with in Germany and France, and in our own kingdom in Derbyshire, and some other counties. It takes an excellent polish, and is very fit for ornamental works, where no great strength is required.

PHIALS, vases used by the ancients in the construction of vaults; they were made of a slightly conical form, so as to fit into each other, and were manufactured of a light material, so as to ease the weight and thrust of the vault.

PHIDIAS, in biography, an Athenian, the most celebrated sculptor of antiquity. His distinguishing character was grandeur and sublimity; and he particularly studied optical effect. To this purpose it is related, that having, in competition with Alcamenes, made a statue of Minerva to be placed on a column; the work of the latter appeared so finished when viewed on the ground, that it was universally admired, whilst that of Phidias seemed to be a mere rough sketch; but when both were seen from their destined situations, the beauties of the first were lost, while the second produced the most striking effect. After the battle of Marathon, he converted a block of marble, which the Persians had brought for a trophy of their expected victory, into a fine statue of Nemesis, the goddess of Vengeance. His reputation was so high at Athens, that Pericles regarded him as his particular friend, and appointed him superintendent of all the public edifices with which that city was decorated. One of his greatest performances was a colossal statue of Minerva, in the temple called Parthenon. In this work he displayed his skill in minute sculpture, no less than his grandeur of conception in the main figure. On the convexity of the goddess's shield was represented the battle of the Amazons, and on its concave surface the combat of the gods with the giants; whilst her slippers were adorned with the fight of the Centaurs and Lapithæ. On her breastplate was a Medusa's head. The base contained the birth of Pandora, with twenty figures of the gods. He is said to have been the first who brought the bas-relief to perfection. His fame and fortune excited envy, and several accusations were brought against him, which he was enabled to repel. At length, he was charged with having introduced the portraits of himself and Pericles in the battle of the Amazons; and this being regarded as a kind of profanation, he was thrown into prison, where, according to Plutarch, he died. Others, however, affirm, that he escaped to Elis, where he afterwards executed his Olympian Jupiter, the most remarkable piece of sculpture in all antiquity. It was a colossal statue, sixty feet high, of incomparable majesty and dignity in its attitude and expression. The name of the artist was engraved on the base. The Eleans, in gratitude for this extraordinary work, settled upon his descendants a perpetual office, the sole duty of which was to preserve the lustre of the statue.

PIACHE, or Piazza, a covered arched walk, or portico. *See* Piazza and Portico.

PIAZZA (from the Italian *piache*) a portico, or covered walk, supported by arches. The word literally signifies a broad open place, or square; whence it also became applied to the walks, or the porticos around them. *See* Portico.

PICTS' WALL, in antiquity, a remarkable piece of Roman work, begun by the emperor Adrian, A.D. 124, on the northern bounds of England, to prevent the incursions of the Picts and Scots.

At first it was made only of turf, strengthened with palisadoes, till the emperor Severus, coming in person into Britain, repaired it, as some say, with solid stone, reaching eighty miles in length, from the Irish to the German sea, through Carlisle and Newcastle; with watch-towers garrisoned, now called *castle-steeds*, at the distance of a mile from each other.

It does not appear with sufficient evidence, that Severus's wall was formed of stone: Bede expressly asserts the contrary, though Spartian intimates that Severus built both a *murus*, *i.e.* a wall of stone, and a *vallum*, or a wall of turf. Bede relates, that "Severus, after several great and difficult engagements, thought it necessary to separate that part of the island, which he had recovered, from the other nations that were unconquered; not with a *murus*, as some think, but with a *vallum*. Now a *murus*," continues he, "is of stone; but a *vallum*, such as they made round a camp, to secure it against the attacks of the enemy, is made of turf, cut regularly out of the ground, and built high above ground, like a wall, with the ditch before it, out of which the turf has been dug; and strong stakes of wood all along the brink." Severus, therefore, drew a great ditch, and built a strong earthen wall, fortified with several turrets from sea to sea. The learned Camden adopts this opinion; and adds, that Severus's wall is expressed by no other word than *vallum*, either in Antoninus or the *Notitia*.

This wall was ruined several times by the Picts, and often repaired by the Romans. At last Aëtius, a Roman general, ordered it to be rebuilt of stone, about the year 420; but the Picts ruining it in the year following, it was thenceforward regarded only as a boundary between the two nations. The wall was eight feet thick, and twelve high, from the ground: it ran on the north side of the rivers Tyne and Irthing, up and down several hills: the tract, or remains of it, are to be seen to this day in many places, both in Cumberland and Northumberland.

The inhabitants of the country pretend, that there was a brazen trumpet, or pipe, so artificially laid in the wall between each castle and tower, that, upon the apprehension of danger at any one place, by the sounding of it, notice might be given to the next, and then to the third, &c., whence it derived the ancient name *cornage;* and in the inside a sort of fortified little town, now called Chester, the foundations of which appear, in some places, in a square form.

PICTS' HOUSE, a name given to the remains of some ancient buildings not uncommon in the Scottish isles, the erection of which is attributed to the Picts. They are composed of large stones uncemented, built up in a conical form, and are of various sizes. Some consist of only a single chamber, with one external wall, others have an outer and inner wall, about two feet distant from each other, the space between being occupied by a winding stair. There is an example at Kirkwall, the form of which is that of a truncated cone, the height being about 14 feet, and its circumference at the base, 384 feet. "It is probable," says a writer on the subject, "that it was surrounded by two walls, but the quantity of rubbish rendered this circumstance difficult to ascertain. Internally, it consists of several cells or apartments, the principal one of which is in the centre, built with large flat stones without cement, the one immediately projecting over that below, so as gradually to contract the space within as the building rises, till the opposite walls meet at the top, when they are bound together by large stones laid across. Six other apartments of a similar form and construction, but of little more than half the dimensions, communicate with the central one, each by a passage of about two feet square, on a level with the floor. There does not appear to have been any contrivance for the admission of light. The earth at the bottom of the cells, as deep as could be dug, was of a dark colour, of a greasy feel, and of a fetid odour, plentifully intermingled with bones both of men, of birds, and of some domestic animals. In one of the apartments, an entire human skeleton in a prone attitude was found, but in the others the bones were not only separated from one another, but most of them divided into small fragments. From their appearance, some have supposed the inhabitants to have been cannibals."

PICTURE (from the Latin *pictura*), an imitation, or representation by lines and colours of any natural object. Such representations are also called *paintings*, from the name of the art by which they are produced; which, being capable of general application, and of great influence upon the mind, has, at all times, since men have cultivated their intellectual powers, been regarded with peculiar interest.

The subject of a picture may be represented in colours, on canvass, wood, or the like; and enclosed in a frame.

Pictures or paintings in oil are preserved by coating them with some transparent or hard substance, as a varnish, in order to secure the colours from the injuries of the air or moisture; and to defend the surfaces from scratches or any damages the painting might receive from slight violence. The substances that have been, or may be used for this purpose, are gum-arabic, dissolved in water, with the addition of sugar or sugar-candy to prevent its cracking; glair or whites of eggs, mixed with a little brandy or spirit of wine, in order to make it work more freely, and a lump of sugar to prevent its cracking; isinglass, used as either of the former, or mixed with a fourth or fifth of its weight of honey or sugar, and varnishes formed of gum resins dissolved in spirit of wine, or oil of turpentine; which last are called *oil-varnishes.*

Paintings in miniature are preserved by plates of glass, or the talc called *isinglass*, placed before them in the frame. Paintings in distemper may be rendered more durable, and preserved from foulness, by varnishing them with hot size, boiled to a strong consistence, in which a fifteenth or twentieth part of honey has been dissolved. Crayons must be preserved in the same manner as paintings in water-colours by plates of glass or isinglass.

When pictures are cut or torn, they may be repaired by laying them on an even board or table, carefully putting together the torn or divided parts with colour laid as a cement, in and over the joint, and keeping them in that situation till the cement is thoroughly dried. The protuberance of the cement may be easily reduced with a penknife, and the repaired part properly coloured so as to correspond with the picture. When part of the cloth is destroyed, a piece of canvass, somewhat bigger than the vacant space, is to be plastered over on the outside of the cloth with white or any other colour, and when it is thoroughly dry, the inequality of the picture in this part is to be filled up with the same matter, properly reduced and coloured.

The art of cleaning pictures and paintings is of great consequence in order to their preservation: in this operation great skill and care are requisite, so that the menstruum used for taking off any foulness may not dissolve the oil in the painting itself, or disorder its colours, and that each sort of varnish with which paintings are coloured may be taken off without injury to the painting. The first and most general substance used for cleaning pictures is water, which will remove any foulness arising from many kinds of glutinous bodies, as sugar, honey, glue, &c., and any varnish of gum-arabic, glair of eggs, or isinglass, without affecting the oil that holds the colours together. Olive oil or butter will dissolve pitch, resin, and other substances of a like kind, without injuring the oil of the painting. Pearl-ashes, dissolved in water, form a proper menstruum for most kinds of matter that foul paintings; but they must be very cautiously used, as they will corrode the oil of the painting, if there be no varnish of the gum resins over it. Soap is of the same nature, and should be cautiously applied, and only to particular spots, that elude all other methods. Spirit of wine will dissolve all the gums and gum resins, except gum arabic, and is therefore very necessary for taking off from pictures varnishes composed of such substances, but it also corrodes the oil of the painting. This is also the case with oil of turpentine, and essence of lemon, spirit of lavender, and rosemary, and other essential oils. With regard to paintings that are varnished with gum-arabic, glair of eggs, or isinglass, the varnish should be taken off when they are to be cleaned. This may be easily distinguished by wetting any part of the painting, which will feel clammy, if varnished with any substance soluble in water. This kind of varnish may be taken off with hot water and a sponge, or by gentle rubbing with a linen cloth dipped in warm water. If paintings, on this trial, appear to be varnished with gum resins, or such substances as cannot be dissolved in water, they may, in some cases, be sufficiently cleaned by a sponge with warm water; and any remaining foulness may be removed by rubbing the painting over with olive oil made warm, or with butter, which should be wiped off with a woollen cloth; and if the picture require farther cleaning, wood-ashes or pearl-ashes may be used in the following manner: take an ounce of pearl-ashes, and dissolve them in a pint of water; or take two pounds of wood-ashes, and stir them well in three quarts of water, once or twice in an hour for half a day. Then pour off the clear fluid, and evaporate it to a quart or three pints; wash the painting well with a sponge dipped in either of these leys, and rub gently any foul spots with a linen cloth till they disappear. If this method fail, recourse must be had, first to spirit of wine, then to oil of turpentine, and if these are ineffectual, the essence of lemons: with either of which the foul spots should be slightly moistened, and the part immediately rubbed gently with a linen cloth. After a little rubbing, if oil of turpentine or essence of lemon has been applied, olive oil should be put upon the spot; and water, if spirit of wine has been used; which should be taken off with a woollen cloth; repeating the operation till the foulness be removed. When paintings appear to have been varnished with those substances that will not dissolve in water, and, after the use of the above means, retain their foulness, the following method will succeed; place the picture or painting in a horizontal situation; and moisten, or rather flood, by means of a sponge, the surface with very strong rectified spirit of wine: keep the painting thus moistened, by adding fresh quantities of the spirit, for some minutes; then flood the whole surface copiously with cold water; wash off the whole without rubbing; and, when the painting is dry, repeat the operation till the whole varnish is taken off.

The art of removing paintings in oil from the cloth or wood on which they are originally done, and transferring them to new grounds of either kinds of substance, is of great use. For those on cloth or canvass, the method is as follows: let the decayed picture be cleansed of all grease that may be on its surface, by rubbing it very gently with crumb of stale bread, and then wiping it with a very fine soft linen cloth. It must then be laid, with the face downwards, on a smooth table covered with fan-paper, or the India-paper: and the cloth on the reverse must be well soaked with boiling water, spread upon it with a sponge, till it appears perfectly soft and pliable. Turn the picture with the face upwards, and, having stretched it evenly on the table, pin it down with nails at the edges. Having melted a quantity of glue and strained it through a flannel, spread part of it, when a little stiffened, on a linen cloth of the size of the painting, and when this is set and dry, lay another coat over it; when this becomes stiff, spread some of the glue, moderately heated, over the face of the picture, and lay over it the linen cloth already prepared in the most even manner, and nail it down to the picture and table. Then expose the whole apparatus to the heat of the sun, in a place where it may be secured from rain, till the glue be perfectly dry and hard; when this is the case, remove the picture and linen cloth from the table. Turn the picture with the face downwards, and let it be stretched and nailed to the table as before; then raise round its edge a border of wax, as in the etching of copper-plates, forming a kind of shallow trough with the surface of the picture; into which pour a proper corroding fluid, as oil of vitriol, aquafortis, or spirit of salt, but the last is to be preferred: dilute either of these with water to such a degree, determined by previous trials, that they may destroy the threads of the original canvass or cloth of the picture, without discolouring it. When the corroding fluid has answered this purpose, drain it off through a passage made at one end of the border of wax, and wash away the remaining part by repeatedly pouring quantities of fresh water on the cloth. The threads of the cloth must be then carefully picked out till the whole be taken away. The reverse surface of the painting, being thus wholly freed from the old cloth, must be well washed with water by means of a sponge, and left to dry. In the mean time prepare a new piece of canvass of the size of the painting; and having spread some hot glue, purified as before, and melted with a little brandy or spirit of wine, over the reverse of the painting, lay the new canvass evenly upon it while the glue is hot, and compress them together with thick plates of lead or flat pieces of polished marble. When the glue is set, remove these weights, let the cloth remain till the glue is become perfectly dry and hard. Then the whole must be again turned with the other side upwards, and the border of wax being replaced, the linen cloth on the face of the painting must be destroyed by means of the corroding fluid; particular care is necessary in this part of the operation, because the face of the painting is defended only by the coat of glue which cemented the linen cloth to it. The painting must then be freed from the glue by washing it with hot water, spread and rubbed on the surface by a sponge. The painting may afterwards be varnished as a new picture; and if the operation be well conducted, it will be transferred to the new cloth in a perfect state.

When the painting is originally on wood, it must first be detached from the ceiling of the wainscot where it was fixed; and the surface of it covered with a linen cloth, cemented to it by means of glue, as already directed. A proper table being then provided, and overspread with a blanket, or thinner woollen cloth, laid on in several doubles; the painting must be laid upon it with the face downwards, and fixed steady: and the board of wood on which it was done must be planed away, till the shell remains as thin as it can be made, without damaging the paint under it. The process is afterwards the same as that in the case of paintings on canvass, till the painting on wood be in like manner transferred to a cloth or canvass.

PIEDROIT (French) in architecture, a pier or square kind of pillar, part of which is hid within the wall. It only differs from a pilaster in having no regular base and capital, which the other has. *See* Pilaster.

This term is also used for a part of the solid wall annexed to a door or window; comprehending the door-post, chambranle, tableau, leaf, &c.

PIER (from the French *pierre*, a stone) a mass of stone, &c., opposed against the force of the sea, or great river, for the security of ships that lie at harbour in any haven.

Piers are also used in architecture for a kind of pilasters, or buttresses, raised for support, strength, and sometimes for ornament.

Piers, *Circular*, also called *massive columns*, are with or without caps, and are frequently seen in Norman architecture.

Piers of a Bridge, the supports of the arches over the openings, when more than one, not including the supports at the extremities, which are called *abutments*. *See* Bridge.

M. Belidor observes, that when the height of the piers is about six feet, and the arches are circular, it is sufficient to make their thickness the sixth part of the width of the arch, and two feet more; but when the arches become of a great span, the thickness of the piers may be reduced to the sixth part; but then the depression of the two feet does not take place at once; that is, in an arch of about forty-eight feet, three inches are taken off for every six feet of increase of the width of the arch. The thickness of the piers supporting elliptic arches is greater than in the former proportion: thus, in an arch of seventy-five feet wide, the thickness of the pier, whose height is about six feet, should be 13.5 when the arch is circular, and fifteen feet when it is elliptical. The same author makes the abutments one sixth part more than the piers of the largest arch; and Mr. Muller has calculated a table, containing the thickness of the piers of bridges.

Rectangular piers are seldom used except in bridges over small rivers; in all others they project from a bridge by a triangular prism, which presents an edge to the stream, in order to divide the water more easily, to prevent the ice from sheltering there, as well as vessels from running foul against them. This edge is terminated by the adjacent surfaces at right angles to each other at Westminster Bridge; but those of the Pont-royal, at Paris, make an acute angle of about 60 degrees. Engineers, however, in their later constructions, make this angle to terminate by two cylindric surfaces, whose bases are arcs of 60 degrees.

PIGGERY, the place where hogs or swine are lodged.

PIG-STY, the name of the place where hogs are kep[t]. Buildings of this kind should always be large and com[]modious.

PILA, or Pile. *See* Piles.

PILÆ, according to Vitruvius, square blocks placed upo[n] the epistylia, immediately over the columns, to support th[e] timbers of the roof.

PILASTER, (from the French, *pilastre*, or Italian, *pila[s]tro*,) in architecture, a square column, sometimes insulate[d] but more frequently let into a wall, and only projecting wit[h] a fourth or fifth part of its thickness.

The pilaster borrows the name of each order, and has th[e] same proportions, capitals, members, and ornaments, wit[h] the columns themselves.

The pilasters in the Attic order are sometimes at equ[al] distances, and sometimes coupled; but this depends on th[e] intercolumniation of the order below. If the Attic order b[e] straight, and immediately over it, it must partake of the sam[e] distances, and stand over the column in the lower order.

Pilasters are made, usually, without either swelling or d[i]minution, as broad at top as at bottom: though some of th[e] modern architects, as M. Mansard, &c., diminish them at to[p] and make them swell in the middle, like columns; partic[u]larly when placed behind columns.

Pilasters, M. Perrault observes, like columns, become o[f] different kinds, according to the manner in which they ar[e] applied to the wall. Some are wholly detached, and calle[d] by Vitruvius *parastatæ;* others have three faces clear out o[f] the wall; others two; and others only one: these are a[l] called by Vitruvius *antæ*.

Insulated pilasters are but rarely found in the antique[.] The chief use they made of pilasters was at the extremitie[s] of porticos, to give the greater strength to the corners.

There are four principal things to be regarded in pilasters[,] viz., their projecture out of the wall, the diminution, the di[s]position of the entablature, when it happens to be commo[n] to them and to a column, and their flutings and capitals.

1. The projecture of pilasters, which have only one fac[e] out of the wall, is to be one-eighth of their breadth; or, a[t] most, not above one-sixth. When they receive impost[s] against their sides, their projecture may be a quarter of thei[r] diameter. They are made to project in different proportion[s] to their diameters, as one-eighth, one-fourth, one-half, an[d] three-fourths; but are never used gracefully quite square[,] except at angles; and then only in massive buildings, as th[e] portico at St. Paul's, Covent Garden.

2. Pilasters are but seldom diminished, when they hav[e] only one face out of the wall. Indeed, where they stand i[n] the same line with columns, and the entablature is continue[d] over both, without any break, the pilasters are to have th[e] same diminution with the columns; that is to say, on the fac[e] respecting the column; the sides being left without any dim[i]nution. When they are diminished, they have an ill effect[,] where it becomes necessary to make them correspond wit[h] the lines of the columns at top, as is sometimes the case i[n] porticos and returns, then it is better for the architect t[o] make them entirely of the smallest diameter of the colum[n] to which they are opposed.

3. Pilasters are sometimes fluted, though the column[s] they accompany are not so; and, on the other hand, th[e] columns are sometimes fluted, when the pilasters that accom[]pany them are not. The flutings of pilasters are always od[d] in number, except in half pilasters, meeting at inward angles[,] where four flutings are made for three, &c.

4. The proportions of the capitals of pilasters are the sam[e] as to height with those of columns, but they differ in widt[h;] the leaves of the former being much wider; because pila[sters]

ers, though of equal extent, have only the same number of leaves for their girt, viz., eight. Their usual disposition is to have two in each face in the lower row, and in the upper row one in the middle, and two halves in the angles, in the turns whereof they meet. Add to this, that the rim of the vase, or tambour, is not straight, as the lower part is, but a little circular, and prominent in the middle. In pilasters that support arches, the proportions, Palladio shows, must be regulated by the light they let in; and at angles, by the weight they are to sustain. For which reason, says Sir Henry Wotton, a rustic superficies best becomes them.

Pilaster, *Demi*, or Membretto, a pilaster that supports an arch: it generally stands against a pier, or column.

Pilasters, in ship-building, flat columns, or ornaments, made of deal, fluted or reeded, with moulded caps and bases, and placed in the middle of the munnions, which part the lights of the stern and quarter-galleries; also on the munnions of the bulkheads of the captain's cabin, &c.

Pilaster-Masses, in Gothic architecture, piers of a rectangular plan capped with impost mouldings.

PILE. *See* Piles.

Pile, a word used among architects, for a mass or body of building.

Pile-Driver, a machine for driving piles into the ground, of which there are many kinds; some are worked by a great number of men, who raise a heavy weight to a small height, and then let it fall upon the pile, till, by reiterated blows, they drive it to the required depth. This machine is extremely simple. A long thick plank of wood is fixed up close to the pile, having a mortise through the upper end, in which a pulley is fitted; a rope goes over this to suspend the rammer, which is a large block of hard wood, properly hooped, to prevent it from splitting. In rising and falling, it slides against the face of the plank, and is guided by irons, which are fixed to the ram, and bent round the edges of the plank, in the manner of hooks. The plank, when placed upright, is secured by guy-ropes, in the manner of the mast of a ship; the end of the great rope which suspends the ram, has ten or twelve small ropes spliced into it, for as many men to take hold, and work it by; they raise the ram up two or three feet by pulling the ropes all together, and then letting them go, the ram falls upon the pile-head. When the pile becomes firm enough to cause the ram to rebound, they take care to pull the ropes instantly after the blow, that they may avail themselves of the leap it makes.

This is the simplest form of the machine. Others, instead of a plank, have two upright beams attached together, at such a distance as to leave an opening between them for the reception of a piece of wood which is affixed to the ram, and by this means it is guided. Instead of guy-ropes, these are usually fixed upon a base, consisting of a triangular frame, on one angle of which the uprights are erected; and from the other two angles, braces arise, inclined so as to reach the uprights at one-half or two-thirds of their height, to steady them. This plan is very convenient for driving piles in corners; but for driving in rows, it is more advantageous to have the uprights fixed at the middle of one side of the triangular base, and have stays from all the three angles. A machine of this kind, with a ram of beech, four feet long and one foot square, may be worked by ten or twelve men, at the rate of twenty-four blows per minute, and fixes the pile very quickly. To estimate the force of the rammer, its weight ought to be multiplied into the velocity it acquires in falling. Thus, if a rammer weighing 500lbs. drop from four feet, it will fall in half a second, and have at the time of percussion a velocity capable of carrying it uniformly eight feet in half a second, without any farther help from gravity; so that we must multiply 500 by 16, or its weight by the number of feet it would fall in a second, and the product, 8,000, gives the momentum of the stroke. If a capstan, pulley, or windlass, be made to raise the rammer to a considerable height, and then, by an easy contrivance, loosen it at once from its hook, the momentum of the stroke will always be as the square root of the height from which the rammer fell.

Notwithstanding the momentum, or force of a body in motion, is as the weight multiplied by the velocity, or simply as its velocity, when the weight is given or constant; yet the effect of the blow will be nearly as the square of that velocity; the effect being the quantity the pile is driven into the ground by the stroke. For the force of the blow, transferred to the pile, being destroyed in some certain definite time by the friction of the part within the earth, which is nearly a constant quantity, and the spaces in constant forces being as the squares of the velocities; therefore, the effects, which are those spaces sunk, are nearly as the square of the velocities, or, which is the same thing, nearly as the heights fallen by the ram or hammer to the head of the pile.

For large works, such as bridges, &c., the piles are driven by a different kind of machine: this has a very heavy iron ram, with mechanical powers, by which it is raised to a very considerable height, and then let fall, instead of continually repeating small blows. These are sometimes worked by horses, or steam-engines.

Figures 1 and 2.—A, A, the uprights, erected on the frame, B, and supported by the braces, C; connected by the cross feet, *a*, at bottom, and the piece, D, at top; in this the pulley, *b*, for the rope, *d*, is fitted. Fillets of iron are fixed withinside the uprights, A, A, and enter grooves made in the edges of the great iron ram, E, which is thereby guided as it rises and falls: F is a piece, called *the follower* (see *Figures* 3 and 4) consisting of a wooden block, sliding between the uprights, and mortised to receive the iron tongs, *e*, which take hold of an eye on the top of the cast-iron ram: the rope is attached to the follower by an iron hoop, *f*, through which the centre pin of the tongs passes. On the base, *a* B, of the machine, an iron frame is bolted, to contain the windlass, G, on which the rope, *d*, winds. On the end of the windlass a cog-wheel, *g*, is fixed, and a pinion upon the axis, *h*, engages its teeth. Motion is given to the spindle, *h*, by the winches, *k*, fixed to each end of it, and the fly-wheel, *l*, regulates its motion, when turned by two men at each handle. The pile is of course included in the space between the two uprights, A, A, before it is driven down; and the ram, being engaged by the tongs, *e*, is drawn up by turning the handle, *k*, till the tails, *n*, of the tongs come to the inclined planes, *m*, *Figure* 1: by these they are closed together, which opening the lower ends, disengages them from the eye of the ram, and it falls upon the head of the pile immediately. The men at the handles shift the spindle, *h*, endwise, which disengages the pinion from the wheel, and then the weight of the follower, F, runs back the windlass, G, and descends till its tongs take hold of the ram, ready to take it up again. The inclined planes, *m*, are not fixed to the uprights, A, A, but are connected together by pieces of wood, which embrace the uprights, and these have holes through them to receive iron bolts, which also pass through the uprights. By this means the inclined planes can be shifted, to set them at any required height, that they may, by discharging the ram at the proper height, give a blow proportioned to the pile to be driven. The tongs are sometimes made with rollers in the ends, *n*, *n*, as shown in *Figure* 12, that they may act more easily in the inclined planes. Other machines have a kind of latch, shown in *Figure* 11, instead of the tongs; in this, *f* represents the iron loop for the rope;

the centre pin of which, passing through the latch, *r s t*, catches the eye of the ram by the hook, *t*, and is discharged by the line *r*, when the men snatch it. The weight, *s*, is to cause the hook to catch; and the loop, *f*, is attached to the wooden follower, which guides it between the uprights.

Machines of this kind are frequently actuated by steam-engines. A pulley, fixed on the end of the spindle, *h*, in place of the handle, *k*, receives an endless rope from some wheel put in motion by the engine; one man then attends it, to throw the spindle endwise at the proper time, to permit the descent of the follower; but we have seen one in which levers, and a connecting rod from the inclined plane, *m*, were used to disengage the spindle the moment after the follower discharges the ram; by adopting these means much expense of labour would be saved, as the steam-engine which is afterwards to be employed in pumping the water out of the coffer-dams, would drive the piles for them and for the foundations.

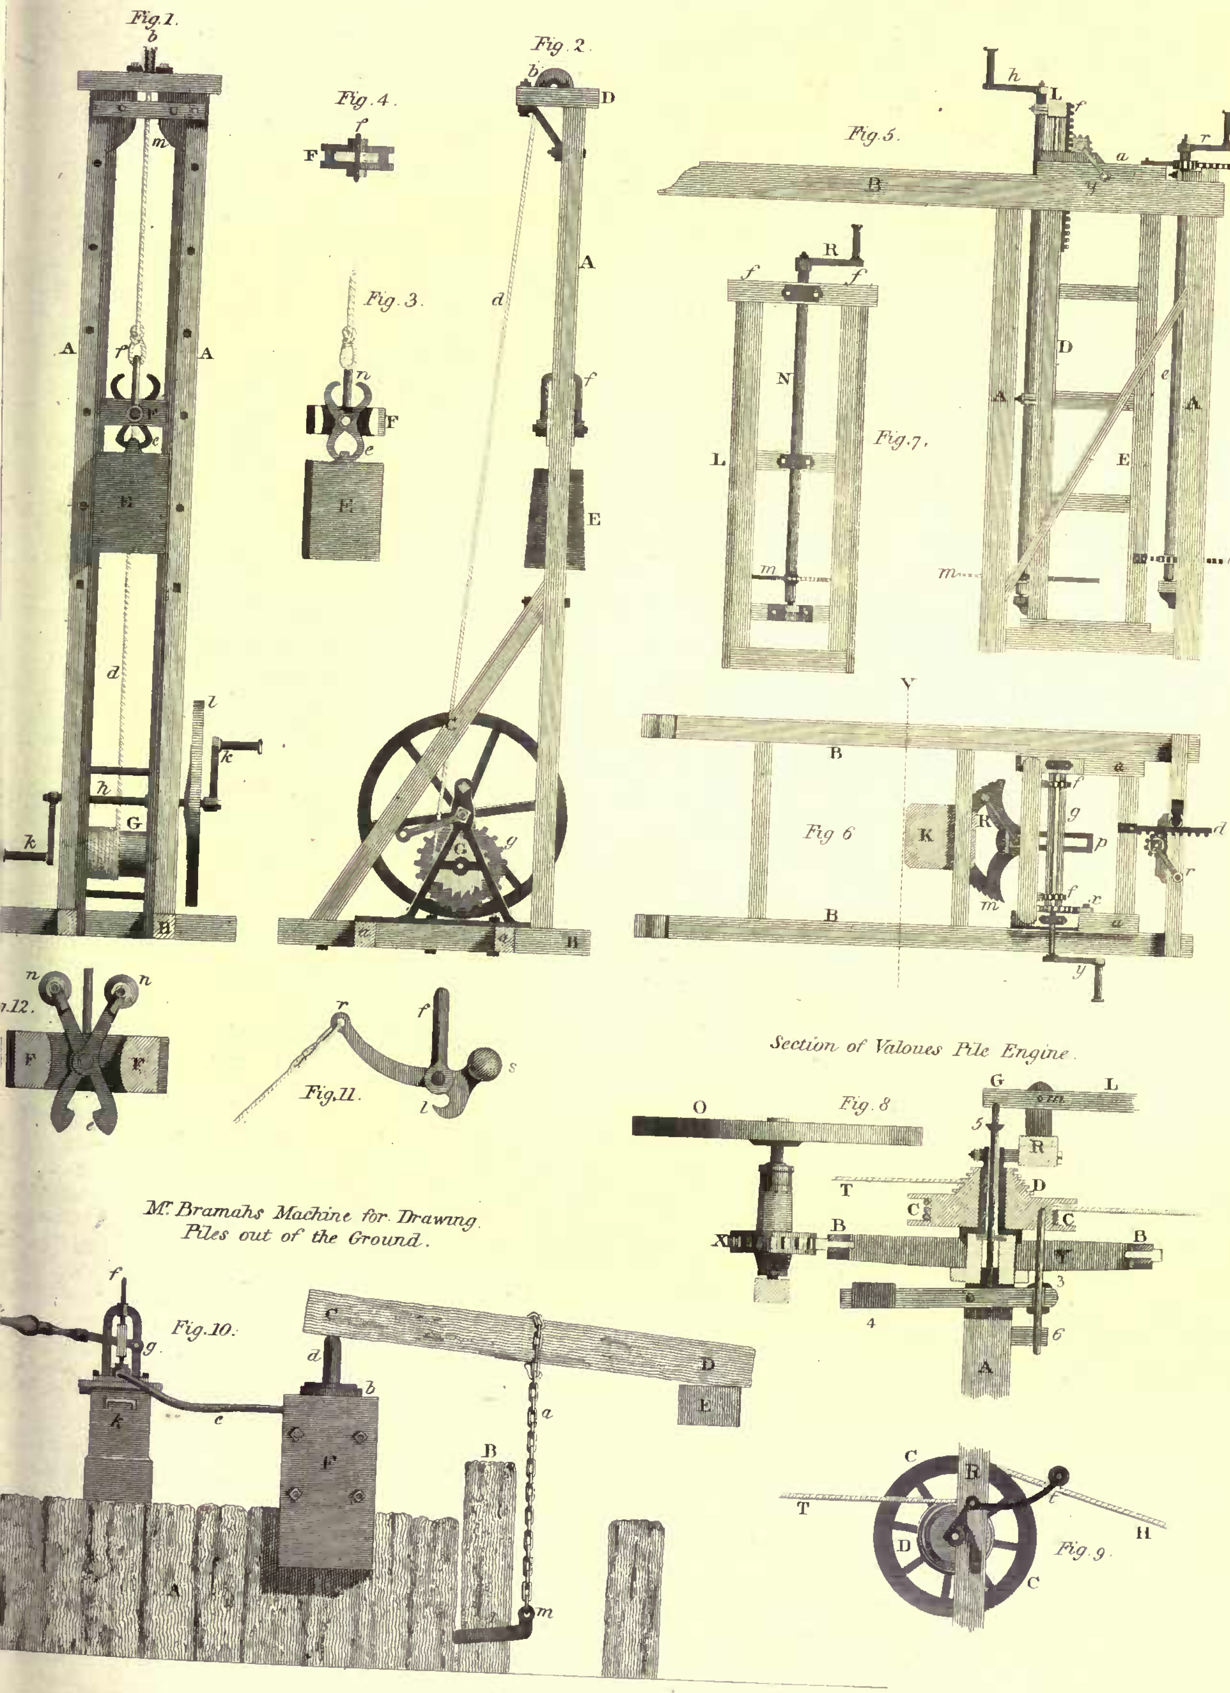
The piles of the works of Westminster-bridge, whilst it was building, were driven by a horse-machine, invented by Mr. Valoue. A pair of the uprights, such as represented in *Figures* 1 and 2, but thirty feet high, were erected at one end of a frame, which supported a vertical shaft, turned round by the horses, and the framing was of course large enough to admit a circular walk of sufficient size for them to work in, when they drew the ends of arms or levers projecting from the vertical shaft. The whole was erected upon a platform, which was built over a barge in the manner of a deck. The vertical shaft had a wheel or drum upon it, to wind up the rope of the follower, and it was in the construction of this part that the invention lay. A section of the upper part of the vertical shaft and drum is given in *Figure* 8, and a plan in *Figure* 9. Here A is the great upright shaft, or axle, turned by the horses attached to the levers, which are not shown. The cog-wheel, B, turns the pinion, X, having a fly, O, at the top to regulate the motion, and to act against the horses, and keep them from falling, when the ram is disengaged. The drum, C, is loose upon the axle of the shaft, A, but is locked to the wheel, B, by the bolt, Y. On this drum the great rope, H, is wound, one end of it being fixed to the drum, and the other to the follower, passing over proper pulleys. In the follower are contained the tongs, which take hold of the ram, by the staple for drawing it up, as described in *Figure* 2; D is a spiral, or fusee, fixed to the drum, C, on which winds the small rope, T: it goes over a pulley, and has a small counterpoise hung to the end of it, which hinders the follower from accelerating as it goes down to take hold of the ram; for, as the follower tends to acquire velocity in its descent, the line, T, winds downwards upon the fusee on a larger and larger radius, by which means the counterpoise acts stronger and stronger against it; and so allows it to come down with only a moderate and uniform velocity. The bolt, Y, locks the drum to the great wheel, being pushed upwards by the small lever, 3, which passes through a mortise on the shaft, A, and turns upon a pin; the lower end of the bolt is guided by passing through a piece of wood, 6, fixed into the great shaft, and the upper end passes through an arm of the wheel; the lever, 3, has a weight, 4, which always tends to push up the bolt, Y, through the wheel into the drum; G L is the great lever, turning on the centre, *m*, and resting its end, G, upon the forcing bar, 5, which goes down through a hollow in the shaft, A, and bears upon the little lever, 3. The other end of the lever, L, is long enough to reach the uprights, and has there a small rope, extended from its end up to the inclined planes, so that the follower, when drawn to the highest, pulls this rope, and raises the long end, L, of the lever, depressing the other, and forcing the bar, 5. By the horses going round, the great rope, H, is wound about the drum, C, and the ram is drawn up by the tongs in the follower, till they come between the inclined planes, which, by shutting the tongs at the top, open them below, and so discharge the ram, which falls down between the uprights and the pile, and drives it by a few strokes as far into the ground as it can go, or as is desired; after which, the top part is sawed off close to the mud, by an engine for that purpose. Immediately after the ram is discharged, a piece upon the follower takes hold of the rope, which raises the end L, of the lever L G, and causes its end, G, to descend, and press down the forcing-bar, 5, upon the little lever, 3, which, by drawing down the bolt, Y, unlocks the drum C, from the great wheel, B; and then the follower being at liberty, comes down by its own weight to the ram; and the lower ends of the tongs slip over the eye of the ram, the weight of their heads causing them to fall outwards, and fasten upon it: then the weight, 4, pushes up the bolt, Y, into the drum, which locks it to the great wheel, and so the ram is drawn up as before. As the follower comes down, it causes the drum, C, to turn backward, and unwinds the rope from it, while the horses, the great wheel, the pinion X, and the fly, go on with an uninterrupted motion; and as the drum is turning backward, the counterpoise is drawn up by its rope, T, winding upon the spiral fusee, D.

There are several holes in the under side of the drum, and the bolt, Y, always takes the first that it finds, when the drum stops by the falling of the follower upon the ram, till which stoppage the bolt has not time to slip into any of the holes. But the same effect is more certainly produced by a crooked lever, *t*, *Figure* 9, fixed on the framing, R, over the end of the vertical shaft; one end of this has a roller, which is pressed upon by the great rope, H, while the other end holds down the catch, 5, of the forcing bar, but as soon as the great rope slackens, it retires, and gives liberty to the small lever, 3, to push up the bolt. As long as the great rope has a tension upon it, to support the weight of the ram, or follower, the crooked lever is kept in close contact with the forcing-bar, and when that is depressed (to discharge the bolt, Y) by locking over its catch, 5, the crooked lever keeps it down, till the follower touches the ram; the great rope then slackens, and the spring, *v* H, discharges the crooked lever from the catch of the forcing-bar, and gives liberty to the small lever, 4, to push up the great bolt, and to lock the drum to the great wheel, when the ram is drawn up again, as before.

The peculiar advantages of this engine are, that the weight of the ram, or hammer, may be raised with the force of horses instead of men; that when it is raised to a proper height, it readily disengages itself, and falls with the utmost freedom; that the forceps, or tongs, are lowered down speedily, and instantly of themselves again lay hold of the ram, and lift it up; on which account this machine will drive the greatest number of piles in the least time, and with the fewest labourers.

The piles at Westminster bridge, when driven by the above machine till they were quite firm, were cut off, under water, by a machine to a level with the surface of the ground, to build the piers upon. This machine consisted of a framing adapted to fit upon the upper part of the pile, and fixed fast thereto. The lower part of this frame formed guides for the saw, which reciprocated horizontally at a certain depth beneath the top of the pile, and had weights to cause it to advance up to the cut. The saw was put in motion by ropes from each end, which were conducted, over proper pulleys, to two men standing on a float or raft at the surface. After fixing the machine, before the sawing wa

PILE DRIVING MACHINE.



begun, the whole machine was suspended by a tackle, which therefore took up the top part of the pile with the machine as soon as it was cut off. This was the invention of Mr. Etheridge, carpenter to the works at Westminster bridge; it was very effective, as the time employed in cutting off a fir pile of 14 or 16 inches square, in 10 feet depth of water, was seldom more, and often less, than a minute and a half. A machine, more convenient than this in its application, and not less effective, was also invented by Mr. Foulds, to whom the Society of Arts presented a gold medal for the invention; see *Figures* 5 and 7, where A A B is the external frame, consisting of four parallel rails, A, framed into two others, B, at right angles, with proper cross pieces to unite them, and inclined to strengthen the whole: within this frame a second, or internal frame, D E, is situated; like the other, it has four parallel pieces, D and E, connected together into one frame by cross pieces; at the top it has two pieces, *a*, *a*, which rest upon the beam, B, and suspend its weight, and on these it is capable of sliding backwards and forwards between B B, always preserving its parallelism, because it is moved by the racks, *d*, *d*, affixed to it, one at top, and the other at the bottom; the pinions for both are fixed on a vertical axis, *e*, supported in the external frame; therefore, by turning the handle, *r*, the internal frame with the saw is advanced to the pile, as at K, *Figure* 6. The saw itself is sustained in a frame, L, *Figure* 7, which fits, in the manner of a sash-frame, between the two beams, D, of the internal frame, and has racks, *f*, *f*, (dotted) behind it, which work in pinions on an axis, *g*, extended across the frame, and by the handle, *y*, it is capable of being drawn up and let down, or detained at any height by a ratchet-wheel and click, *x*; the saw, *m*, is fixed upon a spindle N, supported in bearings on the frame, L, and turned by the handle, R, at the top; the saw is connected with the spindle by a piece of iron, *p*, having a mortise through it for the reception of the spindle, to which it is fastened by a nut beneath; by this means the edge of the saw may be advanced as the work goes on.

In using this machine, the beams, B, are fixed across a barge, which is ballasted till they are horizontal, and the spindle of the saw is therefore vertical in this state; it is moored with her side against the pile, K, to be cut off, as shown by the dotted line, V, *Figure* 6; then, by the rack and pinion, *f g*, the saw is adjusted in height to the level where the pile is to be cut; by the handle, *r*, it is advanced to the pile, K, whilst, by the other handle, R, the saw is kept in continual motion backwards and forwards, till the pile is cut through, and the piece is taken into the barge; it then proceeds to cut off the next by the same means. By this machine, temporary piles, used in coffer-dams, may be cut off level with the bottom, when the work is finished, which is a very superior method to drawing them up out of the ground, as is the usual practice; because this must necessarily make a deep ditch or trench all round the pier or foundation, and tend to loosen the ground.

To draw piles out of the ground when they have been driven fast, requires a very great force. There are different methods of exerting this force: one for drawing them in water, is by having a very strong barge, with a windlass at one end to receive a strong chain, which is passed several times round the head of the pile, and made fast to the barge; two long beams are laid upon the barge, to form a railway for a small waggon to run upon from one end to the other, loaded with stones of several tons weight; when this is wheeled to one end of the barge, it will, of course, depress it in the water, elevating the other; then, in this state, the lowest end of the barge is chained to the pile, by putting a very large bolt through it, and passing a chain round the pile under this bolt a great many times; the carriage is then wheeled to the other end of the barge by a windlass and rope; this tends to raise the end to which the pile is fixed; and when the carriage is so far advanced that it exerts a sufficient power, it will draw up the pile, if the chain is properly fixed; and then the carriage is returned to draw another pile. A plan was adopted at Waterloo Bridge, for drawing the useless piles by one of Mr. Bramah's hydrostatic cylinders. This is represented in *Figure* 10, where A is supposed to be the top of a range of piles forming the coffer-dam, and B the pile to be drawn. A chain, *a*, is made fast to the pile, and carried many times round a large beam, C D, the end, D, of which rests upon a fulcrum, or support, E, consisting of a block, supported on the head of a neighbouring pile, &c. F is a block of two pieces of wood, screwed together in two places, and enclosing between them a cast-iron cylinder, *b*, into which is fitted the piston, or cylinder, *d*, the joining being made tight by a collar of leather; *e* is a small copper pipe, communicating with the cylinder, and also with a small forcing-pump, the piston, *f*, of which, is actuated by the lever, *g h*; the pump is fixed upon the top of a small cistern, *k*, to contain water. Now, by working the lever of the pump, water is injected into the cylinder, *b*, which protrudes the piston, *d*, from it with a force proportioned to the force exerted upon the lever, in the same degree as the areas of the pump to that of the cylinder multiplied by the proportions of the lever, *h*. By this means, the power of one or two men is increased to such a degree as to draw up the largest pile; the copper pipe, *e*, is made to unscrew at several joints, which are provided with leather, to make them tight; by which the pump is separated when the machine is to be removed. As it has no connection with the beam or lever, D, the cylinder is frequently employed in the manner of a hand-jack, for any purposes where enormous weights are to be lifted for a small space. The same figure also shows a very complete way of catching fast hold of the pile, instead of putting a bolt through the pile-head to stop the chain under: it is simply a strong iron ring, *l*, large enough to drop over the pile loosely, and having a strong shank or eye, *m*, projecting from it to run the chain through; when this is drawn, the ring jambs so forcibly upon the wood of the pile as to draw it out of the ground rather than slip off, for it holds faster in proportion to the force.

The theory of Mr. Valoue's engine depends on the following principles, viz.—1. If the resistance of the ground and the masses of the piles be equal, the depths to which they will be driven with a single blow will be as the product of the weight of the ram into the height through which it falls.

2. If the masses of the ram, and heights through which it falls, are both equal, the depths to which the piles will be driven will be in the inverse ratios of the masses of the piles into the superficies of that part of them which is already immersed in the earth.

3. If all these be unequal, the depths will be in a ratio compounded of the direct ratio of the heights through which the ram falls into its mass, and the inverse ratio of the mass of the pile into its immersed superficies.

4. If the weights of the ram be equal, and also the weights of the piles, the depths to which they will be driven will be as the heights through which the ram falls directly, and the immersed superficies of the piles. Or, because the immersed superficies are as the depths through which the piles are already driven into the earth, these depths are simply as the square roots of the heights through which the ram falls.

These principles are founded on the general supposition that the space through which the weight falls is estimated by the product of its mass into the square of its velocity, or into the height through which it falls.

Hence it is inferred, that the distance through which a pile will be driven by each succeeding blow, will be less and less, as the superficies of that part of the pile which is immersed in the ground increases; and, consequently, that there is a certain depth, beyond which a pile of a given mass and scantling cannot be driven; the mass of the ram and the height through which it falls at first being assigned.

At the close of the year 1843, a new method of sinking piles by atmospheric agency, was patented by Dr. Potts. In this invention the piles are of cast-iron, and hollow, and are lowered by drawing out the sand or soil through the centre by means of an air-pump. The pile is closed at the top with an air-tight cap, through which a pipe passes to a receiver, and from this again another pipe connected with an air-pump. By this means a communication is kept up between the pump and the interior of the pile, and by working the former the air is exhausted from the pile, the sand rises through the interior into the receiver, and the pile gradually sinks into the vacuity so produced. This method of piling has been successfully employed on the Goodwin Sands by the Trinity Board, the piles being driven through the sands to a depth of 75 feet, when they reached a solid foundation. These piles are especially adapted for such situations; they are attended, however, in many instances, with some disadvantage, for by removing the earth occupied by the piles, they lose that firmness of position which is ensured in the old method by its compression. This defect is somewhat compensated for by the injection by hydraulic pressure of certain chemical solutions, and hydraulic cements round the feet of the piles, to consolidate the earth on which they stand, and give them a firm bearing.

The most important of all inventions for this purpose is Nasmyth's steam-hammer, which consists of a steam cylinder, through a steam-tight aperture in the bottom of which the piston-rod passes, having the hammer, or "monkey," suspended from it. The steam admitted at the bottom of the cylinder raises the piston with the monkey attached to it, and in so doing, closes the induction and opens the eduction pipe, which reverses the motion, and the monkey falls with great force upon the head of the pile beneath. The following description of the action of this machine is extracted from a contemporary, and has especial reference to its employment at Morice Town, Devon.

"There are two features which most remarkably distinguish this important invention from all pile-driving machines. These consist, in the first place, in the direct manner in which the elastic power of the steam is employed to lift up the mass of iron by whose fall on the head of the pile it is driven into the ground; secondly, in the peculiar manner in which the block of iron and its guide-case and cylinder are made to sit, as it were, on the shoulders of the pile, so as to predispose and assist it in its descent into the ground. In this manner, the entire dead-weight of this part of the apparatus is rendered available, and made to act in a most important degree as a portion of the pile-driving agency, and as the entire part of the apparatus follows the pile down, it never ceases for one instant to yield a most important assistance towards the attainment of the desired object. The energy and rapidity of the blows, which are dealt out on the head of the pile at the rate of upwards of 70 per minute, is such, that, assisted by the dead-weight of the apparatus sitting upon the shoulders of the pile, it is seen to sink into the ground in steps varying from 6 feet to 3 inches per stroke,—the whole operation of driving the pile, 60 feet in length, occupying little more than from two and a half to four minutes,—in fact, such is the ease and rapidity with which these enormous piles are driven into the ground by these powerful machines, when compared with the old system, that the spectator is as much inclined to laugh at the ridiculous contrast, as to be astonished at its vast powers, and the perfect control under which it is placed. The whole movements are governed by one handle, regulating the supply of steam from the boiler to the cylinder and piston, which yields the requisite rising and falling motion of the monkey or hammer that drives the pile. We are particularly attracted by the simple and efficient contrivance which Mr. Nasmyth has adopted for carrying the steam from the boiler to the cylinder on the head of the pile, namely, by wrought-iron jointed pipes, which fold up in the most beautiful manner in a succession of joints or lengths, so as to accommodate the length of steam at all the various heights of the apparatus, which, having to descend through a perpendicular space of upwards of 50 feet in following down the sinking, double up or fold together in the most perfect yet simple manner. The same boiler which supplies the steam to the actual pile-driving apparatus, likewise supplies steam to a small engine, which is employed to give the requisite locomotive action to the whole apparatus in either direction, so as to cause it to move from pile to pile. The same small engine hoists and pitches the piles in the most perfect manner; also raises the pile-driving apparatus to the head of the highest pile, some of which are 66 feet in height, and places it on the shoulders of the pile with the utmost ease and exactness. Some idea of the performance may be formed when we state, that it drives a pile of 66 feet in length in four minutes, while, with the ordinary machines, upwards of 15 or 20 hours would be occupied in doing the same work, to say nothing of the entire absence of all damage to the head of the pile, which, in the case of the employment of Mr. Nasmyth's machine, is not in the slightest degree injured; while in driving such a pile by the ordinary machine, the head of the pile is so shattered by the repetition of its destructive and ineffectual blows, as to require to be cut off and reheaded several times during the operation. Practical pile-drivers will have some idea of the remarkable superiority in the action of Mr. Nasmyth's machine, when we inform them, that the iron hoop hitherto employed to preserve the head of the pile from being split into matches, is, in the steam pile-driver, entirely dispensed with, and the heads of the piles, after driving, bear scarcely any evidence of force having been applied to them."

Pile-planks, are planks whose ends are sharpened, to drive into any canal or water, close to each other, in order to form a dam, by which the water may be stopped and discharged. *See* Piles.

Pile-sheeting, the same with dovetail piling.

Piles, in hydraulic architecture, are beams of timber, or stakes of wood, driven firmly into the ground, for various purposes; as, for forming a foundation for buildings, piers of bridges, &c., in which cases they are driven quite down into the ground, or are cut off level with its surface, with a view of obtaining a solid bearing for the weight of the intended superstructure.

Amsterdam, and some other cities, are wholly built upon piles. The stoppage of the breach in the banks of the Thames at Dagenham, was effected by dovetail piles; that is, by piles mortised into each other by a dovetail joint.

Piles are not employed for foundations, unless the ground is suspected to be unsound, or when the weight to be borne is exceedingly great. They make the foundation solid, by reaching deep into the earth, down to a more substantial stratum than that of the surface. Indeed, the manner of fixing the piles, by driving them by repeated blows of a powerful machine till they will go no farther, ensures that they come to a good bearing.

Piles are also used for making the faces of wharfs, banks of rivers, piers for the sea, &c. For these purposes they are driven in rows, but only a sufficient depth in the earth to make them stand firm, and support the planking or framing which is fixed against them. These piles are usually driven rather in an inclined position. For temporary defence against the water, in laying the foundation of bridges, &c., piles are always required; they are employed in different ways to form an enclosure, or water-tight wall, called a coffer-dam, round the area where the work is to be laid, and from which space the water is drawn by pumps. This is the most difficult of all kinds of piling; because it must stand a great height above the ground, have sufficient strength to resist the pressure of water, and be perfectly close and tight. In navigable rivers detached piles are driven, and very firmly fixed, to mark the enclosures where barges are to lie, and to fender off others from them, as well as to moor them to.

Piles are in general formed of square timber, tapering if the tree happens to be so, cut to a sharp point at one end, and shod with iron to enter the ground. The other end is bound by a strong iron hoop, to prevent the pile-head from splitting by the violence of the blows which drive it down. When they are to be driven quite below ground, small trees, if sufficiently straight, may be used without squaring; but for coffer-dams, square piles are always used, except for filling up a row between such square piles. When they are to touch each other, flat ones, called *pile-planks*, are used; they are three or four inches thick, according to the depth of water, and have grooves formed in their adjacent edges, to receive tongues or slips of wood, which make the joints quite tight. This method is termed *sheet-piling*. To enclose an area for a coffer-dam, two rows, or walls of piles, are usually driven one within the other, at a distance usually equal to the depth of water where they are driven; or, if the current is rapid, once and a half. The space between these is filled with clay, so as to form a mound or rampart of that material, defended on the outside and inside by wooden walls of piles. To make these walls, large square piles are first driven, at a distance of ten or twelve feet asunder, in the line of the intended range of the dam; horizontal tie-beams are then extended from one pile to the next, on the inside, and sometimes on the outside also, each tie being notched into the piles, so that its outer edge is in a line with the inside of the groove for the plank-piles, which are to be driven down to fill up the spaces between the piles, and will be guided by these ties to stand exactly vertical, and in a straight line. The first plank-piles are fixed adjacent to the main piles, and thus they are continued from both ends of the interval, till the planks meet in the centre, where the last plank is inserted, and, being formed rather wedge-like, it makes all the rest tight. The pile-planks are cut inclined, or wedge-like, on one side only, to form the point, by which means the point is in the line of one of the edges of the plank. When a plank pile is to be driven adjacent to another, this edge is applied to the one already fixed, and then, as it is driven, the inclined or wedge-like edge entering the ground, causes the pile to approach, and press very close to its neighbour; and it is chiefly by this means they are made to fit water-tight. The fillets are made by spiking a ledge or ruler of wood fast upon the edge of one plank, and a groove of corresponding depth and width is ploughed in the edge of the adjacent plank to receive it.

The square *gauge* or *guide* piles, as they are termed, are usually composed of whole timbers from twelve to fourteen inches scantling, but the plank piles, or sheet-piling, as well as the horizontal ties or *walings* of half-timbers, being of the same width, but only half the thickness of the square piles.

Piles of cast-iron were first employed by Mr. Mathews in the formation of Bridlington harbour, in which work he made use of sheets of iron 8 or 9 feet long by 2 feet in width, and half an inch thick, so contrived at the sides, that each pile should form a dovetail joint with the adjoining one. Mr. Ewart, however, was the first who brought this kind of piling into general notice; he took out a patent for his invention in 1822. These piles consisted of plates of iron from 10 to 15 feet in length, $14\frac{1}{2}$ inches in width, and $1\frac{1}{2}$ inch in thickness; they have a flanch running down the centre, and one at each extremity, turned off at an acute angle with the face. To connect these together, he made use of a smaller pile only 6 inches wide, but having a flanch at each side corresponding with those at the sides of the larger plate, so as to form a dovetail joint with them. Where a greater length of piling was required, a method of lengthening them was adopted, by placing one above another, and securing the horizontal joints by means of dovetail cramps.

Mr. Ewart's piles have been extensively adopted, especially by Mr. Hartley, in the Liverpool docks, who has employed them successfully, and speaks favourably of their employment in such works as coffer-dams. He states, that considerable care is required in keeping the piles in a vertical position, as they are apt to shrink every blow, and drive slanting. They require to be driven between two heavy balks of timber to keep them in a straight line, as they expose very little section to the blow of the ram, and are so sharp, that they are easily driven out of a right line. There is another very necessary precaution to be taken, which is the keeping the fall of the ram in the same line as the pile; otherwise, the ram descending on the pile, and not striking it fairly, all parts equally, the chances are, that, if in a pretty stiff stratum, the head breaks off in shivers, and the pile must be drawn, which is sometimes no easy matter.

Mr. Mylne has also employed those piles to a considerable extent, especially in a large coffer-dam opposite the New River Company's establishment at Broken Wharf, where he succeeded in driving the larger and smaller piles or cramps simultaneously, the usual practice being to drive them separately.

A work on a much larger scale was constructed of the same material by Mr. Cubitt at the sea entrance of the Norwich and Lowestoft navigation; but the form of the piles was, in this instance, of a somewhat different description. The wall consisted exclusively of sheet piling without any guide-piles whatever, each pile being 30 feet long, 18 inches broad, and $1\frac{1}{2}$ inch thick, having a deep flanch in the centre, without any dovetail or other jointing at the sides; the perfectness of the joints depending entirely upon close and accurate driving. As some assistance to the driving, a pair of strong wrought-iron cheeks, projecting two or three inches beyond the edge of the pile, were riveted on to the lower end, which served as a guide or groove to keep the piles flush. The entire length of wharfing thus constructed was about 2,000 feet.

Another work of importance is that of Walker and Burgess at the Brunswick Wharf, in front of the East India Docks at Blackwall, of which we copy the following description, as given by Mr. Borthwick in the Transactions of the Institution of Civil Engineers.

"The first operation was to dig a trench two yards deep in the intended line, and this was immediately followed by the driving of the timber guide-piles. The deepening in front, which, to give the required depth of 10 feet at low water, was as much as 12 feet, was not done until near the conclusion of the work; to have effected it in the first instance would, without any countervailing advantage except some saving in the driving, have been attended with the double expense of removing the ground forming the original bottom between the old and new lines of wharfing, and afterwards refilling the void so left by a material that would require time to make it of equal solidity; and even if this had been otherwise, such an attempt would have endangered the old wall, or rather would have been fatal to it. The permanent piling was next begun, the main piles being driven first at intervals of seven feet, and the intermediate spaces or bays then filled in, working always from right to left, towards which the drafts of the sheet-piles were pointed. The ground is a coarse gravel, with a stratum of the hard Blackwall rock occurring in places, and some trouble was occasionally experienced from its tendency to turn the piles from the proper direction; but due attention being paid to the form of the points, the drawing was, on the whole, effected pretty regularly, but few of the bays requiring closing piles made specially for them, so that the work may be said to be nearly iron and iron from end to end; at the same time, the vertical joints of the piling being all covered, as will be noticed presently, any slight imperfection, in this respect, is no serious detriment to the work as a whole.

"The main piles are in two pieces, the lower end of the upper one being formed so as to fit into a socket on the top of the under length, and the joining made good by means of a strong screw-bolt; the only object of this was to insure a supply of truer castings, and lessen the difficulty of transporting such unwieldy masses from Northumberland and Staffordshire to London. Each sheet-pile is secured at the top by two bolts to the uppermost wale of the woodwork behind, and the edge of the end-ones of each bay, it will be observed, pass behind the adjoining main pile, while the other joints are overlapped by the bosses with which all the sheet-piles, except the closers, are furnished on one side. Besides adding to the perfection and security of the works, by breaking the joints, so that the water, if it penetrate, (as, even with the best pile-driving, it will,) cannot draw the backing from its place, these projections appear to me to relieve the appearance of the otherwise too uniform space, and a like effect is produced by the horizontal fillets on the lower edges of the plates above, which also mask the joints. These plates filling up the space over the sheet-piling, are bolted to the main piles and to each other, in the manner shown, and the joints stopped with iron cement. Where the mooring-rings come, the plates are cast concave, with a hole perforated in the middle, to allow a bolt to pass through, and this bolt is secured, as well as the land-ties, from the main piles to the old wharf, which was not otherwise disturbed, or to needle-piles driven adjoining to it. The backing consists of a concrete of lime and gravel, in the proportion of about one to ten, extending down to the solid bottom. The coping, with the water-channel in its rear, is of Devonshire granite; the water is conveyed from the channel at intervals by pipes extending from gratings in the bottom, in a slanting line, to the lowermost plate, and discharging themselves immediately above the sheet-piling. The main piles were originally proposed to be hollow, but this was given up on further consideration of the uncertainty of procuring sound castings of the intended form, and of the greater liability to break afterwards from a blow sideways.

"The solid form was therefore adopted, according to which the lower lengths weighed about 28 cwt., and that this was not too much, was shown by the circumstance of several of the piles, particularly the early ones, breaking in the testing, or driving, and showing in the fracture the danger of even a slight defect. The greater care subsequently taken at the foundry, and probably also greater experience in driving, made accidents of this kind of rare occurrence in the later stages of the work; and it may be mentioned as no bad proof of the care of all parties, that of upward of 600 piles, including both descriptions, only 16 broke in driving—7 being of one sort, and 9 of the other: the failure was in five cases attributed to strains in driving, and to imperfections of casting in the other eleven. The sheet-piles, which bear a considerable resemblance in their general outline to those used at Downes wharf ten years before, were proposed to be an inch thick, but it was found necessary to increase this dimension, and some of them was as much as $1\frac{1}{4}$ inch; the average, however, was not above $1\frac{1}{8}$ inch, and weight of each pile 17 cwt.; the length of the wharf is about 720 feet, and the whole weight of iron used, upwards of 900 tons.

"The crab engine was employed invariably, the heads of the piles being covered with a slip of three-quarter inch elm, to distribute the force of the blow equally over the iron, and so prevent jarring. The monkeys used, weighed from 13 to 15 cwt. each, and it was found necessary to limit the fall to a height of 3 feet 6 inches, and sometimes less; when the resistance proved more than usually great, the pile showed a tendency to turn from its straightforward course. The driving throughout was very hard, more especially at the west end, where the sheet-piles in four bays, could not be forced to the full depth, the space above being in two of them made up with two plates in height, and in the other two admitting only one instead of three, as in the rest of the work. Driving was the only means resorted to, or indeed practicable, in the gravelly soil that prevailed. Had the bottom been clay, or other similar substance, the plan of boring, to receive the points, might probably have been partially adopted in the main piles with advantage; but I should say, certainly not to the extent of depending mainly upon it for getting the piles home to their places."

Piles similar to the above have been employed in many situations, differing only in matters of detail, which we do not think it requisite more fully to describe.

Piling of cast-iron seems to be very well adapted for coffer-dams, wharf-walls, embankments, and such works, but is not to be substituted for timber when employed for foundations, for unless based upon a very firm stratum, they are not so secure against sinking when heavily loaded; nor, on account of their small sectional area, do they compress and consolidate the soil through which they pass to the same extent as timber pilings, and this compression greatly assists in forming a solid foundation for the superstructure. Another disadvantage which attends the use of this material, is the deterioration which it undergoes by the action of water upon it, and especially of sea-water.

The screw-pile introduced by Mr. Mitchell, is admirably adapted for loose and moveable strata, and has been found very useful in situations where all other means had failed. This pile consists of a spindle of the required length, with a broad cast-iron plate or disc, in a spiral or helical form, attached to the lower end, so as to form a screw by means of which the pile is secured in the ground. The following account of them is taken from a summary of a paper read by Mr. A. Mitchell, and published in a cotemporary.

"The origin of the screw-pile was the screw-mooring which was designed for the purpose of obtaining, for an especial purpose, a greater holding power than was possessed by either the ordinary pile, or any of the usual moorin anchors or blocks, of however large dimensions. It was proved by experiment, that if a screw with a broad spiral flange were fixed upon a spindle, and forcibly propelled by rotary motion to a certain depth into the ground, an enormous force would be required to abstract it by direct tension, and that the power employed must be sufficient to drag up a mass of the form of a frustum of a cone reversed, the base being at the surface of the ground, and the section of the apex being equal to the diameter of the screw. The extent of the resisting mass must of course depend upon the natural tenacity of the soil; even in this reasoning it must be evident that a vertical force was calculated upon, but as practically that seldom or never occurred, the angle of tension and the curve of the buoy-cable again gave the moorings greater power. This was found to be correct in practice, and the applications of these moorings became very extensive. An arrangement was made with the port of Newcastle-on-Tyne, by which, for the sum of £2,500, the right of fixing the moorings in the Tyne was given; and Mr. Brookes, the engineer, showed that last year, (1847,) whilst in the neighbouring port damage was done to the shipping to the extent of nearly £30,000, no injury was sustained in the Tyne, entirely owing to the sound holding of Mitchell's screw-pile moorings.

"It naturally occurred to Mr. Mitchell, that the same means of resistance to downward pressure might be used, and he proposed to apply it for the foundations of lighthouses, beacons, and other structures, which for maritime purposes it might be desirable to place upon sand and mud banks, where hitherto it had been considered impracticable to place any permanent edifices. In the year 1838, a plan for a structure of this nature for a lighthouse on the Maplin Sand, at the mouth of the Thames, was laid before the corporation of the Trinity House, supported by the opinion of Mr. James Walker, their engineer. The 9 iron piles, 5 inches in diameter, with screws 4 feet in diameter, were accordingly driven 22 feet deep into the mud, and, with proper precaution, they were allowed to stand for two years, before any edifice was placed upon them. The lighthouse was subsequently constructed, and, as was testified by Mr. Walker, had stood perfectly until the present time (March, 1848"). The plan of the piling in this instance was octagonal, one pile being driven in each of the angles of the octagon, and another in the centre, making in all 9 piles, which were fixed in their places in 9 consecutive days, being screwed to a depth of 22 feet in the bank. The piles were made of malleable iron, 5 inches in diameter, and 26 feet long, with a cast-iron screw, 4 feet in diameter, screwed to the foot.

"Another lighthouse was erected to point out the entrance to the harbour of Fleetwood on Wyre; and under the advice of Captain Denham, R.N., the screw-piles were adopted. The spot fixed on was the point of a bank of loose sand about two miles from the shore. Screw-iron piles, with screws of 3 feet in diameter, were forced about 16 feet into the bank, and upon them timber-supports, 48 feet in vertical height, were fixed, to carry the house and lantern. This structure was completed in six months, and it was said to have never required any repairs to the present time," (March, 1848.)

Another method of piling was invented by Dr. Potts, but as this is connected more especially with PILE DRIVING, it has been described under that article, and does not demand any further observation in this place.

PILLAGE, among builders, a word sometimes used for a square pillar, standing behind a column to bear up the arches; having a round base and capital, as a pillar has.

PILLAR (from the Italian *piliere*, or French *pillier*) a kind of irregular column, round and insulate; but deviating from the proportions of a just column.

Pillars are always either too massive or too slender for regular architecture. In effect, pillars are not restrained to any rules; their parts and proportions are arbitrary. Such, for instance, are the pillars which support Gothic vaults, and other buildings, &c.

A square pillar is a massive work, called also *pier*, or *piedroit*, serving to support arches, &c.

A butting-pillar is a butment, or body of masonry, raised to prop, or sustain, the thrust of a vault, arch, or other work.

It seems not impossible for stone to be cast into the shape of pillars. We find mention made in the *Philosophical Transactions* (No. 481, p. 328, in *note*,) of two pillars of stone at Fontevraud, in France, each about 60 feet high, all of one solid piece, which are said to have been run. Pillars of stone were anciently erected as sepulchral monuments, near the highways; and also in memory of some victory. We find traces of this custom in Cornwall and Wales, where these pillars are often found, and called *meinigwir*, a stone for play, perhaps in memory of funeral games; and sometimes *llech*, that is, *tabula saxea*.

Pompey's pillar is a famous monument of antiquity, constructed of red granite, and situated on a rock, about a mile without the walls of Alexandria, in Egypt. By the mensuration of Edward Wortley Montagu, Esq., the capital of the pillar, which is Corinthian, with palm-leaves, and not indented, is 9 feet 7 inches high; the shaft 66 feet $1\frac{1}{4}$ inch; the base 5 feet $9\frac{3}{4}$ inches; the pedestals 10 feet $5\frac{1}{2}$ inches; the height from the ground 92 feet: though Dr. Pococke, by the shadow, determined the whole height to be 114 feet; and its diameter 9 feet and an inch. It is perfectly well polished, and only a little shivered on the eastern side. Nothing can equal the majesty of this monument: seen from a distance, it overtops the town, and serves as a signal for vessels. Approaching it near, it produces, says Savary, an astonishment mixed with awe. One can never be tired with admiring the beauty of the capital, the length of the shaft, nor the extraordinary simplicity of the pedestal. This prodigious mass stands, as on a pivot, on a reversed obelisk; and was erected, as many have supposed, either by Pompey, or to his honour. But as no mention is made of it by Strabo, Diodorus Siculus, or any other ancient writers, Mr. Montagu concludes that it was not known before the time of Vespasian, and that it was erected to his honour. In proof of this opinion, he found within the circumference of the pillar a medal of Vespasian, in fine order.

Savary, on the authority of Abu'lfeda, who calls it "the pillar of Severus," ascribes it to this emperor; alleging, that he visited Egypt, gave a senate to Alexandria, and deserved well of its inhabitants. Accordingly, it is said that this column was a mark of their gratitude. The Greek inscription, half effaced, which is visible on the west side when the sun shines upon it, was legible, without doubt, in the time of Abu'lfeda, and preserved the name of Severus. Nor is this the only monument erected to him by the gratitude of the Alexandrians. In the midst of the ruins of Antinoë, built by Adrian, is seen a magnificent pillar, the inscription on which is still remaining, dedicated to Alexander Severus.

Denon has given a drawing of this pillar, with the marked dimensions of its various parts: he makes its whole height a fraction more than 92 feet; and the height of the shaft, which is of a single piece, 63 feet $1\frac{3}{10}$ inch. It acquired, as this author says, the name of Pompey's pillar in the 15th century. A monument, as he supposes, had been raised by

Pompey at Alexandria, but it had disappeared, and was thought to be recovered in this pillar or column, which has since been converted into a trophy erected to the memory of Septimius Severus. It is, however, placed on the ruins of the ancient city; and in the time of Septimius Severus, the city of the Ptolemys was not in a ruinous state. To support this column by a solid foundation, an obelisk has been sunk in the earth, on which is placed a very clumsy pedestal, having a fine shaft, and surmounted by a Corinthian capital of bad workmanship. If the shaft of this column, continues Denon, separating it from the pedestal and the capital, once belonged to an ancient edifice, it is an evidence of its magnificence, and of the skill with which it was executed. It ought, therefore, to be said, that what is called Pompey's pillar is a fine column, and not a fine monument; and that a column is not a monument. The earth about the foundation of this pillar having been cleared away by time, two fragments of an obelisk, of white marble, the only monument of that substance seen by Denon in Egypt, have been added to the original base, to render it more solid. After having observed that the column, entitled Pompey's pillar, is very chaste both in style and execution; that the pedestal and capital are not formed of the same granite as the shaft; that their workmanship is heavy, and appears to be merely a rough draft; and that the foundations, made up of fragments, indicate a modern construction; it may be concluded, says our author, that this monument is not antique; and that it might have been erected either in the time of the Greek emperors, or of the caliphs: since, if the capital and pedestal are well enough wrought to belong to the former of these periods, they are not so perfect but that art may have reached so far in the latter.

PINION, an arbor, or spindle, in the body of which are several notches to catch the teeth of a wheel that serves to turn it round. Or a pinion is a lesser wheel, which plays in the teeth of a larger.

PINNACLE, (from the Latin, *pinna*, or *pinnaculum*,) the top or roof of a house, terminating in a point. This kind of roof, among the ancients, was appropriated to temples; their ordinary roofs being all flat, or made in the platform-way. It was from the pinnacle that the form of the pediment took its rise.

But the term is more generally applied to the slender and spire-like terminations in Gothic architecture, which rise from the top of buttresses, roofs, and other parts of an edifice. They form a very beautiful enrichment to the more delicate carvings in screens, shrines, and other works of a decorative character.

PINNING, the fastening of tiles together with pins of heart-of-oak; for the covering of a house, &c.

Pinning-up, the process of driving the wedges in underpinning the upper work, so as to make a good bearing upon the work below.

PIPE, a tube for the conveyance of water, gas, steam, soil, &c., made of various materials, as lead, iron, earthenware, &c.

PISCINA, (from the Latin, *pisces*, *fish*,) a large bason in an open public place or square, where the Roman youth learned to swim; it was surrounded with a high wall, to prevent the casting of filth into it.

Piscina, was also used for the square bason in the middle of a bath.

Piscina, or Probatica, (from the Greek, *πραβατον*, *sheep*,) a pool or reservoir of water, near the court of Solomon's temple; here the cattle, destined for sacrifice, were washed. By this piscina it was, that our Saviour wrought the miraculous cure of the paralytic. Davilier observes, there are still remaining five arches of the portico, and part of th bason of this piscina.

Piscina, or Lavatory, among the Turks, a large baso placed in the middle of the court of a mosque, or under th porticos that encompass it. Its form is usually a long square It is built of stone or marble, furnished with a great numbe of cocks, wherein the Mussulmans wash themselves befor they offer their prayers.

Piscina, the perforated stone usually found in a niche on th right-hand side of the altar, in our ancient churches and cha pels, into which the water used in washing the hands of th officiating priests, and other sacred ablutions, was cast.

Piscinas were almost always placed on the south side o the altar, and usually in the south wall, but sometimes in th east wall. They were of various degrees of ornamentatior some being very plain, and others elaborately enriched; no unfrequently we find a double niche, and sometimes a singl niche, with a sink and shelf above it, which is supposed t have been used as a credence-table.

PISE, a term applied to a peculiar mode of forming build ings of different kinds, but more especially those designe for farm-purposes, with some sort of stiff earthy material of a loamy quality. It is an easy, economical, and convenien method, which had its rise on the continent, and has been ha recourse to in different parts of this kingdom, as in Bedford shire, Lancashire, &c.

The difference between this, and the common mud-walling consists in the earth being pressed in moulds, by which it i rendered much more compact, and is not subject to crack s readily in the drying.

PIT OF A THEATRE, all that space between the am phitheatre, or galleries, and the theatre, or stage; called, by th ancients, *orchestra*: and by the French, *parterre*. This bein the most commodious part, it was here the Roman senate wa placed. It has its name, *pit*, in Latin, *cavea*, from its bein sunk below the level of the stage.

PITCH, in building, the vertical angle of a roof, or th proportion between the height and span; as, when th height is one-fourth, one-third, or one-half of the breadth o the building. If the height is one-half of the breadth, th inclination of the planes, forming the vertical angle, is a rig angle.

In former times, the vertical angles of roofs were made s very acute, that the length of the rafter was three-fourt of the breadth of the building; but, in the present day, whe the coverings are mostly of slate, mansions and dwellin houses have the height of the roof one-fourth or one-thi of that breadth; though in some country-places, the practi still continues of making the rafters three-fourths of t breadth of the building, which they call *true-pitch;* but wh the length of the rafters is equal to the breadth of the buil ing, the pitch is denominated *Gothic*.
